Imaging of the nervous system encompasses a wide variety of modalities that have undergone rapid evolution in the past few decades. Plain film analysis of the skull and spine, although still employed, is not routine in the initial investigation of patients with neurological signs and symptoms. Computed tomography (CT), developed in the 1970s, remains a common radiographic technique, particularly for the acutely traumatized patient. Magnetic resonance imaging (MRI), which came into widespread clinical usage in the 1980s, has supplanted CT for evaluation of many suspected pathological processes of the brain and spine. Depending on availability, MRI is often the initial study ordered, particularly in an outpatient setting. MRI continues to be a rapidly evolving field, encompassing techniques such as magnetic resonance angiography (MRA) and spectroscopy. Myelography, introduced in the early 1900s, has been replaced to varying degrees by MRI owing to the noninvasive nature of the latter. Myelography is still regarded as useful in visualizing the intradural nerve roots and is performed in selected cases, particularly when MRI is contraindicated. Throughout the century, myelography has evolved into a much safer examination, owing to development of contrast agents with dramatically reduced neurotoxicity. Angiography, introduced in 1927, remains the gold standard for evaluation of neurovascular disease. Interventional neuroradiology, a field that has evolved in the past two decades, offers patients therapy through angiographic techniques. Ultrasonography is most useful in the evaluation of the neonatal brain and spine as well as extracranial vascular disease. Transcranial Doppler (TCD) studies are useful in selected patients for assessing intracranial vascular disease. Ultrasonography has also been employed in the operative setting. Positron emission tomography (PET) and single photon emission computed tomography

PLAIN FILM ANALYSIS

Basic Principles and Techniques

The standard views of the skull are the posteroanterior (PA), lateral, anteroposterior (AP), half-axial (Towne), and base. The PA view demonstrates the frontal and ethmoidal sinuses, frontal bones, nasal cavity, superior orbital rims, and mandible. The frontal, parietal, temporal, and occipital bones, the sella turcica, the orbital roofs, the mastoid region, and the lateral aspect of the facial bones are demonstrated on the lateral view. The Towne view shows the zygomatic arches, the foramen magnum, the occipital bone, and the mastoid region. The base view demonstrates the basal structures of the skull. To evaluate the facial bones and sinuses, the occipitomental (Waters) view is often used.

Conventional radiographic examination of the spine plays a critical role in the initial evaluation of the trauma patient. Because the cervical cord is prone to damage from unnecessary manipulation, the initial radiographic examination is usually limited to two or three projections that provide the optimum amount of clinically pertinent information. Plain film examination of the spine is also an invaluable tool in the screening of patients for degenerative, inflammatory, and neoplastic conditions and serves as an excellent imaging modality by alerting the physician to the presence and degree of abnormalities. Of all the spine examinations involving radiation, plain film radiography gives the lowest dose, averaging 0.2 rad to the ovaries for a four-view lumbar examination. The testicular dose is 10 to 50 percent of the ovarian dose.

Normal Findings

The skull varies considerably in shape and consists of a superior portion, the vault, and an inferior portion, the base. Along the base lie the orbits, sella turcica, and the temporal bones. The skull bones are composed of outer and inner tables of compact bone separated by the diploic space containing bone marrow. The inner table contains grooves for vascular structures such as the middle meningeal artery branches, and care should be taken not to confuse these for linear fractures. Pacchionian depressions house arachnoid granulations that are related to venous lacunae communicating with the superior sagittal sinus.

From the midline they commonly extend 2.5 to 3.0 cm, and any inner table depression beyond that distance should be considered something else, possibly an inner table erosion secondary to a neoplasm. Beyond age 3 the cranial sutures appear similar to the adults, and portions undergo actual closure at variable ages. Normal intracranial calcifications consist of dural, pineal, habenular, choroid plexus, arachnoid granulation, and basal ganglia calcifications. The latter can be seen in hypothyroidism and pseudohypothyroidism, but are most often physiological.

For the spine, the lateral view is the single most useful projection because it can demonstrate most post-traumatic lesions of the cervical spine. The lateral projection clearly demonstrates the vertebral bodies, apophyseal joints, anterior arch of the atlas, atlanto-odontoid distance, odontoid process, spinous processes, and disc spaces. A mandatory requirement is the demonstration of the C7 vertebral body. The four smooth contour lines of the normal cervical spine are apparent on the lateral view and should be evaluated to exclude interruption or angulation. The lines include the anterior and posterior vertebral lines, the spinolaminar line (defines the posterior margin of the spinal canal), and the posterior spinous line. Evaluation of the prevertebral soft tissues can also be performed because the retropharyngeal and retrotracheal spaces are adequately demonstrated.

The anterior projection demonstrates the C3 to C7 vertebral bodies, intervertebral disc spaces, lateral masses, uncinat processes, uncovertebral (Luschka) joints, and the spinous processes that, superimposed upon the bodies, resemble teardrops. To provide adequate visualization of C1 and C2, a variant of the anteroposterior projection is often obtained, termed the *open-mouth* or *odontoid view*. The atlanto-occipital and atlantoaxial joints, odontoid process, and lateral masses of C1 and C2 are effectively demonstrated.

The oblique view of the cervical spine demonstrates neural canal stenosis secondary to degenerative spur formation arising from the uncinat processes anteriorly or from the respective facet joint posteriorly. The oblique view of the lumbar spine is the single most useful view in evaluating for suspected spondylolytic defects through the pars interarticularis.

Types of Detectable Abnormalities

With the advent and marked success of both CT and MRI, the clinical utility of skull and spine radiography has declined. However, it remains useful in the detection and diagnosis of fractures, abnormal calcifications, developmental anomalies, and osteolytic or osteoblastic disorders. Degenerative spinal conditions and osteophytic changes are still commonly evaluated with spine films.

Neurological Applications in Diagnosis and Treatment

GENERALIZED DISEASES

Metabolic and Systemic Diseases. Renal osteodystrophy, hyperparathyroidism, and acromegaly represent some of the metabolic and endocrine disturbances that the skull responds to. However, the importance of radiographic findings has decreased with the routine laboratory determination of certain diseases. The skull characteristically demonstrates mottling of the vault, manifesting a "salt and pepper" appearance. Occasionally, cystlike lesions, or brown tumors, may occur. The findings in renal osteodystrophy are identical to those of primary hyperparathyroidism. Findings in acromegaly include thickening of the calvarium and expansion of the supraorbital ridge and frontal sinus, but the clinical manifestations and hormonal assay are more sensitive and objective determinations of disease severity.

CRANIAL DISEASES

Neoplasms and Destructive Lesions. Skull radiography remains valuable in the evaluation of the destructive lesions and metabolic abnormalities. By far the most common neoplastic involvement of the skull is secondary to metastasis or invasion from adjacent neoplasm. Metastatic carcinoma, multiple myeloma, and lymphoma usually present as lucent or lytic lesions and represent the most common malignancies affecting the calvarium. Breast carcinoma commonly manifests as large and variable-sized lucencies. In males, prostate carcinoma is the most common cause of osteoblastic metastasis. There is little to differentiate osteomyelitis from neoplasm radiographically but, fortunately, osteomyelitis of the calvarium is rare in North America and many other parts of the world.

Structural and Developmental Abnormalities. Several acquired abnormalities can be demonstrated by plain films. Fibrous dysplasia classically features sclerosis, lucency, and thinning and bulging of the inner table. This entity can be confused with Paget's disease but is encountered in a younger age group and often ceases to grow at about the third decade of life. The classic calvarial presentation of eosinophilic granuloma is that of a sharply circumscribed lucency involving the diploe and inner and outer tables, similar in appearance to that of a destructive lesion. Indeed, the differential considerations are metastatic neoplasm, infection, and recent surgical repair. Hemangiomas of the calvarium usually have a diagnostic appearance on plain film. They are typically discrete, predominantly lucent areas with a reticular or "spoke wheel" trabecular configuration, and a prominent diploic vascular channel is frequently identified entering the lesion. The initial or lytic phase of Paget's disease results in areas of sharply demarcated lucency termed *osteoporosis circumscripta*. Subsequent stages demonstrate enlarged, coarsened trabeculae, thickening of the cortex, and nonhomogeneous patchy densities referred to as a "cotton wool" appearance. Paget's disease can be confused with other entities, but the patient's age, blood chemistry, and involvement of other bones aid in the formulation of an appropriate differential diagnosis.

Developmental alterations can also be demonstrated on radiographic examination of the skull. Sutural abnormalities such as premature closure (craniosynostosis) or widening (from increased intracranial pressure seen in aqueductal atresia and Dandy-Walker syndrome) can be identified. Decreased size of one half of the cranium along with the

compensatory, ipsilateral skull thickening are key findings in the Dyke-Davidoff syndrome of cerebral hemiatrophy secondary to in utero and perinatal internal carotid artery infarction. Childhood anemias and sickle cell disease classically demonstrate generalized skull thickness or density. Decreased thickness and density can be seen in osteogenesis imperfecta. Defects in bone can occur with cranial myelomeningoceles, dermal sinuses, and epidermoids.

Trauma. Skull radiography is generally not indicated for cranial trauma because many patients with a skull fracture have no neurological sequelae and many with severe intracranial abnormalities have no associated skull fractures. A patient with significant cranial injury or post-traumatic neurological symptoms should be evaluated by CT. There are two situations in which the skull fracture itself poses a clinical threat. The depressed fracture and fracture associated with a penetrating injury are of great concern. However, the symptoms associated with such injuries will invariably direct the clinician to use CT for evaluation. Plain films are valuable in demonstrating facial fractures, which often occur in recognizable patterns. Cortical disruption and displacement of osseous fragments represent direct signs of fracture. Indirect signs include paranasal sinus opacification or air-fluid levels, orbital emphysema, and soft tissue prominence. One side of the facial skeleton should always be compared with the other, and asymmetrical radiodensities should be regarded as suspicious findings.

SPINAL DISEASES

Spinal Fractures and Post-Traumatic Spinal Destabilization. Most unstable of all cervical spine injuries, the flexion teardrop fracture can be identified on the lateral view.¹ This fracture, characterized by anterior avulsion of a teardrop-shaped fragment by disruption of the anterior longitudinal ligament as well as fracture of the posterior elements and posterior displacement of the involved vertebrae, should be distinguished from the stable extension teardrop fracture. Although also demonstrating an anteriorly displaced fragment, this injury shows no subluxation and the spinolaminar and posterior vertebral lines are preserved. The lateral view can also effectively demonstrate unilateral or bilateral locked facets (unstable), dens fractures (type 2 unstable), the stable clay-shoveler (fracture of the C6/C7 spinous process), and simple wedge fractures.

Symmetrical and bilateral fractures involving the anterior and posterior arches of C1 characterize the unstable Jefferson fracture, best demonstrated on the open-mouth odontoid view. Odontoid fractures, with emphasis being placed on transverse fracture through the base (type 2, unstable), can often be diagnosed on this view even though detail of an injury is often lacking. The anteroposterior view affords identification of fractures involving the bodies of C3 through C7 as well as abnormalities of the intervertebral disc spaces and uncovertebral joints.

Familiarization with the radiological findings that indicate instability is imperative in evaluation of the trauma patient.¹ These findings include displacement of the vertebrae, disruption of the posterior vertebral body line, and widening of the apophyseal joints. Widening and elongation of the vertebral canal with evidence of increased interpedicular distance also indicates instability. The single presence of any of these findings represents enough radiological proof to assume instability. The same principles for determining the stability of a cervical spine injury apply to those of the thoracolumbar spine.

The anteroposterior and lateral views compose the standard radiographic projections for evaluating traumatic thoracic spine injuries. For lumbar spine evaluation, anteroposterior, lateral (including a view of L5 through S1), and oblique views are traditionally obtained. By using the same general principles mentioned earlier, burst fractures, fracture/dislocations, and distraction fractures can be identified. The Chance, or "seat-belt" fracture, is an injury at the thoracolumbar junction that can be stable or unstable, depending on the extent and severity. Fracture/dislocations are notoriously unstable.

Degenerative and Inflammatory Bone Disease. Osteoarthritis, degenerative disc disease, spondylosis deformans, and diffuse idiopathic skeletal hyperostosis represent degenerative conditions that involve the spine and will frequently coexist in the same patient. The anatomical site of degenerative change determines the type of degenerative disease.¹

Degenerative changes involving the synovial joints (atlantoaxial, costovertebral, apophyseal, and sacroiliac) produce osteoarthritis of these structures. The defining radiological features are identical to other synovial joints and include joint space narrowing, subchondral sclerosis and cyst formation, and osteophyte formation. The mid and lower cervical and lumbar spine frequently demonstrate apophyseal joint degenerative changes. Involvement of the apophyseal joints often discloses gas within the joint, termed the *vacuum phenomenon*. This is virtually pathognomonic for an advanced degenerative process. Oblique views can be valuable in demonstrating posterior osteophytes, which may encroach on the neural canal sac. Frequently, however, CT is required to demonstrate such findings.

Degenerative disc disease is secondary to degenerative changes within the intervertebral disc and may also manifest the "vacuum phenomenon" in long-standing degenerated discs. Disc space narrowing and marginal osteophytosis of the adjacent vertebral bodies are also prominent features of this entity. Degenerative spondylolisthesis can be seen in patients with degenerative disc disease and apophyseal joint arthritis ([Fig. 23-1](#)).

Abnormalities of the annulus fibrosus can promote anterior and anterolateral disc herniation leading to the formation of anterior and lateral osteophytes, a process termed *spondylosis deformans*. Indeed, the primary radiological feature of this entity is extensive osteophytosis and, unlike degenerative disc disease, the disc spaces are relatively well preserved.

Diffuse idiopathic skeletal hyperostosis (DISH) demonstrates extensive osteophytosis without significant sclerosis or intervertebral disc space narrowing. Flowing ossification is characteristically seen along the anterior aspect of the vertebral bodies, stretching across the disc space. The findings are secondary to ossification involving the ligaments, entheses, and fibrous articulations. The radiological characteristics are best demonstrated on the lateral view.

The offending bacterial organism of the infectious spondylitis can be varied, with staphylococci, streptococci, *Escherichia*

Figure 23-1 Cervical spondylosis. A, Lateral x-ray of cervical spine demonstrates chronic degenerative disc disease from C3-4 through C6-7 with varying degrees of disc space narrowing and associated endplate spur formation at ea/B. Right anterior oblique x-ray of cervical spine demonstrates multilevel neural canal stenosis from C3-4 through C6-7 secondary to chronic degenerative spur formation arising from the uncinat processes.

coli, *B.*, *Proteus*, and *Pseudomonas* being the most common. Bacterial spread is usually by the hematogenous route, being common in immunocompromised individuals and intravenous drug abusers, but it may also be iatrogenic, occurring after spinal surgery, lumbar puncture, and discography. The most common location is the lumbar region, and the lesion is detected on plain radiographs by loss of disc space stature along with rarefaction of the adjacent endplates. If untreated, significant vertebral body involvement here may lead to collapse of the vertebral body, resulting in wedge deformity, focal kyphosis, and scoliosis. The inflammatory process may extend beyond the confines of the vertebral body into the paraspinal soft tissues or posteriorly into the epidural space of the central canal with abscess formation and thecal sac compression. CT and MRI allow excellent visualization of the extent of these inflammatory processes, which cannot be adequately assessed with plain film radiography.

The most common location for spinal tuberculosis is the lower thoracic and upper lumbar regions. The granulomatous process usually begins in the anterior third of the vertebral bodies and spreads along the spinal axis beneath the paraspinal ligaments. The intervertebral disc space in tuberculous spondylitis remains relatively intact for a longer period of time than in pyogenic infections. In untreated chronic cases of spinal tuberculosis, paraspinal, paravertebral, and psoas abscesses frequently occur. The psoas abscess may calcify.

Neoplasms. By far the most common extradural malignancy of the spine is the metastatic lesion. Although breast and prostate cancer are known for their osteoblastic or sclerotic lesions, most metastases are osteolytic. Spine metastases can involve all vertebral levels but most commonly affect the lower thoracic and lumbar spine.

The most common plain film finding is pedicle destruction, even though, in adults, the initial site of involvement is typically the vertebral body. Pathological compression fractures, multiple lytic vertebral body lesions, and paraspinal soft tissue masses are other common expressions of metastatic neoplasms. A discriminating eye can sometimes detect an indistinct posterior vertebral body margin, a clue to epidural metastatic disease. MRI, however, is a highly sensitive imaging study that can portray epidural and paraspinal soft tissue involvement as well as cord compression. Breast, lung, and prostate cancer are commonly associated with epidural spinal cord compression. Other common adult metastatic primary lesions include renal cell carcinoma, melanoma, lymphoma, multiple myeloma, and sarcoma.

COMPUTED TOMOGRAPHY

Basic Principles and Techniques

The advent of CT was one of the most exciting developments in the history of neuroimaging. For the first time, direct visualization of the brain became possible. Although MRI has surpassed CT in displaying neuroanatomy and pathology, CT remains a mainstay for several reasons. Wider availability and lower costs of CT are considerations in today's managed care environment. CT is easier to perform in the setting of acute trauma and in the ventilated patient. Owing to the speed with which CT images can be obtained, high-quality studies are more feasible in the patient unable to cooperate for examination. Patients with implanted devices such as cardiac pacemakers, spinal stimulators,

aneurysm clips, and other surgical implants are not MRI candidates, as well as patients harboring ferromagnetic foreign bodies. Disadvantages of CT include need for iodinated contrast material to visualize vessels and many intracranial pathological processes, artifacts related to beam hardening (which particularly limits evaluation of posterior fossa structures) or the presence of metallic foreign bodies, and difficulty in obtaining planes other than the axial. The last of these particularly limits evaluation of the spine.

CT is a technique in which a tightly collimated x-ray beam is directed through the patient. The patient is placed in the CT gantry, and the x-ray beam travels in a circular path around the patient. Detectors 180 degrees opposite the beam measure x-ray attenuation, or removal of the photons from the beam. The x-ray beam is collimated in a range from 1 to 10 mm, depending on the size of the structure being examined. The patient is moved by the same increment as the slice thickness for contiguous images of the area of interest. The signal from the radiation detector must be digitized by means of an analog-to-digital converter so that the image can be constructed using a computer algorithm. Images are reconstructed with air seen as black and bone as white. Air is the tissue with the least attenuation of x-rays and on the Hounsfield scale (named after Godfrey N. Hounsfield, the inventor of CT) is arbitrarily designated as -1000. Bone, the greatest attenuator, is designated as +1000, with water as 0. Table 23-2 lists the approximate Hounsfield units for anatomical tissues encountered on head CT, in order from dark to bright. Resolution of small structures is a function of pixel size, determined by field of view (typically 23 cm for a routine head) and matrix size (typically 512).

The latest CT technique is helical CT, which requires a new system or updated hardware and software to perform. Helical CT differs from conventional CT in that the patient is moved continuously through the x-ray beam, dramatically shortening scanning times. There is some loss of resolution with this technique as scanning times decrease, such that in routine brain imaging, helical scanning is not employed. Helical scanning is useful when a rapid collection of data is necessary, such as in the traumatized or uncooperative patient. Helical scanning has made CT angiography possible, because rapid collection of images is needed after a bolus of contrast medium is injected.

The typical radiation dose for a head CT is 40 to 60 milligray (mGy). There are a number of factors influencing

TABLE 23-2 -- APPEARANCES OF TISSUES ON CT

tissue	Hounsfield Unit	Gray Scale

dose, such as voltage (kVp), current (mA), scan time (seconds), field of view, rotation angle, filtration, collimation and section thickness, and spacing. The dose distribution also depends on the size, shape, tissue density, and elemental composition of the patient.

Morbidity of CT is mainly that of reactions to intravenous contrast medium administration. Although today nonionic contrast medium is available with significant reduction in the number and severity of adverse reactions, its use has not yet become routine, owing to significantly higher costs. Patient conditions in which only nonionic contrast medium should be administered include prior reaction to iodinated contrast medium, asthma, multiple allergies, cardiac disease, and pulmonary hypertension.

Patients with allergic histories can also be given a steroid pretreatment consisting of prednisone, 50 mg, orally 13, 7, and 1 hour before dye injection with diphenhydramine (Benadryl), 50 mg, 1 hour before if desired. In this patient population, it is preferable to avoid contrast medium-enhanced CT if at all possible, with MRI providing an excellent alternative. If MRI is contraindicated, and the patient has a history of laryngospasm or hypotension with previous use of contrast medium, an anesthesiologist should be present during the contrast medium administration. Acute renal failure is an absolute contraindication to the administration of contrast medium. Renal insufficiency should be regarded as a relative contraindication, and again MRI is recommended as the study of choice. Patients on dialysis can be imaged safely with contrast medium, preferably with dialysis planned soon after the study.

CT can be used to guide stereotactic brain biopsy, a technique that is especially helpful for tissue diagnosis of small or deep-seated lesions. Stereotactic radiation therapy, stereotactic craniotomy, brachytherapy, and management of brain stem lesions can also be planned from CT images. For most stereotactic procedures the patient is placed in a device such as a Brown-Robert-Wells head ring, CT scanning is performed, and the lesion of interest is targeted using the head ring as an external reference. A computer transforms the two-dimensional coordinates of rods fixed in the head ring and the targeted lesion into three-dimensional space so that

the trajectory of the biopsy needle can be planned.^[12] Frameless stereotactic techniques have also been developed.

The standard head CT is performed with the gantry angled parallel to the orbitomeatal line obtaining images in the axial plane. Five-millimeter sections are obtained through the posterior fossa to ensure adequate visualization of the fourth ventricle with 10-mm sections through the supratentorial space. Thinner sections (1-3 mm) are employed for detailed examination of small anatomical regions such as the temporal bone, sella, orbits, and paranasal sinuses. Coronal imaging is essential for evaluation of these structures and may be used to visualize lesions in the tentorial region or at the vertex. Coronal imaging requires repositioning the patient in the gantry with the neck hyperextended either supine or prone. Patients with cervical spine disease, airway obstruction, or obesity may not be able to tolerate positioning for coronal imaging, and intubated patients cannot be placed in this position.

Filming of head CT images is done at narrow windows (60-80 HU) to accentuate the minor difference in Hounsfield

Figure 23-2 Twenty-three-year-old man status post motor vehicle accident. A, An acute frontal subdural hematoma causes compression of the left lateral ventricle, but it is difficult to see at routine brain windows. B, At subdural windows (150), the hematoma is identified subjacent to the calvarium.

units between white and gray matter, with white matter being slightly lower in attenuation. In cases of trauma, metastatic disease, bone infection, or neoplasm, bone windows (2000-4000 HU) should be obtained to evaluate for fracture, bone destruction, or hyperostosis associated with meningiomas. Bone windows are also useful in detection of intracranial air and can separate air and fat density. At these windows, the brain is not seen. A bone algorithm, a computer reconstruction technique, can also be employed and is particularly useful in evaluating small or thin bones, such as the ossicles, facial bones, and skull base. This gives detailed bone information, but the images cannot be filmed at brain windows because they will be unsatisfactory. Subdural windows (150-200 HU) are necessary to identify the acute subdural hematomas, which blend in with the calvarium on routine brain images ([Fig. 23-2](#)).

Normal Findings

A normal unenhanced head CT scan shows midline position of the third and fourth ventricles and the septum pellucidum/fornix positioned between the lateral ventricles. The bodies of the lateral ventricles need not be symmetrical. Mild differences in the sizes of the frontal, temporal, and occipital horns are common. There should be density discrimination between the white matter (centrum semiovale, corona radiata, internal capsule, and brachium pontis) and gray matter. No focal white matter low densities should be seen in young or middle-age patients. Patients older than the age of 65 may show mild periventricular hypodensities as part of the normal aging process. Ventricular and subarachnoid space size is variable between individuals. In general, the ventricles and subarachnoid spaces are small in younger patients and increase in size with increasing age. In an older patient, the ventricles should not be dilated out of proportion to the subarachnoid space size.

Normally calcified structures are the pineal gland and the glomus of the choroid plexus in the trigone of the lateral ventricle. Calcification may be seen throughout the choroid plexus, including the temporal horns and the outlets of the fourth ventricle. Occasionally, the habenula (directly anterior to the pineal gland) may show calcification. The arteries of older patients are not uncommonly calcified. Calcification of the globus pallidus can be physiological and becomes more prominent with advancing age. Calcification in dural structures, including the walls of venous sinuses, is seen as a normal variant. Excessive calcifications of vascular or dural structures may indicate an underlying pathological process.

Arteries and veins show normal enhancement owing to the higher attenuation of blood containing iodinated contrast material. Lack of a blood-brain barrier and the tight junctions between endothelial cells, allow enhancement of the dural structures (falx and tentorium) and pituitary gland. The choroid plexus in the ventricular system usually shows mild to moderate enhancement owing to its vascular nature. This enhancement can be prominent in the outlets of the fourth ventricle, simulating a vascular lesion.

In evaluation of spine CT, the intervertebral disc is seen as having a higher density than that of the contents of the spinal canal. The spinal canal has relatively low attenuation owing to the presence of cerebrospinal fluid (CSF), particularly in the lumbar region. The nerve roots of the cauda equina may be visualized in the posterior portion of the thecal sac. Roots in the cervical and thoracic subarachnoid space cannot be visualized unless intrathecal contrast medium is present. The intervertebral foramina contain mostly fat, which outlines the dorsal root ganglion and is best appreciated in the lumbar region. In the cervical region, soft tissue density of the nerve root is seen in the inferior neural foramen, whereas in the lumbar spine the root is seen in the superior aspect of the foramen. The osseous structures should be smooth with no encroachment upon the central canal, neural foramina, or lateral recesses. Linear lucencies representing veins may be seen in the vertebral

bodies and are corticated, distinguishing them from fracture lines. The basivertebral venous plexus exits the vertebral body midway between the superior and inferior endplates and has a dorsal calcified cap that should not be mistaken for an osteophyte. The ligamenta flava are visualized particularly in the lumbar spine but should not indent the thecal sac.

Types of Detectable Abnormalities

COMPUTED TOMOGRAPHY WITHOUT CONTRAST MEDIUM ENHANCEMENT

Computed tomography is an excellent study to evaluate for acute intracranial hemorrhage, particularly in the subarachnoid space ([Fig. 23-3](#)). Acute hemorrhage is detected as high attenuation owing to clot retraction with separation of the high-density erythrocytes from lower density plasma. Unclotted active bleeding may be detected in epidural hematomas as a relative lucency.

Edema is identified as low attenuation owing to the presence of increased water content. Cytotoxic edema associated with infarct or diffuse anoxia is seen as low density in the gray matter, representing abnormal accumulation of intracellular water ([Fig. 23-4](#)). Vasogenic edema is the abnormal accumulation of extracellular water in the white matter seen as "fingers" or "fronds" of low attenuation following white matter tracts.

CT is valuable in detecting mass effect including subfalcine,

Figure 23-3 Middle-aged woman presenting with what she reported as the worst headache of her life and third nerve palsy. Acute subarachnoid hemorrhage is present in left-sided basal cisterns secondary to rupture of a posterior communicating artery aneurysm. Central lucency represents the aneurysm.

Figure 23-4 Thirty-four-year-old woman status post cardiorespiratory arrest and resuscitation. CT shows severe diffuse cerebral (cytotoxic) edema with loss of white-gray matter differentiation and compression of ventricles and subarachnoid spaces secondary to anoxia.

descending transtentorial (uncal), ascending transtentorial, and transsphenoidal herniations (see [Chapter 1](#)). Cerebellar tonsillar herniation can be missed secondary to beam hardening artifact at the level of the foramen magnum.

Evaluation of ventricular size can be done by CT. Enlargement of the temporal horns out of proportion to the lateral ventricular bodies is helpful in recognizing hydrocephalus, as is dilatation of the ventricles with relative effacement of sulci. CT can be used to follow ventricular size after shunting.

CT is very useful for detecting intracranial calcifications, such as those seen in congenital infections, vascular lesions, metabolic disease, and neurocutaneous disorders. The location and distribution of calcifications is key in differentiating these various causes. The identification of calcification in a neoplasm aids in

differential diagnosis.

Although congenital brain malformations can be seen on CT, MRI is the modality of choice owing to direct multiplanar imaging with visualization of structures such as the corpus callosum and improved sensitivity for migrational abnormalities. CT is complementary in the evaluation of encephaloceles and meningoceleles in regard to identifying bone defects.

CT is preferred for evaluating acute fractures of the calvarium, skull base, and spine. Fractures are identified as lucencies without sclerotic margins. These features aid in differentiating fractures from vascular grooves or sutures. In the spine, CT can demonstrate bone impingement on the central canal. Epidural hematomas are occasionally but

Figure 23-5 Twenty-three-year-old man status post motor vehicle accident. A, Bone windows from a lumbar CT reveal a burst fracture of L5. B, Soft tissue window demonstrates an anterior epidural hematoma at the L1 level.

not consistently identified (Fig. 23-5). The spinal cord is not directly visualized.

CT and MRI provide complementary information about neoplasms of the vertebrae, particularly in the case of hemangioma if the MR signal characteristics are atypical (Fig. 23-6).

Infection of the spine is better evaluated by MRI, although CT can provide information about bone destruction.

Many pathological processes of the extracranial head and neck can be identified by CT. High-resolution thin-section CT is the test of choice for evaluation of the middle ear

Figure 23-6 Fifty-five-year-old man with asymptomatic mass lesion identified on chest x-ray. CT myelogram reveals hyperdense spiculated lesion of the T7 vertebral body with soft tissue components in the paraspinal and epidural space consistent with hemangioma.

structures and paranasal sinuses owing to its exquisite bone detail highlighted by air. CT affords better evaluation of the paranasal sinuses, although the intracranial extent of neoplasm or infection is best evaluated by MR. CT and MR can both be used for the evaluation of the orbits, with the orbital fat providing excellent contrast for the optic nerve and extraocular muscles with either technique. CT provides information about calcification, which may be seen in tumors, drusen, and vascular lesions.

COMPUTED TOMOGRAPHY WITH CONTRAST MEDIUM ENHANCEMENT

In general, it is preferable to perform MRI than to perform CT with contrast medium enhancement. MRI is more sensitive to subtle changes in tissue signal and is superior to CT in initial as well as follow-up evaluation of enhancing lesions such as neoplasms, infection, and vascular lesions. MRI affords evaluation of masses in multiple planes and is especially useful in surgical or stereotactic irradiation planning. Meningeal disease is better evaluated by MR and can be missed on CT owing to volume averaging with the skull and also the normal bright enhancement of the meninges.

Contrast medium-enhanced CT is useful in patients who cannot undergo MRI and when MRI is not readily available. Contrast medium aids in the detection of intracranial lesions that may otherwise be poorly delineated or invisible on unenhanced CT. Patterns of enhancement can be helpful in differential diagnosis of intracranial masses.

CT is not as sensitive in the detection of white matter and neurodegenerative disorders as MRI and should not be used as the primary imaging modality. If MRI is contraindicated, CT may identify white matter lesions secondary to demyelination or dysmyelination, and contrast medium enhancement is occasionally useful in differential diagnosis.

Figure 23-7 One-year-old male with tuberous sclerosis. CT without contrast reveals periventricular calcifications, the largest at the left foramen of Monro.

Neurological Applications in Diagnosis and Treatment

CT is useful in detecting structural abnormalities causing multifocal, focal, or subcortical cerebral dysfunction. Evaluation of the brain stem is generally limited to the midbrain and upper pons. CT has limited usefulness in the evaluation of the spinal cord and nerve roots. CT is not useful in the evaluation of neuromuscular disease.

CRANIAL DISEASES

Intra-axial Disorders. CT can often identify lesions responsible for cerebral dysfunction and is ordered in the acutely ill neurological patient with a history of trauma, stroke, "worst headache" of life, anticoagulation or bleeding diathesis, or seizure. In any case of suspected acute intracranial hemorrhage, intravenous contrast medium should not be administered because contrast medium enhancement and acute extravascular blood have similar attenuation characteristics. Likewise, evaluation for infarction should be performed without contrast medium enhancement to exclude hemorrhage and also because subacute infarction may show mild enhancement such that it is indistinguishable from normal cortex. Scans performed within the first 24 hours of clinical symptomatology of infarct may not reveal any detectable abnormality. Early signs of middle cerebral artery infarct include hyperdensity of the artery (thrombus, embolus), loss of differentiation of insular cortex and lentiform nucleus from adjacent capsular white matter structures due to edema, and effacement of the sylvian fissure and sulci.

Differential diagnosis of enhancing lesions includes primary brain neoplasm, metastasis, abscess, infarct, demyelinating disease, resolving hematoma, and vascular malformation. Abscesses, metastases, and high-grade primary neoplasms incite prominent vasogenic edema, whereas other enhancing lesions usually show less edema. Demyelinating disease shows ring or solid enhancement in the acute stage, commonly in a periventricular location. Resolving hematomas show ring enhancement 1 to 2 weeks after hemorrhage at the margin of the hematoma bed. Arteriovenous malformations demonstrate enlargement of feeding arteries and draining veins with central dense enhancement representing the nidus. Cavernous angiomas show enhancement in a solid pattern and are often hyperdense without contrast medium owing to calcification.

Intracranial calcifications are seen in a variety of disease processes. Arteriovenous malformations, aneurysms, and cavernous angiomas all may contain calcifications. Of the neurocutaneous disorders, tuberous sclerosis and Sturge-Weber show characteristic patterns. Patients with tuberous sclerosis demonstrate calcifications that are mainly periventricular in location (Fig. 23-7). Patients with Sturge-Weber syndrome show a gyriform pattern of calcification seen in the posterior temporal, parietal, and occipital cortex. Patients with neurofibromatosis may also demonstrate parenchymal calcifications in the basal ganglia and elsewhere. Excessive basal ganglia calcifications are seen in many metabolic disorders usually related to calcium metabolism. Neoplasms that calcify include gliomas (particularly oligodendrogliomas), meningiomas (Fig. 23-8), ependymomas, craniopharyngiomas, and choroid plexus papillomas. The most common acquired intracranial infection to demonstrate intracranial calcification is cysticercosis.

CT plays a complementary role to MRI in evaluation of patients with cranial nerve palsies. CT excels in evaluation

of the bony skull base and can detect pathological processes such as tumor, infection, and primary bone lesions as they encroach upon, enlarge, or destroy foramina. Because all the cranial nerves have a close relationship to the skull base, bone detail thin-section scanning should be obtained in all patients with these palsies. Of the cranial nerves, only the optic nerve can be directly visualized by CT. Patients with monocular visual loss may demonstrate enhancement and/or enlargement of the optic nerve.

SPINAL DISEASE

Magnetic resonance imaging is generally the test of choice for evaluating upper or lower motor neuron disease localized to the spinal cord, spinal roots, or plexi. In particular, CT should not be used as a primary imaging modality in suspected spinal cord compression because soft tissue lesions such as abscesses, hematomas, and sometimes disk herniations may be missed. CT serves a complementary role in defining bone lesions causing spinal cord compression once the level of interest has been identified by MR or myelography (if MR is contraindicated). Metastatic disease, discogenic disease with osteophyte formation and calcification of disc material/ligaments, infection, and primary bone tumors or metabolic lesions are examples of pathological processes in which CT can add information to MRI. CT can visualize nerve roots surrounded by low-attenuation fat particularly in the lumbar neural foramen and is useful in evaluating bone encroachment on the neural foramina from endplate osteophyte formation, facet degeneration, or unciniate process osteophytes of the cervical spine. CT myelography can visualize nerve roots and the spinal cord in the thecal sac and is particularly useful in the patient who cannot undergo MRI.

MAGNETIC RESONANCE IMAGING

Basic Principles and Techniques

Gorter is given credit for the origin of the concept of nuclear magnetic resonance (NMR) in 1936. [13] Work was continued by Purcell and Block in the mid 1940s with their Nobel Prize winning discovery of the magnetic resonance phenomenon. Experimentation was limited to very small quantities of materials that were contained within a vacuum chamber. In the late 1960s, Jackson reported NMR experiments on animal tissues. Damadian, in 1972, was the first to describe whole-body NMR for medical diagnosis. Shortly after, in 1973, Lauterbur theorized using magnetic field gradients to create a position-dependent NMR signal. The first MR images of detailed human anatomy were produced by Aberdeen in 1976. The widespread clinical use of MRI began approximately in 1980 and continues to grow at an exponential pace.

NMR is the science that forms the basis for MRI. Abundant water molecules within the human body contain protons that act as microscopic magnets. When the human body is placed into a static main magnetic field, approximately 50 percent of the magnets align parallel to this main magnetic field. The remainder align in an antiparallel fashion. These magnets cancel each other out, although approximately one in a million bar magnets is not canceled out and creates the basis of a tiny magnetic net vector. These microscopic magnets form the basis of the intrinsic signal that is used to generate clinical images. These net magnetic vectors align with the axis of the main magnet and rotate at a specific frequency known as the Larmor frequency. A second type of magnetic field known as gradient fields is used to augment the main magnetic field and allow for anatomical localization of the specific spinning protons. Finally, there is a third type of magnetic field known as a resonance frequency field referred to as a radiofrequency (RF) pulse. This RF pulse is a very low amplitude that oscillates near the Larmor frequency that is 63.87 MHz for a 1.5-Tesla (T) MR image. When the RF pulse is applied, the spinning protons become excited and flip their orientation to a predetermined flip angle, which is usually 90 degrees for a spin-echo technique. When the RF field is turned off, these excited spinning protons convert to a relaxed state, releasing energy. This energy can be measured with head, body, or surface coils and forms the basis for image formation.

The intrinsic high tissue contrast medium for MRI is one of the major strengths of this modality. Whereas CT uses differences in x-ray attenuation coefficients of two adjacent tissues, the MR signal is intrinsic and is generated by changing the proton spins in response to an external RF pulse. The different macromolecular characteristics of the intercellular and extracellular protons within the water molecules determines the intrinsic MR signal that is displayed for diagnostic interpretation. The macromolecular spin magnetization returns to its equilibrium state through a process defined by two relatively independent relaxation times, referred to as T1 and T2.

After a 90-degree RF pulse the proton magnetization net vector rotates from the axis of the main magnet (z axis, longitudinal magnetization) to the transverse plane (x and y axes, transverse magnetization). When the RF pulse ends, the longitudinal magnetization recovers toward 100 percent in an exponential manner. The time it takes for the proton to recover 63 percent of its longitudinal magnetization is referred to as *T1* or *spin-lattice relaxation*. In a similar fashion, when the RF pulse ends, the transverse magnetization is 100 percent and decays toward zero. The time it takes the proton to lose 63 percent of its transverse magnetization is termed *T2* or *spin-spin relaxation time*. The energy signal formed during this decay process is referred to as a free induction decay (FID). This signal is intrinsically weak. It is enhanced by the addition of a second 180-degree RF pulse, which follows the first 90-degree RF pulse. This second RF pulse refocuses the protons and creates a spin-echo signal. The time from the 90-degree pulse to the spin-echo signal is termed the *TE*. This process is repeated, and the repetition time between the 90-degree pulses is called *TR*.

Images can be created that have relative T1 weighting (T1WI) or T2 weighting (T2WI) by varying the TR and TE. A T1WI has a TR less than 1000 msec and a TE less than 50 msec. A T2WI has a TR greater than 2000 msec and a TE greater than 60 msec. An intermediate so-called proton density weighing has a TR greater than 2000 msec and a TE less than 40 msec.

Normal Findings

There are basic MR signal patterns of normal tissues in the brain. These patterns are shown in [Table 23-3](#).

Types of Detectable Abnormalities

The MR signal characteristics of a lesion on T1WI and T2WI enables the differential diagnosis of any particular brain abnormality to be narrowed. A summary of signal characteristics is shown in [Table 23-4](#). There are specific and nonspecific patterns of MR signal regarding normal and abnormal tissues. The most specific patterns are seen with respect to CSF, fat, bone, and stages of intracranial hemorrhage.

CSF has decreased signal on T1WI, intermediate signal on proton density, and increased signal on T2WI. When evaluating a cystic lesion, one must determine if the lesion follows CSF signal characteristics on all pulse sequences. If the lesion does not, it is considered atypical. Lesions that follow CSF signal typically represent arachnoid cysts or dilated CSF spaces secondary to encephalomalacia. Complicated fluid may show increased signal on both T1WI and T2WI. These abnormalities suggest the presence of proteinaceous or complex hemorrhagic fluid and may harbor malignancy.

Fat has increased signal on T1WI and decreased signal on T2WI. Lesions that follow this pattern most commonly represent fat containing congenital lipomas and teratogenic tumors. Confirmation of a fatty lesion can be obtained with a fat saturation RF pulse sequence.

Each stage of hemoglobin molecular breakdown has its own peculiar imaging signature based on the MR signal. That is, the stages of hemorrhage whether acute, subacute, or chronic, generate unique changes that are uniquely shown only by MRI. These signals range from nearly isointense to hypointense signal as seen in

acute hemorrhages to increased signal seen on both T1WI and T2WI observed in late subacute or chronic hemorrhages. [14], [19] The signal patterns of brain hemorrhage are summarized in Table 23-5.

MR signal patterns are recognizable with common diseases such as cerebral edema, neoplasm, abscess, infarcts, or demyelinating processes. These entities demonstrate a nonspecific pattern of decreased signal on T1WI and increased signal on proton density and T2WI. Therefore, to obtain a differential diagnosis with a high degree of accuracy, this information is linked with anatomical location, morphology, and a degree of contrast medium enhancement. These, with good clinical history, all help in arriving at a correct differential diagnosis.

Neurological Applications in Diagnosis and Treatment

In general, owing to high tissue contrast between tissues and multiplanar imaging, MRI is the study of choice to evaluate all lesions in the brain and spine. CT, however, is more sensitive than MRI for the evaluation of calcifications, subtle fractures, and subarachnoid hemorrhage. Additionally, MRI cannot be performed in patients who have intraorbital

foreign bodies, pacemakers, or non-MRI compatible artificial heart valves, vascular clips, or ventilators. When approaching a lesion that is seen on an MR image of the brain, the specific location of this lesion must be identified. If one begins superficially and moves inward toward the deeper spaces of the brain, the first important space would be the extracalvarial soft tissues, consisting of skin, muscle, and facial structures. The bony calvarium is next composed of the outer table, bone marrow within the diploic space, and inner table. The next space to consider is the extra-axial structures, which include the epidural, subdural, and subarachnoid spaces. The layer beneath the subarachnoid space is the pia mater, which is closely adherent to the gray matter cortical ribbon. Deep to the pial layer lies the intra-axial structures. These structures include the cortical gray matter, the underlying white matter, the ventricular system, the deeper basal ganglionic structures, followed by the brain stem. On routine MRI of the brain there are additional structures to examine, including the orbits, sinuses, temporal bone, and skull base.

CALVARIAL RELATED LESIONS

Benign growths or neoplastic processes include neurofibroma in a patient with neurofibromatosis (type I), soft tissue fibromas, and dermoid or epidermoid tumors. Bone abnormalities include secondary metastatic lesions and rare primary osteogenic sarcomas or giant cell tumors. Secondary neoplastic processes that involve the diploic (marrow) space are leukemia and lymphoma.

Inflammatory lesions within the extracalvarial soft tissues typically include benign processes such as sebaceous cysts or cellulitis. Primary calvarial inflammatory lesions include osteomyelitis or an infected postoperative bone flap.

Bony lesions and congenital fibro-osseous lesions such as fibrous dysplasia or Paget's disease are common calvarial abnormalities. A common marrow disorder is conversion from fatty marrow to hematopoietic marrow in patients with anemia. Primary loss of normal hematopoietic elements with conversion to dense fibrous matrix will be seen in myelofibrosis.

CRANIAL DISEASES

Extra-axial Space Lesions. Congenital tumors of epidermal and mesodermal origin that arise from the skull base and cerebellopontine angle are typically epidermoid tumors. These tumors are usually eccentric and are locally invasive. Congenital tumors that contain all three embryonic layers are dermoid tumors. These tumors tend to occur in the midline at the skull base and within the suprasellar cistern. More aggressive neoplasms to consider are ependymomas, which arise from ependymal cells most commonly within the fourth ventricle or cerebellopontine angle. Secondary neoplastic involvement of the pachymeninges include lymphoma, metastasis from lung or breast, or possibly an adenocarcinoma from an unknown primary tumor. These lesions may represent a single metastatic foci of diffuse carcinomatosis.

The most common tumor is a meningioma, which represents a primary neoplasm of the dura ([Fig. 23-9](#)). Inflammatory processes such as epidural empyema from

Figure 23-9 Olfactory groove meningioma. A, Axial T2-weighted image shows a mass attached to the anterior falx (dural extension). Note relative low signal on T2WI and surrounding signal. B, Coronal T1-weighted image after contrast shows homogeneous enhancement of the dural based extra-axial mass.

an adjacent sinus infection may occur. Subdural effusions have been described in children with systemic *Haemophilus influenzae* infections. The most common inflammatory process to consider is a meningitis, which may be of viral, fungal, or bacterial origin.

An important pattern of abnormality is diffuse pachymeningeal thickening with homogeneous enhancement following an intravenous injection of contrast agent (gadolinium). The differential diagnosis includes carcinomatosis, sarcoidosis, meningitis, or a more recently described entity referred to as central CSF hypotensive pachymeningitis.^[16] The exact cause of this last entity is not well understood, but it is believed to be related to either a CSF leak or an abnormal CSF metabolic process.^[16] One of the more common extra-axial lesions is a post-traumatic epidural or subdural hematoma. Lesions within the subarachnoid space that follow CSF signal on all pulse sequences and demonstrate mass effect represent congenital or post-traumatic (acquired) arachnoid cysts.

Intra-axial Space Lesions. Small focal lesions at the gray matter/white matter junction, which demonstrate mass effect, surrounding edema, and contrast medium enhancement most commonly represent metastatic lesions. Large enhancing masslike lesions that involve both the gray matter and white matter and that do not follow a wedge-like distribution typically represent primary brain gliomas. Low-grade (I, II) gliomas typically do not enhance, whereas higher-grade gliomas (III, IV) usually do. A low-grade neoplastic process must also be considered if there is a focal, nonenhancing enlargement of the gray matter cortex that continues to have mass effect over a 3- to 4- week interval. This lack of change will help differentiate a low-grade glioma from a cortical infarct.

Peripheral cortical inflammatory processes secondary to meningitis may lead to a cerebritis that may subsequently form a focal abscess. Viral inflammatory processes of the cortex and subcortical white matter may occur and are most commonly secondary to a herpesvirus infection. Multifocal enhancing lesions in the gray matter/white matter junction, brain stem, and cerebellum may represent multifocal abscesses in the appropriate clinical setting ([Fig. 23-10](#)).

A wedge-shaped lesion that involves both white matter and gray matter and follows a vascular distribution usually represents an infarction from cerebrovascular disease. Acute infarctions may become evident on routine T2WI spin-echo images within 12 to 24 hours of onset. The most sensitive pulse sequence is a water diffusion coefficient weighted technique.^[17] This pulse sequence can detect an infarct within the first few hours of onset. Peripheral vascular venous occlusions of the superior sagittal sinus or adjacent cortical draining veins may lead to a cortical or a cortical/subcortical venous infarction.

Lesions that primarily involve the white matter are most commonly secondary to small vessel occlusive disease or a demyelinating process. Small rounded infarctions less than 1 cm within the deep white matter, basal ganglion, cerebellum, or brain stem in an adult older than 50 years of age most commonly represent lacunar infarctions. Also in this population, tiny lesions within the periventricular white matter are usually secondary to small vessel ischemic disease. Demyelinating lesions secondary to multiple sclerosis may mimic this appearance but typically are present in younger adults. Lesions of multiple sclerosis may present as early as the second decade as rounded or ovoid lesions in the periventricular deep white matter. Ovoid lesions that are perpendicular to the long axis of the body of the lateral ventricles represent demyelination within perivascular spaces termed *Dawson's fingers*. Additional lesions are commonly present in the corpus callosum and brain stem. In children younger than the age of 10, periventricular white matter lesions and basal ganglionic, brain stem, or cerebellar lesions may represent an acute disseminated encephalomyelitis, which is a postviral or postvaccine autoimmune process ([Fig. 23-11](#)). Multiple sclerosis and acute disseminated encephalomyelitis are the most common acquired leukoencephalopathies. Another leukoencephalopathy to consider is human immunodeficiency virus (HIV) encephalopathy, which is a diffuse process. Multifocal lesions with minimal mass effect and no abnormal contrast medium enhancement in an immunocompromised patient may represent progressive multifocal leukoencephalopathy. Postirradiation and/or postchemotherapeutic leukoencephalopathy

Figure 23-10 Cysticercosis. A, Axial T2-weighted image shows two parietal lobe lesions with up sign. B, Coronal T1-weighted image after contrast shows small ring-enhancing lesions.

Figure 23-11 Acute disseminated encephalomyelitis. Axial T2-weighted image shows multiple white matter lesions.

should be considered. There are a wide variety of congenital dysmyelinating disorders, the most common of which are metachromatic leukodystrophy, adrenoleukodystrophy, and Canavan's disease. All of these dysmyelinating diseases represent congenital enzymatic defects.

Within the deeper basal ganglionic structures, brain stem, or cerebellum, the most common lesions are focal infarctions and demyelination. Much less common lesions include focal encephalitis or gliomas. Focal mass lesions within the brain stem or cerebellum may occur within an older adult and most commonly represent metastasis. A primarily cystic lesion with an enhancing mural nodule within the cerebellum in a child represents a pilocystic astrocytoma. In a young adult, a similar-appearing lesion most likely represents a hemangioblastoma, which may be part of von Hippel-Lindau disease. A focal expansile lesion within the brain stem most commonly in the pons in a young child typically represents a brain stem glioma ([Fig. 23-12](#)). In a child, the primary differential diagnosis for a posterior fossa mass includes in decreasing frequency: a primitive neuroectodermal tumor (medulloblastoma), brain stem glioma, cerebellar pilocystic astrocytoma, and ependymoma.

Vascular malformations are most commonly found within the intra-axial space, although they may be present extra-axially. These lesions represent a spectrum from benign cavernous angiomas, which have a low bleeding potential, to arterial venous malformations that carry a bleeding potential of 2 to 4 percent per year.^[17] Cavernous angiomas lesions have characteristic appearances of lobulated blood-filled channels with a rim of hemosiderin. Arterial venous malformations have serpiginous tangles of flow voids with adjacent feeding arteries and draining veins.

Primary neoplasms, although uncommon, do occur. These tumors include choroid plexus papillo or carcinoma, central neurocytomas, which are characteristically attached to the septum pellucidum ([Fig. 23-13](#)), interventricular meningiomas, and ependymomas. Colloid cysts typically originate within the region of the roof of the anterior portion of the third ventricle and typically are usually benign. Occasionally, these cysts may cause acute hydrocephalus and rarely death in a young adult from brain herniation.

MAGNETIC RESONANCE IMAGING OF THE SPINE

Since the mid 1980s, MRI of the spine has attained acceptance as the premier modality in the evaluation of spine diseases. MRI is eloquent in the evaluation of both benign or malignant spinal processes and is unique in its inherent noninvasive ability to image the spinal cord and surrounding structures such as CSF, dura, and adjacent ligaments. The utility of spine MRI can therefore be discussed in terms of the three classic categories of spine disease: extradural, intradural-extramedullary, and intramedullary processes.

A frequent cause of epidural disease is intervertebral disc pathology. MRI can uniquely image the intervertebral disc directly, without the use of contrast material. Disc integrity can be assessed in terms of degeneration, abnormal disc bulges, or herniations. High-resolution T2-weighted images of the disc can diagnose annular and circumferential tears that previously required injection of contrast material (i.e., CT discography). Any affect on spinal contents, either the spinal cord or existing nerves in the cervical and thoracic regions, or nerve impingement on

Figure 23-12 Brain stem glioma. Midline sagittal T1-weighted image shows a focal enlargement of the pons with decreased signal.

47

Figure 23-13 Central neurocytoma. Axial post-contrast T1-weighted image show a heterogeneously enhancing, rounded intraventricular mass within the anterior portion of the lateral ventricle.

either the cauda equina or existing nerve roots in the lumbar region can be assessed. Additionally, inherent signal aberrations within the intervertebral discs can also be analyzed for primary intrinsic disc abnormalities such as infectious discitis and associated vertebral osteomyelitis.

Although MRI is inherently poor for showing dense, cortical bone, it is extremely useful in the evaluation of infiltrative bone marrow diseases. Both degenerative and malignant bone marrow changes can be detected and categorized based on MR signal patterns. Benign processes such as post-traumatic bone edema, fatty bone marrow infiltration, or benign neoplasms such as primary vertebral hemangiomas can be readily distinguished from carcinomatous changes (i.e., vertebral plasmacytoma or frank metastatic disease with or without vertebral destruction or paravertebral soft tissue involvement). MRI is also useful in the analysis of degenerative spondylosis and complications of spondyloarthropathies as well as in the evaluation of benign or malignant spinal canal or foraminal stenosis. MRI is pivotal in the emergency evaluation of post-traumatic spinal cord compression.

Infrequently, intradural extramedullary masses present for evaluation. In the cervical and thoracic regions, meningiomas, neuromas, and arachnoid cysts predominate, whereas, in the lumbar spine, schwannomas, ependymomas, or, rarely, intradural disc herniations are more common. Occasionally, intradural extramedullary metastases are encountered that may stud the spinal cord and meninges with metastatic deposits.

MRI is uniquely sensitive in detecting the presence of intramedullary spinal cord diseases. Common primary intramedullary neoplasms that can be elucidated include astrocytoma, ependymoma, and spinal cord hemangioblastoma. Contrast medium-enhanced MRI can help differentiate tumoral cord edema, as seen in these entities from the primary tumoral masses. Other causes of abnormal signal within the spinal cord include inflammatory or demyelinating diseases such as acute disseminating encephalomyelitis, transverse myelitis, or multiple sclerosis. The evaluation of spinal cord edema, secondary to trauma, either from chronic discogenic disease or in situations of acute complex fracture injuries is becoming increasingly essential, particularly in national trauma centers.

MAGNETIC RESONANCE ANGIOGRAPHY

Basic Principles and Techniques

Techniques have been developed to image the flowing blood. MRA and magnetic resonance venography (MRV) are used to study the flow in various vessels and have proved to be robust in routine clinical examination of vascular diseases. In this section the basic underlying principles of MRA and the major clinical uses are discussed.

There are two major MRA techniques that are used in MRI that exploit either the longitudinal spin magnetization or transverse spin magnetization of the protons in blood to visualize flowing blood. They are the time-of-flight (TOF) technique, which utilizes the inflow-outflow of the moving spins within the selected imaging volume to image the blood flow and the phase-contrast technique, which utilizes the flow-induced phase variations of the MRA signal caused by the motion of the blood. These MRA techniques depict the blood flow as bright in contrast to the dark surrounding stationary tissues. The MRA data are postprocessed with a maximum intensity projection algorithm and may be displayed in multiple angiographic projections. The MR method to examine the venous sinuses in the head is MRV. A two-dimensional TOF technique is used that has the advantage of sensitivity to slower-flowing venous structures and the ability to cover a large area.

Normal Findings

The TOF method uses the longitudinal magnetization, such that the blood flowing into the selected volume during the RF excitation period is fully relaxed, whereas the magnetization from the stationary tissue is saturated, and hence the signal from the blood is brighter compared with that of the stationary tissue. This phenomenon was first described in a nonimaging context by Singer.^[18] After RF excitation, the longitudinal magnetization recovers exponentially with time constraint T1 and is typically much longer than with T2 weighting. In a volume of stationary tissue and flowing blood, during every TR interval, the

magnetization recovers incompletely throughout the volume, acquiring T1 weighting that suppresses particularly the signals with longer T1. This is referred to as saturation. The degree of T1 weighting depends on the solution of the Bloch equation, which is a function of TR, T1, and the excitation flip angle σ . Usually, a TR of 30 to 100 msec and flip angles of 10 to 60 degrees are used. These imaging parameters can be optimized for maximum suppression of the stationary tissues and better flow visualization.

In TOF imaging, faster flow through a vessel lumen running perpendicularly through the slice partially or completely exits the slice in the interval between the 90- and 180-degree excitation pulses.^[19] Consequently, the 180-degree pulse fails to invert the nuclei and the signal is diminished. However, with slow flow, washout of the spins between the 90-degree and the 180-degree pulses is minimal. The previously excited outgoing slice is replaced during the TR interval by the inflow of fully magnetized spins from outside the volume, giving a brighter signal than the one acquired from stationary tissue. This phenomenon is generally referred to as entry phenomenon or flow-related enhancement. Furthermore, the heavy T1 weighting associated with these short TR sequences suppresses stationary tissue, an important contributor to the contrast between the stationary and the flowing signal. The TOF method primarily uses this flow-related enhancement phenomena to image the blood vessels.

Two major techniques exist in TOF MRA: two-dimensional TOF (2D TOF) and three-dimensional TOF (3D TOF) imaging techniques. Two-dimensional TOF is advantageous because of its sensitivity to slow flow rates, minimal saturation effects for normal flow velocities, and short acquisition times (5 to 7 minutes). Although widely used, the technique has a few limitations. The appearance of the moving blood varies when the imaging plane is not perpendicular to the slice select direction. Owing to the inplane flow, the blood vessels that run parallel to the imaging plane experience multiple RF pulses and eventually become saturated. Hence, the portion of the vessel traversing the imaging plane may exhibit some reduction in signal intensity and appear artifactually narrowed or even discontinued. Preliminary work with 2D TOF and magnetization transfer (MT) in the carotid artery bifurcation has shown an improved signal-to-noise ratio (SNR) and greater sharpness of vessel margins.^[20] Contrary to the 2D TOF technique, the 3D TOF MRA technique offers a wide number of advantages over its 2D counterpart. The 3D volume acquisition techniques offer superior SNR and high spatial resolution and are sensitive to fast and intermediate flow. Also, the other major advantage of this technique is that the acquisition can be made in thin slices, thereby reducing voxel size and hence decreasing intravoxel dephasing of the moving blood. The use of surface coil along with small imaging voxels has been shown to significantly improve SNR and vessel conspicuity in normal and diseased carotid arteries.^[21] Three-dimensional TOF is relatively insensitive to slow flow and is effective only for relatively small 3D volumes, because blood is saturated by multiple RF pulses while traversing the slab. Recently, MRA using 3D TOF with MT has been widely used in routine clinical imaging of the circle of Willis owing to their excellent stationary tissue suppression capabilities.^[22] Preliminary work with 3D TOF acquired with dual 20- and 60-degree flip angles demonstrates improved SNR and vessel definition.^[23]

In contrast to TOF, the phase-contrast angiography technique uses the flow-induced phase variations of the MRA signal caused by the motion of the blood. These phase shifts induced by the flow can be selectively modulated using bipolar flow-encoding gradients, and images of flow can be generated. With this strategy, two sets of data are acquired under identical conditions, except that the polarity of the bipolar flow encoding gradients is alternated during data acquisition. This modulates the velocity-induced phase shift for spins having macroscopic motion (flowing blood) and has no effect on stationary spins. MRA projections are created by subtraction of one data set from another, remove the signal from stationary tissues, and retain the signal from the flow. Moreover, the phase shift of the image can also be used to obtain a phase map of the image. This phase map is usually displayed in gray scale and indicates the regions where flow has occurred.

The two most popular methods that are currently used image the slab volume either with sequential time-averaged 2D slices^[24] or with simultaneous acquisition of 3D volume slabs^[25] and are generally referred to as 2D or 3D phase-contrast angiography. The 2D phase-contrast angiograms, like 2D TOF, are obtained as sequential individual slices. In 3D phase-contrast MRA the data are collected in three dimensions. This has several advantages over the 2D phase-contrast technique, such as isotropic voxels, reduction in phase variations, and flexibility in cross-sectional presentation of the feature of interest. However, the overall imaging time is much higher as compared with the 2D technique. In the past few years, cine phase-contrast MRA, a variant of 2D phase-contrast MRA in which cardiac gating is used to generate images at different points within the cardiac cycle, has become widely used. This method has been used to analyze temporal flow of blood in carotid arteries in the neck^[26] and flow of CSF in the brain.^[27]

Neurological Applications in Diagnosis and Treatment

CRANIAL DISEASE

Carotid Bifurcation Lesions. One of the primary uses of MRA is the evaluation of the lesions in the carotid artery bifurcation. Atherosclerotic lesions within the carotid bulb and proximal internal carotid artery are major factors contributing to the development of cerebrovascular ischemia. The appropriate treatment of patients with asymptomatic and symptomatic carotid stenosis remains controversial. The North American Symptomatic Carotid Endarterectomy Trial^[28] and the European Carotid Surgery Trial^[29] demonstrated that patients with transient ischemic attacks or nondisabling stroke ipsilateral to a carotid stenosis of 70 percent or more have been found to have a significant incidence of further strokes. In a group of patients with asymptomatic carotid stenosis of 50 percent or more, Hobson and associates and the Veterans Affairs Cooperative Study Group showed that carotid endarterectomy reduced the overall incidence of ipsilateral neurological events in this population.^[30] Although the exact degree of carotid

stenosis that would affect patient management (i.e., medical or surgical) has not been definitely determined, these studies have set the current trends. Noninvasive techniques that accurately measure the degree of carotid stenosis will continue to be a very important part in the workup of these patients. [Figure 23-14](#) shows an example of an MR angiogram of a complex stenosis.

Atherosclerotic disease is most prevalent at arterial bifurcations and usually involves the carotid bulb of the internal carotid artery. The development of plaque and stenosis at the carotid bulb is believed to be related to the anatomy of the carotid bifurcation and associated complex hemodynamic forces that cause microscopic intimal injury and subsequent initiation of the atherosclerotic cascade. The complex flow (vortices, separation of flow streams, and slow flow) within the carotid bifurcation is well demonstrated using computer simulation based on images obtained by digital subtraction angiography (DSA) and MRA.^[21]

Complex flow is one of the major causes of intravoxel dephasing, which leads to signal loss in MRA. An example of MRA signal loss distal to a carotid stenosis is

shown in [Figure 23-15](#) . Comparison is made with DSA and computer simulation of temporal blood in this vessel.

DSA remains the gold standard to characterize carotid bifurcation disease; however, numerous investigations have shown that noninvasive MRA has the potential to replace DSA as a screening test and gold standard.^[31], ^[32]

Figure 23-14 Carotid bifurcation of a patient with arteriosclerosis. *A*, Digital subtraction arteriogram (DSA) shows mild stenosis in proximal carotid bulb (*short arrow*), moderate to marked stenosis in external carotid artery (*open arrow*), and marked stenosis (approximately 85%) in distal bulb/proximal internal carotid artery (*long, thin arrow*). Contrast medium collection probably represents ulceration (*large arrowhead*). Ascending pharyngeal artery (*small arrowhead*). *B*, Axial two-dimensional TOF (surface coil). Accurate demonstration of moderate to marked stenosis in external carotid artery (*open arrow*). Small elongation of mild stenosis in proximal bulb (*arrow*). Slight exaggeration of marked stenosis (to approximately 90 percent) in distal bulb/proximal internal carotid artery (*long, thin arrow*). Signal is lost within the proximal portion of this stenosis. Ulceration (*large arrowhead*) and ascending pharyngeal artery (*small arrowhead*) are identified. (From Faro SH, Vinitski S, Ortega HV, et al: Carotid magnetic resonance angiography: Improved image quality with dual 3-inch surface coils. *Neuradiology* 1996;38:403-408.)

Figure 23-15 Carotid bifurcation of patient with atherosclerotic disease. *A*, Selected digital subtraction arteriogram of carotid artery bifurcation showing a mild to moderate (approximately 33%) stenosis in the proximal internal carotid artery. Exaggeration of the degree and length of stenosis is present. For color simulation of vascular flow pattern in the carotid bifurcation in this patient during the acceleration phase of systole, see the CD-ROM. (From Faro SH, Vinitski S, Ortega HV, et al: Carotid magnetic resonance angiography: Improved image quality with dual 3-inch surface coils. *Neuradiology* 1996;38:403-408.)

Lesions in the Circle of Willis. The primary use of MRA of the circle of Willis is to evaluate the presence of an unruptured aneurysm that came to medical attention due to the incidental discovery of this lesion by MRI. The use of MRA as a screening test to identify congenital berry aneurysms before rupture in groups at risk (e.g., adult polycystic kidney disease, family history of an aneurysm) would also be desirable. Several studies have shown the sensitivity of MRA to detect congenital aneurysms 5 mm or greater is approximately 90 percent.^[33], ^[35] [Figure 23-16](#) shows an aneurysm detected with MRA. Aneurysms smaller than 5 mm do rupture, although the incidence is reduced. MRA is considered an accurate noninvasive screening test for patients at risk for aneurysms. DSA is required for preoperative planning.

Other Applications. Patients with the diagnosis of thrombosis of the superior sagittal sinus or transverse sinuses can be followed with serial MRV studies ([Fig. 23-17](#)). Vascular malformations, either pial (intramedullary) or dural (extramedullary), may be detected with MRA. Serpiginous flow patterns and voids, either within or extrinsic to the spinal cord, can suggest specific diagnoses. Even the presence of unexplained spinal cord edema may suggest angiodysgenic myelomalacia (Foix-Alajouanine syndrome) in the presence of an underlying vascular malformation. Intravenous contrast medium administration in MRI of the spine further aids in the delineation of spinal cord tumors and has proved helpful in the evaluation of the postoperative spine, particularly in the differentiation between nonenhancing recurrent disc herniation from enhancing postoperative scar.

MYELOGRAPHY

Basic Principles and Techniques

The beginning of myelography has its "roots" in the early 1900s when subarachnoid injections of air were performed to localize spinal cord tumors. This technique of pneumomyelography was eventually supplanted by the subarachnoid injection of an iodized poppy seed oil, Lipiodol, the myelographic medium of choice during the 1930s. Lipiodol had its disadvantages, including a very high viscosity, its immiscibility with CSF (thereby making it difficult to perform satisfactory diagnostic studies as well as remove on completion of the study), and its irritating nature to the leptomeninges. In 1940, Pantopaque was introduced. This oil-based contrast agent was less viscid and less irritating to the leptomeninges than Lipiodol. Its lower specific gravity allowed it to flow more freely in the subarachnoid space with less tendency to form large irregular globules; and, accordingly, removal on completion of the study was easier to perform than its predecessor. Pantopaque soon became the contrast medium of choice in the United States until the late 1970s, although it was still far from being an ideal subarachnoid contrast agent. Its relative immiscibility in CSF resulted in its inability to enter nerve root sleeves, thereby making it difficult to evaluate far posterolateral disc abnormalities. A 20-gauge spinal needle or larger was required during Pantopaque insertion and removal, and the use of this relatively large size needle commonly resulted in spinal headaches from CSF leakage at the puncture site. Furthermore, Pantopaque was still difficult to remove in entirety after completion of the study. When left behind, Pantopaque was absorbed slowly at the rate of approximately 1 ml/yr, which could produce local changes of arachnoiditis.

In the early 1930s experimental studies were carried out

Figure 23-17 A. MRV shows loss of flow related signal in the proximal and distal and straight sinuses (SS) and superior sagittal sinus (SSS) in a patient with dehydration and dural sinus thromb. Follow-up MRV showed reconstitution of the SSS and SS.

with Abrodil, a water-soluble organic iodine compound widely used in the Scandinavian countries for lumbar myelography. Abrodil never achieved popularity in the United States as a result of its marked hypertonicity, in comparison to CSF, which produced significant irritation to the leptomeninges and neural elements. Water-soluble myelography was revitalized in the United States during the early 1970s with the introduction of Conray and Dimer-X, salts of iodinated acids. These compounds, like Abrodil, caused significant neurotoxic effects, including meningeal and radicular irritation, as a result of their hypertonicity.

As a result of ongoing investigations, metrizamide was marketed as a synthetic nonionic water-soluble contrast medium that had a much lower osmolality than the salts of iodinated acids. This contrast agent provided safe examination of the entire spinal column without significant neurotoxicity.

Within recent years, in an attempt to further reduce the incidence of serious side effects, other nonionic water-soluble contrast agents, such as Isovue and Omnipaque, have been synthesized and are now in wide use. In many institutions, iopamidol (Isovue) is used for subarachnoid injections. In the concentration used for lumbar myelography (200 mg iodine/ml), iopamidol is only mildly hyperosmolar when compared with CSF (413 vs. 301 mOsm/kg H₂O) and has dramatically fewer neurotoxic side effects than the salts of iodinated acids. Iopamidol is rapidly excreted in the kidneys with undetectable plasma levels at 48 hours in the absence of renal dysfunction. The most common adverse reactions are headache, nausea, vomiting, and transient worsening of neck, back, or leg symptomatology. Hypotensive collapse and shock are rare, with only isolated reports being found in the literature. The usual recommended adult dose range for iopamidol when performing myelographic procedures is 2000 to 3000 mg iodine. This is equivalent to 10 to 15 ml Isovue-M200, which is used for lumbar myelography, and to 10 ml maximum Isovue-M 300, which is used for cervical myelography via lumbar injection.

Before a myelogram is performed, certain information should be obtained from all patients. In those individuals with a prior history of dye allergy, bronchial asthma, hay fever, and food allergies, premedication with corticosteroids and antihistamines is indicated to prevent or minimize possible allergic reactions. Patients should also be well hydrated before and after the myelographic procedure. Dehydration may contribute to acute renal failure in patients with a history of diabetes, advanced vascular disease, or pre-existing renal disease. Knowledge as to current prescription and nonprescription medications as well as underlying disease states is extremely important. Specifically, elective studies should not be performed on patients who are receiving oral or intravenous anticoagulants, and the use of aspirin should be discontinued for approximately 48 hours before the myelographic procedure. Drugs that lower the seizure threshold such as monoamine oxidase inhibitors, tricyclic antidepressants, and central nervous system stimulants should be withheld for 48 hours before and after the myelographic procedure. Routinely, serum creatinine, blood urea nitrogen, and coagulation profile including prothrombin time, partial thromboplastin time, and platelet counts are obtained within the week before the myelographic procedure.

During lumbar myelography, a 22-gauge spinal needle is inserted either in the midline between the spinous processes or slightly off midline through the rhomboid fossa at the level of L2-L3. This puncture site is preferred over the L3-L4 through L5-S1 levels because of the higher incidence of herniated discs and spinal stenosis at these lower levels. Alternatively, if premyelography imaging studies or certain clinical information is available, the puncture site can be performed at these lower lumbar levels when significant disease is known to exist at the level of L2-L3. The lumbar injection should be performed slowly over a period of 1 to 2 minutes to avoid excessive mixing with CSF and subsequent loss of contrast medium as well as premature cephalad dispersion.

In most instances, cervical myelography can be adequately performed by means of a lumbar puncture with subsequent fluoroscopic guidance of a more concentrated dose of contrast medium into the cervical region by gravity. Alternatively, a lateral C1-C2 puncture can be performed with the needle placement in the posterior third of the spinal canal between the C1-C2 neural arches. At all costs, intracranial entry of a bolus of contrast medium should be avoided because this could possibly lead to acute neurotoxic effects.

Meticulous radiographic technique is essential to obtain quality diagnostic examinations. Low voltage (Kvp) with optimal milliampere-seconds (mas) maximizes contrast detail. Air gaps should also be eliminated to reduce scatter and increase edge sharpness. In both the lumbar and the cervical regions, AP, lateral, shallow, and steep oblique views should be obtained with the addition of AP and lateral views of the conus during lumbar myelography. For thoracic myelography, AP and lateral views are routinely filmed.

Postmyelography CT of abnormal disc levels should be performed in the prone position with imaging deferred for at least 4 hours to reduce the degree of contrast within the desired area to be studied. Before obtaining the postmyelogram CT scan, the patient should be helped to roll over several times to thoroughly mix the contrast medium and avoid pooling in dependent portions of the spinal canal.

Routine postprocedure orders include keeping the patient's head elevated 30 to 45 degrees for 12 to 24 hours with close neurological monitoring. Oral fluids should be encouraged and diet prescribed as tolerated. All movements should be monitored by hospital personnel and performed slowly with the patient's head maintained in an upright position.

Normal Findings

Routinely, with either cervical or lumbar myelography, there is symmetrical filling of the nerve root sleeves without evidence of nerve root displacement or nerve root sleeve truncation. The size and direction of the spinal roots vary at different levels. The largest roots are the lower lumbar and upper sacral roots, which innervate the lower extremities. Accordingly, the roots of the lower four cervical and

first thoracic nerves are also large, owing to their upper extremity innervation. The upper cervical and remaining thoracic nerve roots are rather small in comparison, and the lower sacral and coccygeal nerve roots are the smallest. Discrepancies in length and direction of spinal nerve roots is secondary to the spinal cord being much shorter than the vertebral canal. In the cervical region, the relatively short nerve root traverses the lower portion of its respective neural canal in a horizontal direction. The thoracic nerve roots are directed obliquely downward, with the length and degree of obliquity increasing from the upper to the lower thoracic levels. Because the spinal cord ends at approximately L1, the lumbar, sacral, and coccygeal nerve roots descend in a nearly parallel course, with the length of the roots increasing successively from above downward. This group of nerve roots below the level of termination of the cord is termed the *cauda equina*. The thecal sac should have a smooth contour without evidence of narrowing or mass effect from extradural abnormalities. There should be smooth tapering of the distal thecal sac at a

variable distance below the L5-S1 disc space to a smooth "pencil point" appearance. The silhouette of the cervical and thoracic cord as well as the appearance and position of the conus should be closely scrutinized for intramedullary expansile lesions.

Types of Detectable Abnormalities

The use of water-soluble intrathecal contrast medium has markedly decreased over the past 10 to 15 years with the introduction of CT and, more recently, MRI. Before these more advanced imaging tools, water-soluble myelography was the gold standard in evaluating patients with back pain and had the ability to evaluate spinal stenosis, disc bulges and herniations, other extradural impressions on the thecal sac, spinal cord enlargement, and various inflammatory conditions. However, intrathecal contrast medium enhancement still lacked sensitivity in evaluating lateral disc herniations and the specificity in determining the exact cause for extradural impressions on the thecal sac and cord enlargement. With the use of CT and MRI, it is now possible to further define the factors contributing to spinal stenosis and to offer a much more exact and detailed differential diagnosis for the etiology of intramedullary lesions. With this added preciseness has come the general acceptance of these imaging modalities over myelography by other physicians not formally trained in radiological sciences.

Certain situations still warrant the use of water-soluble myelography. In extremely obese patients, in whom image resolution is significantly degraded on both CT and MRI studies, myelography in conjunction with postmyelography CT of abnormal levels still plays an important role in the diagnosis of spinal disease. Likewise, in patients with marked claustrophobia, in patients in whom MRI is contraindicated (e.g., those patients with intracerebral aneurysm clips, pacemakers, transcutaneous electrical nerve stimulation units, orbital metallic foreign bodies), or in patients with postoperative metallic internal fixation devices, myelography and postmyelography CT are the imaging studies of choice. In our experience, myelography, in conjunction with postmyelography CT, is as sensitive in the evaluation of subtle cases of arachnoiditis as MRI.

Neurological Applications in Diagnosis and Treatment

EXTRADURAL SPINAL LESIONS

The most common disorder seen while performing myelography is the extradural defect. Ventral extradural defects at the level of the disc space are caused by a variety of conditions, including disc bulges, disc herniations, posterior endplate spur formation, epidural hematomas, inflammatory processes, and epidural tumor, with or without associated adjacent bone involvement. Anterolateral extradural defects at the level of the disc space are routinely caused by posterolateral disc herniations, which will also result in nerve root displacement or nerve root sleeve truncation and the classic double-density sign seen on a lateral radiograph with the patient in the prone position ([Fig. 23-18](#)). Posterior and posterolateral extradural defects at or near the level of the disc space are usually the result of chronic degenerative changes of the posterior elements, including hypertrophic facet disease, ligamentum flavum hypertrophy, and the occasional synovial cyst arising from a markedly degenerated facet joint. Less common causes include metastatic disease to the posterior elements in association with a posterior epidural tumor component. An anterior or anterolateral extradural defect not limited to the disc space level could be the result of a migrated free disc fragment, epidural hematoma, inflammatory process, or metastasis. Far lateral disc herniations within the lateral aspect of the neural canal that extend beyond filling of the nerve root sleeve are radiographically silent on myelography. Similarly, a significant percentage of disc bulges and herniations at the L5-S1 level are nondescript using conventional myelography owing to the rather prominent anterior epidural space at this level that allows for posterior extension of disc material without associated thecal sac compression or nerve root displacement.

INTRAMEDULLARY SPINAL LESIONS

Intramedullary lesions causing enlargement of the cord or conus with concomitant narrowing of the adjacent subarachnoid space include primary cord neoplasms such as ependymomas, astrocytomas, and hemangioblastomas; metastases; inflammatory conditions such as sarcoidosis and abscess formation; cord hematomas and infarcts; vascular malformations; and congenital lipomas, dermoids, and epidermoids. Although these groups of lesions will most certainly cause widening of the silhouette of the cord or conus, the intrinsic pathology and extent of these intramedullary lesions are far better imaged with MRI.

INTRADURAL EXTRAMEDULLARY SPINAL LESIONS

Intradural extramedullary lesions such as meningiomas and the majority of neurofibromas can be adequately studied with myelography followed by CT. Whereas the intrinsic characteristics of these lesions is best evaluated with

43

Figure 23-18 A, Prone cross-table lateral view of lumbar myelogram. Prominent ventral impressions upon the contrast column are present at L3-4 and L4-5. Much milder ventral impressions are seen at L2-3 and L5-S1. A so-called double-density sign consistent with an eccentric posterior disc herniation is present at L3-L4 and L4-5. B, Prone left anterior oblique view of lumbar myelogram. Left-sided filling defects are present at L3-4 and L4-5 secondary to eccentric posterior disc herniations at both C. Axial CT scans at and just below L3-4 disc space demonstrate moderate-sized broad-based central and left-sided posterior disc herniation extending into left lateral recess. This eccentric posterior disc herniation would account for the double density sign seen in

MRI, myelography and postmyelography CT still play an important role in the presurgical evaluation of these lesions. Subtle cases of arachnoiditis or the determination of the level of a dural tear in a postoperative pseudomeningocele is as adequately visualized with myelography and postmyelography CT as with MRI ([Fig. 23-19](#)). Myelography and postmyelography CT are excellent diagnostic tools in evaluating patients with brachial plexus traction injuries presenting with nerve root sleeve tears and nerve root avulsion injuries. The communication of intradural and extradural arachnoid cysts, sacral cysts, and Tarlov cysts with the subarachnoid space can be accurately evaluated with myelography and postmyelography CT.

NEUROANGIOGRAPHY

Basic Principles and Techniques

Diagnostic neuroangiography is the study of the central nervous blood vessels and related cervicocerebral vasculature using radiographs during the injection of intravascular contrast media. Cerebral angiography was first introduced by Moniz in 1927 and remains a vital tool in the neuroradiological evaluation of cerebrovascular diseases. Although neuroangiography had been historically used to evaluate many types of central nervous system diseases, CT and MRI have largely supplanted diagnostic angiography in the primary evaluation of central nervous system diseases.^[36] State of the art CT and MRI offer advanced vascular imaging capabilities, yielding excellent "angiographic" types of information. Nevertheless, diagnostic neuroangiography continues to remain the gold standard in the evaluation of vascular diseases related to the head, neck, and spine.

The goal of neuroangiography is to define and outline the cerebral vasculature, both for diagnostic and potentially therapeutic purposes. Typical cerebral angiography is performed using the femoral arterial approach to gain access to the cerebrovascular arterial tree. Alternatively, in selected cases, the axillary, brachial, or direct cervical approaches

Figure 23-19 Adhesive arachnoiditis A. Anteroposterior view of lumbar myelogram. The thecal sac below the level of the L2-3 disc space is narrowed and featureless with central clumping of distal nerve roots giving the appearance of a pseudocord. Note absence of posterior elements at L3 and L4 secondary to prior decompressive laminectomy surgery. A small amount of contrast has inadvertently been injected into L2-3 disc space during lumbar pLB. Postmyelogram CT scan through the L3-4 disc space. Central clumping of lumbosacral nerve roots with "pseudocord" appearance is once again noted. Large bilobed pseudomeningocele protruding through laminectomy defect into deep and superficial soft tissues represents postoperative complication secondary to dural tear with continued CSF leak.

may be used as necessary. After access, nonselective catheterization of the aortic arch or selective catheterizations of the cervical arteries (specifically, the carotid or vertebral arteries) can be performed. Contrast medium is injected through the catheter with simultaneous radiographic filming of appropriate vascular territories such that diagnostic images of the cerebral vasculature are obtained. Current microcatheter technology also permits superselective angiographic analysis of smaller branch vessels of the brain, for both diagnosis and management of intracranial diseases.

Conventional film-screen technology in modern cerebral angiography has largely been replaced by digital subtraction technology. State-of-the-art digital suites now image with a 1024^[2] matrix resolution, providing exquisite vascular detail. In addition, digital angiography allows rapid image acquisition, instantaneous review, and pixel shifting capabilities, providing vascular resolution unsurpassed by conventional filming. For these reasons, conventional film screen angiography is rapidly becoming outmoded and most new, dedicated neuroangiographic suites are now constructed solely with digital angiographic capabilities.

Normal Findings

Neuroangiography is used today, primarily as a diagnostic modality in the evaluation of patients with vascular diseases of the central nervous system. Typical four-vessel cerebral angiography includes selective catheterizations of both internal carotid and vertebral arteries with angiographic filming in the AP, lateral, or oblique planes as needed. Angiographic filming is acquired during the arterial, capillary, and venous phases, because each phase reveals important vascular information. For example, the arterial phase is critical in the evaluation of entities such as cerebral aneurysms, cervical or intracranial arterial stenosis, or arterial occlusions. In contrast, the capillary and venous phases may reveal important data regarding vascular malformations, tumor neovascularity, venous stenoses, or venous thrombi. The measurement of the intracranial transit time of contrast material may further provide insight regarding focal or diffuse central nervous system abnormalities. Therefore, all phases of the angiographic study can provide important information regarding the overall health of the central nervous system. Yet, angiography maintains flexibility in that studies may be tailored to answer specific clinical questions.

Risks of neuroangiography are generally related to the complexity of the angiographic procedure, with an estimated 1 percent overall incidence of neurological deficit and a 0.5 percent incidence of persistent deficit.^[37] Risks include local bleeding or arterial injuries secondary to vascular access. The intraarterial positioning of an angiographic catheter within the arterial tree carries a risk of injury to the intimal lining of the arterial wall, particularly in patients with pre-existing atherosclerosis. This, coupled with the intra-arterial injection of contrast media, presents a risk of arterial dissection or stroke due to distal embolization. Lastly, there are potential risks associated with the use of iodinated contrast material, including allergic reactions and systemic organ effects such as renal damage. In preparing to study a patient with an allergic history, the

current recommendation is 50 mg of prednisone orally 13, 7, and 1 hour prior to the procedure. Diphenhydramine 50 mg orally may also be administered 1 hour prior to the procedure.

Types of Detectable Abnormalities

Angiography may be useful in detecting vascular lesions causing focal or bilateral cerebral dysfunctions, subcortical dysfunctions, or brain stem or spinal cord abnormalities. Abnormal size and contour of the lumen, abnormal distribution of vessels, and abnormal sequences of vascularization (early or late) can be seen. Additionally, displacement of vessels by extrinsic lesions can be detected along with endovascularization from tumors. In the section that follows, angiography is discussed in relationship to diagnosis and management of patients with ischemic brain disease, intracranial aneurysms, vascular malformations, and neoplasms. Although intracranial masses and their mass effects classically distort the cerebral vasculature, the primary diagnosis of intracranial masses has shifted to CT and MRI and is not addressed in this section. Angiography is not currently useful in the evaluation of peripheral nervous system or neuromuscular diseases.

Neurological Applications in Diagnosis and Treatment

CRANIAL LESIONS

Ischemic Cerebrovascular Disease. Diagnostic angiography in ischemic brain disease allows evaluation of the cerebral circulation from the aortic arch level to the terminal intracranial vessels.^[38] This provides a thorough evaluation for vascular lesions potentially causing stroke. Lesions most commonly diagnosed are atherosclerotic in origin. However, stenosis may be secondary to other entities, such as fibromuscular dysplasia, dissection, intimal hyperplasia, or radiation-induced vasculopathy. Cerebral angiography is also useful in evaluating patients with suspected vasculopathies. Angiography can uniquely identify abnormal regions of arterial narrowing or beading as seen in extracranial or intracranial arteritis ([Fig. 23-20](#)).

A primary goal in cerebrovascular disease therapy is stroke prevention. Hemodynamically significant stenosis carries an increased stroke risk, particularly when involving the carotid artery. Angiography remains key in detecting both extracranial and intracranial disease and allows precise characterization of inner plaque contour, including assessment of ulceration and stenosis measurement.

Traditionally, surgical treatments such as carotid endarterectomy have been the treatment of choice in the correction of cervical or intracranial stenosis. A growing literature now supports the use of endovascular techniques as an alternative in controlling cerebrovascular disease.^[39] The use of percutaneous transluminal angioplasty (PTA) in the treatment of subclavian, vertebral, or even carotid territory stenosis is growing. Advancing stent technology has further added to the success of carotid arterial PTA, and furthermore, these techniques have been extrapolated to intracranial use. Intracranial PTA is now technically feasible in both the carotid and vertebral territories. Combination therapy may also be considered for tandem lesions.

Stroke literature now supports prompt neurointervention with thrombolytics in patients who generally present with major cerebral arterial occlusive disease within 6 hours of acute neurological symptoms. In these cases, angiography

precisely localizes sites of arterial occlusion and accesses collateral vasculature. Microcatheter delivery of thrombolytic agents directly into the occlusive thrombus can potentially re-establish normal arterial flow. This treatment has the potential to avert an impending stroke or significantly reduce the overall extent of cerebral infarction.

Brain infarction or hemorrhage occasionally may result secondary to venous occlusive disease. The identification of venous thrombus ordinarily is established by CT or MRI. Angiography may be necessary when the diagnosis is obscure. Angiography can demonstrate absence of flow within a dural sinus or identify intraluminal filling defects. When necessary, a thrombosed dural sinus can be treated with direct microcatheter delivery of thrombolytics, resulting in clot lysis. The treatment goals are to reduce vascular congestion and re-establish normal venous outflow.

Aneurysms and Vascular Malformations. Cerebral angiography remains the gold standard in the evaluation of patients suffering from subarachnoid hemorrhage. A complete angiographic evaluation of all cerebral arteries, particularly the circle of Willis bifurcations, is mandatory ([Fig. 23-21 A](#)). Generally, in cases of suspected brain aneurysm, all cerebral vessels are studied because of the frequency of multiple aneurysms. Standard four-vessel angiography detects aneurysms in 85 percent of patients who present with subarachnoid hemorrhage. If initial angiography is negative, repeat angiography is generally indicated in 10 to 14 days, increasing aneurysm detection rate by approximately 5 percent. Many neurosurgical centers favor prompt neurosurgical or endovascular intervention in cases of acute subarachnoid hemorrhage. This is in an effort to eliminate the incidence of aneurysm rebleeding and sudden death. In addition to standard neurosurgical clipping, the Guglielmi Detachable Coil (GDC) system has been approved by the Food and Drug Administration, offering an endovascular alternative for treatment of intracranial aneurysms⁴⁰ (see [Fig. 23-21 B](#)).

Cerebral angiography is pivotal in the evaluation of central nervous system vascular malformations, particularly arteriovenous malformations (AVM). Although MRI is highly sensitive in detecting central nervous system malformations, precise vascular mapping of AVM remains essential. Angiography uniquely shows detailed information regarding the angioarchitecture of AVM (i.e., feeding arteries, nidus, and draining veins) ([Fig. 23-22](#)). Also, additional risk for AVM rupture, such as associated feeding arterial pedicle aneurysms or venous stenosis, can be identified. Treatment options such as surgical resection, endovascular embolization, radiotherapy, or combination remain dependent on precise angiographic characterization.

Neoplasm. The assessment of neovascularity may be

warranted in the evaluation of selected intracranial tumors, particularly when surgical resection is planned. Embolization procedures in these types of cases are not intended to be curative. Rather, embolization is used to reduce blood loss at surgery and help lower overall perioperative surgical morbidity. Intracranially, embolization is most commonly applied to bulky extra-axial tumors such as meningiomas to facilitate surgical resection. Cervical angiography and embolization may be helpful in managing the abnormal vascularity associated with head and neck tumors. These techniques can be useful in patients with paragangliomas of the head and neck, metastatic nodal disease from thyroid or kidney, and Castleman's disease. In these types of cases, the angiographic tumor blush can be quite intense and presurgical embolization can be very helpful.

SPINAL VASCULAR LESIONS

Spinal angiography remains key in the analysis of vascular disorders of the spine. Vascular malformations of the spinal cord lead to serious spinal cord morbidity and paralysis. The treatment plan frequently depends on angiographic delineation of these malformations. Angiography delineates the intramedullary or extramedullary location of the AVM nidus, the feeding arteries including their relationship to the artery of Adamkiewicz, and venous drainage ([Fig. 23-23](#)).

Neovascularity secondary to spinal cord tumors can be

demonstrated angiographically, providing complementary information to CT and MRI. In selected cases, spinal embolization can also be a useful adjunct.⁴¹ For example, vertebral hemangiomas, aneurysmal bone cysts, giant cell tumors, or metastatic disease of the spine can demonstrate intense vertebral neovascularity. Preoperative embolization can be valuable to attaining a successful surgical resection.

ULTRASONOGRAPHY

Diagnostic ultrasonography (US) uses sound waves above the audible level to generate diagnostic medical images. US operates on the principles of sound propagation; therefore, the patient is not exposed to ionizing radiation. US has various imaging applications, with specific uses in neurological disorders. It is readily available in hospitals or outpatient imaging facilities, and it typically is less costly than other, comparable diagnostic imaging modalities. Routinely, images are obtained in real time, within a gray scale format. US uses a variety of transducers, which are available for different applications. Diagnostic US can be coupled with Doppler devices, with or without color, allowing flow measurements in vascular structures, such as commonly employed for carotid artery studies.

Basic Principles and Techniques

Ultrasonography depends on the presence of sonographic "windows," which allow sound wave propagation and detection of echo signals. These signals form the basic sonographic units for image generation. Therefore, as a general rule, US is indicated when visualization of the target object is not blocked by intervening bone or air, such as calvarium or bowel gas. This limitation does not completely negate the use of US in the evaluation of adult brain disorders, as discussed later. The usefulness of US as an imaging tool in pediatrics is particularly appealing owing to its inherent lack of ionizing radiation.

Carotid US consists of gray scale imaging to assess location and extent of plaque and Doppler to measure flow velocities and degree of stenosis. Color may be added to the Doppler to improve visualization of the flow lumen and optimize the Doppler angle. The term *carotid duplex*, currently in vogue, represents the union of these entities. Measurements of peak systolic velocity (PSV) and end-diastolic velocity (EDV) are made in the distal common carotid artery, carotid bulb, and cervical internal carotid artery. Color information enhances the ability of carotid duplex in the identification of maximal flow velocity points and further is useful in allowing precise transducer placement in patients when high-flow jets are encountered.

The bony calvarium severely inhibits sound propagation, which has limited the ability of US to directly image the brain in adults. However, research led to the development of transducers capable of measuring intracranial flow velocities of key vascular structures despite the presence of intervening bone. This technology resulted in the development of TCD, the study of the intracranial arteries using the spectral analysis of blood flow velocity. The technique

generally employs a 2-MHz pulsed Doppler transducer. Vessel identification is based on the cranial window utilized, transducer position, and depth of sample volume. The direction and velocity of blood flow is recorded, noting the relationship to the terminal internal carotid and response to common carotid artery compression. ^[42], ^[43] Unfortunately, TCD may be limited by the thickness of the calvarium, which simply may not allow the measurement of intracranial Doppler signals.

Normal Findings

Direct brain imaging in the pediatric age group is possible owing to the presence of large fontanelles, which normally remain open until age 6 to 9 months and thereby provide adequate windows to extensively image the brain. Routine imaging consists of a series of coronal and sagittal images typically obtained through the anterior fontanelle. Additional views can be obtained through other windows as necessary. Details regarding cerebrum and cerebellum are routinely seen and include views of the cerebral hemispheres, the deep ganglionic structures, thalami, ventricles, and posterior fossa.

Carotid imaging is typically performed with either a 5- or 7-MHz linear array transducer maintaining a duplex Doppler angle between 30 and 60 degrees and a sample size of 2 to 4 mm. Transverse and longitudinal images of the cervical carotid artery are routinely obtained that provide anatomical detail regarding the cervical carotid bifurcations. Normal flow velocities in the carotid arteries range between 60 and 100 cm/sec. The cervical vertebral arteries can also be evaluated, but this examination is inherently limited owing to the bony spine. The goal of vertebral artery US is to identify stenotic or occlusive disease or retrograde flow such as seen in subclavian steal syndrome. Representative images can be obtained with Doppler waveforms recording the presence and direction of flow.

Types of Detectable Abnormalities

In infants and very young children, brain structures can be visualized and congenital anomalies thereby detected. Differences in transduction by tissue, fluid, and blood permit a differentiation of hydrocephalus, cysts, and hemorrhage. Various tumors and vascular disorders, especially vascular malformations, can also be detected with US. In newborns up to 6 months of age, spinal cord lesions can also be detected with US because the posterior elements are membranous rather than bony. In adults, US is used primarily for evaluation of vascular lesions of the head and neck, specifically, stenosis, obstruction, and dissection.

Neurological Applications in Diagnosis and Treatment

CRANIAL LESIONS

Intracranial Hemorrhage and Premature Infants. Due to advances in neonatology, increasing numbers of

TABLE 23-6 -- GRADES OF INTRACRANIAL HEMORRHAGE

Grade	Description
I	Subependymal hemorrhage into one or both germinal matrices
II	Germinal matrix hemorrhage with intraventricular extension, no hydrocephalus
III	Germinal matrix hemorrhage with intraventricular extension and hydrocephalus
IV	Germinal matrix hemorrhage with intraparenchymal extension

infants are evaluated for neurological disorders secondary to prematurity. This coupled with primary neurological diseases has led to wide use of US as a leading diagnostic imaging tool in the neurological evaluation of children. ^[44] Regions of the brain hemorrhage can be readily diagnosed and graded, typically on a scale of 1 to 4 (Table 23-6). Hemorrhages can range in size from a small, solitary petechial hemorrhage to multiple large parenchymal hemorrhages with associated ventricular changes. Noninvasive follow-up imaging of these hemorrhages can be repeated as necessary without concern for radiation exposure. Small, germinal matrix hemorrhages, common in premature infants, carry the best long-term neurological prognosis (Fig. 23-24). In contrast, intraventricular hemorrhages may be seen in premature infants, representing a higher-grade hemorrhage. Larger parenchymal hemorrhages represent the more severe spectrum of premature brain injury and typically result in long-term neurological deficits. Hydrocephalus may complicate brain hemorrhage, which can be readily diagnosed and followed with US.

Congenital and Acquired Neonatal Disorders. US can provide useful information regarding other intracranial pediatric abnormalities, particularly in the newborn period.

Figure 23-24 Cranial ultrasound of infant demonstrating left germinal matrix hemorrhage (arrow).

For example, congenital abnormalities such as Chiari malformations, agenesis of the corpus callosum, anencephaly, aqueductal stenosis, holoprosencephaly, and encephaloceles can be evaluated. Congenital pediatric neoplasms that occur in the first year of life such as choroid plexus papilloma and carcinoma, gliomas, primitive neuroectodermal tumors, and vascular disorders (e.g., the vein of Galen malformation) can be elucidated. Infectious diseases of the brain may result in abnormal intracranial fluid collections, complicating meningitis or encephalitis. US can be useful in providing guidance for needle aspirations of these collections.

Limitations of US include decreased detection rates of convexity lesions, such as extra-axial hemorrhages or masses (i.e., subarachnoid hemorrhage). Periventricular

leukomalacia, or the effects of perinatal asphyxia can be imaged but can also be challenging to recognize. As necessary, US information can be supplemented by other imaging tests, such as CT or MRI to improve detection of conditions not recognized by US.

INTRACRANIAL VASCULAR LESIONS

The indications for TCD continue to evolve but primarily focus on stroke prevention. TCD is useful in inferring the presence of intracranial stenosis or occlusions of major intracranial arteries and may further document routes of collateral circulation. One important role for TCD is for screening and follow-up of intracranial vasospasm complicating subarachnoid hemorrhage. Vasospasm typically peaks on days 3 through 7 after SAH. TCD is useful in screening these patients for the onset of vasospasm, before clinical symptomatology ([Fig. 23-25](#)). This allows for early treatment planning, before the patient becomes symptomatic. TCD can be useful intraoperatively, for example, providing continuous intraoperative recording of the middle cerebral artery during carotid endarterectomy, and, therefore, can help identify patients needing an indwelling shunt. Other developing indications of TCD include screening patients for intracranial stenosis that complicates sickle cell disease, identification of flow disturbances in migraine, and identification of AVM. In the latter instance, the nidus of AVM can be analyzed showing routes of supply and drainage and may further show flow reductions in AVMs after interventions. Lastly, TCD may be useful in accessing venous diseases such as sagittal sinus thrombosis and may play a future role in brain death determination.

VASCULAR LESIONS IN THE NECK

The prevalence of stroke in the United States has led to development of screening modalities aimed toward recognition and correction of stroke risk factors. Increasingly, atherosclerotic disease involving the cervical carotid and vertebral arteries is recognized for its inherent risk in stroke. The Asymptomatic Carotid Atherosclerosis Study demonstrated benefit in ipsilateral stroke reduction with carotid endarterectomy for patients with asymptomatic stenoses of extracranial carotid artery greater than or equal to 60 percent.^[45] The North American Symptomatic Carotid Endarterectomy Trial demonstrated strong benefit with carotid endarterectomy in symptomatic patients with ipsilateral carotid stenosis greater than or equal to 70 percent.^[46] Therefore, because the majority of strokes are currently believed to be embolic in etiology, carotid screening becomes justified. The presence of significant stenosis of the carotid bifurcation is now generally accepted as an indication for intervention in both asymptomatic and symptomatic patients.

US of the cervical vasculature has several key advantages compared with other imaging modalities as a screening study.^[47]^[48]^[49] These include patient comfort, lack of procedure risk, and high sensitivity and specificity in detecting cervical stenosis. Information regarding surface contour and internal characteristics of plaque can be routinely obtained. US limitations include operator dependency and possible error,

Figure 23-25 Transcranial Doppler image of left middle cerebral artery showing elevated flow velocities in the left middle cerebral artery status post subarachnoid hemorrhage consistent with vasospasm.

428

field of view limitations (thorax inferiorly and the mandible superiorly), technical problems related to vessel tortuosity, and kinking, dense calcifications, and the potential to miss a trickle of blood in cases of high-grade, 99 percent stenosis. The latter, in particular, continues to justify the need for additional imaging studies in cases of suspected complete carotid occlusion and in cases in which information beyond the US field of view is needed. Indications for cervical US include evaluation of cervical bruit, transient ischemic attack, and stroke. [Figure 23-26](#) demonstrates an example of a severe cervical carotid bifurcation plaque with angiographic correlation. US is also useful in following progression of atherosclerosis in cases of known plaque or in detecting other cervical pathologies, such as arterial dissection ([Fig. 23-27](#)).

At many institutions, carotid stenosis is graded based on a sliding scale developed by Bluth.^[50] Mild carotid stenosis results in broadening of the normal ultrasonic spectral waveform with mild elevation of PSV due to turbulent flow from small plaques. In contrast, higher degrees of stenosis results in higher flow velocities, which can be seen in both systole and diastole. Generally, PSV greater than 130 cm/ sec indicates moderate stenosis whereas PSV greater than 250 cm/sec indicates severe stenosis. Systolic and diastolic ratios between the stenotic internal carotid artery and the common carotid artery are also calculated and, if increased, may further indicate regions of carotid narrowing. Ratio analysis can aid in identifying false-positive and false-negative results in conditions such as systemic hypertension. Routinely, all high-flow jets are also recorded. A point can be reached in which flow velocities can diminish. These areas can further define abnormal regions of critical carotid stenosis.

PEDIATRIC SPINAL LESIONS

Imaging of spinal abnormalities is useful in children up to 3 to 6 months of age as the posterior elements are membranous not bony. Beyond this age, these elements calcify and generally US would then need to be complemented with another imaging modality. Early evaluation and differentiation of neural tube defects, such as lipomas, meningoceles, myelomeningoceles, and tethered spinal cord, is possible. US can evaluate the subcutaneous structures and allow for recognition of abnormal spinal canal development, including spinal cord abnormalities. Even in older children, the presence of abnormal skull dimples, pores, or hair tufts can be evaluated for underlying spinal dysraphism. Rarely, US can be useful in evaluating spinal neoplasm or syrinx development.

POSITRON EMISSION TOMOGRAPHY AND SINGLE PHOTON EMISSION COMPUTED TOMOGRAPHY

Basic Principles and Techniques

The original work of radionuclide emission tomography was formed by Kuhl and Edwards in 1963.^[51] This research demonstrated the initial use of radionuclide tracers to create axial reconstructed images. It became apparent that the relative low resolution of this technique research was a limitation begun to focus on the functional imaging capabilities of this technique. Early work with CT in the early 1970s demonstrated the correlation between focal lesions in the brain and lesions demonstrated by radionuclide emission tomography. Single photon emission

41

Figure 23-27 A, Ultrasound of right internal carotid demonstrating flap consistent with arterial dissection (arrow). B, Diagnostic right internal carotid angiogram confirming arterial dissection.

computed tomography (SPECT) imaging uses radionuclides that release gamma radiation. Gamma cameras detect the radiation released in 360 degrees and creates multiplanar re-formation of these data. In the early 1980s iodine-based radionuclides were initially used to determine symmetrical brain function. The uptake and distribution of such radionuclides within the brain is believed to be proportional to blood flow.^[52] Major breakthroughs occurred in the late 1980s with the introduction of technetium-99m-labeled compounds, the most common of which was hexamethylpropylene amineoxime (HMPAO).

A second major technique that investigates functional and, to a lesser degree, anatomical details within the brain is positron emission tomography (PET). This procedure uses positron-emitting radionuclides in distinction to SPECT imaging, which uses gamma emitters. Positron-emitting particles decay by releasing two annihilation radiation particles into opposite directions that are at 180 degrees to the other. The data are postprocessed and reformatted into multiple planes. Sokoloff, in 1977, described ¹⁴C-deoxyglucose.^[53] This was a major advancement in functional imaging of the brain that enabled the measurement of glucose uptake and metabolism. Shortly after, the most commonly used PET agent, ¹⁸F-deoxyglucose (FDG), was introduced. The development of ligands associated with specific neurochemical receptors or other proteins has broadened the use of PET and SPECT to include a growing number of degenerative or biochemical disorders.

Normal Findings

Radionuclides are evenly distributed into the brain parenchyma for both PET and SPECT scanning. The calvarium and ventricles represent photopenic regions. The brain images can be displayed in axial, coronal, or sagittal projections. Under normal conditions, when a subject performs a motor, language, visual, or other sensory task, ¹⁸F-deoxyglucose PET scans will identify increased glucose metabolism in the involved cortical region.

Types of Detectable Abnormalities

SPECT and PET imaging have showed comparable detection of diseased states. In chronic pathological states, the cerebral blood flow demonstrated by SPECT correlates to abnormal metabolic activity that is shown by PET imaging. Unfortunately, PET imaging requires cyclotron produced nucleotides. This, as well as the great cost of this techniques, has limited this procedure to major research facilities. SPECT imaging is more accessible owing to recent advances in stability of radionuclides and in computer technology. These factors have led to a significant increase in the resolution of the SPECT images. PET and SPECT can detect generalized hypometabolism in anoxia, degenerative disease, trauma, and aging or a focal hypometabolism. Hypermetabolism due to increased blood flow into tumor or infection can be detected as well as seizure foci. In degenerative illnesses with neurotransmitter defects (e.g., Parkinson's disease and Huntington's disease), focal deficits can be detected, although these applications remain largely in the research realm.

Neurological Applications in Diagnosis and Treatment

CEREBROVASCULAR DISEASE

Cerebrovascular disease is the third leading cause of death in the United States. The ability to rapidly diagnose

42

acute stroke has both therapeutic and prognostic value. Acute intra-arterial thrombolysis of a recently formed thrombus is a new pioneering procedure that may significantly decrease the morbidity and mortality of cerebrovascular disease. PET is able to demonstrate a rise in regional oxygen extraction fraction indicating an evolving stroke. These changes are often demonstrated earlier and show a more extensive tissue damage than what is predicted by CT or MRI. However, work with diffusion-weighted MRI suggests that this may be the most sensitive imaging study for acute stroke.^[54] In patients with reversible ischemic injury there is a decrease in regional cerebral blood flow that is termed *misery perfusion*. These patients would have a false-positive PET and SPECT scan. Areas of chronic infarction generally demonstrate decreased regional cerebral blood flow and oxygen and glucose metabolism.

SPECT scanning can identify areas of decreased blood flow in patients with acute infarcts that were not seen on CT. A diagnostic test to identify high-risk patients who would benefit from surgical intervention of an arteriosclerotic lesion within the carotid bifurcation would be of great value. A pharmacological stress test with acetazolamide, which causes cerebrovascular dilatation and increased regional cerebral blood flow, has been investigated.^[55] Others have investigated the prognostic value of the ratio of regional cerebral blood flow to regional cerebral blood volume.^[56] The regional cerebral blood volume can be determined with technetium-99m-labeled red blood cells. As the regional cerebral blood flow decreases, the regional cerebral blood volume increases to maintain perfusion. This procedure has been described as an indicator of cerebral perfusion reserve, thus defining a patient's risk for infarction. SPECT and PET have also demonstrated "luxury perfusion," which represents the areas of subacute stroke that receive increased blood flow in relation to the nonaffected brain. This is most likely due to an increase in an aerobic metabolism in the region of infarction. SPECT has also demonstrated hypoperfusion of the contralateral cerebellum in patients with cortical strokes termed *crossed cerebellar diaschisis*. This is believed to be secondary to disruption of the corticopontine tracts uniquely seen by SPECT.

BRAIN TUMORS

The majority of tumor investigation imaging has been with PET. FDG is the primary positron emitter used today. In general, high-grade neoplasms demonstrate increased metabolism whereas low-grade neoplasms demonstrate relatively decreased activity. There has been high correlation between metabolic activity determined by PET and histological grade of the neoplasm.^[56],^[57] One of the many uses of PET scanning is to distinguish tumor recurrence from radiation necrosis. Areas of radiation necrosis are diagnosed by focal areas of decreased metabolic activity, whereas tumor recurrence shows increased metabolic activity. PET remains one of the most sensitive tests to differentiate between these two entities.

SPECT has a more limited role in the evaluation of brain tumors. Some enthusiasm has been displayed with the use of SPECT to differentiate a lymphoma from toxoplasmosis in immunocompromised patients. Imaging with thallium-labeled gamma emitters demonstrates increased activity within lymphomas and decreased activity within toxoplasmosis^[58] ([Fig. 23-28](#)).

DEMENTIA

There have been numerous studies that have described decreased regional glucose metabolism in healthy older subjects within the frontal, parietal, and temporal lobe regions.^[59] Current PET normalizes regional values using internal standards such as the cerebellum or calcarine fissure region.

Within the past decade there has been much excitement about the use of PET and SPECT to evaluate dementia. Alzheimer's disease is the most common cause of dementia

Figure 23-28 A 30-year-old HIV-positive male presents with mental status change. A, MR (post-contrast T1W1) demonstrates a focal masslike lesion with ring enhancement within the right frontoparietal area. The primary differential diagnosis is between lymphoma and toxoplasmosis. B, Thallium SPECT scan shows abnormal increased uptake representing a primary CNS lymphoma.

43

in the United States. Characteristic patterns of decreased regional glucose metabolism within the parietal and temporal lobes have been described in patients with AD.^[60] In these patients there is a relative preservation of the calcarine fissure region, sensory motor region, cerebellum, and the basal ganglion region. Decreased metabolic rates for oxygen have also been reported in the same regions that demonstrate areas of decreased glucose metabolism in patients with Alzheimer's disease.^[61] Patients with progressive Parkinson's disease have a similar pattern, as seen in patients with Alzheimer's disease. Multiple-infarct dementia occurs after multiple lacunar infarctions. PET generally demonstrates multifocal regions of decreased glucose metabolism^[62] that typically correlate to focal lesions demonstrated on CT scans and MR images. A significant decrease in glucose metabolism within the frontal and temporal lobes has been described in patients with Pick's disease.^[63] Patients with Huntington's chorea, a disorder of the extrapyramidal system, have shown a decrease in glucose metabolism within the caudate nuclei.^[64] These findings may present before atrophy of the caudate nuclei demonstrated on CT or MRI.

Decreased regional cerebral blood flow demonstrated with SPECT has shown a similar pattern of decreased glucose metabolism in comparison to PET. Most investigators believe that SPECT is a test of equal sensitivity to characterize dementia.

CEREBRAL TRAUMA

In severe head trauma there is a strong association between a diffuse axonal injury and decreased metabolism within the brain. It has been demonstrated that diffuse and focal areas of decreased metabolism improve over time as a patient recovers from head trauma. Correlations have been found between post-traumatic decreases in glucose metabolism identified by PET and decreased regional cerebral blood flow identified with SPECT. Focal lesions identified on CT demonstrate a larger area of abnormal regional cerebral blood flow by SPECT.^[65] A goal of SPECT research in head trauma has been to use this method to characterize prognosis of focal lesions as well as diffuse axonal injury.

SEIZURE DISORDERS

SPECT and PET have been investigated as complementary noninvasive studies for localization of a seizure focus. CT, MRI, and electroencephalography (EEG) are the primary noninvasive methods used to localize a seizure focus but do not always identify a lesion. These patients quite often require invasive placement of intracerebral depth electrodes. SPECT has demonstrated decreased regional cerebral blood flow within a seizure focus between seizures and increased regional cerebral blood flow ictally. PET studies have shown decreased metabolism between seizures within a seizure focus and increased metabolic activity ictally. In both SPECT and PET, up to approximately 80 percent of patients who demonstrated a focal EEG abnormality also demonstrated an associated perfusion or metabolic activity defect within the same region.^[66] The rapid availability of cyclotron-produced nucleotides is, in general, a limiting factor for the use of PET again for the ictal stage. HMPAO is the SPECT radionuclide of choice. This tracer is taken up by the brain during the first vascular pass and does not redistribute after the first few minutes. Imaging may be obtained up to 3 to 4 hours after the seizure ictus. There is an additional increased sensitivity if an ictal SPECT scan can be obtained. SPECT has been a major noninvasive imaging modality to help localize a seizure focus. Research suggests that a more stable SPECT imaging agent, ethyl cystinate dimer, which is chemically more stable than HMPAO, will become the radionuclide of choice.

DEGENERATIVE DISORDERS: PARKINSON'S DISEASE AND HUNTINGTON'S DISEASE

PET can use a number of ligands other than glucose, and these applications are of particular interest in neurological disorders involving neurotransmitter abnormalities. Parkinson's disease and Huntington's disease are the prototypical examples (see [Chapter 34](#)) of such conditions, but dystonias and other movement disorders have also been studied with PET. To study the activity of the nigrostriatal dopaminergic system, fluorodopa, a derivative of levodopa, is usually used. Receptor agonists can be used to study postsynaptic function of the same system. Whereas these ligand "probes" remain research tools at the present time, increasing experience may lead to their use in regular clinical neurological practice. In animal models of Parkinson's disease, there is a good correlation between fluorodopa uptake and striatal dopamine content. An even higher correlation exists between uptake and the number of dopamine cells in the substantia nigra zona compacta, the area specifically affected in Parkinson's disease. In patients with severe clinical disability from Parkinson's disease, their fluorodopa scans show lower uptake than those of patients with mild disease. Possible future applications may be the use of such scans in patients with tremors in whom the diagnosis of Parkinson's disease is clinically unclear. It may also prove useful in monitoring the success of such therapies as tissue transplants. In Huntington's disease, most PET attention has focused on its putative utility in preclinical detection and the monitoring of clinical progression.

ELECTROENCEPHALOGRAPHY

Basic Principles and Technique

Electroencephalography is a noninvasive technique in which the electrical activity of the brain is recorded from the scalp to evaluate the function of the brain. It is thus complementary, rather than an alternative, to neuroimaging techniques. The differences in voltage between electrodes placed in different regions of the scalp are recorded and amplified. The polarity, frequency, amplitude, distribution, and changes with time of this activity are then studied to determine whether the findings are normal or abnormal and whether they suggest any particular type of underlying pathological process.

Electrodes are placed on the scalp based on standardized, internationally agreed locations (the 10-20 system).^[1] The potential difference between pairs of scalp electrodes (bipolar derivation) or between individual scalp electrodes and a common reference point such as the linked ears (referential derivation) is then recorded as the electroencephalogram (EEG) on moving paper or viewed on the screen of an oscilloscope. Recordings are made simultaneously from pairs of electrodes in an organized sequence or pattern termed a *montage*, which is generally either longitudinal or transverse in orientation.^[2] In longitudinal montages, recordings are made from electrodes in a sagittal plane; in bipolar derivations, recordings are between linked pairs of electrodes, whereas in referential derivations, the recordings are between each electrode and the reference point. In transverse montages, recordings are made from electrodes in a straight coronal plane. The recordings are then displayed in anterior-to-posterior or left-to-right sequences.

For recording purposes, the input from each pair of electrodes (or from active and reference electrodes) is connected to the two inputs of a differential amplifier in such a way that the input from the active electrode is connected to input one and from the reference electrode (or, with bipolar recordings, from the more posterior or right-sided electrode) to input two. The recording arrangement is such that an upward deflection indicates either increased negativity at the electrode connected to input one or increased positivity at input two.

In recording the EEG, an attempt is generally made to activate abnormalities by hyperventilation for about 3 minutes, and also by photic stimulation at flash rates up to 20 Hz. Other common activating procedures include sleep during the recording procedure and sleep deprivation on the night before the examination.^[3]

It is sometimes necessary to monitor the EEG for several days in patients with episodic behavioral disturbances to record during some of the episodes and determine whether they have electrocerebral accompaniments such as occur with epileptic seizures. This can either be undertaken in a long-term video EEG monitoring unit in the hospital or, in some instances, by recording the EEG with an ambulatory cassette EEG system. The latter approach can be undertaken in the home setting and does not require continuous supervision by specialized personnel. Tapes last for 24 hours and can generally be reviewed in less than 1 hour.^[4]

The traditional method of EEG interpretation depends on visual analysis, which is subjective and very time intensive. Quantitative or automated (computerized) techniques for analysis are being developed but are not yet in widespread use for routine purposes.

It is important to distinguish between cerebral activity and artifactual discharges of biological or nonbiological origin. Bioelectric artifacts include ocular, cardiac, respiratory, movement, muscle, and sweat artifacts. These various artifacts have characteristic appearances that facilitate their recognition. Artifacts may also arise from the equipment or electrodes and especially from variation in electrode impedance. Other artifacts may arise from the environment in which the recording is made, such as from other electrical equipment, intravenous infusion lines, and static electricity generated by nylon clothing.

The electrocerebral activity recorded from the scalp consists not of action potentials but of the summated synaptic potentials from large numbers of cortical neurons. It thus reflects the summated excitatory and inhibitory postsynaptic cortical potentials. This activity is markedly attenuated by the skull and scalp and is therefore considerably greater when recorded from the cortical surface.

Normal EEG Activity

The cerebral activity recorded at electroencephalography is generally rhythmic, that is, it consists of regularly recurring waveforms of similar duration and morphology. It is widely believed that the rhythmicity is imposed on the cerebral cortex by a thalamic pacemaker.^[5]

Activity recorded in the human EEG is characterized by its frequency. In normal adults, a posteriorly predominant 8- to 12-Hz rhythm is present and is attenuated by eye opening; this is designated the alpha rhythm ([Fig. 24-1](#)). Faster-frequency activity, or beta activity, is also present to a variable extent, has a generalized distribution, and is enhanced by certain medications such as benzodiazepines. Activity slower than 8 Hz is designated as theta (4 to 7 Hz) or delta (less than 4 Hz) activity. Such slow activity is a normal feature of certain stages of sleep but is generally not present in awake alert adults.

Abnormal EEG Activity

The pathophysiology of abnormal EEG activity is multifactorial and difficult to clarify. Increased excitability of the cerebral cortex probably accounts for cortical spike activity. More generalized spike-wave bursts probably depend on thalamocortical projections. The delta activity recorded under certain pathological circumstances probably reflects lesions involving predominantly the cerebral white matter. When subcortical nuclei are involved, either alone or in association with pathology affecting the cerebral cortex itself, paroxysmal slow activity is seen and may include spike discharges.^[6]

Slow activity sometimes occurs with a localized distribution and varies in rhythm, rate, and amplitude with time. Such a focal polymorphic slow-wave disturbance, when present continuously, suggests an underlying structural lesion involving the cerebral white matter ([Fig. 24-2](#)) but provides no clue as to its nature. Transient polymorphic slow-wave activity is suggestive of either migraine or a postictal state after a partial (focal) seizure.

Intermittent rhythmical slow activity may occur with a frontal emphasis in adults or an occipital emphasis in children and is a nonspecific finding that has been described in a variety of settings, including metabolic disturbances, hydrocephalus, and diencephalic lesions.

A diffusely slowed record during wakefulness is nonspecifically abnormal but is seen most commonly in patients with diffuse encephalopathic processes such as a metabolic disturbance or encephalitic disorder ([Fig. 24-3](#)). It may also reflect long-standing diffuse cerebral dysfunction such as occurs in patients with a perinatal static encephalopathy.

Focal attenuation of EEG activity reflects destructive disease of the cerebral cortex, whereas more diffuse attenuation may result from severe encephalopathic processes and occurs also in certain degenerative disorders such as Huntington's disease. Electroencephalographic silence or inactivity, in recordings made under conditions to enhance the presence of any underlying low-voltage EEG activity, is suggestive of neocortical brain death but may also occur in patients who are hypothermic or have taken an overdose of drugs that depress the central nervous system (CNS) ([Fig. 24-4](#)).^[7] In some instances, the EEG consists of bursts of mixed-frequency activity occurring on a relatively quiescent background. This so-called burst-suppression pattern may occur with any severe encephalopathy, such as after severe cerebral anoxia or after head trauma, after overdose of CNS depressant drugs, and with anesthesia.

Epileptiform discharges consist of abnormal paroxysmal events containing sharp waves or spike discharges, at least in part. A spike discharge is a potential having a sharp contour and a duration of less than 80 msec, whereas a sharp wave has a duration of between 80 and 200 msec. They may occur without any clinical correlates or significance but are found interictally with a greater incidence than normal in patients with epilepsy.

Periodic lateralized epileptiform discharges (PLEDs) are lateralized epileptiform discharges that occur with a regular periodicity. They occur in association with acute hemispheric pathology such as an infarct or rapidly expanding tumor,^[8] ^[9] typically in obtunded patients with a focal neurological deficit and often recurrent seizures, and

Figure 24-1 A posteriorly predominant 9-Hz alpha rhythm is present when the eyes are closed and is attenuated by eye opening in the EEG of this normal subject. Electrode placements in this and succeeding figures are as follows: Fp, frontopolar; F, frontal; C, central; P, parietal; O, occipital; T, temporal; A, earlobe; Sp, sphenoid. Right-sided placements are indicated by even numbers, left-sided placements by odd numbers and midline placements by Z.

are commonly replaced after several weeks by a continuous polymorphic slow-wave disturbance.

Repetitive complexes consisting of slow waves, sharp activity, or both occur with a regular periodicity and generalized distribution in various disorders. Such periodic complexes are especially characteristic of certain infective disorders of the brain but may also occur after severe cerebral anoxia, head injury, or generalized seizures, with deep anesthesia, and in cerebral lipidosis.

Certain EEG patterns are worthy of mention because they are frequently regarded as abnormal when, in fact, they are simply normal variants of no pathological significance. Such patterns include 14- and 6-Hz positive spikes, small sharp spikes (sometimes referred to as benign epileptiform transients of sleep), wicket spikes, 6-Hz spike-wave activity, and rhythmical temporal bursts of sharpened theta activity, all of which occur most commonly during drowsiness or light sleep. ^[1]

Clinical Uses of the EEG

The EEG is useful in the evaluation of patients with several types of neurological disorders, including seizures, encephalopathy, and focal cerebral abnormalities. It also provides an ancillary aid to the diagnosis of brain death and may suggest certain specific neurological diagnoses when characteristic EEG findings are recorded in patients with clinical disorders of uncertain nature.

EPILEPSY

The EEG is important in the evaluation of patients with known or suspected epilepsy. The interictal occurrence of epileptiform activity in a patient with an episodic behavioral disorder that may represent seizure activity increases markedly the probability of epilepsy. ^[9] In patients with epilepsy, the EEG findings help to classify the seizure disorder, often permitting a distinction between seizure types when this cannot be made clinically. For example, the EEG findings permit typical absence seizures to be distinguished from complex partial seizures and generalized seizures to be distinguished from partial seizures having rapid secondary generalization ([Fig. 24-5](#)). Such findings therefore suggest the appropriate anticonvulsant drug for treating individual patients and provide a guide to prognosis. A guide to prognosis is also provided by the background EEG

Figure 24-2 EEG showing a focal polymorphic slow-wave disturbance in a patient with a right frontal glioma.

Figure 24-3 Diffusely slowed EEG in an obtunded patient with a metabolic encephalopathy.

Figure 24-4 Electroencephalogram showing electrocerebral silence in the EEG of a brain-dead patient following attempted resuscitation after cardiopulmonary arrest.

Figure 24-5 EEG in a woman with complex partial seizures, showing focal spike discharges in the right central region.

activity--a slowed background implies a poorer prognosis than otherwise. In addition, a normal background activity EEG permits certain epileptic syndromes with specific prognostic implications to be recognized. For example, benign rolandic epilepsy of childhood has a characteristic interictal EEG pattern (rolandic spikes) and a good prognosis, whereas anterior temporal spike discharges are typically associated with complex partial seizures and imply a poorer outcome.

When surgery is under consideration for the treatment of medically intractable seizures, the EEG has a major role in localizing seizure foci, provided that actual seizures can be recorded. This generally requires admission to a hospital, where the EEG can be recorded continually while patients are video-monitored.

The interictal EEG findings may suggest certain characteristic seizure disorders. *Hypsarrhythmia* refers to a pattern characterized by high-voltage, irregular slow activity with superimposed multifocal spike discharges. It is typically found in children with infantile spasms, although some children with infantile spasms do not have this EEG pattern and it is sometimes found in patients without infantile spasms. ^[10] Generalized spike-wave activity suggests primary generalized epilepsy when it occurs interictally at 3 Hz and is bilaterally symmetrical and bisynchronous ([Fig. 24-6](#)) and Lennox-Gastaut syndrome when it is at 1 to 2 Hz and irregular in frequency and morphology. Polyspike-wave activity occurs with myoclonic epilepsy, including juvenile myoclonic epilepsy of Janz.

The ictal EEG recorded during a tonic-clonic convulsion

Figure 24-6 Burst of generalized 3- to 4-Hz spike-wave activity occurring interictally in a patient with primary generalized epilepsy.

is always abnormal, but the findings may be obscured by muscle and movement artifact. A transient attenuation of ongoing electrocerebral activity or the development of low-voltage fast activity heralds the onset of the seizure ([Fig. 24-7](#)), followed by the appearance of rhythmic, repetitive activity at about 10 Hz that gradually becomes intermixed with increasing amounts of slow activity until the record is characterized by spike-wave activity as the tonic phase of the seizure is succeeded by the clonic phase. This is followed in turn by a transient attenuation of the background EEG and then by irregular slow activity before the EEG reverts to its preictal appearance. During tonic seizures the EEG shows generalized, repetitive spike activity or an attenuation of the ongoing background activity. During a typical absence attack, by contrast, the EEG is characterized by 3-Hz spike-wave activity; and during myoclonic seizures it is characterized by polyspike-wave activity at 4 to 5 Hz. The EEG may show no ictal accompaniments during simple partial seizures, and this should not be taken to imply that the seizures are nonorganic in origin. In other patients with such seizures and in those with complex partial seizures, the EEG shows rhythmic, organized, localized discharges ([Fig. 24-8](#)) with or without spike activity that may become more generalized as the seizure proceeds and may be followed postictally by a transient flattening of the traces and then by polymorphic slow activity with a localized or generalized distribution.

During tonic-clonic (major motor or grand mal) status epilepticus the EEG shows repeated electrographic seizures. The EEG is not required for diagnostic purposes, however, except when patients have been paralyzed pharmacologically to facilitate management; when coma has been induced to control refractory status, the EEG has an important role in monitoring the level of anesthesia. In patients with nonconvulsive status epilepticus, the basis for the abnormal mental status can only be recognized by the EEG finding of continuous, generalized spike-wave activity (so-called spike-wave stupor) or repeated partial seizures. This underscores the

importance of obtaining an EEG in any patient with a change in mental status of uncertain basis.

FOCAL CEREBRAL PATHOLOGY

With the advent of new imaging techniques, the role of the EEG in screening patients for suspected focal intracranial pathological processes has declined, except in developing countries. In fact, however, the EEG detects disturbances of function whereas imaging procedures detect structural abnormalities, so that the two approaches are complementary, not alternatives. EEG abnormalities are sometimes generalized in patients with focal intracranial pathology, detracting from the value of the technique in localizing the lesion but emphasizing its importance in reflecting the extent of functional impairment. Thus, generalized slowing of the EEG commonly reflects a disturbance in the level of consciousness. Even when focal abnormalities are present, they generally provide no indication as to the nature of the underlying pathology. They typically consist of a localized slow-wave disturbance (see [Fig. 24-2](#)) or an attenuation of background electrocerebral activity, sometimes accompanied by focal spikes or sharp waves.

Figure 24-7 EEG recorded at the onset of a generalized clonic-tonic-clonic seizure, showing the development of bisynchronous low-voltage generalized fast activity that then becomes intermixed with increasing amounts of slow activity as the seizure continues.

ABNORMAL STATES OF CONSCIOUSNESS

The EEG is an important means of investigating patients with a disturbance of consciousness. It may suggest the cause of the abnormal mental state, helps to determine the depth of coma, and provides a guide to prognosis. Moreover, the EEG is an important means of distinguishing between unconscious states and neurological disorders simulating unconsciousness, such as the locked-in syndrome, in which the EEG is normal or shows only minor nonspecific changes. In patients with a disturbance of consciousness due to diffuse cerebral dysfunction, the EEG typically showed generalized slowing (see [Fig. 24-3](#)) without focal or lateralizing features. In some metabolic encephalopathies, triphasic waves are conspicuous, but these are a nonspecific finding. When epileptiform discharges or electrographic seizures are found in the EEG, they suggest that a postictal state or status epilepticus is responsible for the obtundation.

In coma after head injury, the EEG is likely to be diffusely slowed but focal abnormalities (slowing, spike discharges, or an attenuation of activity) may be superimposed. These localized abnormalities may relate to hematoma or cerebral contusion, ischemia, or edema.

Alpha-pattern coma designates coma associated with alpha-frequency activity in the EEG. The alpha-frequency activity is usually widespread in distribution and nonreactive to external stimuli. It is found most commonly after a cardiac or cardiorespiratory arrest and also occurs after pontine strokes and occasionally with a drug overdose. Alpha-pattern coma was originally thought to imply a poor prognosis, but the outlook relates more to the cause of the coma than to the presence of alpha-frequency activity in the EEG.^{[11], [12]}

In some comatose patients the EEG shows a burst-suppression pattern, indicating a severe encephalopathic process such as an anoxic encephalopathy. The finding of electrocerebral silence indicates that irreversible brain damage and neocortical brain death have occurred. A similar finding may also relate to hypothermia or the presence of CNS depressant drugs, however, and these conditions must always be excluded before prognostic implications are ascribed to the EEG changes.

OTHER APPLICATIONS

In patients with encephalitis or meningoencephalitis, the EEG typically shows diffuse slowing without any specific features. Characteristic abnormalities are, however, found in certain infectious disorders of the brain. In herpes simplex encephalitis, periodic lateralized complexes may occur over one or both temporal regions, usually repeating once every 1 to 4 seconds ([Fig. 24-9](#)).^[13] These discharges may take up to 2 weeks to develop, and their absence does not exclude the diagnosis. Their presence provides strong support for it, however, and their bilateral occurrence implies a poorer prognosis for survival than otherwise. In

Figure 24-8 Repetitive focal spike activity arising in the right anteromesial temporal region (right sphenoidal electrode at Sp2) at the onset of a complex partial seizure in a patient with epilepsy.

Figure 24-9 Repetitive complexes occurring in the right temporal region of a child with herpes simplex encephalitis.

Figure 24-10 EEG of a patient with Creutzfeldt-Jakob disease showing periodic complexes that often have a triphasic configuration.

subacute sclerosing panencephalitis, generalized periodic complexes are seen, often lasting for up to 3 seconds and with an interval 3 to 15 seconds between complexes. A similar pattern is sometimes observed in patients who have taken phencyclidine.^[14] In Creutzfeldt-Jakob disease ([Fig. 24-10](#)), periodic complexes are typically triphasic in configuration and occur at a rate of approximately 1 Hz. Their occurrence in patients with a rapidly progressive dementia strongly supports the diagnosis.^{[15], [16]}

The EEG findings are of little relevance to the diagnosis of migraine. They are usually normal, but focal or generalized slow activity may be found, especially during or immediately after migrainous attacks. Epileptiform transients are also encountered in some patients.

Abnormalities may be found in demented patients and consist usually of a nonspecific loss of the alpha rhythm and the presence of excessive slow activity. Focal slowing may also occur, especially in Alzheimer's disease. A normal EEG in no way excludes a diagnosis of dementia, but a diffusely abnormal record supports a diagnosis of dementia as opposed to pseudodementia. The EEG findings may suggest the cause of the dementia, such as in Creutzfeldt-Jakob disease or subacute sclerosing panencephalitis, or when a focal structural lesion is present.

The EEG findings after head trauma reflect the severity of injury and level of consciousness. They do not improve the ability to predict which patients are likely to develop post-traumatic epilepsy.

POLYSOMNOGRAPHY

Basic Principles and Technique

Disorders of sleep are common and often respond well to treatment. Polysomnography is important in diagnosing and characterizing such disorders. It involves recording the EEG on two or a few channels to characterize the stage of sleep while recordings are also made of eye movements, mentalis muscle activity (chin EMG), electrocardiogram, respiration, and oxygen saturation. Respiratory movements are recorded by measurement of air flow through the nasal passages and the mouth using thermistors and by recording thoracoabdominal excursions with surface electrodes. Oxygen saturation is measured using an ear oximeter. A microphone can be taped to the face to record snoring.

Normal Polysomnographic Findings

The EEG shows a characteristic sequence of events during sleep. During drowsiness (Stage 1 sleep) the alpha rhythm is attenuated and the background consists of mixed frequencies. Rolling eye movements are characteristic. During Stage 2 sleep, the background EEG consists of diffuse theta and slower activity superimposed on which are vertex sharp waves, sleep spindles (bursts of 12- to 14-Hz activity that occur bilaterally in the central regions), and K-complexes (high-voltage slow-wave complexes). During slow-wave (Stages 3 and 4) sleep, high-voltage theta and slower activity is present, with activity at 2 Hz or less being present for up to 50 percent of the time in Stage 3 sleep and for more than this in Stage 4 sleep. Tonic activity is present in the mentalis muscle during these stages of sleep. During rapid eye movement (REM) sleep, the EEG resembles that of Stage 1 sleep but rapid eye movements occur in all directions and tonic muscle activity is either absent or markedly reduced.

Sleep goes through these various stages sequentially

from Stage 1 to Stage 4 and then back to Stage 2 over about 90 minutes, following which REM sleep occurs. Such sleep cycles usually occur about three or four times each night, with the amount of REM sleep increasing in later cycles.

Abnormal Findings and Clinical Uses of Polysomnography

Polysomnography is important in the investigation of patients with excessive daytime somnolence, disorders of initiating and maintaining sleep, disorders of the sleep-wake cycle, and disorders associated with certain sleep stages (parasomnias).

It is important in confirming the existence of insomnia and characterizing its nature by determining, for example, whether it is associated with nocturnal myoclonus or periodic leg movements. Some patients complain of insomnia but, in fact, have a normal amount of sleep. Patients with complaints of excessive daytime somnolence may have sleep apnea, which can be diagnosed by polysomnography. Apnea is defined in this context as the cessation of air flow at the mouth and nostrils for at least 10 seconds, whereas hypopnea refers to a reduction in respiratory air flow to one third of its basal value, with an associated reduction of abdominal and thoracic respiratory movements and a decline in oxygen saturation. The number of respiratory irregularities per hour of sleep can be calculated by dividing the number of apneic and hypopneic episodes by the total sleep time in minutes and multiplying the result by 60. A value of 5 or less is regarded as within the normal range.^[17] Polysomnography further indicates whether sleep apnea syndrome relates to a central disturbance, an obstructive disturbance in the oropharynx ([Fig. 24-11](#)), or a mixed disorder. Sleep apnea is dangerous because various cardiac abnormalities may occur during the apneic episodes, sometimes resulting in death. Polysomnography permits the severity of the syndrome and the presence of cardiac abnormalities to be determined, thereby indicating the need for prompt therapeutic intervention.

Another important cause of excessive daytime sleepiness is narcolepsy, which is diagnosed by the multiple sleep latency test. This quantifies the time required to fall asleep and allows the recognition of abnormally short latencies for going into REM sleep.^[18] Patients are monitored for five periods of 20 minutes at intervals of 2 hours, during which they are allowed to fall asleep; between these periods, they are kept awake and alert. A mean daily score of less than 5 minutes indicates a pathological level of daytime sleepiness. The number of sleep-onset REM periods (with REM sleep occurring within 15 minutes of sleep onset) is determined. Normally, REM sleep does not occur during these periods; two sleep-onset REM episodes strongly support a diagnosis of narcolepsy. The sensitivity and specificity of the test, however, are not clearly defined.^[20]

Certain complex behavioral disorders may disrupt sleep. These parasomnias are best characterized also by polysomnography. They tend to occur particularly during slow-wave sleep, and precise diagnosis facilitates appropriate treatment. In other patients, seizures may occur during sleep and these can be recognized by the study. Further discussion of sleep disorders is provided in [Chapter 54](#) .

EVOKED POTENTIALS

Stimulation of certain sensory systems leads to the generation of cerebral potentials that can be recorded over the scalp with surface electrodes. The latency and morphology of these evoked potentials depend on the eliciting stimulus. Evoked potentials are generally of low voltage and are

Figure 24-11 Polysomnogram of a patient with obstructive sleep apnea. An obstructive apneic episode is seen during REM sleep and is characterized by cessation of air flow associated with oxygen desaturation, accompanied by attempted respiratory movements of the thoracic and abdominal musculature.

intermixed with background EEG activity. For this reason, they are not easily seen without computer averaging of a number of responses so that signals that are time locked to the stimulus are enhanced whereas other electrocerebral activity is averaged out.

Evoked potential recordings provide a means of detecting lesions in the afferent pathways under study. They assess the functional integrity of these pathways, whereas imaging techniques such as magnetic resonance imaging evaluate their anatomical basis. Thus, evoked potential studies sometimes reveal abnormalities missed by magnetic resonance imaging, and vice versa. The findings may be important for diagnostic purposes, in following the course of certain neurological disorders, or for determining the extent of pathological involvement.^[21] In patients with known pathological processes involving the CNS, evoked potential studies help to detect and localize lesions. Subclinical abnormalities may be detected in a variety of disorders, and multifocal abnormalities occur not only in multiple sclerosis but also in a variety of different settings. The electrophysiological findings must therefore be interpreted in the clinical context in which they are obtained. Evoked potential studies are also helpful in the evaluation of ill-defined complaints to categorize more precisely the functional integrity of any afferent pathways that may be responsible for the symptoms in question.^[21]

The clinical utility of the various evoked potential studies in widespread use depends on the context in which they are obtained. Although some investigators have attempted to localize lesions on the basis of the electrophysiological findings, precise localization by this approach may not be possible. The generators of many of the recorded components are not known with confidence, and some components may have multiple generators.

Evoked potentials have been used to monitor neural structures at risk during surgical procedures, such as correction of scoliosis, in an attempt to minimize or prevent neurological damage. When an evoked potential abnormality occurs during the surgical procedure, it is hoped that alteration or reversal of the procedure may prevent or minimize damage. However, the utility of intraoperative monitoring is not well established in most circumstances. Moreover, even if an electrophysiological change occurs intraoperatively, it sometimes remains unclear whether this simply predicts an adverse outcome rather than actually permitting that outcome to be prevented if the surgical technique is modified. Nevertheless, in limited contexts, it is clear that intraoperative monitoring is beneficial. During posterior fossa surgery, for example, recordings of brain stem auditory evoked potentials are helpful in monitoring the status of the eighth cranial nerve to prevent its damage, and stimulation of the seventh cranial nerve aids in identifying this nerve and ensuring its functional continuity. Similarly, somatosensory evoked potential studies to monitor spinal cord function seem to reduce the morbidity associated with the surgical correction of scoliosis.

VISUAL EVOKED POTENTIALS

Basic Principles and Technique

Monocular stimulation generates a cerebral response that is best recorded over the occipital region. Either a flash or a pattern that occurs without change in background luminance can be used to elicit the response. Responses to approximately 100 stimuli are generally averaged to obtain robust and unambiguous potentials. For pattern stimulation, the seated subject looks at the center of a television screen on which is displayed a checkerboard pattern of white and black squares. The pattern reverses at about 1 Hz so that the white squares become black, and vice versa, without change in total luminance. The size of the checks is usually between 15 and 50 minutes of arc at the subject's eye, and the entire pattern should subtend at least 10 degrees of visual angle. Pattern-reversal stimuli generate robust responses and have a higher yield of abnormalities than flash stimuli. Small checks (15 to 30 minutes) preferentially activate the macular region and are the most widely used stimulus.

Normal VEP Findings

The typical visual evoked potential (VEP) elicited by a pattern-reversal stimulus is a negative-positive-negative complex that is recorded maximally in the midoccipital region with reference to either the midfrontal region or the linked ears.^[22] The positivity is the most conspicuous and consistent of these potentials and has a latency to its peak of approximately 100 msec ([Fig. 24-12](#)). It is therefore called the P100 response, and it is to this component that attention is directed.

In analyzing the VEP, the latency of the P100 response is measured after stimulation of each eye and then the interocular difference in latency is determined. These values are compared with normal values obtained using an identical stimulation and recording technique. This is important because certain physical attributes of the stimulus (such as its contrast or the check size) normally influence the response latency. The amplitude of the response and the latency of the preceding and succeeding negativities (the N75 and N145, respectively) are of uncertain clinical utility, but absence of the P100 is abnormal.

Figure 24-12 Visual evoked potential elicited by 50-minute checks and recorded between the midoccipital and midfrontal monocular stimulation with regiA, a normal subject, andB, a patient with a past history of optic neuritis. Two trials are superimposed to show the replicability of the findings. The P100 response in B is prolonged to 146 msec.

Abnormal Findings and Clinical Uses of the VEP

Visual evoked potentials are useful in evaluating the function of the anterior visual pathways. They are not useful in evaluating lesions posterior to the optic chiasm.

In patients with an acute optic or retrobulbar neuritis, the P100 response is initially lost; with time, it recovers and is then found to have a markedly prolonged latency that generally persists indefinitely (see [Fig. 24-12](#)),^[23]^[24] even if apparently complete clinical recovery occurs. The VEP is therefore an important means of evaluating patients with suspected optic neuritis and may be delayed even when magnetic resonance imaging of the optic nerve is normal.^[24] Abnormalities may relate to either recent or long-standing pathological processes. The VEP may be abnormal in patients without a past history of optic neuritis, thereby providing evidence of subclinical involvement of the optic nerve. For this reason, it is useful to record the VEP in such patients when multiple sclerosis is a diagnostic possibility.^[25]

Other disorders may also lead to VEP abnormalities. In particular, ocular pathology (e.g., refractive error, inability to focus on the pattern stimulus, or glaucoma) may be responsible. Compressive, ischemic, toxic, or nutritional optic neuropathies may also produce VEP changes, and abnormalities occur in Leber's hereditary optic atrophy.^[26]^[27] Compressive lesions of the optic nerve typically lead to VEPs that are markedly abnormal in shape as well as delayed in latency^[28]; in ischemic or toxic neuropathies, the response is usually markedly attenuated in amplitude without being delayed significantly.^[28] The findings, however, have always to be interpreted in the clinical context in which they were obtained.

The VEP findings are of little help in the evaluation of lesions posterior to the optic chiasm. It has been suggested that VEPs can be used to evaluate the visual fields, but the approach is time consuming, requires the close cooperation and attention of patients, and is no better or even less sensitive than standard tests of perimetry.^[29]^[30] In patients with cortical blindness, the VEP may be normal or abnormal--the presence of a normal response should therefore not lead, in itself, to a diagnosis of nonorganic visual loss.^[31]

The pattern-elicited VEP can be used to measure refractive error or detect amblyopia in preverbal children who are unable to cooperate for behavioral testing.^[32] For refractive purposes, the VEP is recorded while different lenses are placed in front of the eye to determine the lens with which the VEP to small (15 minute) checks is of largest amplitude and shortest latency; this lens will be the optimal one for the patient. By an analogous approach, the interocular difference in size of the VEP elicited by small checks is important as a means of detecting unilateral amblyopia at an early age, when recovery may still be possible.

BRAIN STEM AUDITORY EVOKED POTENTIALS

Basic Principles and Technique

Potentials generated in the auditory nerve and in different regions of the auditory pathways in the brain stem can be recorded at the vertex of the head after auditory stimulation.^[33] These brain stem auditory evoked potentials (BAEPs) occur within 10 msec of the stimulus, which for clinical purposes is a monaural click. This is usually set at approximately 65 dB above the patient's hearing threshold and is delivered through earphones while the opposite ear is masked by white (i.e., mixed-frequency) noise. The attention of the subject is not required. Because the BAEP is of very low voltage, between 1000 and 2000 responses are generally recorded so that the BAEP can be extracted by averaging from the background noise.

Normal BAEP Findings

The BAEP consists of a series of up to seven components (identified by Roman numerals) that occur within 10 msec of the click stimulus and are generated in different regions of the peripheral and central auditory pathways. Wave I and the early part of wave II represent the auditory nerve action potential. Wave III probably arises in the region of the superior olive, whereas waves IV and V arise in the midbrain and inferior colliculus. Waves VI and VII are of uncertain origin and, because of their inconsistency in normal subjects, are of little clinical utility.

The most consistent components are waves I, III, and V, and it is to these that attention is directed when BAEPs are evaluated for clinical purposes. The absolute latency of these components, the intervals between them (the so-called interpeak latencies), and the amplitude of wave V relative to wave I are assessed. Interside differences in interpeak latency are also measured and may reveal minor abnormalities. [Figure 24-13](#) illustrates a normal response.

Figure 24-13 Brain stem auditory potential elicited by monaural stimulation at 75 dB SL and recorded with an ipsilateral mastoid reference, A, a normal subject, and B, a patient with a structural lesion involving the upper pons. Two trials are superimposed to show the replicability of the findings. It can be seen that waves IV and V are markedly attenuated in the response recorded B.

Abnormal Findings and Clinical Uses of the BAEP

The BAEP is an important means of evaluating function of the eighth cranial nerve and the central auditory pathways in the brain stem.

In infants, young children, and adults who are unable to cooperate for behavioral testing, BAEPs can be used to evaluate hearing.^[34] The wave V component of the response is generated by auditory stimuli that are too weak to generate other components. As a screening test of hearing, then, the electrophysiological threshold for eliciting wave V is determined. An impairment of auditory acuity is suggested if a stimulus intensity greater than 40 dB is required. BAEPs provide a sensitive screening test for acoustic neuromas or other lesions in the cerebellopontine angle involving the eighth cranial nerve. Indeed, the BAEP findings may be abnormal at a time when imaging studies show no definite abnormality.

The BAEP is also useful in assessing the integrity of the brain stem (see [Fig. 24-13](#)). Although the auditory pathways have a bilateral course, a unilaterally abnormal BAEP nevertheless suggests an ipsilateral, structural brain stem lesion. The presence of normal BAEPs in comatose patients suggests either that the coma is due to bihemispheric disease or that it relates to metabolic or toxic factors; abnormal BAEPs in this context imply brain stem pathology and a poorer prognosis than otherwise. When coma is due to brain stem pathology, the BAEP findings help in localizing the lesion: alteration of wave V suggests midbrain dysfunction, and alteration of waves I to III indicates a lesion in the lower brain stem.^[35] In patients with brain death, the BAEP should be absent apart from wave I and the early part of wave II, which are generated peripherally. In many patients with suspected brain death, however, all BAEP components, including wave I, are absent, and it is then not possible to exclude other causes (such as technical factors of deafness) for the absent response.^[36]

BAEPs have been used to detect subclinical brain stem pathology in patients with suspected multiple sclerosis.^[37],^[38] However, the yield in this circumstance is less than with the visual or somatosensory evoked potentials, possibly because the auditory pathway is relatively short or is more likely to be spared.

SOMATOSENSORY EVOKED POTENTIALS

Basic Principles and Technique

Stimulation of a mixed nerve or its sensory branch leads to a response that can be recorded from the nerve more proximally or distally (the sensory nerve action potential), as well as over the spine and scalp. The scalp response is small and obscured by the ongoing EEG, and for this reason it is often necessary to average up to 2000 responses after stimulation of a nerve in the arm or 4000 responses with stimulation of a nerve in the leg, depending on the amount of background noise, to obtain well-defined responses.

The SEP depends on the functional integrity of the fast-conducting large-diameter group IA muscle afferent fibers and group II cutaneous afferent fibers and on the posterior columns of the cord, although some fibers may follow a different, extralemniscal pathway. It is elicited for clinical purposes by an electrical stimulus that is sufficient to produce a slight muscle twitch when a mixed nerve is stimulated or to generate a sensory nerve action potential that is about 50 percent of maximum. It is generally well tolerated, even when applied with a repetition rate of about 3 or 5 Hz. SEPs can also be elicited by cutaneous nerve or dermatomal stimulation, but the role of these approaches, especially in the evaluation of suspected radiculopathies, is uncertain. SEPs are best recorded with surface electrodes. Over the scalp, either a bipolar derivation (both recording electrodes placed on the scalp) or a referential derivation (involving a noncephalic reference electrode) may be used.

Normal SEP Findings

SEP components are defined by polarity and latency. With stimulation of a nerve in the arm, recording between the contralateral "hand area" of scalp and contralateral Erb's point, that is, in a referential derivation, demonstrates a P9 potential that reflects activity at or just beyond the brachial plexus. A P13-P14 potential reflects postsynaptic activity in the medial lemniscus, and an N20 component is generated in the primary somatosensory cortex (Fig. 24-14). A variety of other potentials may also be detected but are clinically less helpful and are not discussed further. With stimulation of the tibial nerve at the ankle, a P38 response is recorded over the scalp in the midline and represents activation of the primary somatosensory cortex (Fig. 24-15). Recordings over the cervical spine after stimulation of the nerve in the arm reveals an N13/P13 whereas stimulation of a leg nerve elicits a negative peak over the cauda equina and lumbar spine.

The presence or absence of these obligate components of the response and their latency and interpeak latency are recorded. Amplitude measurements may also be made, but abnormalities should not be based solely on amplitude criteria, except when an obligate response is absent. The absolute latency of individual components, but not the interpeak latency, varies with limb length.

As with the BAEP, it has generally been assumed that different components of the SEP reflect sequential activation of neural generators. However, potentials can be generated by a change in the physical characteristic of the volume conductor as, for example, when an impulse passes from the arm to the axilla. [39], [40]

Abnormal Findings and Clinical Uses of the SEP

Somatosensory evoked potentials are helpful in detecting and localizing lesions of the somatosensory pathways within the CNS but provide no indication about the nature of the underlying pathological processes. They are of little value in evaluating the peripheral nervous system, except when there is concern about the functional integrity of nerves

Figure 24-14 Median-elicited somatosensory evoked potential elicited A, a normal subject by right-sided stimulation, and B, a patient with multiple sclerosis by left-sided stimulation. Two trials are superimposed to show the replicability of the findings. In the responses recorded in the patient, an Erb's point potential is present but responses over the cervical spine and scalp are absent. EP, Erb's point; CV5, 5th cervical spine; i, ipsilateral; c, contralateral; other abbreviations as in earlier illustrations.

that are not easily accessible for conventional nerve conduction studies. [41] SEPs have been used to evaluate patients with suspected radiculopathies. Abnormalities would not be expected in the SEP obtained by a stimulation of a polysegmental nerve trunk in patients with isolated root lesions, and cutaneous nerve or dermatomal stimulation has given conflicting results and should therefore be regarded as investigational. [42]

In patients with multiple sclerosis, SEP abnormalities may indicate the presence of subclinical lesions, thereby helping to establish the diagnosis. [43] The presence of such abnormalities may also suggest that vague sensory complaints have an organic basis when this is hard to determine clinically. The SEP is abnormal in about 80 percent of patients with multiple sclerosis (see Figs. 24-14 and 24-15), but SEP abnormalities are found in only about 30 percent of patients when this is merely a diagnostic possibility. The yield is greater in SEPs elicited by stimulation of a nerve in the legs than the arms and is more likely when there are pyramidal signs in the stimulated limb or legs. [44] The most common abnormality found in patients with multiple sclerosis is loss or marked attenuation of the cervical response after stimulation of the median or ulnar nerve, and there may be an increase in central conduction time. [45] Subclinical SEP abnormalities may also indicate sensory involvement in patients with hereditary spinocerebellar degenerations, hereditary spastic paraplegia, and a deficiency of vitamin B₁₂ or vitamin E, and are therefore not pathognomonic of multiple sclerosis. [43], [46]

SEPs may indicate involvement of the central somatosensory pathways by other disorders at the spinal, brain stem, or thalamic levels. In patients with unilateral lesions of the cerebral hemisphere, the SEPs are often normal unless there is a clinical sensory disturbance, when they may be lost or markedly attenuated.

The SEP has been used to provide a prognostic guide

Figure 24-15 Responses recorded over the popliteal fossa, and over the spine and scalp to stimulation of the left tibial nerve at the ankle. Two trials are superimposed to show the replicability of the findings. A shows the finding in a normal subject, and B shows the response in a patient with multiple sclerosis. No response is present over the scalp in the patient. PF, popliteal fossa; L1, first lumbar spine; L3, third lumbar spine; d, distal; p, proximal; other abbreviations as in earlier illustrations.

in comatose patients. [36], [43], [47], [48], [49] In particular, loss bilaterally of the N20 response after stimulation of the median nerve is commonly associated with a fatal outcome or development of a persistent vegetative state. In patients with unilateral loss of the N20, the outcome is more variable; with bilaterally preserved N20 responses, approximately 50 percent of comatose patients regain useful function, 25 percent remain in a vegetative state, and the remainder die. Based on several other studies, it seems reasonable to conclude that patients with absent cortical SEPs bilaterally are unlikely to recover cognition, but the presence of normal SEPs does not predict that useful recovery will necessarily follow. The bilateral absence of all responses later than the N13-N14 response is supportive of brain death, when this is diagnosed by clinical criteria. [36]

After spinal injury, the SEP findings vary over the scalp after stimulation of a leg nerve, depending on the timing of the examination and the severity of the lesion. The absence of any cortical response in the acute stage after cord injury should not be taken to imply that the lesion is complete or that recovery will fail to occur. Preserved responses or their early return, however, indicate a better prognosis, although the degree of functional recovery varies.

SEPs have been used intraoperatively to monitor cord function, but it is not clear how useful they are in this context. Recent work suggests that this approach is helpful in reducing the morbidity of scoliosis surgery.

MOTOR EVOKED POTENTIALS

Magnetic stimulation of the brain and spine elicits so-called motor evoked potentials (MEPs). This technique is usually well tolerated by patients and poses no immediate safety hazards. The latency of the motor responses can be measured, and central conduction time can be estimated by comparing the latency of the responses elicited by cerebral and spinal stimulation. Abnormalities have been described in patients with a variety of central disorders including multiple sclerosis, amyotrophic lateral sclerosis, stroke, and certain degenerative disorders. ^[50] The clinical utility of these techniques, however, is unclear and at the present time the magnetic stimulation of central structures is regarded as investigational in the United States.

[PreviousNext](#)

ELECTROMYOGRAPHY

Basic Principles and Technique

Electrical activity can be recorded by a needle electrode placed within muscle. The potentials are amplified, displayed on an oscilloscope screen, and fed through a loud-speaker so they can be monitored by ear. Several different types of needle electrodes are in common use, but the most popular is the concentric needle electrode. This consists of a fine silver or platinum wire, insulated except at its tip, that is contained within a pointed steel shaft; the potential difference between the outer shaft and inner wire is recorded.

The electrical activity recorded from muscle, that is, the electromyogram (EMG), provides a guide to the pathological site in patients with disease of the motor units. Pathological processes can be localized to the neural, muscle, or junctional components of the motor units. In neuropathic diseases, the pattern of affected muscles also permits a lesion to be localized to the spinal cord, nerve roots, limb plexuses, or peripheral nerves. The EMG findings are not, however, pathognomonic of specific diseases and do not in themselves provide a definitive diagnosis.

Normal EMG Activity

When a needle electrode is inserted into a muscle, a brief burst of activity occurs for 2 to 3 seconds or less. Once this insertion activity has settled, spontaneous activity is not present in normal muscle except in the endplate region, where endplate "noise" can be recorded and corresponds to the nonpropagated miniature endplate potentials generated by the spontaneous release of acetylcholine at the neuromuscular junctions.

Figure 24-16 Motor unit activity during increasing voluntary effort. The number of units activated increases with the force of contraction, and eventually (bottom trace) individual potentials can no longer be recognized. (From Aminoff MJ: *Electromyography in Clinical Practice*, 3rd ed. New York, Churchill Livingstone, 1998.)

When slight voluntary contraction is initiated, a few of the motor units within the muscle are activated and initially fire irregularly and at a low rate. With increasing effort, they fire more rapidly; and, at a certain firing rate, additional units are recruited. With further effort, so many units are active that individual potentials cannot clearly be distinguished, leading to a complete "interference pattern" on the trace of the oscilloscope (Fig. 24-16).

Individual motor unit action potentials are usually biphasic or triphasic in configuration, but up to 10 to 15 percent are polyphasic, that is, they have five or more phases. They normally have a duration of between 2 and 15 msec and an amplitude of between 300 μ V and 3 mV (Fig. 24-17).

Abnormal EMG Activity

Insertion activity is increased in neuropathic and certain myopathic or myotonic disorders and in myositis. Abnormal

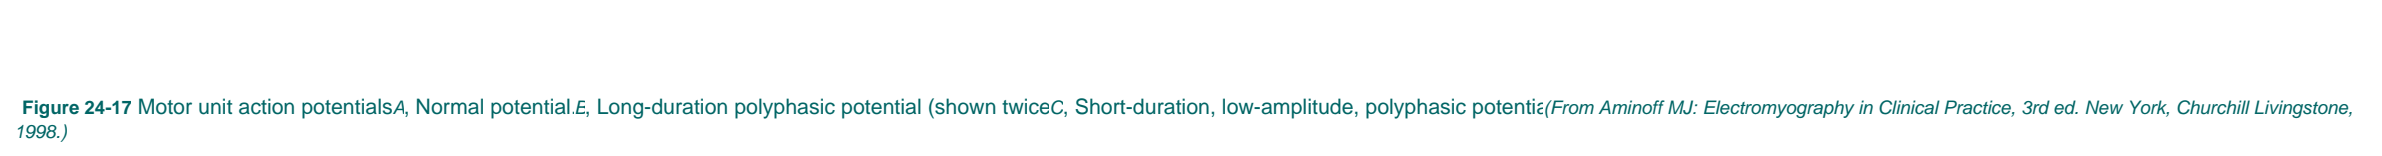

Figure 24-17 Motor unit action potentials. A, Normal potential. B, Long-duration polyphasic potential (shown twice). C, Short-duration, low-amplitude, polyphasic potential. D, Normal potential. (From Aminoff MJ: *Electromyography in Clinical Practice*, 3rd ed. New York, Churchill Livingstone, 1998.)

spontaneous activity is present in various neuromuscular diseases. *Fibrillation potentials* (Fig. 24-18) are biphasic or triphasic discharges with a positive onset except in the endplate region; they have an amplitude of about 300 μ V, have a duration of up to 5 msec, fire up to 20 times per second, and represent action potentials generated in single muscle fibers. They usually fire rhythmically, and this probably reflects oscillations of the resting membrane potential of skeletal muscle fibers. ^[51] *Positive sharp waves* (Fig. 24-19) may be found in association with them and consist of an initial positive deflection followed by a slow deflection in the negative direction. Although similar in size to fibrillation potentials, they often last for 10 msec or more and may discharge at rates up to 100 per second. Fibrillation potentials and positive sharp waves are found in conditions with increased muscle irritability. They occur in denervated muscle but may not appear for 3 to 4 weeks after an acute neuropathic lesion. They are also found in patients with inflammatory disorders of muscle, occasionally in patients with muscular dystrophies, after muscle trauma, in patients with certain metabolic disorders (such as acid maltase deficiency), and in association with botulism.

In patients with chronic partial denervation, as well as

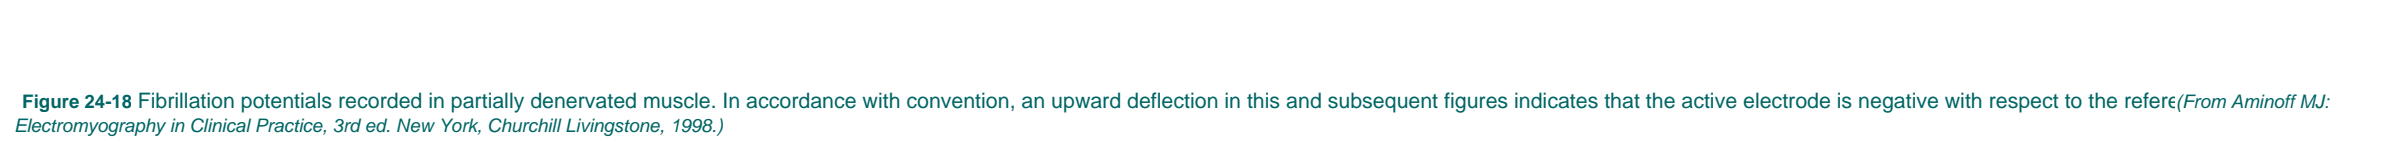

Figure 24-18 Fibrillation potentials recorded in partially denervated muscle. In accordance with convention, an upward deflection in this and subsequent figures indicates that the active electrode is negative with respect to the reference. (From Aminoff MJ: *Electromyography in Clinical Practice*, 3rd ed. New York, Churchill Livingstone, 1998.)

Figure 24-19 Positive sharp waves recorded in partially denervated muscle. (From Aminoff MJ: *Electromyography in Clinical Practice*, 3rd ed. New York, Churchill Livingstone, 1998.)

with certain of the muscular dystrophies or inflammatory disorders of muscle, *complex repetitive discharges* are found. These have a high discharge frequency, but their amplitude and frequency remain constant (Fig. 24-20). They appear to arise in the muscle itself and are probably initiated by a fibrillating muscle fiber that then depolarizes adjacent fibers by ephaptic transmission. ^[52] By contrast, in the *myotonic discharges* (Fig. 24-21) that characterize certain myotonic disorders with delayed relaxation after voluntary contraction, high-frequency trains of action potentials occur spontaneously, wax and wane in amplitude and frequency, and relate to a disorder of the muscle fiber membrane.

Fasciculation potentials have the dimensions of motor unit action potentials (see later) and represent the spontaneous activation of all the muscle fibers in individual units. They produce a sudden dull thump over the loudspeaker. They are found most often with disease of the anterior horn cells but may also occur with other neuropathic disorders, occasionally with certain myopathic disorders (as in thyrotoxicosis), and sometimes as an isolated phenomenon without pathological significance. Studies in patients with diverse lower motor neuron lesions have revealed that they may arise at multiple sites along motor axons or the cell bodies of diseased motor neuron, ^[53] but in most instances they originate at the distal extremity of the axon. ^[54] Myokymic discharges, in which motor unit action potentials discharge spontaneously in characteristic patterns, are discussed below.

The motor unit action potentials may show characteristic abnormalities in various diseases of the motor units. In *myopathies*, the number of muscle fibers in individual motor units is reduced. In consequence, the mean duration and amplitude of the motor unit action potentials is reduced (see Fig. 24-17) and the incidence of polyphasic potentials is increased. Moreover, because the individual units generate less tension than normal, an increased number is recruited for any given degree of voluntary activity. By contrast, in *neuropathic disorders*, the number of motor

Figure 24-20 Spontaneous, high-frequency repetitive discharge of action potentials in a partially denervated muscle. (From Aminoff MJ: *Electromyography in Clinical Practice*, 3rd ed. New York, Churchill Livingstone, 1998.)

units--but not their content of muscle fibers--is reduced; indeed, if denervated muscle fibers have been reinnervated by sprouting from the axon terminals of surviving units, the number of fibers per unit may actually be increased. In consequence, motor unit action potentials may be longer in duration and larger in amplitude than

normal, with an increased incidence of polyphasic potentials, indicating that reinnervation has occurred (see [Fig. 24-17](#)). During mild voluntary activity, there is an increase in the rates at which individual units begin firing and at which they fire before additional units are recruited; and during maximal effort the interference pattern is reduced.

In disorders with *abnormal neuromuscular transmission*, such as myasthenia gravis, motor unit action potentials vary in amplitude and area during continued activity and, in addition, there is an excess of small, short-duration potentials in affected muscle. The variability of the potentials reflects the reduced safety factor for neuromuscular transmission, as a consequence of which there is variation in the number of muscle fibers firing with each discharge of the unit. Single-fiber electromyography is a technique in which action potentials are recorded from two or more muscle fibers belonging to the same motor unit by means of a special electrode, and the temporal variability (or jitter) between the two action potentials at consecutive discharges is measured.^[55] This jitter reflects variation in neuromuscular transmission time in the two motor endplates involved. An increased jitter is therefore to be expected in patients with diseases of neuromuscular transmission, and impulse blocking may also occur.

Myokymic discharges consist of a spontaneously occurring grouped pattern of firing of motor units; double, triple, or multiple discharges occur, followed by a period of silence and then by another grouped discharge. They may occur in patients with radiation-induced plexopathy or myelopathy and occasionally with chronic radiculopathies or entrapment neuropathies, Guillain-Barre syndrome, multiple sclerosis, or gold intoxication; they may also be found in facial muscles in patients with brain stem gliomas.^{[56], [57]}

NERVE CONDUCTION STUDIES

Basic Principles and Technique

Needle electromyography is generally performed in conjunction with nerve conduction studies, which may be undertaken to determine the functional integrity of the peripheral nerves. For motor conduction studies, the nerve is stimulated at two or more points along its course while the electrical response is recorded of one of the muscles

Figure 24-21 A myotonic discharge evoked by electrode movement (From Aminoff MJ: *Electromyography in Clinical Practice*, 3rd ed. New York, Churchill Livingstone, 1998.)

supplied by it. Electrical stimuli are preferred and must be of sufficient intensity to excite all of the fibers in the nerve. The muscle response is recorded by surface or subcutaneous needle electrodes, with the active electrode being placed over the endplate region and the reference electrode over the muscle tendon. The response recorded in this way is called the compound muscle action potential (CMAP), or M wave, and represents the sum of the electrical activity of all of the activated muscle fibers within the pickup region of the recording electrode. The shape, size, and latency of the response obtained by stimulating the nerve at different sites is compared. By measuring the distance between stimulation sites and the difference in latency of the responses elicited by stimulation at these sites, the conduction velocity can be determined for the fastest conducting fibers along the intervening segments of the nerve ([Fig. 24-22](#)). In the arms, the normal range of maximal motor conduction velocity is between 50 and 70 m/sec, while in the legs the corresponding velocities are between 40 and 60 m/sec.

Sensory nerve conduction studies involve stimulating a sensory nerve either orthodromically or antidromically and recording the response at another point along the course of that same nerve. The calculated conduction velocity is the same, but the response is larger with antidromic stimulation. Responses can also be recorded from a purely sensory nerve after stimulation of the parent nerve trunk from which it originates, or vice versa.

In patients with *focal conduction block* involving an individual nerve, the CMAP elicited by stimulating the nerve above the site of the lesion is reduced in amplitude compared with more distal stimulation and, in severe cases, is completely lost. Sensory nerve action potentials are also small or unrecordable when the lesion is located between stimulation and recording sites. With *focal conduction slowing* (but not block), the size of the CMAP is reduced as the distance increases between the stimulating and recording electrodes. Motor and sensory conduction velocities are slowed across the region of the nerve encompassing the lesion, and sensory nerve action potentials may be markedly attenuated or unrecordable because of dispersion. *Axon-loss lesions* are characterized by an attenuated muscle response, by reduced or absent sensory nerve action potentials, and by electromyographic signs of denervation in the affected muscle. Motor or sensory conduction velocity is normal or reduced only minimally, when it can be recorded.

Clinical Uses of Nerve Conduction Studies

Motor conduction studies are helpful in indicating that weakness is due to pathology of the peripheral nerves rather than other parts of the motor unit. Sensory conduction studies may indicate that sensory symptoms are due to an impairment of peripheral nerve function or, when normal, to a lesion proximal to the dorsal root ganglia. Motor and sensory conduction studies are important in determining the presence and extent of a peripheral neuropathy, distinguishing between a polyneuropathy and mononeuropathy multiplex, recognizing the selective involvement of motor or sensory fibers, and following the course of peripheral nerve disease. The nature of the abnormalities found on motor or sensory conduction studies may suggest the type of underlying pathology and, in particular, whether this is primarily axonal loss or segmental demyelination.^[58] Nerve conduction studies are also important as a means of recognizing subclinical polyneuropathies and in detecting and localizing a focal lesion involving individual nerves.

Focal nerve lesions may result from injury or compression

Figure 24-22 Arrangement for measuring motor conduction velocity in the forearm segment of the median nerve. The nerve is stimulated distally (A) and proximally (B), and the evoked potentials are recorded from the abductor pollicis brevis muscle. (Ground electrode not shown.) Maximal motor conduction velocity (m/sec) between the proximal and distal sites of stimulation is calculated by dividing the distance between these sites by the difference in latency of the responses (From Aminoff MJ: *Electromyography in Clinical Practice*, 3rd ed. New York, Churchill Livingstone, 1998.)

at sites of entrapment of the nerve by neighboring anatomical structures. Common entrapment neuropathies include compression of the median nerve at the wrist (carpal tunnel syndrome); the ulnar nerve at the elbow, cubital tunnel, or Guyon's canal; and the peroneal nerve at the head of the fibula. Electrophysiological studies are very important in localizing the lesion in such disorders and also in excluding the possibility of a subclinical polyneuropathy manifest primarily by the entrapment neuropathy. The findings depend on the duration and severity of nerve damage, the rapidity of its evolution, and the underlying disorder.^[59]

F-RESPONSE AND H-REFLEX STUDIES

Basic Principles and Technique

F responses are evoked from muscle as the result of antidromic activation of motor neurons by a peripheral electrical stimulus. The stimulus should be of greater intensity than is required to elicit a maximal CMAP and may not always elicit an F response. F responses are small (usually less than 5 percent) compared with the CMAP ([Fig. 24-23](#)), and their latency and amplitude vary considerably even when the stimulating and recording arrangements remain constant, presumably because different anterior horn cells are activated antidromically. Various parameters of F waves can be measured, but the most popular is the minimum latency of 10 or more responses.

The H reflex, named after Hoffmann who first described it, can be recorded easily only from the gastrocnemius-soleus muscle in the legs and the flexor carpi radialis muscle in the forearm in response to stimulation of the nerve to these muscles. The stimulus required to elicit the response is lower in intensity than is necessary to elicit CMAPs of maximal size ([Fig. 24-23](#)). The afferent pathway subserving the H reflex consists of spindle afferent (Ia) fibers, and the efferent arc is via the alpha motor axons. The H reflex is not easily obtained from other muscles except in infants or patients with pyramidal lesions, limiting its clinical utility.

Normal Findings

The latency of the H or F response depends on a subject's height or limb length, and normal values must therefore be obtained with this in mind to permit appropriate evaluation of the results from patients. It may also be helpful to compare interside differences in latency of the responses in individual patients; for H and F responses from the soleus muscle, or the F responses from the intrinsic hand muscles, this is normally less than 2 msec. [\[60\]](#)

Abnormal Findings and Clinical Uses of F-Response and H-Reflex Studies

F-response and H-reflex studies are sometimes useful in the evaluation of patients with peripheral neuropathies,

Figure 24-23 Diagrammatic representation of the relationship between the direct (M) response, F response, and H reflex, and the intensity of the eliciting stimulus. With low-intensity stimulation of the tibial nerve, an H reflex is elicited from the soleus muscle. As the intensity of stimulation increases, the H reflex declines and a small M wave is seen. With a higher stimulus intensity, the H reflex disappears and the M wave increases in size until it is maximal. Following the maximal M wave, a small F response is sometimes seen. (From Aminoff MJ. *Electromyography in Clinical Practice*, 3rd ed. New York, Churchill Livingstone, 1998.)

particularly when the pathological process is so proximal that conventional nerve conduction studies fail to reveal any abnormalities. A prolongation of the minimum F-response latency may occur in patients having polyneuropathies with involvement of motor fibers, sometimes when conventional nerve conduction studies are normal. Abnormalities are sometimes encountered with radiculopathies, but these patients generally have abnormalities on needle electromyography so that the added F-wave abnormality does not influence management. H-reflex abnormalities (lost or delayed responses) may also be found in patients with polyneuropathies or with a lesion anywhere along the pathways subserving the reflex.

BLINK REFLEX

Basic Principles and Technique

The blink reflex is a polysynaptic reflex that is most conveniently recorded from surface electrodes placed over

455

the orbicularis oculi muscle after electrical stimulation of the supraorbital nerve ([Fig. 24-24](#)). The afferent arc of the reflex is subserved by the trigeminal nerve, and the efferent arc is subserved by the facial nerve.

Normal Findings

The response is characterized by a short-latency (approximately 10 msec) ipsilateral response that is designated R1, followed by a more asynchronous, bilateral response having a latency of 28 to 30 msec that is designated R2 ([Fig. 24-25](#)).

Abnormal Findings and Clinical Uses of the Blink Reflex

The blink reflex may be helpful in revealing the presence of a subtle trigeminal or facial nerve lesion. Ipsilateral trigeminal nerve lesions lead to responses that are either lost or have a prolonged latency bilaterally. A unilateral facial nerve lesion, by contrast, leads to a delayed or absent response on the affected side regardless of which side is stimulated.

The blink reflex may be abnormal with polyneuropathies, thereby indicating the extent of the disorder. Abnormalities may also occur with tumors in the cerebellopontine angle involving either or both nerves or the brain stem and with brain stem lesions involving the central pathways subserving the reflex, such as in multiple sclerosis, sometimes in the absence of clinical evidence of brain stem involvement.

Figure 24-24 Arrangements for eliciting the blink reflex (From Aminoff MJ: *Electromyography in Clinical Practice*, 3rd ed. New York, Churchill Livingstone, 1998.)

Figure 24-25 The blink reflex elicited by electrical stimulation of the right supraorbital nerve in a normal adult. Two separate responses are shown. The R1 component of the response is present only on the side that is stimulated, whereas R2 is present bilaterally. (From Aminoff MJ: *Electromyography in Clinical Practice*, 3rd ed. New York, Churchill Livingstone, 1998.)

REPETITIVE NERVE STIMULATION

Basic Principles and Technique

Electrophysiological techniques are important in the evaluation of neuromuscular transmission. The amount of acetylcholine released by a nerve impulse--and thus the size of the endplate potential--is influenced by preceding activity in the junctional region. This normally is of little consequence, because the amount of acetylcholine released far exceeds that required to generate endplate potentials above the threshold for activating muscle fiber action potentials. Reduction in this safety factor, however, may alter the number of muscle fibers activated by an impulse and thus the size of the CMAP elicited by a supramaximal stimulus to the motor nerve. The size of the electrical response evoked in muscle by two or more supramaximal stimuli, or by a single stimulus applied after a 30-second period of maximal voluntary activity or tetanic stimulation, therefore reflects the efficacy of neuromuscular transmission.

Normal Findings

There is normally no change in size of the responses to paired or repetitive shocks delivered to the motor nerve at rates of up to 10 Hz or in the response to single shocks delivered before and after maximum voluntary activity or tetanic stimulation.

Abnormal Findings and Clinical Uses of Repetitive Nerve Stimulation

Repetitive nerve stimulation is a useful technique for evaluating neuromuscular transmission. In diseases in which such transmission is impaired, the muscle response to repetitive nerve stimulation may show abnormal alterations in size or area. In myasthenia gravis, a progressive decrement in the response may occur with repetitive stimulation (especially at 2 to 3 Hz), or an initial decrement may be followed by a leveling off of the response at a reduced size. Abnormalities are more likely to be found in proximal rather than distal limb muscles and in facial rather than limb muscles. Normal findings do not exclude the diagnosis. By contrast, in patients with Lambert-Eaton myasthenic syndrome or botulism, the response to a single stimulus is abnormally small and stimulation at a slow rate leads to a further reduction in response size; with rapid rates of stimulation, a progressive increase in size of the response occurs.

For the variety of applications it offers, clinical laboratory testing for neurological disease has undergone revolutionary change in recent years. Diagnostic capabilities for metabolic diseases, for rapid detection of infection, and for determining genetic risk factors are only a few examples of recent developments in testing capabilities. Results from the clinical laboratory are the only ways to evaluate for certain neurological disorders. Laboratory tests have become an expensive part of the medical enterprise, but often they can provide the most cost-effective means for answering diagnostic questions.

Abnormalities detected by laboratory testing are not always attributable to a particular neurological disorder. Clinicians sometimes need to apply a process of decision-tree logic to derive useful information from laboratory results. Another limit of abnormal test results is that they do not always point to the mechanism of disease. The latter point was well known to a 19th-century founder of clinical laboratory medicine, Claude Bernard, who made the analogy that "as familiar as we might become with the structure of a mill, there is still much to learn before we would know the craft of a miller." The imprint of disease on the tissues and fluid compartments of the body provides an important but sometimes imperfect tool for solving clinical problems and guiding therapy. False-positive and false-negative findings, other sources of artifactual results, multimodal distributions of normal values, and the constant evolution of new information all are reasons that clinicians need to maintain a broad base of knowledge concerning laboratory medicine.

Certain screening laboratories, including complete blood counts, electrolytes, and tests of renal and hepatic function, are commonly used in the evaluation of many neurological conditions. Other studies such as drug and toxicological screens (see [Chapter 39](#)) as well as nutritional (see [Chapter 40](#)), coagulation (see [Chapter 45](#)), immunological (see [Chapter 50](#)), and enzymatic studies (see [Chapters 30](#) and [31](#)) may be useful in specific clinical settings and are covered in their respective chapters in Part 3 of the textbook. This chapter focuses on the proper use of genetic studies and primary neurological tissue (muscle, nerve, and brain) in the diagnosis of neurological disease.

GENETIC STUDIES

The pace of discovery of genes responsible for hereditary neurological diseases has escalated during recent years. The number of genetically defined disorders already is too large to permit comprehensive coverage of the molecular diagnosis of these disorders in a single chapter. Whereas the diagnosis, evaluation, and treatment of specific inherited neurological disorders are fully described in Part 3 of the textbook, this first section of the chapter focuses on the various techniques available to the clinician in the evaluation of the presence of certain inherited neurological disorders.

The Human Genome

In order to appreciate the current findings and to rationally approach the laboratory investigation of a patient suspected of having a genetic disorder, it is essential to understand some basic principles of genetics and molecular biology. All biological activities depend directly or indirectly on the proteins that lie within cells. The totality of genetic information for an organism is referred to as the genome. The human genome is divided among 23 pairs of chromosomes; females have two X chromosomes and 22 pairs of autosomes (non-sex chromosomes), and males have an X and a Y chromosome in addition to the 22 pairs of autosomes. Genetic information is contained in the linear

sequence of nucleotides, or bases, in deoxyribonucleic acid (DNA). Each chromosome is a single enormous molecule of linear DNA associated with a complex assortment of proteins that play structural, regulatory, and enzymatic roles during DNA replication and gene expression. The autosomes are numbered according to their sizes and contain about 50 million bases in chromosome 22 to more than 200 million bases in chromosome 1. Genetic information is contained within the mitochondrial genome of 16,559 nucleotides. It is important to recognize that this genome only encodes a small proportion of the proteins that constitute mitochondria. The majority of mitochondrial proteins are encoded by the nuclear genome.

It is estimated that 50,000 to 100,000 genes are within the human genome. These genes range in size from nearly 100 bases to about 2.5 million bases. Gene expression is the sequence of processes from messenger RNA synthesis, or transcription, to protein synthesis, or translation. Gene transcription is a complex process and begins with the regulated initiation of transcription from a transcription initiation site. This initiation process is of fundamental importance and is mediated by proteins termed transcription factors. A primary transcript is synthesized down the length of the entire gene from the 5

to the 3 end. The information in most genes is broken into discontinuous pieces termed exons that are separated by introns, or intervening sequences. These introns are removed from the primary transcript through splicing. Most spliced products then have a string of adenosine bases added to their 3 ends. This spliced and polyadenylated product is the mRNA that is then transported to the cytoplasm of the cell and serves as a template for the synthesis of protein. An individual gene, then, is the composite not only of the sequences that code for protein, but also the introns, the transcribed but not translated regions at the 5 and at the 3 ends of the mRNA, and sequences that regulate the transcription initiation, termination, and splicing processes. Regulatory sequences can flank the transcription initiation and termination site or even lie within introns or exons.

The sequence of bases in an mRNA encodes the amino acid sequence of the protein for a gene. Nucleotide information is interpreted in groups of three bases, termed codons. With 4 nucleotide bases, 64 possible codons exist. Four codons are particularly important. AUG encodes methionine, which is always the first amino acid of the primary translation product (which may be cleaved to make a mature protein product). The codons UAG, UGA, and UAA are stop codons. Mutations that cause disease can be as subtle as the substitution of one nucleotide base for another. The consequences of point mutations demonstrate the great variety of effects that result from an alteration in a gene and illustrate most of the key problems that result from mutations. The results of such a mutation depend critically on the location of the mutation within the gene as well as on the particular bases that are involved. If the mutation lies within the coding region (also known as the open reading frame), the result could be the substitution of one amino acid for another. Some point mutations result in no change of the amino acid and are termed silent mutations. Other protein coding region mutations can result in the conversion of an amino acid encoding codon into a termination or stop codon. A mutation affecting an initiation codon would prevent translation initiation unless another AUG codon was present elsewhere. Point mutations can occur outside of the coding region with the resulting consequences including obliteration or creation of splice sites, destruction or creation of transcription initiation, termination, and regulatory sites.

Mutations can also result from deletions or insertions, which can range in size from a single nucleotide to thousands of nucleotides. When an insertion or deletion lying within the coding region for a protein involves a number

TABLE 25-1 -- SELECTED DISORDERS WITH TRINUCLEOTIDE REPEAT

Disorder	Gene	Chromosome	Repeat Unit	Normal Range/Pathological Range	Other Mutations
Huntington's disease	Huntingtin	4p16.3	CAG	15 to 20/39 to 100	--
Machado-Joseph disease (MJD)/SCA III	MJD	14q24.3	CAG	13 to 36/68 to 80	--
X-linked spinal and bulbar atrophy	Androgen receptor	Xq11	CAG	15 to 20/40 to 100	--
SCA I	Ataxin-1	6p23	CAG	--	--

Friedreich's ataxia	Frataxin FRDA	9q	GAA	7 to 20/200 to 900	Leu106Ter, splice acceptor mutation intron 3, ILe154Phe

SCA, spinocerebellar ataxia; DPPLA, dentatorubropallidoluysian atrophy.

of bases that are not a multiple of 3, then the coding frame is disrupted, resulting in a protein sequence that diverges from the normal sequence from that point on, unless a second mutation restores the proper reading frame.

A recently recognized but important category of mutations, which is considered a subtype of an insertion, is the trinucleotide repeat expansion mutations ([Table 25-1](#)). These mutations are characterized by an elongation of a gene region with repeats of a three-nucleotide sequence. The precise sequence varies among the disorders, as does the scale of expansions. Some general distinctions can be drawn. When the trinucleotide, or triplet, repeat unit lies outside of the coding region,

the expansions may be very large. For example, the mutations that cause fragile X mental retardation syndrome (FRAXA) (see [Chapter 32](#)) are expansions of a region involving the trinucleotide CCG that lies in the 5' untranslated, but transcribed portion of the gene. Normally, 5 to 50 CCG repeats exist in this region, but affected individuals may have hundreds or even thousands of repeats. Expansions of over several hundred CTG triplet repeats have been found in patients with myotonic dystrophy (Steinert's disease). The repeat unit CTG is normally present in only 5 to 27 copies and lies in the 3' untranslated region of the myotonin gene. The Friedreich's ataxia triplet repeat unit GAA lies within the first intron of the frataxin gene. Normal individuals have 7 to 22 GAA repeats, whereas individuals with Friedreich's ataxia have about 200 to 1000 repeats. Interestingly, point mutations in the FRAXA and Friedreich's ataxia genes can also cause mental retardation and Friedreich's ataxia, respectively. The other type of triplet repeat mutations involves repeats of the nucleotide bases CAG, which encode the amino acid glutamine and lie within the coding domains of their respective genes. Not only is the repeat unit the same for these disorders, but also the scale of the repeat expansion is quite similar; whereas the length of the normal repeat is approximately 20, affected individuals have 40 or more repeats. To date, all mutations of this type are of special importance to neurologists, because the major syndromes affect the brain, spinal cord, or muscles.

Testing Methods

High-Resolution Karyotype. The genetic test with the lowest resolution is the karyotype analysis. In this test, a sample of cells, for example blood leukocytes or amniotic fluid cells, is grown in tissue culture medium in the presence of mitotic inhibitors that arrest cells at metaphase. The cells are then "squashed" to spread the chromosomes on a microscopic slide. The chromosomes are then stained to reveal a pattern of bands along the length of the chromosome arms. This form of testing is able to assess whether the cells have the normal number of chromosomes and whether interchanges between the chromosomes (translocations) have occurred. Depending on their size, this analytical method can also detect some deletions or duplications of chromosomal regions. A typical high-resolution test can detect deletions and insertions of approximately 10 million base pairs or more. Smaller deletions or duplications (submicroscopic deletions) will not be detected, including the duplication found in most patients with Charcot-Marie-Tooth 1A (CMT1A) or Pelizaeus-Merzbacher disease (see [Chapter 36](#)).

Fluorescent In Situ Hybridization. Fluorescent in situ hybridization analysis is a useful method for determining deletions or duplications of specific chromosomal regions. This technique involves staining chromosomes by hybridization with a nucleic acid probe. This probe is visualized by being covalently labeled with a fluorescent molecule that can be detected with a conventional fluorescence microscope. Typical probes range from a few thousand bases to tens of thousands of bases in length. In addition to staining, chromosomal spreads prepared as described above for conventional karyotype analysis can be used to stain chromosomes in interphase or nonmitotic cells. This method is advantageous because the DNA is not tightly wound into densely packed chromatin, so that relatively closely spaced fluorescent markers may be resolved microscopically. This technique may detect the 1.5 million base duplication in CMT1A, the approximately 1 million base duplications seen in most patients with Pelizaeus-Merzbacher disease, or the submicroscopic deletions responsible for the Smith-Magenis and the Prader-Willi/Angelman syndromes (see [Chapter 32](#)).

Single Gene Mutation Screening. Mutation detection specificity and sensitivity concerns apply to molecular diagnostic testing as well as to conventional biochemical testing. It is important to understand the nature of mutations that are known to occur in a gene in question as well as the range of potential mutations that can occur for any gene. The types of mutations that can cause a genetic disease determine the comprehensiveness or sensitivity of a screening test. The trinucleotide repeat disorders represent a group of genetic diseases that can be screened easily and with great sensitivity, because the mutations are of a single type and occur in a single region of their respective genes. However, screening for disorders such as X-linked Charcot-Marie-Tooth disease (connexin 32 gene) or myotonia congenita (skeletal muscle chloride channel) is difficult because different affected families will often have unique, or private, mutations such as single base changes, or small insertions or deletions. Although caused by many private mutations, some genetic disorders can be screened for by relatively convenient tests due to the nature of their mutations. Whereas the responsible gene for Duchenne and Becker muscular dystrophies (dystrophin) is an extremely large gene with many exons, mutations are fairly sizable (tens or hundreds of bases) deletions in most cases (see [Chapter 36](#)). Because particular gene regions are so-called hot spots for these deletions, polymerase chain reaction (PCR) simultaneous amplification (so-called multiplex PCR) of the dystrophin gene regions most often deleted is able to detect mutations in about 75 percent of cases. Neurofibromatosis 1, another genetic disorder affecting a large gene caused by many private mutations, may lead to the premature termination of protein synthesis of the neurofibromin protein (see [Chapter 32](#)). Because the neurofibromin gene is expressed in white blood cells, an assay, the premature protein truncation test, was developed to screen leukocyte RNA for the neurofibromin mRNA. The mRNA can be specifically amplified and then used as a template for in vitro protein synthesis. After electrophoresis

of the synthetically generated neurofibromin and detection by antibody on Western blot, mutations can be reliably inferred if the immunoreactive neurofibromin is smaller than the normal protein. The premature protein truncation assay is now commercially available and reported to detect mutations in the neurofibromatosis 1 gene in 70 percent of individuals who fulfill clinical criteria. When mutations are not found in a clinically affected individual, mutation detection is more problematic. Currently no commercial laboratory offers testing for mutations in the remaining 30 percent of neurofibromatosis 1 individuals.

At present, numerous methods are available to screen for genetic mutations. PCR amplification is a technique that is critical to many of these tests because it enables the generation of large amounts of DNA. Routine PCR is limited to the amplification of specific, small (up to several hundred base pairs in length) regions of a single gene bracketed by a pair of opposing DNA primers that define the origins and directions of DNA synthesis of a target gene. Because each strand of the double helix can be used as a template for DNA synthesis in each repetitive cycle of DNA denaturation, primer annealing, and DNA synthesis, a doubling in the number of amplified DNA regions occurs. Thus, a several billion-fold amplification of a gene region is readily achievable from a small amount of DNA from the visual 30- to 35-cycle amplification. As previously mentioned, PCR is the basis for detecting trinucleotide repeat expansion mutations and deletions of the dystrophin gene. It is also used to amplify segments of a gene suspected of having a mutation, and the PCR products are then used in a variety of assays to screen for the mutations.

Single-Strand Conformation Polymorphism Analysis. Single-strand conformation polymorphism analysis has the capability of detecting single base mutations and is a very valuable means of screening for small mutations. PCR products, generally a few hundred bases in length, when denatured and subjected to electrophoresis usually show measurable differences in electrophoretic migration, due to the differences in conformation of the dissociated single strands of DNA. Mutations in a gene may further alter the electrophoretic migration of dissociated DNA strands, which have been PCR amplified. This technique is the basis of single-strand conformation polymorphism analysis, which when properly designed, can detect at least 80 percent of point mutations as small as a single base difference within the region amplified. If precise definition of the mutation is required, direct sequencing of the PCR product is undertaken.

Allele Specific Oligonucleotide Hybridization. Allele specific oligonucleotide hybridization is primarily used to detect specific point mutations. With properly designed oligonucleotides, single-stranded DNA probes of about 20 bases in length can detect either the normal or mutant gene variant by hybridization of the probes to PCR-amplified DNA segments.

Direct Gene Sequencing. The definitive method for the detection of point mutations involves direct gene sequencing. Whereas for large genes (neurofibromatosis 1, dystrophin), such a direct screen is impractical with the current level of technology. It is the method of choice for certain small genes. For example, the entire prion protein gene-coding region conveniently lies within a single exon that can be amplified by PCR with a single pair of primers. Current methods can now readily scan the entire coding sequence of the gene in cases of suspected hereditary prion mutations. With relatively short and few exons, other genes, such as the proteolipid protein gene that is mutated in Pelizaeus-Merzbacher disease, are also amenable to direct sequencing for mutation screening.

Restriction Fragment Length Polymorphism Analysis. Mutations that alter the sequence of a gene may, by chance, create or abolish a sequence cleavable by bacterial proteins termed restriction endonucleases. These enzymes cut double-stranded DNA wherever a specific short, usually 4 to 10 bases, sequence occurs. The discovery of these enzymes was key to the advances made in recombinant DNA technology and modern molecular analysis. When a restriction site is created or abolished, the pattern of DNA fragments generated by the appropriate enzyme is also changed. The methods of gene hunting that rely on restriction fragment length polymorphism (RFLP) analysis take advantage of restriction site variation not only within the gene itself, but also at site variations that lie outside, yet nearby, the gene in question. For example, before the discovery of the Huntington disease gene, RFLP analysis of samples gathered from whole families was the mainstay of genetic diagnosis of presymptomatic individuals (see [Chapter 34](#)). Restriction site variations that lie outside but nearby the Huntington's disease gene were used to mark the abnormal chromosome with a high (over 95 percent) reliability, even though these restriction site polymorphisms were not the cause of the disease.

Southern Blot Hybridization. There are several neurogenetic syndromes that are caused by increased or decreased numbers of otherwise normal genes. Charcot-Marie-Tooth 1A and Pelizaeus-Merzbacher disease are most often caused by duplications of the peripheral myelin protein-22 (PMP22) and proteolipid protein genes, respectively (see [Chapter 30](#) and [Chapter 36](#)). Hereditary neuropathy with predisposition to pressure palsies is due to a loss of one copy of the PMP22 gene. One method to detect these changes is to compare the signal intensity of the altered gene region with that of a gene region lying outside the duplicated or deleted portion. The original method used for this procedure relies on the standard Southern blot technique, in which genomic DNA (isolated from peripheral

leukocytes) is digested with an appropriate restriction endonuclease. The DNA is then subjected to agarose gel electrophoresis and transferred to nylon membranes for hybridization to labeled gene probes. For dosage analysis, a gene probe spanning the junction of the normal and dose-altered genomic region is hybridized to the filter. If a restriction enzyme site exists that separates the normal from altered copy number regions, the probe hybridizes to a normal level to a DNA restriction fragment in the normal copy region. In contrast, if the copy number for the gene is increased or decreased, the probe hybridizes greater or lesser intensity, respectively.

Limitations of Testing

The clinician must recognize that the sensitivity of genetic testing varies among clinical conditions and apply

TABLE 25-2 -- METABOLIC DEFECTS THAT PRODUCE EXERCISE-INDUCED MUSCLE SYMPTOMS

Disorders of carbohydrate metabolism
Myophosphorylase deficiency (McArdle's disease; type V glycogenosis)
Phosphofructokinase deficiency (Tarui's disease; type VII glycogenosis)
Phosphoglycerate kinase deficiency (type IX glycogenosis)
Phosphoglycerate mutase deficiency (type X glycogenosis)
Lactate dehydrogenase deficiency
Phosphorylase b kinase deficiency
Disorders of lipid metabolism
Carnitine palmitoyl transferase deficiency
Long-chain acyl-coenzyme A dehydrogenase deficiency
Short-chain 3-hydroxyacyl-coenzyme A dehydrogenase deficiency
Defects of the respiratory chain
Defects of complex I, complex III, and complex IV
Coenzyme Q10 deficiency
Others
Myoadenylate deaminase deficiency
X-linked myopathy with abnormal dystrophin
Idiopathic

Modified from Rifai Z, Griggs RC: Metabolic myopathies. In Samuels MA, Feske S, Mesulam MM, et al (eds): Office Practice of Neurology, New York, Churchill Livingstone, 1996, pp 600-604.

testing methods in the appropriate context. The molecular test for Huntington's disease is very sensitive and specific, but other clinical conditions exist in which adult-onset chorea may be present. As an example, dentatorubropallidoluysian atrophy (see [Chapter 35](#) _ also has an autosomal dominant pattern of inheritance but is caused by triplet repeat expansion of a gene distinct from that causing Huntington's disease. The diagnosis of neurofibromatosis 1 is best established clinically, because the search for gene mutations is currently too laborious to be practical in most cases. Whereas the premature protein truncation test is the most sensitive molecular test for this disease, it detects abnormalities in only about 70 percent of affected individuals.

In disorders in which the gene product, generally a protein, is functionally well-characterized, it is usually more effective to screen for the presence of abnormalities by functional testing. For example, the lysosomal storage diseases are caused by defective enzymes that can be directly assayed. Thus, the most effective screening test is a direct assay of enzyme function or of substrates or breakdown products of the enzyme in question in serum, urine, or skin fibroblasts. Genetic diagnosis of mitochondrial disorders is complicated because the diseases result from mitochondrial DNA mutations that are not reflected in the genomic DNA and the proportion of mutant mitochondria can vary tremendously from tissue to tissue (see [Chapter 31](#) _.

For diseases caused by mutations of the nuclear genome, it is generally sufficient to analyze DNA extracted from peripheral blood leukocytes. Genomic DNA can be isolated from other tissues as well. When PCR analysis is performed, it is sometimes possible to extract sufficient DNA from archived paraffin-embedded or formalin-fixed tissue. For the molecular diagnosis of mitochondrial diseases, however, it is sometimes necessary to test an affected tissue, such as muscle, because the distribution of normal and mutant mitochondria in an individual may be very heterogeneous, such that the blood mitochondria may be normal, whereas the tissue mitochondria are abnormal.

In the setting of genetic testing, in which molecular test results not only provide diagnostic information but also may predict the onset of disease, the clinician must advise patients of the potential implications of obtaining genetic information as it relates to their health and economic and social well-being, as well as that of their relatives. Adverse genetic risk information could potentially affect an individual's employment and insurance status. Confidentiality must be maintained according to the patient's wishes in all situations. Counseling must be included as part of any genetic testing program and should include discussions with geneticists or genetic counselors as well as psychiatrists or psychologists in specific disorders for which predictive testing is possible.

MUSCLE ENZYMES AND BIOPSY

Forearm Exercise Testing

Muscle fibers develop tension and shorten, thereby producing movement. These processes, including contraction and relaxation, are coordinated by the nervous system and are energy-requiring. Skeletal muscle meets its energy demands by converting chemical energy into mechanical energy. One feature unique to skeletal muscle, compared with other tissues, is the energy requirement difference between its resting and fully active states, a value that can approach two to three orders of magnitude.^{1,2} When the metabolic energy demands of active muscle cannot be met by the available energy sources, muscle fatigue and dysfunction occur. In such settings, when abnormalities of muscle biochemistry are responsible for the decreased energy supply, the term *metabolic myopathies* is applied. For diagnostic purposes, these disorders can be divided into two groups: (1) exercise-induced (dynamic) myopathies, in which symptoms such as weakness, cramping, myalgias, and stiffness appear during exercise; and (2) stable, or slowly progressive (static), myopathies (see [Tables 25-2](#) and [25-3](#)).^{1,2} Muscle energy metabolism may be assessed through exercise testing. The results of these studies may

TABLE 25-3 -- METABOLIC DEFECTS THAT PRODUCE STATIC MUSCLE WEAKNESS

Disorders of carbohydrate metabolism
Acid maltase deficiency (type II glycogenosis)
Debrancher enzyme deficiency (type 111 glycogenosis)
Brancher enzyme deficiency (type IV glycogenosis)
Phosphorylase b kinase deficiency
Phosphofructokinase deficiency
Myophosphorylase deficiency
Disorders of lipid metabolism
Muscle carnitine deficiency
Systemic carnitine deficiency
Mitochondrial myopathies

Modified from Rifai Z, Griggs RC. Metabolic myopathies. In Samuels MA, Feske S, Mesulam MM, et al (eds): Office Practice of Neurology. New York, Churchill Livingstone, 1996, pp 600-604.

refine the differential diagnosis and reduce the cost of the microscopic analysis. Additionally, when the microscopic evaluation is unrevealing, provocative exercise testing may confirm the presence of a metabolic defect. Common types of exercise testing include (1) forearm (grip) exercise that primarily provides information about the integrity of glycolytic metabolism; (2) incremental bicycle ergometry that yields information about the integrity of aerobic metabolism; and (3) ³¹P magnetic resonance spectroscopy that provides information about the intracellular metabolites of energy metabolism (i.e., adenosine triphosphate [ATP], inorganic phosphate, and phosphocreatine). Because exercise testing is an important part of the investigation of muscle disease, particularly with disorders of skeletal muscle energy metabolism, it is essential that physicians understand skeletal muscle energy metabolism.

SKELETAL MUSCLE ENERGY METABOLISM

Although muscle contraction is ATP-consuming, the ATP content of a contracting muscle changes little during a sustained contraction. Interestingly, muscle ATP stores are incapable of sustaining a muscle contraction for more than a single second. Phosphocreatine, a high-energy compound with an intramuscular concentration approximately four- to five-fold that of ATP, permits rapid ATP regeneration through the rephosphorylation of adenosine diphosphate (ADP). This reaction is catalyzed by creatine kinase, an enzyme found in large quantities in skeletal muscle tissue. Nevertheless, this anaerobic energy source is depleted in less than a minute, and even when combined, these two sources of readily available energy are incapable of maintaining high-intensity exercise. For this reason, skeletal muscle tissue must rely on other energy sources when sustained exertion is necessary.

In the nonfasting individual, the energy requirements of skeletal muscle are met by the metabolism of either carbohydrate (e.g., glycogen, glucose) or lipid (e.g., free fatty acids). The principal source of carbohydrate for skeletal muscle metabolism is intracellular glycogen, which is formed from blood glucose, via glycogenesis, and stored within the myocyte. When energy is required, glycogen is hydrolyzed to glucose (glycogenolysis) and then to pyruvate (glycolysis). In addition to pyruvate, glycolysis also generates ATP and nicotinamide adenine dinucleotide hydrogen (NADH) (reduced form of nicotinamide adenine dinucleotide [NAD⁺]). Under aerobic conditions, pyruvate is subsequently metabolized to acetyl-CoA. The latter compound enters the Krebs' (tricarboxylic acid) cycle, yielding further molecules of ATP and NADH, as well as flavin adenine dinucleotide hydrogen (FADH₂). The reducing equivalents generated by glycolysis and the Krebs' cycle (i.e., the NADH and FADH₂) enter the electron transport system, a chain of enzymes located on the inner mitochondrial membrane, and are oxidized. The energy released from their oxidation is used to drive the phosphorylation of ADP to ATP. The maximum derivable energy from the aerobic metabolism of one molecule of glucose is 38 molecules of ATP. Conversely, under anaerobic conditions, because pyruvate is converted to lactate and the generated reducing equivalents cannot be metabolized by the electron transport system, only four molecules of ATP are generated from one molecule of glucose. Hence, the metabolism of carbohydrate is much more energy-efficient in the presence of oxygen (i.e., aerobic metabolism) than in its absence (i.e., anaerobic metabolism). The skeletal muscle fatigue (i.e., the inability to maintain high-intensity exertion for more than several minutes) associated with anaerobic glycolysis results from end-product accumulation (ADP, inorganic phosphorus, hydrogen ion), not from a lack of oxygen.^{1,2} Although blood glucose can be used directly, most carbohydrate energy is derived from glycogen. Unlike carbohydrate storage, which is primarily intramuscular, lipid storage is primarily extramuscular. For this reason, the primary source of lipids during skeletal muscle metabolism is plasma free fatty acids; the lipid present within the myocyte contributes to a much lesser extent. Since the rate of free fatty acid mobilization is slow, the contribution of lipid metabolism during initial energy generation is limited. In addition, although carbohydrate can undergo both aerobic and anaerobic metabolism, lipid can only be metabolized aerobically and consequently cannot be utilized during anaerobic conditions.

As expected, the exact ratio of carbohydrate and lipid utilized for muscle energy metabolism, a topic recently summarized in an editorial by Layzer,³ reflects many variables, including the intensity of exertion and its duration, the blood concentration of free fatty acids and oxygen, the amount of blood flow to the muscle, the muscle glycogen concentration, and the muscle's capacity for oxidative metabolism. At rest and during light exercise, skeletal muscle tissue metabolism is aerobic, and consequently it aerobically metabolizes free fatty acids for its energy. As the degree of intensity increases, the supply of lipid-derived energy becomes unable to keep pace with the energy requirement. For this reason, a greater proportion of energy must be contributed by carbohydrate. In general, enough glycogen is available to work intensively for 3 to 4 hours.^{1,2} Should effort continue after the glycogen supply is depleted, the slower rate of lipid metabolism immediately diminishes the magnitude of the ongoing effort. At maximum intensity (e.g., sprinting at full speed), skeletal muscle energy is supplied through anaerobic glycolysis. Initially, the readily available energy substrates are exhausted (i.e., ATP and phosphocreatine), and aerobic glycolysis begins. Although simultaneous changes enhance oxidative metabolism (i.e., increased blood flow to muscle, increased oxygen uptake), they are insufficient to meet the energy demands of maximum exertion. Thus, anaerobic glycolysis occurs and pyruvate is converted to lactate. As lactate accumulates, oxygen debt increases, a term that refers to the additional oxygen required, during recovery, to oxidize the accumulated lactate. Again, this level of exertion can be maintained only for several minutes.^{1,2} Through aerobic exercise training, athletes enhance their muscles' capacity for oxidative (aerobic) metabolism. Thus, during submaximal efforts, the blend of substrate used contains a greater percentage of lipid and, for this reason, less glycogen. As a result, the glycogen supply lasts longer, as does the individual's endurance.

TECHNIQUE

Forearm exercise testing can be performed in a number of ways. Traditionally, the patient was asked to repetitively

squeeze a handheld ergometer while a blood pressure cuff was maintained above systolic pressure. The blood pressure cuff, by inducing ischemia, ensures that

oxidative phosphorylation cannot occur. A simple technique for evaluating lactate production in response to ischemic forearm exercise was described by Munsat in 1970.¹ In that report, rested and fasting individuals squeezed a handheld ergometer, with a workload of 4 to 7 kg-m, at 60 Hz for 1 minute. (Alternative methods are to sustain 1.5-second contractions that are separated by 0.5-second rest periods for 1 full minute² or squeezing a hand dynamometer to 50 percent of maximum grip strength until exhaustion--usually about 10 minutes.³) Although the serum lactate concentrations vary significantly among the studied individuals (the standard deviation approximated 60 percent of the mean), their *relative change* (rather than their absolute change) is fairly constant for a given individual. The serum lactate concentration peaks within 5 minutes (within 3 minutes for 90 percent of the tested individuals) of work cessation at a value that is three- to five-fold greater than the initial resting value. Because ischemic work induces pain, it is fortunate that the best correlation between the degree of serum lactate rise and the total work performed occurs when the exercise period is limited to 1 minute, a period of ischemic exercise that most individuals can tolerate. The relationship of forearm work and lactate production without ischemia was also evaluated and appears to produce comparable results, provided the workload exceeds 6 to 7 kg-m. In other words, the work intensity must be sufficiently strenuous to exceed the individual's aerobic threshold, thereby inducing anaerobic energy metabolism. This technique avoids the use of blood pressure cuff-induced ischemia, which may be hazardous to patients with glycolytic defects (may cause severe muscle necrosis).^{4, 5}

Regardless of the technique used, the anaerobic condition blocks oxidative phosphorylation, thereby ensuring dependence on anaerobic glycolysis. Pre-exercise and postexercise (1, 2, 4, 6, and 10 minutes) venous lactate and ammonia levels are determined from venous blood samples collected from a catheter placed in an antecubital vein proximal to the deep veins of the forearm (e.g., the median vein). A three-way stopcock can be connected--blood samples are obtained from the side port and a slow infusion of normal saline maintains catheter patency. Normally, the lactate value rises three- to five-fold (resting level is mmol/L) within 1 to 2 minutes, whereas the ammonia value rises two- to ten-fold within 2 to 5 minutes of exercise.^{6, 7, 8} In the presence of a metabolic disorder, however, different metabolite patterns may be observed--with a *defect in glycolysis*, ammonia elevation occurs, but lactate elevation is diminished or does not occur. With *myoadenylate deaminase deficiency*, lactate elevation occurs, but elevation of ammonia does not. In the setting of *mitochondrial disorders* lactate elevation is excessive, and with *poor effort*, neither lactate nor ammonia concentrations increase. As expected, with *disorders of lipid metabolism*, the metabolite profile is normal. Although the major source of blood lactate is muscle, the blood lactate concentration rises with anxiety, hyperventilation, muscular activity, and food intake and, therefore, the patient should be relaxed, still, and in a fasting state.⁹

Muscle Biopsy

The decision to proceed with a muscle biopsy is made after a thorough medical and neurological history, examination, laboratory evaluation, and electromyogram study, thereby permitting the formulation of a preliminary diagnosis and, hence, dictating the studies required of the muscle biopsy specimen. The history characterizes the weakness (e.g., its rate of onset, distribution, time course, precipitants [e.g., exercise-induced], associated symptoms, and family pedigree). The clinical examination quantifies the weakness and identifies any associated features (e.g., myotonia). The laboratory assessment (e.g., serum creatine kinase, urine myoglobin) screens for abnormalities of the blood and urine, and electromyography provide information typically not obtainable in other ways, including (1) the identification of a disorder other than a myopathy (e.g., motor neuron disease, neuromuscular junction defect), thereby avoiding an unnecessary muscle biopsy; (2) further characterization of the myopathy (e.g., its distribution, its associated electrical features [e.g., fibrillation potentials]), thereby further defining the diagnostic possibilities; and (3) the identification of the best muscle for biopsy. As expected, the information obtained from the muscle biopsy specimen is related to the underlying disorder, as well as its severity and rate of progression. When the patient is free of muscle weakness, the muscle biopsy is unlikely to show any significant changes. Other important variables influencing the yield of the muscle biopsy include (1) the particular muscle biopsied; (2) the way in which the muscle biopsy specimen is processed; and (3) the particular studies performed on the specimen. Consequently, this subsection includes a discussion of these important variables. Most important, however, it is necessary for the clinician, the person performing the biopsy, the pathologist, and, when indicated, the referring pathology laboratory to carefully plan their approach to the evaluation of the muscle specimen.

MUSCLE SELECTION AND TECHNIQUE

Myopathic processes do not affect all skeletal muscles equally. Therefore, a risk of sampling error among muscle biopsy specimens is always present. For this reason, it is paramount to select the muscle that will most likely yield the desired information. Important clinical and electrodiagnostic data to consider in making this determination include (1) the degree of involvement of the muscle; (2) the rapidity of onset of the disease process; (3) the muscle's history; (4) the pathological familiarity of the muscle; (5) the accessibility of the muscle; and (6) the electromyographic examination findings. A clinically unaffected muscle should be avoided, because it may not be involved pathologically. A severely affected muscle is also avoided, since it may only show endstage features (e.g., atrophy, fat, and fibrosis) rather than the distinguishing features of a specific disorder. Although a moderately affected muscle should be sought in patients with a slowly progressive disorder, a more severely affected muscle may provide the greatest diagnostic yield in individuals with acute disorder. The chosen muscle additionally should neither be involved

with another disease process (e.g., radiculopathy) nor have suffered a recent (i.e., within 1 month) injection or needle electrode examination (i.e., electromyography). The needle electrode examination should generally be performed on only one side of the body (and this should be clearly labeled in the chart) and is used to help in the identification of a muscle meeting sampling criteria so that the homologous muscle in the contralateral extremity may be sampled. In general, the most frequently biopsied upper extremity muscles are the deltoid and biceps brachii, and the most frequently biopsied lower extremity muscles are one of the quadriceps (e.g., vastus lateralis) because the range of normal for these muscles is well-defined. Although the gastrocnemius is frequently cited as a useful muscle, it should be avoided because of its type 1 muscle fiber predominance, its greater susceptibility to random pathological changes, and its pennate nature.¹⁰ The problem with pennate muscles (i.e., muscles in which the tendon insertion extends throughout the muscle) is that inadvertent sampling near the myotendinous junction can occur. This region tends to have more central nucleation, muscle fiber size variability, and split muscle fibers. As expected, the muscle chosen must be easily accessible.

The technique of muscle biopsy is usually not difficult in the hands of an experienced individual. The skin and subcutaneous tissues are anesthetized (e.g., 2 percent Xylocaine [lidocaine]), while carefully avoiding muscle infiltration. A small incision is then placed in the belly region (i.e., away from the myotendinous junction) along the long axis of the muscle and is extended only to the fascia. In most cases, three specimens are collected: (1) an unclamped specimen for histochemistry (the most important piece); (2) a clamped specimen for electron microscopy; and (3) a clamped specimen for histopathology. A fourth specimen can be obtained and frozen in the event further studies are deemed necessary.

The *specimen for histochemistry* should be 2 to 3 cm in length and about as round as a pencil. It should be handled gently by its ends using tweezers and placed in a cool, normal saline-moistened piece of gauze to prevent drying out (soaked gauze may interfere with freezing and produce artifacts). The gauze-wrapped muscle specimen is then placed in a screw-cap vial for later freezing. The specimen should be rapidly transported to the pathology laboratory, otherwise it may lose its enzymatic activity. Many techniques exist for the preparation of the frozen specimen. Typically, it is gently immersed in a Pyrex beaker containing 2 inches of liquid nitrogen-cooled isopentane (minus 140° to 155° C), frozen for roughly 30 seconds, and then removed and immediately placed in a previously cooled specimen container (e.g., another screw-cap vial). When the specimen is sent to an outside reference laboratory, the specimen container should be placed in an insulated shipping container filled with dry ice.

The *specimen for electron microscopy* can be slightly smaller and should be gently raised (e.g., with Metzenbaum scissors) just high enough to permit the placement of a muscle clamp. The clamp is then locked and the muscle specimen cut just *outside* the clamped sites. Clamping helps avoid contraction artifact. A less cumbersome technique involves the suturing of the muscle tissue specimen (e.g., with 3-0 silk) to a piece of tongue depressor before excising it (i.e., it is sutured in situ). Once removed, the muscle specimen is then placed in a 4 percent buffered glutaraldehyde fixative (or Karnovsky's fixative).

The *specimen for histopathology* is obtained similar to that for electron microscopy, with the exception that it is fixed in formalin. The fixed specimens should be shipped separately from the frozen specimen. It is important to include the patient's name, the sampled muscle, the procurement time, and a brief note detailing the clinical presentation and workup findings to date, as well as a list of pending studies. Importantly, when specialized studies are planned (e.g., mitochondrial DNA studies), larger tissue specimens may be necessary. For this reason, the reference laboratory should be contacted before performing the muscle biopsy so that the required amount of tissue is procured.

Individual subsection authors: Genetic studies, James Garbern; Muscle enzymes and biopsy, Mark A. Ferrante; Nerve tissue, William Kupsky; Brain and meningeal tissue, William Kupsky.

The indications for an open biopsy, as opposed to a needle biopsy, are unsettled. There are two major advantages of open biopsies--a larger specimen can be obtained and the specimen can be fixed at its in situ length, thereby preventing contraction artifact. The two major advantages of a needle biopsy are the limited scarring and the ability to sample multiple sites (in either the same or different muscles) in a single session. Disadvantages of this technique include the smaller specimen size and greater orientation difficulty. In general, the experience of the person performing the biopsy and the expertise of the laboratory personnel dictate

which technique is utilized.

DIAGNOSTIC STAINING METHODS

Overview. A brief overview of pertinent neuromuscular anatomy and physiology, including muscle fiber types, is a necessary preface to a discussion of the various stains and reactions. Skeletal muscles are composed of muscle fibers and connective tissue elements termed endomysium, perimysium, and epimysium. Epimysium surrounds the muscle belly and also lies between fascicles. Fascicles are surrounded by perimysium and are composed of groups of muscle fibers that are individually surrounded by endomysium. Small arteries, arterioles, veins, and nerve twigs are contained within the perimysium. Unlike the epimysium, which may contain adipose tissue, the perimysium of adults is usually devoid of adipocytes. Muscle fibers are cylindrical, polygonal (in adult cross sections), multinucleated syncytia derived from myoblast fusion. The muscle cytoplasm is termed sarcoplasm, and the muscle membrane is termed sarcolemma. Muscle nuclei (roughly five per fiber in cross section) are located just below the sarcolemma (up to 3 percent may be more centrally placed). Satellite cells are located subjacent to the sarcolemma and are covered by the basement membrane, which surrounds the entire muscle fiber. These function as a reserve cell population (discussed later). Each muscle fiber contains hundreds of myofibrils that are composed of repeating subunits, termed sarcomeres, containing the contractile elements (e.g., actin, myosin). Tubular extensions of the sarcolemma, termed T-tubules, extend transversely into the muscle fiber between the myofibrils. These structures permit the passage of electrical activity into the depths of the muscle fiber, thereby ensuring a maximal contraction. A second intermyofibrillar system of tubules is the sarcoplasmic reticulum, which is

oriented parallel to the myofibrils (i.e., perpendicular to the T-tubules). The ends of these tubules are dilated into cisternae. The T-tubules are surrounded on both sides by the terminal cisternae of the sarcoplasmic reticulum. The nearness of these structures permits the electrical activity traversing the T-tubules to induce calcium release from the sarcoplasmic reticulum, thereby initiating muscle contraction. These tubular structures, as well as the aqueous sarcoplasm and mitochondria, are collectively termed the intermyofibrillar network.

There are two major types of muscle fibers, type 1 and type 2, each with different histochemical and physiological properties that give them specificity for certain activities. Type 1 fibers contain more oxidative enzymes, mitochondria, capillaries, and myoglobin and are hence best suited for aerobic metabolism and nonfatiguing activities (e.g., standing still). Type 2 fibers contain fewer mitochondria, more abundant glycogen and glycolytic enzymes, and are best suited for anaerobic metabolism and, consequently, those activities requiring maximal energy outputs (e.g., bench-pressing). Type 2 fibers are further subdivided into types 2A, 2B, and 2C. The type 2A fibers are more oxidative in nature than the type 2B fibers; type 2C fibers are present in fetal muscle, as well as regenerating muscle. Individual human skeletal muscles are composed of both muscle fiber types. The functional unit of movement is the motor unit, which consists of all the muscle fibers innervated by the same lower motor neuron. Its size, like that of the muscle fiber (discussed later), is dependent on the particular muscle. Although different types of muscle fibers compose an individual human skeletal muscle, the muscle fibers of a given motor unit are all identical in type (since this determination is made by the innervating lower motor neuron). The muscle fibers of a given motor unit normally are randomly distributed among the muscle fibers of other motor units. Although the relative abundance of fiber types among different muscles varies, the proportion of muscle fiber types observed in adults is as follows: type 1 (30 to 40 percent), type 2A (20 to 30 percent), and type 2B (40 to 50 percent); thus, there are roughly twice as many type 2 fibers as type 1 fibers, whereas in children, the ratio of type 1 fibers to type 2 fibers is nearly equal. Type 1 fiber predominance is present when more than 55 percent of the fibers are type 1, whereas type 2 fiber predominance occurs when more than 80 percent of the muscle fibers are type 2. The mean diameter of powerful muscles is 85 to 90 microns, as opposed to weaker, more distal muscles that have a mean diameter of 20 microns. The muscle fiber type also influences diameter. In general, the diameter of type 1 fibers is less than or equal to that of type 2 fibers. Regarding gender, male type 1 fibers are equal to those of females, whereas male type 2 fibers are larger than those of females, a reflection of hormonal influences.

Frozen Specimen. This, the most important specimen, is utilized for a variety of histochemical stains and reactions, some of which are listed in Table 25-4. The hematoxylin and eosin stain is useful for characterizing the general morphology (e.g., myocytes, nuclei, connective tissue, blood vessels, nerves, etc.) of the skeletal muscle specimen. The hematoxylin component identifies cell nuclei, and hence nuclear position, and muscle cross-striations; the eosin portion counterstains the cytoplasm reddish pink.

TABLE 25-5 -- SELECTED STAINS AND REACTIONS AND THEIR USEFULNESS IN EVALUATING SKELETAL MUSCLE

STAINS	
Hematoxylin and eosin	Hematoxylin: nuclei, cross-striations (purple) Eosin: cytoplasm (red), connective tissue (darker red)
Modified Gomori trichrome	Nuclei, mitochondria, T-tubules sarcoplasmic reticulum (red); myocytes (blue-green)
Periodic acid-Schiff	Glycogen (purple; type 1 >2; glycogen storage disorders)
Oil red O	Lipid (orange; type 1 >2; lipid storage disorders)
REACTIONS	
NADH-TR	T-tubules, sarcoplasmic reticulum, mitochondria Type 1 (dark); type 2A (intermediate); type 2B (light)
Succinate dehydrogenase	Krebs' cycle enzyme; selectively stains for mitochondria
Cytochrome-c oxidase	Respiratory chain enzyme (orange-brown; type 1 >2)
ATPase (pH 4.3)	Type 1 (dark); type 2 (light)
ATPase (pH 4.6)	Type 1 (dark); type 2A (light); type 2B (intermediate)
ATPase (pH 9.4)	Type 1 (light); type 2 (dark)
Acid phosphatase	Degeneration (stains red; background fir green)
Alkaline phosphatase	Regeneration (stains black; background yellow)
Nonspecific esterase	Acetylcholinesterase (yellow-red; type 1 >2)

Connective tissue appears darker with eosin staining. The modified Gomori trichrome stain stains nuclei and mitochondria red and myocytes blue-green. This stain is useful in identifying ragged-red fibers. The periodic acid-Schiff (PAS) stain causes glycogen to appear purple. This stain readily identifies glycogen storage disorders, as well as capillaries. Oil red O stains lipid orange. Its utility, like that of the Sudan black stain, is in the identification of lipid storage disorders. Nicotinamide adenine dinucleotide dehydrogenase-tetrazolium reductase (NADH-TR) is an oxidative enzyme reaction that, like other reactions of this type, reflects the concentration of mitochondria within myocytes. This reaction colors myocytes purple-gray. By highlighting the sarcoplasmic reticulum, T-tubules, and mitochondria (i.e., the intermyofibrillar network), this reaction causes the sarcoplasm to take on a granular appearance. Although oxidative enzyme reactions differentiate the different muscle fiber types (i.e., type 1 > 2A > 2B), these reactions should not be used for fiber typing since atrophied type 2 fibers appear darker (i.e., appear like type 1 fibers). Succinate dehydrogenase, a Krebs' cycle enzyme, selectively stains mitochondria, as does cytochrome-c oxidase, a respiratory chain enzyme. Thus, unlike NADH-TR, the tubular elements are not highlighted. These two reactions can be used to determine whether intermyofibrillar aggregates are mitochondrial or tubular elements. The myofibrillar ATPase reaction is the most accurate method of muscle fiber typing. The color characteristics are determined by the preincubation pH. In short, acidic

pHs (e.g., 4.3, 4.6) cause type 1 fibers to appear darker than type 2 fibers, whereas alkaline pHs (e.g., 9.4) cause the type 2 fibers to appear darker. When preincubated at pH 4.3, the type 2A and 2B fibers are lighter than the type 2C fibers, which are intermediate in intensity; at pH 4.6, the type 2A fibers are lighter than the type 2B and 2C fibers, which are intermediate in intensity. Thus, preincubation at pH 4.3 permits the 2C fibers to manifest. Acid phosphatase, a lysosomal enzyme, facilitates the identification of degeneration (since necrotic fibers have increased lysosome content), inflammatory cells, and lysosomal storage disorders (e.g., acid maltase deficiency). Acid phosphatase is stained red, whereas the background is green. The alkaline phosphatase reaction stains regenerating fibers black, as well as normal capillary basement membranes; the background is yellow. Nonspecific esterase highlights endplates, lysosomes, and macrophages. It also identifies recently (i.e., within 6 months) denervated muscle fibers. The denervation-induced atrophy causes these fibers to appear smaller and darker. Sulfonated

alcian blue stains amyloid "sea foam" green; it stains mast cells red. The alkaline Congo red stain causes amyloid to appear red, and, when viewed under polarized light, an apple green birefringence is observed.

These stains and reactions, on transverse section, permit the shape, diameter, and intermyofibrillar pattern of the myocyte, as well as the arrangement and proportion of muscle fiber types, to be determined. Adult muscle fibers appear polygonal and their cross sectional diameters vary, depending on the specific skeletal muscle (discussed earlier). Within a given section, they are somewhat uniform. The intermyofibrillar pattern is best demonstrated with the histochemical reactions for oxidative enzymes and should appear uniform. Two examples of the histopathological features that disrupt the intermyofibrillar network include target fibers and central cores. Since the muscle fiber types of different motor units are interspersed, normal muscle shows a checkerboard pattern of light and dark fibers. This same reaction permits the recognition of fiber type disproportion and those disorders confined predominantly to one muscle fiber type (e.g., atrophy, cytoarchitectural abnormalities). When atrophy is identified, it should be further characterized as to muscle fiber type involved. When atrophy is due to a chronic denervating disease, the checkerboard pattern of type 1 and type 2 fibers is altered by collateral sprout-related reinnervation. Thus, the adjacent atrophied myocytes are of the same histochemical fiber type. Conversely, when atrophy is due to disuse, the checkerboard arrangement of muscle fiber types is maintained because collateral sprouting does not occur. Certain cytoarchitectural abnormalities are more pronounced in one muscle fiber type ([Table 25-5](#)).

Target fibers are a cardinal feature of neurogenic disorders and are composed of three "rings": (1) a central light-staining ring; (2) an intermediate dark-staining ring; and (3) a peripheral normal-staining ring. They are most predominant among type 1 muscle fibers. With central core disease, the NADH-TR reaction produces central unreactive zones, termed central cores, among affected myocytes. Thus, these structures are composed of two rings: a central ring of absent staining surrounded by a normally staining periphery. Again, type 1 fibers are mainly affected. Rod

TABLE 25-5 -- PREFERENTIAL FIBER TYPE INVOLVEMENT

PREFERENTIAL ATROPHY

Type 1 fibers: Myotonic dystrophy (prominent), nemaline myopathy, centronuclear myopathy, congenital fiber type disproportion

Type 2 (especially 2B) fibers: Disuse, corticosteroid excess (exogenous, endogenous)*

CYTOARCHITECTURAL ABNORMALITIES

Type 1 fibers: Target fibers, central cores (central core disease), rod bodies (nemaline myopathy), motichondrial abnormalities

Type 2 fibers: Tubular aggregates

*Type fiber atrophy, especially if limited to type 2B fibers, is a nonspecific finding most frequently indicating disuse.

bodies (nemaline myopathy), which originate from Z disc material, appear reddish purple in the modified Gomori trichrome stain. Because a small number of muscle fibers in muscular dystrophy and polymyositis have been noted to contain these structures, a diagnosis of nemaline myopathy requires the presence of numerous rod bodies in many muscle fibers. As previously noted, the modified Gomori trichrome stain is also useful in the identification of mitochondria and the tubular system of muscle. This stain readily identifies subsarcolemmal collections of mitochondria, termed ragged-red fibers, as well as sarcoplasmic reticulum-derived collections, termed tubular aggregates. Both of these abnormalities stain red. Because tubular aggregates are also highlighted by the NADH-TR reaction, but not by the succinate dehydrogenase reaction, they are easily differentiated from mitochondrial aggregates. Although these structures are frequently seen with hyperkalemic periodic paralysis, they are not diagnostically specific for this condition. Rimmed vacuoles have blue margins with hematoxylin and eosin and red margins with the modified Gomori trichrome stain. They are seen in association with inclusion body myopathy, oculopharyngeal muscular dystrophy, distal myopathy, and denervated muscle.

Regarding the two other specimens, the glutaraldehyde-fixed specimen is embedded in plastic for electron microscopy (discussed later), whereas the formalin-fixed specimen is embedded in paraffin for light microscopy. Paraffin sections, which are routinely stained with hematoxylin and eosin (viewed in polarized light) and trichrome (viewed in bright field optics), can serve several purposes. Longitudinally oriented sections permit the identification of cross-striation loss, inflammatory infiltrates, and blood vessel wall changes, and can also serve as backup material.

Specialized Studies. Immunocytochemical techniques utilize commercially prepared antibodies to identify absent or abnormal proteins (e.g., dystrophin, laminin, complement cascade components) and to characterize cell types (e.g., lymphocyte subclasses), among other functions. For example, antibodies against dystrophin can confirm the diagnosis of Duchenne muscular dystrophy when blood tests are uninformative; antibodies against cell markers can demonstrate immune deposits distinctive of dermatomyositis; and antibodies against the membrane attack complex can identify cells targeted for destruction by the immune system. Enzyme histochemistry permits the biochemical analysis of muscle homogenates for specific enzymes (e.g.,

phosphofructokinase) and electron microscopy is available when ultrastructural examination of the tissue specimen (e.g., diagnosis of congenital myopathies, inclusion body myopathy, mitochondrial inclusions, tubular aggregates, and others) is required.

Moreover, some histopathological changes are pathognomonic of a particular disorder. In general, the more specialized the study, the more likely its results will have pathognomonic significance (e.g., immunocytochemical studies [dystrophin], electron microscopy [inclusion body myopathy, congenital myopathies with pathognomonic ultrastructural features], and enzyme histochemistry studies for specific enzymes). In addition, certain morphological features, such as atrophy, are indicative of an underlying muscle disorder. For example, perifascicular atrophy, in which the muscle fibers near the edges of the fascicle are atrophied, is the hallmark of dermatomyositis, whereas panfascicular atrophy is indicative of Werdnig-Hoffmann disease.

DIFFERENTIATING MYOPATHIC AND NEUROGENIC CHANGES

The histopathological features observed in skeletal muscle biopsies can be subdivided into two pathological processes--those due to interruption of innervation (i.e., neuropathic changes) and those due to dysfunction of the muscle fiber itself (i.e., myopathic changes). Because nerve and muscle pathophysiologies dictate the observed changes, a brief overview of this topic initiates this subsection. As previously discussed, the functional unit of movement is the motor unit. This structure consists of a single lower motor neuron, its peripherally directed axon, and all of the muscle fibers it innervates. With lower motor neuron and motor axon disorders, because the affected axons undergo wallerian degeneration, the muscle fibers of an entire motor unit are denervated. Denervated muscle fibers undergo several changes, including downregulation of contractile element synthesis and contractile element resorption, both of which permit their survival, albeit in an atrophied state. If these muscle fibers are not reinnervated within approximately 20 months, they will be replaced by connective tissue. With incomplete nerve lesions, the uninvolved motor axons can sprout collaterals to the denervated muscle fibers, thereby "adopting" them. This process increases the number of muscle fibers innervated by the adopting lower motor neuron. With myopathic disorders, random muscle fiber loss occurs, rather than loss of whole motor unit territories. However, collateral sprouting may still occur with a myopathy. When a portion of a muscle fiber is degenerated (i.e., segmental necrosis), the muscle fiber functions as two separate fibers, the portion with the motor endplate (i.e., the innervated fiber) and the portion without it (i.e., the denervated fiber). Because the regenerative capacity of muscle is considerable, the denervated portion can be adopted by collateral sprouting. Also, precursor cells (satellite cells) proliferate and fuse with each other to regenerate the destroyed portion of the muscle. Muscle fibers that are not reinnervated undergo degeneration, a process associated with extensive collagen deposition and fatty infiltration.

Histological Features Associated with Neuropathic Processes. Histological features associated with neuropathic processes include angular atrophic fibers, group atrophy, fiber type grouping, target fibers, nuclear bags, and the presence of minimal interstitial fibrosis. Of these features, the most typical attribute is atrophy, a process resulting in the appearance of small angulated (in cross section) muscle fibers, not selective for fiber types, scattered throughout the specimen. The atrophy also causes the intensity of staining to increase; thus, the denervated fibers appear darker (e.g., nonspecific esterase). Normally, the intermixing of muscle fiber types produces a random checkerboard pattern when skeletal muscle tissue is stained using fiber type-specific techniques. Because collateral sprouting increases the number of muscle fibers innervated by the adopting lower motor neurons and, as previously discussed, converts them to its own histochemical type, fiber type grouping occurs. For this reason the normal checkerboard staining pattern of muscle fibers diminishes. As denervation continues, assuming reinnervation keeps pace, larger and larger groups of contiguous fibers of the same histochemical type are observed (the sine qua non of reinnervation). Atrophy of these groups produces grouped atrophy, the hallmark of chronic denervation. The extreme version of grouped atrophy is panfascicular atrophy, a feature indicative of Werdnig-Hoffmann disease. Fiber type grouping must be distinguished from fiber type predominance (discussed earlier).

Histological Features Associated with Myopathic Processes. Primary disorders of muscle may affect solely the sarcolemma, a single region (segment) of the muscle fiber, or the entire muscle fiber. Thus, the histological features observed vary with the particular myopathic process. Features considered to be indicative of a

myopathic process include rounded fibers, central nucleation, muscle fiber size variability, fiber splitting, segmental necrosis, muscle fiber necrosis (degeneration), cellular inflammation, myophagocytosis, regeneration (i.e., basophilic fibers), an increase in connective tissue elements, and structural abnormalities (e.g., vacuoles [glycogen, lipid], ragged-red fibers [mitochondrial myopathies], granulomas [sarcoid], and microorganisms [toxoplasmosis, trichinosis], as well as those structural changes associated with various congenital myopathies [e.g., rod bodies, central cores]). Centrally located nuclei may be observed in up to 3 percent of normal muscle tissue specimens, but when present in a higher percentage, this indicates an underlying myopathy. This finding is especially prominent in the muscle fibers of patients with myotonic dystrophy (see [Chapter 36](#)). In fact, when internal nuclei appear in most of the muscle fibers of the sample, this diagnosis is strongly implicated. However, when a *single* central or paracentral nucleus appears in essentially every myocyte, the diagnosis of centronuclear myopathy is indicated. The combination of atrophy and hypertrophy contributes to the wide variability of muscle fiber size. Because muscle fiber splitting normally occurs near myotendinous junctions, muscle biopsies from this region may appear myopathic and, consequently, sampling in this region is discouraged. When viewed in cross section, connective tissue septae, often with adjacent nuclei, are seen traversing the affected (i.e., split) muscle fibers. When muscle fiber necrosis destroys only a portion of the myocyte, the term segmental necrosis is applied. In this situation, proliferating satellite cells may regenerate the de

stroyed segment, thereby reinnervating the portion lacking a motor endplate. Features of regeneration include basophilic sarcoplasm (due to the rich ribonucleic acid content) and large nuclei with prominent nucleoli. However, when reinnervation occurs by collateral sprouting, small foci of fiber type grouping may be observed. Hence, small patches of fiber type grouping should not be considered synonymous with a neuropathic process. Inflammatory cell collections may have a perivascular distribution (e.g., collagen vascular disorder, dermatomyositis) or be most pronounced intracellularly (e.g., facioscapulohumeral dystrophy). With dystrophic myopathies, the thin connective tissue layers separating individual muscle fibers thicken and the muscle fibers may undergo considerable fibrosis. Regarding disease tempo, muscle fiber necrosis, basophilia, and myophagocytosis are features typical of an active myopathic process, whereas muscle fiber splitting is more characteristic of a chronic myopathy.

NERVE TISSUE

Biopsy of the peripheral nerve has somewhat limited use. It is generally performed in suspected neuromuscular diseases in order to aid in the distinction between segmental demyelination and axonal degeneration, particularly when the clinical evaluation, laboratory studies, and electrophysiological examinations are nondiagnostic or contradictory. Nerve biopsy may also be useful in the diagnosis of a number of specific disorders with characteristic findings that may involve a peripheral nerve such as amyloidosis, vasculitis, sarcoidosis, and some neoplasms.^[12] Diagnostic nerve biopsy is generally restricted to a relatively expendable sensory nerve such as the sural, although portions of peripheral motor nerve twigs may be available for examination as part of muscle biopsy. Because of the limited amount of nervous system tissue available for examination and the relatively limited repertoire of pathological findings, peripheral nerve biopsy has a high chance of being noninformative unless the procedure is performed to answer a specific question in the context of the other clinical and electrophysiological findings.

Nerve Selection and Techniques

Biopsy of peripheral nerve is usually completed either as a full-thickness nerve biopsy (i.e., a complete transection of the nerve to remove a segment), or as a fascicular biopsy (i.e., a longitudinal dissection of the nerve to remove segments of only one or several fascicles), sparing at least a portion of the nerve. Full-thickness nerve biopsy is considered technically easier to perform and is preferable when the pathological evaluation should include both nerve fibers and surrounding connective tissue and vascular structures. Fascicular nerve biopsy usually produces a smaller deficit and is favored when larger nerves are biopsied. The choice of peripheral nerve biopsy site is limited by the potential deficits arising from nerve transection. The most common sites are the sural nerve or the superficial peroneal nerve, both subcutaneous sensory nerves in the lower extremity. In occasional cases, the superficial radial nerve in the upper extremity or the greater auricular nerve is also sampled. As noted earlier, concomitant biopsy of skeletal muscle to include small intramuscular nerve twigs may supplement the examination of the peripheral nervous system. Peripheral nerve biopsy may also be combined with skin biopsy, removing an ellipse of overlying skin, when morphological or tissue culture examination of skin is desired for diagnosis of metabolic or degenerative disease. The sample amount is varied and should be judged, on the one hand, by the amount of tissue needed for the proposed studies and, on the other hand, by the fact that deficits arising from transection of the nerve during biopsy will not necessarily be increased by removing the extra centimeter or two that transforms a nondiagnostic biopsy into a useful diagnostic tool. For most purposes, a 2- to 3-cm segment of full-thickness nerve or fascicles is adequate to provide tissue for standard light and electron microscopic examination, including preparation of teased nerve fibers and frozen section.

Testing Methods

The usual morphological techniques for examination of peripheral nerve include standard light microscopy and electron microscopy, supplemented by morphometric studies, examination of teased nerve fibers, and examination of frozen sections when special studies such as immunohistochemistry, are needed ([Table 25-6](#)).^[13] For light and electron microscopy and teased nerve studies, specimens are usually fixed in glutaraldehyde solution. Cross sections are standard and useful for morphometric studies. Longitudinal sections are also useful for demonstrating some pathological findings, including focal processes such as vasculitis that may be irregularly distributed along the length of the nerve and missed in a given cross section. For light microscopic examination, resin-embedded sections stained with dyes such as toluidine blue give good morphological resolution. The same tissues can be subsequently processed for electron microscopy. Formalin-fixed or glutaraldehyde-fixed paraffin-embedded tissues and frozen sections give less resolution but generally permit examination of larger expanses of tissue and may be useful for some special stains, including some immunohistochemical procedures. Teased

TABLE 25-6 -- MORPHOLOGICAL EXAMINATION OF PERIPHERAL NERVE

Technique	Fixation	Use
Routine light microscopy	Formalin, paraffin Glutaraldehyde, paraffin, or resin	Survey (vasculitis, amyloidosis) Survey
Frozen specimen light microscopy	None	Special stains (immunohistochemistry metachromasia)
Teased nerve examination	Glutaraldehyde, osmium	Myelin internodes
Electron microscopy	Glutaraldehyde, osmium, resin	Fine structure

nerve fiber preparations, involving the dissection of single nerve fibers from fascicles of fixed nerve, are used for examination of sequential internodes of myelin along the fiber and are essential for proper assessment of various conditions involving axonal degeneration, regeneration, segmental demyelination, and remyelination. Morphometric procedures allow for the scoring of abnormalities.

BRAIN AND MENINGEAL TISSUE

In the earlier part of this century, diagnostic brain biopsy was often considered a technique of last resort. The development of improved imaging techniques such as computerized tomography and magnetic resonance imaging now permits a high degree of definition of lesions, including both anatomical localization and pathological characteristics. Concomitant developments in neurosurgical techniques, including stereotactic or computer-guided neurosurgery, microsurgical techniques, and intraoperative neurosurgery such as electrocorticography, now permit access to brain tissue with relatively little morbidity, even in vulnerable areas such as motor cortex, the diencephalon, and the brain stem.^{[14], [15], [16]}

Diagnostic biopsy of a brain lesion, possibly followed by resection, is now essential in the diagnosis and management of most primary brain tumors and often plays a role in the management of metastatic disease as well. Diagnostic brain biopsy may also play a role in the management of other mass lesions of a non-neoplastic nature, such as distinguishing between reactive and neoplastic mass lesions. Diagnostic brain biopsy currently also has a more limited use in certain forms of infectious, degenerative, or metabolic diseases that affect the brain. In some of these disease categories, the need to sample brain tissue has been lessened because of the development of improved imaging studies and other ancillary diagnostic techniques. Recent rapid developments in genetics and molecular diagnosis may further supplant the need to obtain central nervous tissues in some circumstances but may also create as yet unforeseen needs for brain tissue. In addition, brain tissue resection is part of the management of some forms of chronic intractable epilepsy.

Despite the improvements in neurosurgical and other clinical practice, removal of nonregenerating brain tissue is still accompanied by risk of permanent neurological deficit. Additional risks of intraoperative complications such as hemorrhage, cerebral infarction, or infection, and of postoperative complications such as scarring with formation of an epileptic focus must also be considered. The decision to remove brain tissue must be balanced between the attendant risks and the utility of a tissue diagnosis.^[17]

Tissue Selection and Techniques

Diagnostic brain biopsy is usually performed as stereotactic biopsy or open craniotomy.^[18] Stereotactic brain biopsy, using computerized tomography or magnetic resonance imaging guidance, is usually completed by the aspiration of tissue through a needle inserted into the area of the lesion. Although this technique is particularly useful in cases in which the lesion is small, deep-seated, or located in a sensitive area such as the motor cortex or deep nuclei, the amount of tissue removed is small and may hinder diagnosis. The procurement of multiple biopsies along the needle trajectory, however, may provide a more complete picture of the pathological process. For accessible lesions, open craniotomy permits the intraoperative assessment of pathological processes by direct observation and may be performed when biopsy and resection are contemplated. This procedure may also be considered when maintenance of the anatomic relationship of the biopsy specimen is desired. Stereotactic localization techniques can also be applied to open craniotomy procedures and are sometimes useful in planning and monitoring resections.

The choice of biopsy site depends on the suspected diagnosis.^[18] In the setting of a structural or mass lesion (brain tumor), whether neoplastic or non-neoplastic, tissue from the area of imaging abnormality is the obvious choice, although the pathological lesion and the imaged lesion may not be equivalent. Infiltrating gliomas, for example, may extend well beyond the area of contrast enhancement seen on imaging studies, and occasional lesions that appear discrete on imaging studies such as MRI may be remarkably ill-defined and elusive in the operating room or in the pathology laboratory. In the case of a mass lesion, the amount and pattern of sampling should also be guided by the suspected diagnosis. The amount of tissue sufficient for diagnosis cannot be predicted and often depends on the nature of the disease process. A few cells from a cerebrospinal fluid or needle aspiration of tissue may be sufficient in the diagnosis of metastatic carcinoma or lymphoma, whereas even postmortem examination of the entire brain may be inadequate to establish a precise diagnosis in some degenerative or metabolic diseases.^{[17], [19]} Direct communication between the clinician and the pathologist prior to the surgical procedure is the best method of ensuring that tissue sampling is appropriate.

Intraoperative evaluation of tissue samples by frozen section or other preparation has several roles. Frozen sections may provide a specific diagnosis in some cases, but in many situations a definitive diagnosis can be made only after evaluation of all tissue specimens and with adjunctive studies. Frozen sections are sometimes used to guide resection of a mass lesion. In many cases, particularly in primary biopsies of undefined lesions, frozen section is most useful in the assessment of whether the tissue sample appears adequate to answer the clinical question. It also is useful in the selection and processing of the tissue for other pertinent studies, even if a precise diagnosis cannot be rendered intraoperatively.

In the case of large tumors, abscesses, or other reactive lesions, the abnormal brain region may be heterogeneous. Sampling of central areas of complete tissue necrosis in tumors or abscesses may not yield diagnostic tissue. The relationship of the lesioned tissue to the adjacent brain is often important in assessing the nature of the pathological process, e.g., demonstrating the infiltrating border in gliomas, the presence of residual or recurrent tumor in radiation necrosis, or the boundary between demyelinated or necrotic brain and normal brain. Microorganisms are often present at the expanding edge of infectious lesions but

TABLE 25-7 -- DIAGNOSTIC BRAIN BIOPSIES: COMMON TISSUE TECHNIQUES

Evaluation	Biopsy Technique	Fixative	Staining
Cytological	Imprint/touch Smear/squash	Alcohol	Rapid hematoxylin and eosin, Diff-Quik Papanicolaou
Routine histological	Frozen section Paraffin section	Alcohol Formalin, B5	Rapid hematoxylin and eosin, metachrome B, special staining

Electron microscopy	Thick section Thin section	Glutaraldehyde/OsO ₄	Toluidine blue Lead citrate/uranyl acetate

absent in the necrotic center. Stereotactic biopsy offers the advantage of obtaining multiple samples along a single needle trajectory and is useful in evaluating heterogeneous lesions such as gliomas, in which different areas of the tumor may show different degrees of malignancy, as well as in reactive lesions.

Intraoperative monitoring of brain function by techniques such as electrocorticography is useful in guiding sampling or resections in sensitive areas such as the motor strip. These techniques are also essential in mapping epileptic foci and can be used in conjunction with conventional imaging studies and special studies such as positron emission tomography.

In the absence of a mass lesion or defined area on imaging studies, noneloquent areas of the cerebrum are generally selected. The type of tissue sampled (gray or white brain matter, leptomeninges, etc.) should also be guided by the suspected diagnosis. The most useful specimen should be large enough to allow for the proper orientation by the pathologist and to be divided into pieces adequate for special studies (see later). For degenerative or metabolic diseases, infectious diseases (viral encephalitis), and for diffuse disorders (cerebral vasculitides), a wedge of brain tissue consisting of cerebral cortex, overlying leptomeninges, and underlying white matter provides the most useful tissue sample and should be large enough to provide material for ancillary studies (biochemical analysis, electron microscopy, etc.).

Testing Methods

Morphological techniques include cytological studies (the evaluation of individual cells in fluids) and histological studies (the evaluation of cells in their tissue context). The latter involve light microscopy with routine and special stains, electron microscopy, histochemistry, and immunohistochemistry. Typical methods of fixation and staining for each technique are summarized in [Table 25-7](#). Ancillary studies that supplement the armamentarium of morphological techniques include microbiology (e.g., bacterial, viral, fungal cultures), cytogenetics (e.g., karyotype analysis), molecular genetics (e.g., polymerized chain reaction), and biochemical analyses.

The choice of morphological and ancillary techniques depends on the nature of the lesion and the available material. Although most pathological diagnoses are made

on sections of formalin-fixed paraffin-embedded tissues stained with hematoxylin and eosin or a comparable general tissue stain, some diagnoses require other stains to be used on the paraffin-embedded tissues or even other methods of tissue handling and fixation (freezing, glutaraldehyde fixation and plastic embedding for electron microscopy, submission of unfixed tissues in special handling media for cytogenetic or microbiologic studies, etc.). Before fixation, tissue should be divided and processed appropriately for these studies. Consideration of the expected diagnosis, obtained from the preoperative workup or from intraoperative frozen section, is essential in the planning and optimal handling of the diagnostic brain biopsy. Familiarity with a particular institution's manual of laboratory procedures that list recommendations for handling tissues for specific test and communication with the neurosurgeon and pathologist in advance of the biopsy procedure are necessary to avoid inappropriate handling of valuable specimens.

Specific Indications

Categories of CNS disease amenable to diagnosis by brain biopsy or mimicking types of disease normally presenting as neurosurgical conditions are summarized in [Table 25-8](#). This disorder can be grouped into conditions that present with mass lesions, focal or multifocal nonmass

TABLE 25-8 -- BRAIN AND MENINGEAL BIOPSY DIAGNOSES

Category	Examples
Neoplasms	Gliomas, metastatic tumors, CNS lymphoma
Infections (inflammatory)	HIV encephalitis, opportunistic infections (toxoplasma, cytomegalovirus, herpes simplex, cryptococcus), bacterial abscess, cysticereosis, tuberculosis, sarcoidosis
Degenerative diseases	Creutzfeldt-Jakob disease, Alzheimer's disease, Picks disease
Vascular diseases	Vasculitis, amyloid angiopathy, vascular malformations
Epilepsy	Mesial temporal sclerosis, dysplasias and malformations, Rasmussen's encephalitis
Metabolic diseases	LeukodystrophiesX storage diseases, mitochondrial diseases

CNS, central nervous system; HIV, human immunodeficiency virus.

lesion abnormalities, and diffuse abnormalities. Mass lesions include most neoplasms and neoplastic or non-neoplastic cysts, some forms of infection (abscesses, cerebritis, tuberculomas, some encephalitides), specific vascular disorders (hemorrhages, early infarcts), malformations or developmental lesions (hamartomas, some migrational abnormalities), and a variety of miscellaneous conditions (sarcoidosis, acute multiple sclerosis, and adrenoleukodystrophy). Conditions that produce imaging study abnormalities that are not necessarily mass lesions include (1) forms of neoplasia (infiltrating gliomas, gliomatosis, lymphomas); (2) cerebrovascular disorders (vasculitides, vasculopathies); (3) infections (viral encephalitis, progressive multifocal leukoencephalopathy, CNS syphilis); (4) degenerative diseases (Creutzfeldt-Jakob disease, Huntington's disease); (5) inflammatory and immunologic disorders (acute disseminated encephalomyelitis, limbic encephalitis, Rasmussen's encephalitis); (6) developmental and malformative disorders (cortical migrational disorders and dysplasias); (7) toxic and metabolic disorders (leukodystrophies, central pontine myelinolysis, mitochondrial encephalopathies); and (8) some forms of epilepsy (mesial temporal sclerosis, malformations). Finally, some conditions show either no imaging study abnormalities or show only atrophy without focal findings, e.g., degenerative diseases (Alzheimer's disease, Parkinson's disease), toxic and metabolic diseases (hepatic encephalopathy, many storage diseases), and most cases of idiopathic epilepsy.

MASS LESIONS ([Table 25-9](#))

Tumors. The differential diagnosis of a mass lesion presumed to be neoplastic can be limited by considering the age of the patient and the location of the tumor. [Table 25-10](#) lists examples of tumors encountered in certain nervous system locations in the pediatric and adult age groups. Diagnostic biopsy is usually directed toward the mass lesion. As noted earlier, the possibilities of tissue heterogeneity and central necrosis should be taken into account by adequate sampling of different areas including the interface between tumor and adjacent brain. A preliminary intraoperative assessment by frozen section is useful

TABLE 25-9 -- DIFFERENTIAL DIAGNOSIS OF SPACE-OCCUPYING CENTRAL NERVOUS SYSTEM LESIONS

Neoplasms	Intra-axial: gliomas, metastatic tumors, lymphoma Extra-axial: meningiomas, neuromas
Infections	Abscesses (bacterial, fungal, parasite), granulomas (tuberculosis, sarcoidosis), necrotizing lesions (toxoplasma, some focal viral encephalitides)
Cerebrovascular	Hemorrhages, acute infarctions
Demyelinating	Acute multiple sclerosis, adrenoleukodystrophy
Cysts	Metastatic neoplasms, primary neoplasms (glioma), primary developmental disorders (meningeal, neuroepithelial, colloid, enterogenous)

to gauge the adequacy of the specimen for diagnosis and to predict how tissues should be handled for ancillary studies. Neoplasms that may present without evidence of a mass lesion and mimic other forms of neurological disease include neoplasms disseminated in the subarachnoid space (metastatic carcinoma, glioma, lymphoma), infiltrating gliomas (low-grade astrocytomas or oligodendrogliomas), and some forms of mixed neuronal and glial neoplasms (dysembryoplastic neuroepithelial tumor, gliomatosis cerebri) and lymphomas. Non-neoplastic mass lesions such as infections can be suspected on intraoperative frozen section evaluation, and appropriate ancillary studies can be done.

Radiation Necrosis. Following therapeutic radiation therapy for intracerebral neoplasms, the distinction between recurrent neoplasm and radiation necrosis is often difficult. Diagnostic brain biopsy is often useful in demonstrating residual or recurrent neoplasm and may show the coagulative tissue necrosis and vasculopathic changes characteristic of radiation necrosis in adjacent brain parenchyma, with or without evident tumor. Diagnostic brain biopsy can be performed as part of the therapeutic removal of necrotic tissue as well.

Non-neoplastic Cysts. Diagnostic biopsy of a cyst wall can be performed as part of cyst fenestration or drainage and may be useful in distinguishing between neoplastic and non-neoplastic cystic mass lesions.

Infections. Infectious diseases of the central nervous system are diagnosed by a variety of means, including assessment of clinical history, standard laboratory studies, serological and microbiologic evaluation of blood and cerebrospinal fluid, and imaging studies. Diagnostic brain biopsy plays a limited role in this setting. In the case of mass lesions or focal brain lesions, diagnostic brain biopsy may be useful in distinguishing between neoplasms and infections. Diagnostic brain biopsy evaluated by morphological and microbiological studies may also be useful in identifying an organism that has failed to be diagnosed by blood or cerebrospinal fluid studies. Diagnostic brain biopsy is also performed when a suspected infectious lesion fails to respond to a trial of antimicrobial therapy. Diagnostic brain biopsy is also performed in some patients with HIV infection and certain CNS complications. The spectrum of possible infectious complications in these patients is large and varied. Common CNS infections include toxoplasma cerebritis, cryptococcal and other fungal infections of the meninges or brain parenchyma, herpes simplex and cytomegalovirus encephalitis, and progressive multifocal leukoencephalopathy (JC virus). Although these infections often present with characteristic clinical and imaging features, a considerable overlap among these infections and primary CNS lymphoma can occur. In HIV patients who fail a trial of antimicrobial agents for a suspected infection, diagnostic brain biopsy may also be useful.

DEGENERATIVE DISEASES

Many degenerative diseases are characterized by neuronal loss and gliosis in various brain structures without distinctive features. Diagnosis by brain biopsy remains inconclusive in many cases. In patients with a rapidly progressive dementia, a distinction can be made between Creutzfeldt-Jakob disease and degenerative disorders by

TABLE 25-10 -- DIFFERENTIAL DIAGNOSIS OF NEOPLASTIC CENTRAL NERVOUS SYSTEM TUMORS

Age	Cerebral Hemispheres	Diencephalon	Posterior Fossa	Cerebral Meninges	Spinal Cord
Adulthood	Astrocytoma, glioblastoma, oligodendroglioma, metastatic tumor, lymphoma	Astrocytoma, glioblastoma, colloid cyst, pituitary adenoma	Metastatic tumor, hemangioblastoma	Meningioma, CN VIII schwannoma, metastatic carcinoma, lymphoma	Meningioma, nerve sheath tumors, astrocytoma, ependymoma
Childhood	Astrocytoma, ependymoma, choroid plexus tumor, primitive neuroectodermal tumor	Germ cell tumors, craniopharyngioma	Medulloblastoma, ependymoma, cerebellar pilocytic astrocytomas, brain stem astrocytoma, choroid plexus tumor	Leukemia, lymphoma	Nerve sheath tumors, astrocytoma

CN, Cranial nerve.

the presence of spongiform changes or prion proteins in the former. In addition, the demonstration of senile plaques and neurofibrillary tangles in a random biopsy of cerebral cortex, while suggestive of Alzheimer's disease, does not exclude the possibility of other forms of neurodegenerative disease or the presence of other concomitant disease. Because of the variability of distribution of the pathological changes in most degenerative disorders, random biopsies may be nondiagnostic. For adequate evaluation, a piece of cerebral cortex with overlying leptomeninges and underlying white matter that can be oriented is desirable. Tissue should be considered potentially infectious, and precautions for Creutzfeldt-Jakob disease should be taken according to local institutional guidelines. The tissue should be fixed and reserved for possible electron microscopy or other studies.

VASCULAR DISEASES ([Table 25-11](#))

Surgical resection of tissue is occasionally performed in the setting of cerebrovascular disease. Diagnostic brain or meningeal tissue biopsy is usually performed when CNS vasculitis is suspected. Resection of brain tissue is usually performed for the diagnosis and treatment of vascular malformations. Symptomatic treatment of acute cerebrovascular diseases, usually hemorrhages and traumatic lesions, by evacuation of hematoma with removal of damaged brain tissue, may provide histological evidence of specific etiologies such as amyloid angiopathy or hypertensive vasculopathy. Some cases of cerebrovascular disease, such as

TABLE 25-11 -- TISSUE DIAGNOSES IN CEREBROVASCULAR DISEASE

Vasculitis	Primary CNS vasculitis, CNS involvement in systemic vasculitis, infectious vasculitis
Vascular malformations	Arteriovenous malformation, cavernous angioma, venous angioma
Vasculopathies and diseases presenting as intracranial hemorrhages	Amyloid angiopathy, hypertensive vasculopathy, vasculitis, primary or metastatic neoplasms, infections
Cerebrovascular diseases mimicking mass lesions	Recent infarction

infarcts, present as mass lesions and may be clinically mistaken for neoplasms.

METABOLIC DISEASES

Diagnosis of metabolic and storage disorders by brain biopsy has been superseded in many conditions by biochemical and molecular genetic analysis of more readily obtainable non-CNS cells and tissues. In cases in which metabolic or storage disease involving the CNS is suspected but no metabolic defect can be identified by other means, random biopsy of cerebral cortex and white matter may provide either positive or useful negative information. Reserved frozen or properly fixed tissues may prove useful later when subsequent clinical clues or testing techniques become available.

EPILEPSY

Some patients with intractable epilepsy may benefit from surgical resection of brain tissue (see [Chapter 52](#)). In patients with complex partial seizures originating in the temporal lobe, temporal lobectomy with partial hippocampectomy may be beneficial. Examination of medial temporal lobe structures may disclose evidence of neuronal loss and gliosis in the hippocampus, amygdala, or adjacent gray matter structures (mesial temporal sclerosis). In occasional cases, other pathological findings (neoplasm, vascular malformation, cicatrix) may account for an epileptogenic focus. In some patients with intractable epilepsy with focal abnormalities demonstrated by electrophysiological, conventional neuroimaging modalities, or physiological imaging modalities such as positron-emission tomography scanning, removal of the focus is indicated. Pathological findings may include cortical migrational abnormalities, dysplasias, vascular malformations, glial scars, neoplasms, or focal infections. More widespread resections such as lobectomy or even hemispherectomy are occasionally performed with patients with established neurological deficits and more extensive malformations or with progressive lesions such as Rasmussen's encephalitis. Despite the finding of a focal lesion on one or more studies, no specific pathology is found in a large percentage of cases.

HISTORY

The cerebrospinal fluid (CSF) has served as an aid to the diagnosis and treatment of a variety of central nervous system (CNS) disorders for more than 100 years. In 1891, Quinke first developed the technique of spinal puncture and introduced it into clinical practice. ^[1] He was the first to use a needle with a stylet, to measure opening and closing pressures, and to pioneer the measurement of CSF glucose, protein, and cell counts. Much of the CSF literature in the early part of the 20th century dealt with changes related to bacterial meningitis and neurosyphilis. ^[2]

The notion that elevated intracranial pressure (ICP) can occur began in 1783 when Alexander Monroe posited that the skull is a closed container and its contents are nearly incompressible. These concepts were expanded in 1824 by George Kellie, who proposed that the volume of the blood within the brain was constant. In 1846, Burrows suggested that the volume of blood within the brain could only change in a reciprocal manner with the CSF and brain parenchyma. This concept formed the foundation of the Monroe-Kellie hypothesis, and modern theories of pressure-volume relationships still refer to this hypothesis. Early anatomists hypothesized that the choroid plexus was the source of CSF because of its location within the ventricles. This hypothesis was substantiated by Dandy and Blackfan ^[3] and then by Harvey Cushing, ^[4] who observed oozing of fluid from the choroid plexus during neurosurgery. Later, Ames provided definitive proof that the majority of intraventricular CSF was produced by the choroid plexus. ^[5], ^[6]

CEREBROSPINAL FLUID AND THE VENTRICULAR SYSTEM

Anatomy

The choroid plexus produces the majority of the CSF in addition to smaller amounts secreted by the ependyma and the perivascular spaces. The choroid plexus is derived embryologically from the neural epithelium and is composed of two layers including a specialized ependymal cell layer composed of the epithelial lining of the ventricular system and a highly vascularized pia mater layer. This bilayered structure, known as the choroidal epithelium, is folded into microvilli and forms a brush border on which cilia are present on the apical surfaces of some of these cells (Fig. 26-1 (Figure Not Available)). The choroidal epithelium with accompanying blood vessels and interstitial connective tissue collectively form the choroid plexus.

The choroidal epithelium shares many of the same characteristics of the blood-brain barrier. The concept of a

Figure 26-1 (Figure Not Available) Diagram of choroidal epithelium demonstrating the ependymal microvilli and cilia forming a brush border into the ventricular lumen. (From Page RB, Leure-dePree AE: Ependymal alterations in hydrocephalus. In Wood JH [ed]: Neurobiology of cerebrospinal fluid. New York, Plenum Press, 1983, p 802.)

blood-brain barrier was first considered in the 19th century when Paul Ehrlich injected dye into the blood of animals and noted that all the organs except the brain were stained. Later, in 1913, Edwin Goldmann injected dye into the CSF compartment and found that the brain was stained but no dye appeared in the blood. From these findings, the hypothesis that the brain was separated from blood and that the brain capillaries provide this barrier was proposed. When electron microscopy became available, it was revealed that capillary endothelial cells rest on a basement membrane and form a tube joined by continuous tight junctions with the merging of the outer leaflets of two adjoining cells. This barrier is involved in protecting the brain from substances in the blood, selectively transporting desired blood constituents, and metabolizing or modifying substances transported between compartments.

The properties of brain endothelial cells that differentiate them from systemic capillaries include complex tight junctions between individual capillary endothelial cells, which provide a high electrical resistance. These junctions are formed through the merging of the outer leaflets of two adjoining cells. Second, little bulk flow of molecules occurs through these cells because of the paucity of pinocytotic vesicles and fenestrae. These two features protect the brain from various neurotoxic agents that may be present in the blood. Only substances that can cross biological membranes owing to their lipophilic character may diffuse unrestricted across the blood-brain barrier. Specific carrier systems, however, do exist in the brain endothelial cells and allow for the controlled exchange of substances between the system blood and the nervous system. These include facilitated diffusion in the case of the glucose transporter and ATP-dependent active transport mechanisms. Third, in addition to the endothelial cells, pericytes, perivascular microglia, and astrocytes contribute to the barrier. Pericytes are contractile adventitial cells and serve as the counterpart to the smooth muscle of large systemic vessels. Whereas evidence exists to suggest that these cells are necessary for the growth and integrity of the capillary endothelial cells and cellular transport, their exact function is unknown. Perivascular microglial cells are derived from bone marrow and most likely migrate to the brain. In proximity to the capillary endothelial cells, these microglial cells most likely serve as phagocytes. Finally, astrocytic endfeet are also closely associated with capillary endothelial cells and are separated from the cell plasma membrane by only the basal lamina. The astrocytes and their associated processes may be involved in the induction of the blood-brain barrier.

The choroid plexus is found in the walls of the lateral ventricles, and this structure is continuous with choroid plexus in the roof of the third ventricle. Additionally, the fourth ventricle contains a T-shaped choroid plexus that projects into the cavity from the roof. Whereas the choroid plexus of the lateral ventricles receives its arterial supply from the anterior and posterior choroidal arteries, the third ventricular choroid plexus is supplied by branches of the posterior cerebral artery. The posterior inferior cerebellar artery supplies the choroid plexus of the fourth ventricle.

After the CSF is secreted by the choroid plexus it circulates throughout the ventricular system and the subarachnoid space that surrounds the brain and spinal cord ([Fig. 26-2](#)).

Figure 26-2 The ventricular system. This diagram demonstrates the flow of cerebrospinal fluid from the choroid plexus to the arachnoid. (From Fishman RA: Cerebrospinal fluid in diseases of the nervous system. In Fishman RA [ed]: Cerebrospinal fluid in diseases of the nervous system, 2nd ed. Philadelphia, W.B. Saunders, 1992, p 8.)

The anatomy of the ventricular system allows for movement of CSF in and around all the major structures of the brain. The lateral ventricles are located within the cerebral hemispheres and communicate with the third ventricle via the foramina of Monroe. The third ventricle lies caudal to the lateral ventricles and is a midline structure within the diencephalon. At its caudal end, the third ventricle is connected by the aqueduct of Sylvius to the fourth ventricle, which is situated between the brain stem and cerebellum. Cerebrospinal fluid then flows into the basal cisterns and subarachnoid space by the lateral foramina of Luschka and the medial foramen of Magendie. From these cisterns, the CSF flows throughout the subarachnoid space and over the hemispheric convexities and around the spinal cord.

CSF is reabsorbed into the venous system by numerous microscopic arachnoid villi and larger but less common arachnoid granulations. The granulations have a collagenous trabecular core with associated channels and a cap of arachnoid cells on the apex. Villi and granulations represent outpouchings of the arachnoid membrane that penetrate gaps in the dura and protrude within the venous sinuses (Fig. 26-3 (Figure Not Available)). Arachnoid villi are also present at various levels of the spinal cord and surrounding spinal nerve roots.

Physiology

SECRETION AND ABSORPTION

It is estimated that the average adult ventricular system and subarachnoid space contain between 90 and 150 ml of

Figure 26-3 (Figure Not Available) The arachnoid villi with outpouchings into the superior sagittal sinus. (From Wood K: Physiology, pharmacology and dynamics of cerebrospinal fluid. In Wood JH [ed]: Neurobiology of Cerebrospinal Fluid. New York, Plenum Press, 1980, pp 1-16.)

CSF with nearly 80 percent being present in the ventricles. The production of CSF occurs at a rate of about 500 ml/d (20 ml/h), and the entire amount of CSF is replenished five times a day. The secretion of CSF by the choroid plexus is linked to the hydrostatic pressure within the plexus capillaries that moves water and electrolytes into the interstitial space and subsequently into the choroidal epithelium (Fig. 26-4 (Figure Not Available)). ^[1] Water and ions are then transferred into the ventricular cavity by either traversing the tight apical junctions or the plasma membrane of the apical villus. Because the secretion of CSF is associated with the transport of sodium, ion pumps are involved in this transfer, and the movement of sodium is linked to the membrane-bound enzyme sodium-potassium-activated adenosine triphosphate (ATP)ase that has been identified on the brush border and intercellular clefts. ^[2] In addition to the sodium-potassium ion exchange at the apical surface, basolateral sodium-hydrogen antiports and apical and basal chloride-bicarbonate antiports are also present in the choroidal epithelium ([Fig. 26-5](#)). Typically, a net secretion of sodium, chloride, and bicarbonate occurs from the plasma to the CSF, yet ion exchanges can occur in either direction and depend on the relative levels of various ions in the cells and the CSF.

The exact mechanisms regulating the action of these ion pumps and the permeability of the choroidal epithelium is incompletely understood, yet a strong correlation exists between the rate of sodium exchange and the rate of spinal fluid formation. ^[3] The rate of sodium exchange is, in turn, partially regulated by the permeability of bicarbonate, and the enzyme carbonic anhydrase is important in this relationship. This enzyme is present in the cytosol of the choroidal epithelium and catalyzes the formation of carbonic acid from water and carbon dioxide. ^[4] Carbonic acid then freely dissociates to bicarbonate and a hydrogen ion that are available to participate in their respective ion pumps. Investigators have demonstrated that a carbonic anhydrase inhibitor such as acetazolamide can reduce CSF sodium exchange by 50 to 100 percent ^[5] and can reduce CSF production significantly. ^[6] Other factors may influence the rate of CSF formation ([Table 26-1](#)), although most findings are based on animal studies and the results cannot necessarily be extended to human physiology.

Because CSF production is in equilibrium with absorption, approximately 0.35 ml of CSF are absorbed every minute. This rate is the bulk flow of fluid and does not

represent the absorption of individual constituents such as ions and proteins. These latter CSF components are exchanged at individual rates that depend on the rate of fluid absorption, the degree of active transport of the solute from the CSF, and the amount of solute diffusion into the parenchyma of the brain and brain capillaries.^[1] The process in which fluid and other molecules move across the villi and granulations to enter the venous system is not entirely understood, but possible mechanisms include direct flow through a tubular system,^[12] the use of giant vacuoles,^[13] pinocytosis, and extracellular transport.^[14]

COMPOSITION

In addition to the major ions, CSF contains oxygen, sugars (e.g., glucose, fructose, polyols), lactate, proteins (e.g., albumin, globulins), amino acids, urea, ammonia, creatinine, lipids, neurotransmitters and their metabolites,

Figure 26-4 (Figure Not Available) Diagrammatic representation of the choroid plexus with respect to the relationship of a variety of ions and small mole(From Wright EM: Transport processes in the formation of the cerebrospinal fluid. Rev Physiol Biochem Pharmacol 1978; 83:1-34.)

hormones (e.g., insulin, gastrin), and vitamins. Whereas the regulation of many CSF constituents is unknown, some are transported into the CSF by facilitated diffusion using a proteolipid carrier (e.g., glucose). In general, CSF glucose

Figure 26-5 Demonstration of the sodium-hydrogen ion, sodium/potassium, and chloride/bicarbonate pumps in a choroid epithelium (Modified from Johansen CE, Parandoosh Z, Smith OR: $\text{Cl} = \text{HCC}_3$ exchange in choroid plexus: Analysis by the DMO method for cell pH. Am J Physiol 1985; 249:478.

concentration is about 60 percent of the serum. CSF concentrations of sodium, chloride, and magnesium are the same or greater than those in the serum; however, potassium, calcium, and glucose concentrations are lower (Table 26-2).

TABLE 26-1 -- FACTORS THAT MAY INFLUENCE THE FORMATION OF CEREBROSPINAL FLUID

Agent	Effect on CSF Production	Presumed Mechanism
Cholera toxin	Increases	Stimulates adenosine monophosphate
Alpha-adrenergic drugs	Increases	Stimulates adenylate cyclase
Hyperosmolality	Decreases	Alteration in ionic concentrations
Hypothermia	Decreases	Unknown
Furosemide	Decreases	Inhibition of the sodium-potassium- chloride co- transport system
Dopamine (D1) antagonists	Decreases	Unknown
Vasopressin	Decreases	Reduces choroidal blood flow
Atrial natriuretic hormone	Decreases	Modulates cyclic GMP activity
Acetazolamide	Decreases	Inhibition of carbonic anhydrase
Ouabain	Decreases	Inhibition of sodium- Potassium ATPase

TABLE 26-2 -- NORMAL CEREBROSPINAL FLUID CONSTITUENTS

Substance	Plasma	CSF
Sodium (mEq/l)	140.0	144.0
Potassium (mm/l)	4.6	2.9
Magnesium (mEq/l)	1.6	2.2
Calcium (mg/dl)	8.9	4.6
Chloride (mEq/l)	99.0	113.0
Bicarbonate (mm/l)	26.8	23.3
Inorganic phosphate (mg/dl)	4.7	3.4
Protein (g/dl)	6.8	0.028 (28 mg/dl)
Glucose (mg/dl)	110.0	50 to 80
Osmolality	0.3	0.29
PH	7.4	7.3
PCO ₂ (mm Hg)	41.1	50.5

ACQUISITION

The technique of the lumbar puncture (LP), or spinal tap, was first developed by Quinke in 1891 and has likely changed little since that time. Before performing an LP to obtain CSF, a patient's coagulation profile should be checked. If the results of these studies demonstrate a thrombocytopenic (platelet count less than 20,000) or a prothrombin time or partial thromboplastin time that is elevated, these abnormalities should be corrected prior to the LP.^[15] In adults, the LP is best performed with the patient in the lateral decubitus position with the head and spine parallel to the floor. This positioning is particularly important for the accurate measurement of the opening and closing pressures. After positioning the patient, certain landmarks should be palpated, beginning with the iliac crest. An imaginary line that runs between the crests will intersect approximately the L3-L4 interspace. Once this area is located, the spinal processes of L3 and L4 should be palpated and between them the interspace may be felt. This procedure is easily accomplished in thin patients but may be difficult in obese or edematous individuals.

When the landmarks are located, the patient should pull the knees into the chest and assume the so-called fetal position. This maneuver helps widen the vertebral interspace. The clinician should appropriately prepare the skin surface using a sterilizing agent and then place the sterile draping. One to two percent lidocaine should be injected intradermally and then is infiltrated into the deeper tissues. Once the patient is anesthetized, a spinal needle with a stylet should be inserted into the skin toward the interspace. Some debate exists as to the optimum gauge of spinal needle that should be used. Although fewer post-LP headaches occur when finer gauge needles are used,^[16] it is more difficult to remove CSF and accurately measure pressures. A 20- or 22-gauge needle is generally used. In order to reduce the risk of post-LP headache, the needle should be advanced with the bevel parallel to the long axis of the spine,^[17] which will prevent the transection of the fibers of the longitudinal ligament. Instead, this technique causes the separation of these fibers. When the needle reaches the longitudinal ligament there will be a slight increase in resistance, yet with continued advancement a sudden decrease in the amount of resistance will occur. When this is felt, the needle has passed through the longitudinal ligament and has entered the subarachnoid space. At this point, the removal of the stylet results in the flow of CSF. If no fluid flows, the stylet should be replaced and the needle should be rotated 90 degrees so that the bevel is oriented cephalad. The needle may need to be further adjusted or reinserted if the CSF fails to flow from the needle. Each time the needle is reinserted, the stylet should be replaced.

When the CSF begins to flow, a manometer may be attached to the hub of the spinal needle, which allows the CSF to flow into the manometer tube. This maneuver should be done immediately in order to avoid spuriously low opening pressure readings. Often some fluid has already been removed. The CSF should be allowed to rise into the tube until a steady state is reached. Coughing, talking, or performing the Valsalva maneuver can falsely elevate the pressure reading. It may also be helpful to allow the patient to come out of the fetal position to reduce the amount of intra-abdominal pressure, which may affect opening pressure measurements. A normal opening pressure ranges from 10 to 20 cm H₂O (approximately equivalent to 5 to 15 mm Hg). Following the measurement of the opening pressure, the CSF can be collected for analysis.

When acquiring the CSF, the clinician should number the tubes and maintain this order during the CSF collection. After the CSF fluid is collected, the manometer should be reconnected and a closing pressure should be measured. This value is usually less than the opening pressure; however, the range of closing pressure values depends on the amount of CSF removed. A low opening pressure may indicate a CSF leak or a spinal subarachnoid obstruction, which does not allow for communication of the lumbar space with the cranium. Disorders that elevate the opening pressure (greater than 20 cm H₂O) are numerous, including mass-occupying lesions and diffuse cerebral inflammatory or toxic processes. The closing pressure is used to assess the pressure reduction after an LP, particularly in cases of therapeutic lumbar puncture. Before withdrawing the spinal needle, the stylet should not be reinserted, to lessen the likelihood of contamination. It is not necessary for the patient to lie supine for any specific amount of time after the LP, because controlled studies have clearly demonstrated that position does not reduce the risk of a post-LP headache.^[18]

The lumbar puncture may also be performed in the sitting position, or CSF may be collected with cisternal or lateral cervical punctures under fluoroscopic guidance. The advantages of performing the LP in a sitting position are threefold: (1) the midline is much easier to determine; (2) some patients find that tightly flexing the hips while sitting is more comfortable than the fetal position; and (3) gravity can assist the flow of the CSF in cases of low CSF pressures. This technique is essentially the same as that of the lateral decubitus position, but the patient is upright. The patient should be asked to sit on the edge of the bed or examination table and lean forward as far as possible. This position is best accomplished with the patient leaning forward on a table that is slightly higher than the bed. With the physician standing behind the patient, the iliac crests are palpated and at the intersection of these structures

* Results on fluids removed at first lumbar puncture are used in most instances. + Increase of protein usually due to presence of adluxe serum. From Fishman RA: Cerebrospinal fluid in diseases of the nervous system. In Fishman RA (ed): Cerebrospinal Fluid in Diseases of the Nervous System, 2nd ed. Philadelphia, WB Saunders, 1992, p 431.

and in the midline lies the L3-L4 interspace. This area is prepped, draped, and anesthetized similarly to the earlier description. Again, the needle is inserted with the bevel facing laterally so as not to tear the fibers of the longitudinal ligament. The angle of insertion is upward in this position, toward the umbilicus. In this position, neither opening or closing pressures can be accurately determined. In order to obtain the pressure readings, the patient may be moved to the lateral decubitus position once the spinal needle is in the subarachnoid space.

Other than the L3-L4 interspace, several other lumbar levels may be used to perform the LP including L4-L5 and L5-S1. More rostral levels should not be attempted because spinal cord trauma may occur. If anatomical restrictions exist such as occurs in severe spinal spondylosis, previous spinal surgery with fusion, or morbid obesity, and impedes the acquisition of CSF levels, an attempt should be made to obtain CSF under fluoroscopic guidance. If this procedure is unsuccessful, CSF may be obtained through a cisternal or lateral cervical puncture. These procedures should be performed by an experienced clinician under radiographical guidance. A cisternal puncture is performed by placing the spinal needle in the cisterna magna and carries the risk of brain stem or upper cervical cord damage. A lateral cervical puncture involves the insertion of the spinal needle in the C1-C2 interspace from a posterolateral approach and also has the risk of damage to the cervical cord.

When an asymmetrical CNS process or an increase in ICP is suspected, a CT or MRI scan should be obtained prior to an LP. If a mass lesion is found, the LP should be delayed. On the other hand, diffuse cerebral processes such as encephalitis, meningitis, or pseudotumor cerebri that frequently elevate the opening pressure, may be benefited by frequent lumbar punctures to lower intracranial pressure (i.e., pseudotumor cerebri^[19] or cryptococcal meningitis^[20]).

Normal and Pathological Findings (see Tables 26-2, 26-3, and 26-4)

The general appearance of CSF is clear and colorless, because it is more than 99 percent water. Color of CSF is observed only in pathological circumstances. Whereas the term xanthochromia means yellow color, it has been used for the presence of other colors as well. Because of this practice, the actual color of the CSF should be stated and a gradation of its magnitude (from 1+ to 4+) should be noted. A yellowish tinge can be found with any cause of a markedly increased protein (greater than 200 mg percent). A yellow or pink color is found when hemoglobin has been released into the CSF from prior bleeding and sufficient time has passed for

its breakdown to bilirubin and other pigments. Oxyhemoglobin is red but becomes pink or yellow when diluted. The concentration of oxyhemoglobin is maximal within the first 36 hours and disappears by 14 days. Bilirubin is yellow and is first detected in the CSF 10 hours after subarachnoid bleeding. Its concentration is maximal at 2 days and may persist for up to a month. Other causes for coloration of CSF include an elevated systemic bilirubin from liver disease; a brownish or gray coloration in the presence of CNS melanoma; and a greenish tinge related to leukemic meningeal infiltration.

Fluid that is obviously blood tinged or bloody indicates a traumatic tap or the presence of a subarachnoid hemorrhage. In traumatic taps, the CSF usually clears as sequential amounts are collected and is unlikely to have a pink-or yellow-tinged supernatant. The CSF may occasionally clot if the ratio of blood to CSF is high. Bloody CSF from subarachnoid hemorrhage does not clear with sequentially collected tubes and may demonstrate xanthochromia if the bleeding occurred over 2 to 4 hours before the LP. If the CSF is acquired over 12 hours after the onset of subarachnoid hemorrhage, virtually all patients' CSF will demonstrate xanthochromia.

Whenever the viscosity of CSF is increased, the most likely explanation is a marked increase of protein content. If sufficient fibrin is present, the free flow of CSF can be impaired and spontaneous clotting of the CSF can occur (Froin's syndrome). Turbidity detected in CSF when a collection tube is twirled in the beam of a bright light is indicative of the presence of at least 200 or more leukocytes per mm³. Turbidity may also be caused by the presence of microscopic fat globules that have traveled to the brain as emboli. The presence of erythrocytes will impart turbidity up to a concentration of 400 cells per mm³, above which there will be pink coloration from their hemoglobin content.

Six common CSF studies include the cell count and differential, Gram's stain and culture, blood glucose, and protein concentrations and direct observation for color and character.

CELL COUNTS

CSF cell counts (red blood count and white blood count) with differentials should be performed on every specimen. Typically, the CSF contains no RBC/mm³ and 0 to 1 WBC/mm³. Cook and Brooks^[2] reported that the normal CSF WBC in 11 patients was 0.826 + 0.733 cells/mm³ with differentials of approximately 66 percent lymphocytes, 33 percent monocytes, and 1 percent polymorphonuclear cells (PMNs). Fishman has also noted that the normal CSF should contain no more than five lymphocytes or mononuclear cells/mm³, and counts greater than 6 cells/mm³ are abnormal. A traumatic LP causes elevations of RBCs and WBCs, but these elevations are differentiated from subarachnoid hemorrhage because the former elevations are high in the first tube but clear in the later tubes. To determine whether an elevated CSF WBC is due to blood from a traumatic tap or other causes, an expected ratio can be used. If the elevated WBC is due to blood in the CSF, one WBC/mm³ for every 700 RBC/mm³ is found. If the WBC exceeds this ratio, its origin must be accounted for from other etiologies such as infection or inflammation.

GLUCOSE

As noted in [Table 26-2](#), the CSF glucose concentration is normally 60 percent of the plasma glucose concentration, and under nonpathological conditions this ratio changes

TABLE 26-4 -- SELECTED DISORDERS AND ASSOCIATED CSF STUDIES

Domain	Disorder	Useful CSF Studies	Expected Results	Comments
CEREBRAL DYSFUNCTION Infectious	Meningitis (purulent)	pr, gl, cell cts, gs, ex, op	pr, gl, CSF PMNs, + gs and cx, + bacterial ag's, op LA	+ cryptococcal ag & india ink in cryptococcal meningitis Mononuclear cells possible in partially rx'd bacterial meningitis
	Meningitis (aseptic)	pr, gl, cell cts	pr, nl gl, CSF WBC (10 to 1000 mononuc cells/mm ³)	PMNs possible in early aseptic meningitis
	Encephalitis	pr, gl, cell cts, gs, cx	mildly pr (50 to 100 mg/dl), nl gl, CSF WBC 50 to 100/mm ³ (mononuc)	Herpes simplex encephalitis
	HIV encephalopathy	pr, gl, cell cts	RBC/xanthochromia, + CSF PCR mildly pr, nl gl, nl or few WBC	
	Neurosyphilis (acute)	VDRL, pr, gl	pr (>45 mg dl), WBC (5 to 500 mononuc/mm ³), + VDRL	CSF parameters may be normal.
	Neuroborreliosis	pr, gl, cell cts, OCB, ab's	pr (100 mg dl), nl or gl, WBC (100 mononuc/mm ³), + OCB, + Lyme ab's	CSF normalizes in stage III
	Tuberculous meningitis	pr, gl, cell cts, op, acid-fast stain, cx	pr (100 to 200 mg/dl), gl (<45 mg dl), WBC (25 to 100 mononuc/mm ³), op	May be spinal block; stain and culture require large amts. of CSF
	Abscess	Not recommended		May be dangerous to perform LP in the face of abscess; risk of herniation or ventricular rupture
	Creutzfeldt-Jakob	pr, gl, cell cts	Normal	14-3-3 protein in CSF (not readily available)
	Progressive multifocal leukoencephalopathy	JC virus PCR	+ JC virus PCR	CSF o/w normal
Cysticercosis	pr, gl, cell cts, op	pr,	CSF eosinophils constitute 20 to 75 percent	

	Cysticercosis	pr, gl, cell cts, op	pr, gl, WBC (mixed w/eosinophilia), op	CSF eosinophils constitute 20 to 75 percent
Cerebrovascular	Stroke	pr, cell cts	mildly pr and WBC	Not routinely performed; LDH, AST and CK-BB in cortical CVA
	Subarachnoid hemorrhage	pr, gl, cell cts, color	pr, gl, RBC, WBC, xanth	pr can be normal or significantly, gl can be normal or slightly
	Venous thrombosis	cell cts, op	RBC, op	WBC may be if 2° to septic thrombosis
Dementia Degenerative	Anoxic brain			Not routinely performed; CK-BB, NSE, MBP may be useful
	Alzheimer's disease	pr, gl, cell cts	normal parameters	Abnormal CSF helps r/o AD
Neoplastic	Huntington's disease	pr, gl, cell cts	normal	Abnormal CSF helps r/o Huntington's disease
	Wilson's disease	pr, gl, cell cts	normal	Abnormal CSF helps r/o Wilson's disease
	Meningeal carcinomatosis	pg gl, cell cts, cyt, op	pr (24 to 1200 m/dl), gl, WBC (PMN), + cyt, mildly op	Large volumes of CSF and multiple LPs increase cytology yield
Metabolic	Craniopharyngioma	cell cts	WBC (mononuc)	A cause of chronic chemical meningitis
	Hepatic encephalopathy	pr, color	pr possible xanth	Not routinely performed. op may be; CSF glutamine
	Uremic encephalopathy	pr, cells cts, urea	mildly pr & WBC, urea	Not routinely performed
	Myxedema coma	pr	pr (100 to 300 mg/dl)	
Demyelinating	Mitochondrial encephalopathies	pyruvate, lactate	pyruvate, lactate	MELAS
	Multiple sclerosis	pr, gl, cell cts, OCB, MBP, IgG index	pr, mildly WBC, nl gl, + OCB, + MBP, IgG index	Abnormal CSF in 90 percent of cases; Pr and cell cts nl in 2/3
Autoimmune	Acute disseminated encephalomyelitis	pr, gl, cell cts, OCB	mildly pr & WBC, nl gl, + OCB	OCBs may disappear after resolution
	Sarcoid	pr, gl, cell cts	pr (50 to 200 mg/dl), mildly gl (30 to 0 mg/dl), WBC (10 to 100 mononuc/mm ³)	ACE in 50 percent, but not specific
	Behcet's disease	pr, cell cts	pr, WBC (mixed response) 10 to 200 cell/mm ²	CSF results quite varied
Other disorders	Angiitis	pr, gl, cell cts, op	pr, gl, WBC (mononuc) op	Abnormal CSF in 80 to 90 percent
	Normal pressure hydrocephalus	Diagnostic high volume LP, op	Gait & mental status improvement after LP, nl op	High volume LP (40 to 50 cc of CSF)
	Pseudotumor cerebri	pr, cell cts, op	pr, nl cell cts, op (250 to 600 mm H ₂ O)	CSF removal may be therapeutic in some cases
	Migraine	See comments		Little available data. May have pr and cell cts in severe complicated migraine
	Generalized seizure	pr, cell cts	nl-pr, mild WBC	Postictal

CRANIAL NERVE DYSFUNCTION	Miller-Fisher variant of GBS	See CBS	See GBS/comments	Pr more common nl than in CBS	
	Opic neuritis	pr, cell cts, OCB	Mild pr (45 to 60 mg/dl), 50 percent with mild WBC (mononuc), + OCB	+ OCB increase risk of MS	
	Lyme disease	cell cts	Mild WBC (mononuc)		
	Bell's palsy	pr, gl, cell cts	nl CSF	Abnormal CSF helps r/o Bell's palsy	
	Trigeminal neuralgia			Not routinely performed; may have substance P and monoamines	
	Kearns-Sayre syndrome	pr	pr (70 to 400 mg/dl)		
MOTOR DYSFUNCTION					
CNS	Parkinson's disease	pr		Not routinely performed. Abnormal CSF helps r/o Parkinson's disease	
	Huntington's disease	See above		Abnormal CSF helps r/o Huntington's disease	
	Wilson's disease	See above		Abnormal CSF helps r/o Wilson's disease	
	Neurosyphilis (paretic)	VDRL, pr, cell cts,	+ + VDRL, pr: 50 to 100 mg/dl, cell cts: 25 to 75 leukocytes/mm ²	CSF abnormalities increase with duration of disease	
	HIV-LV-I	pr, gl, IgG, OCB	mild pr, nl gl, IgG, + OCB	Serum + HTLV-1 ag	
	Poliomyelitis	pr, gl, cell cts	mild pr (50 to 200 mg/dl), nl gl, mild CSF WBC (mononuc)	CSF WBC with time	
	Spinal cord tumor	pr, gl, cell cts, cytology	may be pr, nl gl, WBC (mononuc), + cyt	Froin's syndrome (spinal cord block) may sig	
	Tetanus	pr, gl, cell cts	pr (90 to 150 mg/dl), nl gl, nl cell cts	Care must be taken not to induce tetany. Normal cell cts differentiate from meningitis	
	Stiffman's syndrome	pr, cell cts, IgG, OCB	nl pr, nl cell cts, IgG, ? + OCB		
	Motor Neuron	ALS	pr, cell cts	mild pr & cell cts	Nondiagnostic
		Guillain-Barre (GBS)	pr, cell cts	pr, nl cell cts	Pr peaks between 1 and 3 wks. Cell cts > 5 should prompt search for another cause
	Nerve	Brachial plexopathy	pr, cell cts	mild pr (50 to 60 mg/dl), nl cell cts	
		Chronic inflammatory demyelinating polyradiculopathy (CIDP)	pr, gl, cell cts	pr (100 to 200 mg/dl), nl gl, mild WBC (5 to 50 cell/mm ³)	Similar to GBS; Pr elevation correlates with severity; + WBC in 10 percent
	Inherited neuropathy	pr, gl, cell cts	mod pr (50 to 200 mg/dl), nl gl, nl cell cts		
Muscle	Myopathy or myositis			Not routinely performed	
CEREBELLAR DYSFUNCTION					
	Cerebellitis	pr, gl, cell cts	mildly pr, nl gl, cell cts usually <100/mm ² (mononuc)	Usually secondary to varicella-zoster	
	Paraneoplastic cerebellar disease	pr, cell cts, abs	mild pr, mild WBC (8 to 20 cells/mm ³) + anti-Yo or anti-Hu ab	Anti-Yo in ovarian, uterine, or breast CA. Anti-Hu seen in lung CA	
SENSORY DYSFUNCTION					
Neuropathy	Diabetic	pr, gl, cell cts	pr (50 to 400 mg/dl), nl cell cts, gl (secondary diabetes)		
	CIDP	See above			
	Inherited neuropathies	See above			
	Neurosyphilis (tabes dorsalis)	VDRL, pr, gl, cell cts	3/4 w/+ VDRL, CSF freq o/w WNL	CSF may resemble paretic form, but parameters improve w/progression

proportionately in response to a rising or falling plasma glucose event with a 4-hour lag time. This linear ratio of CSF to plasma glucose concentration decreases as

the plasma glucose exceeds 500 mg/dl. The reason for this decrease is unclear, but it may reflect the saturation of the carrier-mediated transport of glucose at high plasma concentrations.^[1] As a result, it is important to obtain a concomitant serum glucose level at the time of the CSF sample. Although an elevated CSF glucose level (hyperglycorrhachia) results from an elevated plasma glucose level, a decreased CSF glucose concentration (hypoglycorrhachia) may be due to a variety of causes including hypoglycemia. The other etiologies include bacterial meningitis^[24] (including typical bacteria, tuberculosis, and neurosyphilis), fungal meningitis, certain viral meningitides (mumps),^[25] subarachnoid hemorrhage,^[26] carcinomatous meningitis, chemical meningitis, and meningitis resulting from parasitic organisms (cysticercosis, trichinosis, amebiasis). If 0.4 is used as the lower limit of the normal CSF to serum glucose ratio, values below 0.4 have a sensitivity of 80 to 91 percent and a specificity of 96 to 98 percent for bacterial meningitis versus aseptic meningitis (inflammatory cells without evidence of a common bacterial pathogen).^[27],^[28] The CSF glucose value often returns to normal before other CSF determinations (such as protein or lactate), and some investigators have suggested serial determinations to guide treatment decisions.^[29] The CSF glucose level may take several weeks to return to normal despite the normalization of the protein concentration and cell count.^[29]

PROTEIN

The majority of CSF protein is derived from the serum, and the CSF to serum albumin ratio is approximately 1:200. This ratio implies that the entry rate of protein from the serum to the CSF is approximately 200 times less than its exit rate.^[1] The CSF protein concentration varies at different levels of the neuroaxis and generally increases from the cephalad to caudal levels. Elevation in lumbar CSF protein is a nonspecific but sensitive indicator of CNS disease.^[1] Table 26-2 illustrates the various disorders that can cause an elevation in the CSF protein level.^[22] A very high CSF protein concentration (greater than 500 mg/dl) is an infrequent finding but can occur with bacterial meningitis, subarachnoid hemorrhage, or spinal-subarachnoid block. When a significant amount of blood is present in the CSF (e.g., subarachnoid hemorrhage), a correction for the total protein concentration should be calculated. The presence of 1000 RBCs in the CSF results in the increase of protein by 1 mg/dl. A spinal-subarachnoid block can cause Froin's syndrome and is usually the result of a spinal cord tumor and can cause very significant elevations in CSF protein (greater than 1000 mg/dl).^[22] Protein concentrations of 100 mg/dl or greater have sensitivity and specificity for bacterial meningitis of 82 and 98 percent, respectively, as compared with aseptic meningitis,^[30] and if the concentration is 200 mg/dl, the sensitivity is 86 percent and the specificity is 100 percent.^[27] A lower than normal CSF protein level may occur in young children (6 months to 2 years of age), in patients with pseudotumor cerebri, and in patients with unintended loss of CSF from frequent LPs, a lumbar drain, or a lumbar dural CSF leak.

Figure 26-6 Formula for the determination of cerebrospinal fluid immunoglobulin (From Fishman RA: Cerebrospinal fluid in diseases of the nervous system. In Fishman RA [ed]: Cerebrospinal Fluid in Diseases of the Nervous System, 2nd ed. Philadelphia, W.B. Saunders, 1992, p 431.)

Certain proteins arise within the intrathecal compartment. Among these are immunoglobulins produced by CNS lymphocytes, transthyretin (produced by choroid plexus), and various structural proteins found in brain tissue (including glial fibrillary acidic, tau, and myelin basic proteins). The last group of proteins and transthyretin are found only in trace amounts, whereas immunoglobulins comprise a substantial fraction of normal CSF (5 to 12 percent). Electrophoretic techniques can be used to define the gammaglobulins as a heterogeneous group of proteins. Because serum IgG comprises nearly 20 percent of the total serum protein, a variety of formulas have been used to correct the CSF IgG level for the contribution derived from the blood in order to determine the CNS IgG synthesis rate (Fig. 26-6). Contamination of the CSF with blood may significantly elevate the IgG index and the IgG synthesis rate.

The electrophoretic separation of CSF proteins can be accomplished through the use of agarose gel and by the staining of the bands that are produced. Within the gamma region, three patterns of bands may be observed including one clone (monoclonal), many clones (polyclonal), and a few bands (three to five bands, or oligoclonal bands).^[1] Each band represents a homogeneous protein that is secreted by a single clone of plasma cells.

Oligoclonal bands (OCB) are present in the CSF when three to five bands are seen on gel electrophoresis. This finding implies that a single clonal population of plasma cells is responsible for each band. More than one oligoclonal band rarely occurs in normal CSF. A serum sample should also be obtained simultaneously with the acquisition of the CSF to determine whether the OCB are unique to the CSF. Oligoclonal bands are present in 83 to 94 percent of patients with multiple sclerosis, 100 percent of patients with subacute sclerosing panencephalitis, 25 to 50 percent of patients with other inflammatory CNS disorders (CNS lupus, neurosarcoidosis, cysticercosis, Behcet's and viral, fungal, and bacterial infections), as well as most with some brain tumors, and Guillain-Barre syndrome. Because OCBs are present in such varied conditions, their presence offers little to a specific diagnosis.

GRAM STAINING

Examining the CSF with Gram's stain is useful to diagnose bacterial meningitis.^[23] A Ziehl-Neelsen acid-fast stain should also be performed if tuberculous meningitis is a diagnostic possibility. CSF cultures should be done in the setting in which an infectious process is suspected. Bacteria that commonly cause meningitis are routinely cultured on standard preparations. *Mycobacterium* can also be cultured, yet several weeks (or more) may be required to grow these organisms. Viral cultures may be ordered; however,

the yield is generally low. Fungal cultures should be performed in clinical settings of suspected chronic meningitis.

SPECIALIZED TESTS

In addition to these routine studies, various specialized tests may also be useful in specific clinical settings.

The measurement of the CSF acid-base status is not normally part of the routine evaluation of this body fluid. In experimental studies, normal subjects have a CSF pH that is slightly lower than the pH of arterial blood and a pCO₂ that is higher. In contrast, bicarbonate levels are generally equal. Comparisons between CSF obtained through cisternal and lumbar punctures reveal that the pH is typically lower and pCO₂ higher in lumbar CSF. Again, bicarbonate levels are not significantly different. The variations between the cisternal and lumbar CSF samples may reflect differences in rates of local metabolism relative to clearance rates,^[31] and the clinical measurement of the lumbar CSF pH may be an unreliable indicator of the metabolic state of the CNS.

Because the concentration of CSF lactate is dependent on CNS glycolysis,^[32] the measurement of this agent may be helpful in the diagnosis of bacterial meningitis. This concentration of lactate increases proportionally to the number of inflammatory cells in the CSF.^[33] A lactate concentration of 4.2 mmol/L accurately predicted 24 out of 25 cases of bacterial meningitis, whereas no patients with presumed viral meningitis had a lactate level that exceeded this value. Unlike the glucose concentration, CSF lactate levels typically remain elevated for a significant time after appropriate therapy is initiated.^[24] This finding may be helpful in the diagnosis of bacterial meningitis when antibiotics had been given before the acquisition of CSF. Increased lactate may also result from a cerebral hemorrhage, malignant hypertension, hepatic encephalopathy, diabetes mellitus, and hypoglycemic coma.^[34]

The measurement of CSF glutamine can be a helpful test in diagnosing patients with confusion in the setting of hepatic encephalopathy. Glutamine is formed by the combination of ammonia, which is toxic to the CNS, and alpha-ketoglutarate in the brain. This process helps protect the CNS from the effects of ammonia. Normally, the CSF concentration of ammonia is less than one half of arterial levels, but may increase dramatically in patients with hepatic failure.^[1] Although a correlation exists between increased levels of ammonia and glutamine and the severity of encephalopathy, technical difficulties exist that hamper the ability to use these indices in acute settings.^[1]

Various biogenic amines (and their metabolites) may be measured within the CSF, including dopamine (homovanillic acid [HVA]), serotonin (5-hydroxyindoleacetic acid [5-HIAA]), and norepinephrine (3-methoxy-4-hydroxyphenylglycol [MHPG]). Significant ventricular to lumbar gradients exist for HVA and 5-HIAA, although MHPG levels are nearly equivalent. Decreased lumbar CSF levels of HVA and 5-HIAA have been reported in patients with parkinsonism and Alzheimer's disease. Whereas decreased HVA levels have also been documented in the ventricular CSF of patients with dystonia, cerebral palsy, MS, and posthypoxic states, no significant differences in 5-HIAA levels are apparent. Biogenic amine levels have also been studied in psychiatric patients, and whereas normal HVA levels are present in the lumbar CSF of patients with schizophrenia, decreased 5-HIAA concentrations are present in depressed subjects. Increased lumbar CSF MHPG levels have been identified in patients with cerebral infarction and hemorrhage. Animal studies further reveal that changes in biogenic amine levels in the CSF parallel CNS changes; however, delays in the clearance of these metabolites from the CSF complicate the interpretation of the values obtained. Because of these physiological constraints

and the nonspecific nature of changes in biogenic amine levels, their measurement remains a research tool and has little clinical applicability.

Tumor cells can also be found in the CSF and occur in association with neoplasms of the brain or meninges. The cytopathological identification of these cells requires the acquisition of large volumes of CSF (more than 20 ml) and the sample should be brought immediately to the laboratory to minimize cell lysis and morphological changes. Serial LPs may be necessary to obtain positive cytological results. In a study of the usefulness of CSF cytology and autopsy, Glass and co-workers reported that 26 percent of patients with metastatic brain tumors had positive CSF cytology.^[35] In another study, the cytological examination of the CSF identified metastatic involvement of the meninges in 70 percent of cases.^[36] The detection of other CSF markers may be useful for the diagnosis of primary or metastatic malignancies including astroprotein (glioblastoma), carcinoembryonic antigen (carcinomas), beta-2-microglobulin (lymphoblastic leukemia and lymphoma), alpha-fetoprotein (germ cell tumors), chorionic gonadotropin (choriocarcinoma and testicular tumors), and ferritin (carcinomas).^[37]

Finally, it is possible to measure a wide variety of enzymes in the CSF, although few are clinically important and most are not routinely obtained. An elevated lactate dehydrogenase (LDH) may occur in bacterial meningitis^[38] and cortical versus lacunar strokes.^[39] Elevated levels of CSF creatinine kinase-BB are also present in a wide variety of conditions that cause parenchymal damage. Lysozyme levels are increased in processes similar to those previously mentioned, whereas adenosine deaminase elevations can occur in tuberculous meningitis.^[38]

[PreviousNext](#)

INTRACRANIAL PRESSURE

Basic Principles

Intracranial hypertension may result from a wide variety of surgical and medical conditions. The association between elevated ICP and the potential for devastating brain stem herniation has been recognized for centuries. Because the skull is essentially a closed container, its contents have only limited compressibility. The intracranial contents are composed of three compartments: (1) the brain and interstitial fluid, which comprise approximately 80 percent of the intracranial space; (2) intravascular blood, which accounts for 10 percent of intracranial space; and (3) the CSF (in the ventricles and subarachnoid space), which comprises the final 10 percent. In order to maintain physiological ICP, an increase in volume of one compartment must lead to a compensatory decrease in the volume of

another compartment. As an example, diffuse cerebral edema causes an increase in the parenchymal and interstitial compartment that necessitates a compensatory decrease in the amount of blood or CSF (or both) in the intracranial space. Similarly, an increase in the CSF compartment (hydrocephalus) must lead to a decrease in the parenchymal or blood compartments.

The body is able to regulate and modify the diameter of brain arterial vasculature to maintain a relatively constant amount of blood flow over a range of systemic blood pressures that vary among patients ([Fig. 26-7](#)). This regulatory mechanism, termed autoregulation, allows the brain to regulate the flow of blood to meet its metabolic needs. Under normal conditions, the cerebral blood flow ranges between 50 and 60 ml per 100 gm brain per minute (approximately 700 to 850 ml blood/min for the whole brain) and accounts for about 20 percent of the total cardiac output. In patients with chronic hypertension, the graph is shifted to the right (see [Fig. 26-7](#)). The cerebral vasculature is innervated by cholinergic-, noradrenergic-, and neuropeptide-containing neurons; however, it is unlikely that these neurotransmitters contribute significantly to autoregulation, although they certainly contribute to cerebral blood flow. The control of autoregulation more likely arises from the intrinsic sensitivity of the vascular smooth muscle cells to tension across the vessel wall. Additionally, hydrogen ions also have effects on the vessels, and increases in their concentration result in dilatation. The precise role of the mechanisms involved in cerebral vasculature autoregulation under all conditions remains unclear.

Many of the diseases or syndromes that increase ICP do so by causing cerebral edema ([Table 26-5](#)). The pathophysiology of cerebral edema is based on one (or more) of three causes ([Table 26-6](#)). In vasogenic edema, an increase in capillary permeability occurs through the widening of tight junctions and increases in pinocytotic vesicles at the level of the blood-brain barrier. Because a disruption of the blood-brain barrier occurs with this disorder, MRI and CT studies administered with contrast typically demonstrate brain parenchymal enhancement. In cytotoxic edema, a swelling of the neurons, glia, and endothelial cells of the brain is present. Cytotoxic edema occurs in the setting of a decreased energy supply to brain cells (i.e., hypoxia) or osmotic disequilibrium (i.e., dialysis disequilibrium). The third type of cerebral edema occurs with hydrocephalus and results in an increase in interstitial fluid in the periventricular region. Through this mechanism, hydrocephalus raises ICP by increasing CSF volume and causing periventricular cerebral edema.

ICP Monitoring

Recording the ICP was initially performed through LPs in the 1890s by Quinke. Although the opening pressure is

Figure 26-7 This graph illustrates the approximate mean arterial pressures in which the brain is able to autoregulate blood flow (flat portion of graph). The hashed line illustrates the shift to the right in a person with chronic hypertension.

routinely measured at the time spinal taps are performed, this technique is not appropriate for long-term ICP monitoring.

Because clinical signs of elevated ICP, such as the Cushing response (systemic hypertension, bradycardia, and irregular respirations), [\[40\]](#) are usually a late finding

and may never even occur,^[41] it is important to directly measure ICP with an invasive device in appropriate settings. Furthermore, because increases in ICP may result in a decrease in cerebral perfusion pressure (CPP) if autoregulation fails, early intervention can be hastened by the direct measurement of ICP. Normal intracranial pressures range from approximately 10 to 20 cm H₂O (or about 5 to 15 mm Hg). Cerebral perfusion pressure is calculated by subtracting the ICP from the mean arterial pressure (MAP) (CPP = MAP - ICP). Cerebral vasculature autoregulation cannot maintain appropriate cerebral blood flow and perfusion at CPP levels below 50 mm Hg. Long-term ICP monitoring was initiated in the 1950s and 1960s with the introduction of ventricular catheterization. This procedure involves insertion of a sterile catheter into the lateral ventricle that is guided by either skull-based landmarks or through stereotactic placement. Once within the ventricle, CSF may be drained and the ICP can be monitored. The latter may be completed by either direct visualization of the height of the CSF column generated outside the body or through its measurement by an external transducer. Possible complications of the ventricular catheter include subdural, epidural, or intracerebral hematomas and infection. A risk of so-called upward herniation exists if an infratentorial mass is present and CSF is quickly removed from the supratentorial lateral ventricles. Other systems for the measurement of ICP do not involve direct entry into the ventricles. Collectively, these devices are termed intracranial bolts, although this is a misnomer, and historically, they consist of hollow screws that are inserted through the skull and extend into the subarachnoid space. After the placement of these devices, tubing filled with sterile saline is attached to the bolt and a pressure monitor. True bolts are rarely used today, yet multiple systems are available that may use a hollow screw-like device. These devices usually use a pressure transducer or a fiber-optic cable inserted through the hollow bolt that directly measures the pressure within the subdural or subarachnoid space or in the brain parenchyma. Compared with the ventriculostomy, the risk of hemorrhage and ventriculitis is lower with this procedure.

After the ICP monitoring device is inserted, a waveform may be generated. Because the ICP varies with both respirations and the cardiac cycle, positive deflections of 2 to 10 mm H₂O can be observed in a patient who is not receiving positive pressure ventilation immediately after systole and during exhalation. Maneuvers to test the function of the ICP monitor include asking patients to increase their intrathoracic pressure (by using the Valsalva technique), which causes an increase in the ICP. Alternatively, a modified Queckenstedt test may be performed in which the jugular veins are lightly compressed. Because this maneuver causes a decrease in the venous drainage from the brain, an increase in the ICP occurs, and if the intracranial compliance is low this is rapidly observed. Neither of these tests should be performed in patients with critically elevated ICP. In these patients, evidence for plateau waves (acute elevations in ICP [600 to 1300 mm H₂O] that last 5 to 20 minutes and then return to baseline) may be present.

TABLE 26-6 -- TYPES OF CEREBRAL EDEMA

	Vasogenic	Cytotoxic	Hydrocephalus
Pathogenesis	Increased capillary permeability	Cellular swelling	Increased intraventricular fluid
Location	White matter	Gray and white matter	Ventricular, periventricular white matter
Edema fluid	Plasma filtrate	Intracellular H ₂ O and sodium	Cerebrospinal fluid
Extracellular fluid volume	Increased	Decreased	Increased
Syndromes	Tumor, abscess, infarction, hemorrhage, lead encephalopathy, ischemia, meningitis	Hypoxia, osmolality, ischemia, meningitis, Reye's syndrome	Communicating and noncommunicating hydrocephalus

Adapted from Fishman RA: Cerebrospinal Fluid in Diseases of the Nervous System. Philadelphia, W.B. Saunders, 1992.

TABLE 26-7 -- TREATMENT OPTIONS FOR ELEVATED INTRACRANIAL PRESSURE

Treatment	Dose	Advantages	Limitations
Hypocarbica by hyperventilation	pCO ₂ 25 to 33 mm Hg RR 10 to 16/min	Immediate onset, well tolerated	Hypotension, barotrauma, duration usually hours or less
Osmotic	Mannitol 0.5 to 1 g/kg	Rapid onset, titratable, predictable	Hypotension, hypokalemia, duration hours or days
Barbiturates	Pentobarbital 1.5 mg/kg	Mutes BP and respiratory fluctuations	Hypotension, fixed pupils (small), duration days
Hemicraniectomy	Timing critical	Large sustained ICP reduction	Surgical risk, tissue herniation through wound

RR, respiratory rate.

These waves may represent an autoregulatory response to insufficient cerebral blood flow (secondary to elevated ICP) that produces vasodilatation, an increased cerebral blood flow, and, in turn, further elevations of the ICP.^[42] Because of the presumed underlying pathophysiology, the presence of plateau waves suggests a poor prognosis.

The clinical conditions for performing ICP monitoring or ventricular drainage are limited. In severe head trauma with diffuse intracerebral edema, ICP monitoring may aid in guiding therapeutic interventions; however, no randomized, controlled studies exist to determine if ICP monitoring affects long-term outcome. Other conditions that may require ICP monitoring to guide interventions include large intracranial hemorrhages or strokes, encephalitis or bacterial meningitis, acute and fulminant hepatic encephalopathy, intracranial tumors, and Reye's syndrome. In patients with normal pressure hydrocephalus, transient elevations in ICP (similar to plateau waves) may be present during rapid-eye-movement sleep, and documentation of these waves may aid in determining which patients could improve with shunting.

Treatment of Increased Intracranial Pressure

The treatment of increased ICP involves a few standard procedures ([Table 26-7](#)). Perhaps the easiest method for decreasing ICP is proper positioning of the patient and the avoidance of situations that can increase intrathoracic pressure. Placing the patient in an upright (or close to upright) position will lower ICP by promoting an increase in venous flow and will avoid compression of the jugular veins. Additionally, if high pressures associated with positive pressure ventilation are managed, increases in intracranial pressure can be reduced. The administration of intravenous mannitol or hyperventilation can quickly lower ICP in most patients, yet both procedures have possible adverse side effects and are not long lasting. Mannitol treatment may lead to dehydration or electrolyte imbalance as a result of its potent osmotic diuretic effect. The beneficial effects of hyperventilation are short lived because the body quickly compensates for the induced respiratory alkalosis by producing a metabolic acidosis. Theoretically, over-hyperventilation may also lead to significant vasoconstriction with associated cerebral ischemia. Corticosteroids are best used to treat increased ICP in the setting of vasogenic edema (see [Table 26-5](#)) such as occurs with brain tumors or abscesses and have little value in the setting of a patient with a stroke or head trauma. The management of blood pressure is also important in patients with an elevated ICP, because although lowering the systemic blood pressure can lower ICP, it may also lower CPP. Beta blockers or mixed beta and alpha blockers provide the best antihypertensive effects without causing significant cerebral vasodilatation that can lead to elevated ICP. Finally, in rare cases of hydrocephalus, direct drainage of CSF by ventriculostomy may be extremely useful.

27.1 HISTORY AND DEFINITIONS

Neuropsychology is the subspecialty of psychology that studies brain-behavior relationships. Neuropsychology is a diverse field that includes experimental neuropsychology, the study of brain-behavior relationships in nonhumans; cognitive neuropsychology, the study of normal cognition in humans; behavioral neuropsychology, which is the blending of behavioral theory and neuropsychological principles; and clinical neuropsychology, the study of brain-behavior relationships in humans. When physicians request neuropsychological testing for a patient, a clinical neuropsychologist will likely provide the assessment.

In most states, clinical neuropsychologists are licensed as clinical psychologists and have specialized training (both pre- and postdoctoral) in neuropsychology. The major role of clinical neuropsychologists is the assessment of cognitive function in individuals with known or suspected brain damage. Cognitive functions may be conceptualized as those processes by which an individual perceives both external and internal stimuli; selects pertinent stimuli and inhibits nonpertinent stimuli; records, retains, and recalls information; forms associations between stimuli and manipulates information in the pursuit of a goal; and outputs information through the expression of overt behavior. Clinical neuropsychology is based on the premise that assessments of these overt behaviors provide information about the functional integrity of the central nervous system.

The development of the science of neuropsychology is found in the works of Gall,^[1] Broca,^[2] James,^[3] Watson,^[4] Lashley,^[5] Goldstein,^[6] Halstead,^[7] and Luria.^[8] Early theories of the relationship between neurologic functioning and cognition proposed independent modules of function, demonstrated most clearly by the phrenologist Gall. According to this theory, specific brain regions, reflected by bumps on the skull, were associated with specific behavior. Watson's contributions to psychology in general, and neuropsychology specifically, led to an increased sensitivity to the need for empirical data to support theories of cognitive function, and the application of the scientific method to psychological studies. The work of Lashley and Goldstein led to a better understanding of the relationship between brain localization and behavior in neurologically healthy and neurologically damaged individuals. Halstead and Luria, through differing methods, clearly demonstrated that the assessment of overt behaviors could be used to identify brain damage with accuracy.

Although current understanding of the relationship between neuroanatomical structures and behavior rejects the skull-based tenets of phrenology, discovery of the neuroanatomical substrates of cognitive function remains a major goal of neuropsychology. It is hypothesized that cognitive function depends on both localized areas of specific functions as well as recursive connections between multiple brain areas that contribute, in toto, to cognition. In order to understand such a complex system, neuropsychology is a composite field of study integrating various disciplines including psychology, neurology, clinical neurosciences, psychiatry, statistics, and physiology.

The role of clinical neuropsychology is to elucidate the effects of brain damage on behavior, and to be able to account for the influences of other factors such as genetic, developmental, emotional, and experiential contributions on cognitive functioning. In order to accomplish this goal, neuropsychologists assess patients' cognitive function using behavioral tests. Two main approaches to neuropsychological assessment are typically used by clinicians: the quantitative approach, typified by standardized assessment techniques and comparison of individual performance measures against normative expectations, and the qualitative approach typified by in-depth analysis of individual performance characteristics using relatively standardized measures to elicit pathognomonic signs. Although these two approaches developed semi-independently, current practices

442

in clinical neuropsychology incorporate aspects of both.^[9] Not only do neuropsychologists use both quantitative and qualitative approaches to testing, they also test cognitive function in a multidimensional manner. For example, the assessment of verbal memory, a form of cognition, may be assessed by simply asking patients to remember a list of words. This approach to testing is inadequate by itself, however, since verbal memory is more complex than simply remembering lists of words. Therefore, assessment of verbal memory entails testing memory for lists of words, pairs of words, sentences, and short stories, using both immediate recall, delayed recall, and recognition paradigms. Such an assessment strategy provides enough data to fully analyze specific deficits in cognitive abilities that may be shared by multiple processes and allows for a finer discrimination of abilities and impairments.

The complexity and depth of knowledge about brain-behavior relationships are reflected in the vast number of volumes devoted to their description. This chapter provides an overview of adult clinical neuropsychology with the aim of assisting practitioners with the use and interpretation of neuropsychological data.

27.2 OVERVIEW OF TESTING

27.3 Purposes of Neuropsychological Examination

With the advent of modern structural imaging techniques such as computed axial tomographic imaging (CAT), and magnetic resonance imaging (MRI), and even newer functional imaging techniques such as positron emission tomography (PET) and functional magnetic resonance imaging (fMRI), the use of neuropsychological assessments to identify the location and type of CNS lesion has waned.^[1] However, because they identify and quantify both cognitive strengths and deficits, neuropsychological assessments are widely used in current neurological practice.^[2] Indeed, the Therapeutics and Technology Assessment Subcommittee of the American Academy of Neurology rated neuropsychological assessments as an established adjunct to neurological examinations.^[3] Most referrals for neuropsychological assessments are made in five specific domains: patient care, rehabilitation, educational planning, forensic issues, and treatment outcome analyses.

Patient Care. The largest number of referrals for neuropsychological assessments involve issues of patient care. Neuropsychological examinations are particularly informative for conditions in which neuroimaging results and other laboratory findings are not informative. For example, testing is often requested to assess the CNS effects of toxic exposure, mild head injury, dementing conditions, and in differentiating psychiatric conditions from neurologic illnesses. Neuropsychological data can provide valuable information for the identification of these processes as well as the extent of resultant CNS damage.

Neuropsychological examinations may also be used to characterize the patient's current levels of cognitive and emotional functioning in association with a known or suspected CNS process. Often these data are used to monitor changes in the patient's neuropsychological status across repeated examinations,^[4] so the effect of various treatment interventions on cognitive abilities can be assessed. Additionally, since neuropsychological assessments provide detailed information on both intact and impaired abilities, these assessments are useful for providing medical staff and family caregivers information on the patient's strengths as well as deficits. This information is particularly helpful in coordinated efforts to help the patient and family adjust to a given condition and make plans.

A newer application of neuropsychological examinations to neurologic care is the use of screening examinations. In contrast to a full neuropsychological examination, which typically requires from 3 to 12 hours of testing, screening examinations usually require less than 1 hour. A typical screening examination will test functioning in attention, orientation, short-term and long-term memory, expressive and receptive language abilities, abstract reasoning, and intelligence. Although these shorter examinations do not provide the depth of information that a full neuropsychological examination provides, they still provide basic information on the integrity of each of these abilities.^[5] The data from screening examinations are particularly helpful in identifying patients in need of full examinations.

Another purpose of neuropsychological assessment in patient care situations is to assist in the differentiation of psychiatric from neurological illnesses. Often a patient will present with a neurological complaint that does not clearly follow accepted pathophysiological principles. The presentation may be as obvious as functional blindness, but can be as subtle as memory loss owing to severe depression. Neuropsychologists are able to use their training in clinical psychology as well as their knowledge of neurological systems to aid in identifying these conditions.

Rehabilitation. With the increase in cognitive rehabilitative programs for patients with CNS damage, neuropsychologists help to identify patients who can benefit from such efforts, document cognitive abilities in need of rehabilitation, provide goals for therapy, develop individual rehabilitation plans, and track the efficacy of rehabilitative interventions. Neuropsychological assessments are particularly well-suited to address these issues and are a cost-effective addition to rehabilitative efforts.^[6]

Educational Planning. As with other psychological assessments, neuropsychological assessments can provide important information for educational planning, especially for children. Documentation of basic intellectual abilities helps determine appropriate classroom placement (e.g., enriched environment, special education) for school-age children. Such tests also aid in the identification of children with severe intellectual deficits, such as mental retardation. Differences between intellectual ability and academic achievement are used in the identification of specific learning disabilities. In neurological conditions like Gilles de la Tourette's syndrome, neuropsychological assessments can be an integral component to individual educational plans by identifying strengths and weaknesses in academic abilities, as well as indicating co-morbid conditions like attention deficit disorder, hyperactivity, and obsessive-compulsive behaviors.

Forensic Issues. Neuropsychological assessments are used to document the presence and extent of cognitive

impairments following accidents or injury. Levels of present functioning can be compared with estimates of pre-morbid functioning to assign a monetary value to present and future lost abilities.

Treatment Outcomes Research. Neuropsychologists are trained in research designs and methods. With this knowledge they are able to assist in the design, implementation, and analysis of clinical research projects. They are often asked to apply their knowledge of cognitive assessment to suggest outcome measures, which may include standard neuropsychological tests or experimental measures. One example of this is quality of life measures, which are the increasing focus of clinical drug trials and neurosurgical interventions in neurological illness.

27.4 Integration with Neurological Examination

Neuropsychological assessments are ancillary to the typical neurological examination, and establish better precision of the type and extent of cognitive and behavioral deficits found on bedside testing. To accomplish this goal, neuropsychological tests need to be standardized, valid and reliable, and need to make meaningful comparisons of patient-derived data to normative performance.

Standardization of neuropsychological testing procedures allows for the comparison of performance across time and across individuals. Because the interpretation of neuropsychological tests requires consistent assessment methods, neuropsychological tests are standardized to testing environment, presentation of instructions, presentation of testing stimuli, seeking clarification of response from the patient, scoring procedures, and interpretative methods. Standard testing methods provide all patients with an equal opportunity to perform the required task.

Another important aspect to neuropsychological assessment is the use of reliable and valid tests. Reliability refers to the degree to which a given test score represents differences in the behavior of interest as opposed to error. Reliability measures include the degree to which a test provides consistent scores across different time points (test-retest reliability); the degree to which a test provides consistent scores across different examiners (inter-rater reliability); the degree to which the test is internally consistent (split-half reliability); and the degree to which a test provides consistent score across alternate forms of the test (alternate-form reliability).^[7] A valid test is one that measures what it is purported to measure. This aspect of test development and utilization depends upon many factors. Validity measures include the degree to which the items of the test cover the relevant domain of interest but not other domains (content validity); the degree to which the test agrees with either a gold standard of the domain of interest or another test designed to measure the same domain (concurrent validity); the degree to which a test does *not* agree with another test designed to measure a different domain (discriminant validity); and the degree to which a test measures the theoretical construct under study (e.g., intelligence) (construct validity).

The relationship between reliability and validity is statistically constrained. Validity scores cannot exceed the square of reliability scores. Thus, a test can be highly reliable but not valid, but a test can never be valid and not reliable. One way to increase reliability of a given test is the use of standardized testing methods, as discussed above. If the manner in which a test is administered varies across examiners or across testing sessions, extraneous error is introduced, which lowers reliability and validity.

The ability to make meaningful comparisons of an individual patient's performance to normative expectations is constrained by how test performance is interpreted. Neuropsychological assessments are usually requested to identify and quantify some form of cognitive impairment. Thus, neuropsychological tests are designed to assess deficits in performance.^[8] In order to assess impairments, there must be some knowledge of normal expectancies of performance. Thus, testing results must have a referent for comparison, either individual comparisons or normative comparison groups.

Individual comparisons of test performance are the most obvious method for identification of deficits. In individual comparisons previous data from a patient are used to compare with present performance. Thus, if a patient demonstrated above-average performance on a test of verbal memory prior to developing herpes simplex

encephalitis, but performed at the below-average range of performance on the same test following the illness, one could conclude that a decline in verbal memory had occurred. In reality such a situation rarely occurs because neuropsychological data are usually not available from the period prior to disease or trauma. Even when such data are available there are other possible explanations for the decline in performance. If for any reason the scoring on the first or second exam is incorrect, scores are artificially inflated or minimized. Again, standardization of testing methods and concerted efforts to eliminate testing bias help to reduce this occurrence.

A second referent for neuropsychological test performance interpretation is the population-based comparison. This method is most frequently used in neuropsychological assessment and involves the comparison of individual patients' test scores to *norms* that detail performance on the measure of interest by a standardization sample. A relative ranking of the individual's score can then be determined according to the performance of the normative sample. A norm is constructed by sampling a large number of individuals, called the standardization sample, on the measure of interest. The standardization sample should be representative of the population of interest. Thus, if one wishes to develop norms for adult performance on a measure of general intelligence, the standardization sample must include individuals from all relevant age ranges, gender distributions, and educational strata. The norms provided for the Wechsler Adult Intelligence Scale-Revised (WAIS-R)^[16] are an example of such a procedure. The authors of this test gathered a random sample of 1880 adults from four geographic regions of the United States, stratified for age, gender, ethnic background, occupation, education, and urban versus rural residence according to U.S. census data. The test was administered to these individuals, providing a range of performance measures. Thus, the standardization sample is reflective of adults residing in the United States

Figure 27.2.4-1 The normal distribution is approached when many scores of a given test are collected from a random sample. This distribution is symmetrically shaped with common measures of central tendency (mean, median, mode) and equal variance (sd = standard deviation) on either side. The percentages of cases falling within each standard deviation are presented between the dashed lines. The ranking of any single score may be represented by standard deviation units, z score units, or percentile ranking.

at the time of testing, and the norms of WAIS-R performance are reflective of this population.

Random sampling is required for the development of most norms, because a random sample, stratified for pertinent variables, is one of the assumptions of a normal distribution. Sampling theory states that large, random samples of test scores will approach a normal distribution as the sample size approaches infinity. The characteristics of a normal distribution are particularly well-suited to norm development (Fig. 27-1). In a normal distribution the measures of central tendency (mean, median, mode) are unitary and the dispersion of scores (standard deviation) on either side of mean is symmetrical. The shape of a normal distribution has been called a bell-shape curve because it peaks in the middle and trails off as you approach either tail. The characteristics of a normal distribution allow the ranking of average performance. Approximately 68 percent of all cases (or WAIS-R scores in our example) fall within one standard deviation of the mean, and approximately 95 percent of all cases fall within two standard deviations of the mean. This characteristic allows for a meaningful comparison of an individual's score to the standardization sample. Therefore, one can express an individual's performance in terms of standard deviations away from the mean of the standardization sample; z- scores, which represent the individual's score minus the mean of the standardization sample divided by the standard deviation of the standardization sample; or a percentile ranking based on the standardization sample. In most neuropsychological assessments, one of these methods of ranking an individual's performance will be reported.

Comparison of an individual's performance to these norms then provides a meaningful yardstick to identify strengths and weaknesses. If someone is performing above the mean of the standardization sample, that performance is above average for the population. Such a comparison scheme is very helpful in tracking patients' abilities and disabilities. It does, however, raise the question of whether lower than average performance really equals impaired performance. Since the standardization sample assumes normal distributional properties, the probability of occurrence of any score can be calculated. In most clinical neuropsychological assessments, performance is defined as impaired when the probability of obtaining a score that low or lower in the standardization sample is less than 5 percent. This corresponds to the standard level of significance used in most statistical analyses.

Since the standardization sample is used to interpret individual test performance, an important consideration in all neuropsychological assessments is the adequacy of the sample. Even with well-normed tests such as the WAIS-R, care needs to be exercised when comparing specific individuals with the standardization sample. For example, the standardization sample for the WAIS-R has adequate representation of individuals up to the age of 75, but does not provide any normative information for individuals over the age of 75. Thus, if the performance on a 90- year-old patient on the WAIS-R is compared with this standardization sample the results may not truly reflect the performance of all 90-year-old persons.

Many other tests used in neuropsychological assessments have much more limited standardization samples, and as such may be subject to erroneous interpretations. The interpretation of many neuropsychological tests is based on standardization samples of less than 100 scores. Heaton and colleagues^[17] have attempted to generate better norms for many commonly used neuropsychological tests. Their efforts have surely led to improved interpretative methods.

However, even this effort suffers from a lack of generalizability to the populations of interest. This is because the standardization samples they used were not randomly selected but rather were composed of volunteers from limited geographic regions. Therefore, it is important for the consumer of neuropsychological assessment results to be aware of how the interpretations are made and the norms used in those interpretations.

27.5 Hierarchy of Testing Functions

A given cognitive function is usually composed of multiple discrete functions. Memory performance is affected not only by the ability to recognize and recall stimuli but also by the ability to perceive those stimuli, process and store them, and finally reproduce them in an observable fashion. Most neuropsychologists approach patient assessment using a general hierarchy of functions involved in cognition.

The primary components of this hierarchy are the perception of stimuli, ability to attend to the stimuli, and the ability to generate some form of response. In consideration of these issues, one of the first cognitive functions to be tested in almost all examination formats is level of consciousness (Chapter 1). If a patient is comatose there is little need to conduct neuropsychological testing. Testing of sensory systems (usually visual, auditory, tactile, and proprioceptive) is also conducted to ensure adequate stimuli processing. Finally, in order to assess a patient, a competent effector system that enables responding must be present. Therefore, testing of basic motor, vocal, and praxis abilities is conducted. If deficits are noted in any of these basic abilities, the neuropsychologist uses that information in the interpretation of other cognitive tests to increase or decrease confidence in those results. Once these three levels of abilities have been tested, testing of higher cognitive functions (such as intelligence, reasoning, language) can begin.

27.6 Testing Batteries Versus Individualized Testing

There are two basic approaches to testing methods in neuropsychological assessments: the use of comprehensive testing batteries or the use of individualized testing. Each approach has its strengths and weaknesses, and most neuropsychologists use a combination of these two approaches to capitalize on the strengths and minimize the weaknesses.

THE BATTERY APPROACH

Neuropsychological testing batteries provide a structured approach to the assessment of cognitive function. Although there are many neuropsychological testing batteries, two batteries are most commonly used: the Halstead-Reitan Battery^[18] and the Luria-Nebraska Neuropsychological Battery.^[19] The Halstead-Reitan Battery is a collection of tests that Halstead found to discriminate normal individuals from patients with organic brain disease. The core of the Halstead-Reitan Battery includes six tests developed by the authors (measuring abstract reasoning, tactile performance, tactile/visual-spatial memory, rhythm perception and memory, speech-sound perception, and primary motor speed) and seven tests developed by other individuals (measuring intelligence, psychomotor speed, sequencing abilities, language function, sensory function, grip strength, and personality functioning). The entire battery requires at least 6 hours for administration, not including scoring and interpretation, so testing often requires multiple visits. The original standardization sample for the development of the Halstead-Reitan Battery norms were inadequate. Recently, new norms have been generated using a larger and perhaps more representative standardization sample.^[17] The Halstead-Reitan Battery appears to be adequate in discriminating brain-damaged individuals from neurologically healthy individuals, but is not sensitive to mild cognitive impairment or to precise localization. Despite these limitations, the Halstead-Reitan Battery is the most commonly used neuropsychological assessment battery.

The Luria-Nebraska Neuropsychological Battery^[19] developed out of the extensive investigations of behavioral neurology conducted by the Russian neurologist Luria and the work of Christensen,^[20] who brought Luria's theories and methods of neuropsychological testing to America. The battery uses selected Luria test items that best discriminate brain-damaged patients from neurologically healthy individuals. It consists of 269 individual items that are scored on a zero (no impairment) to 2 (impairment) scale. The test items are simple and complex commands and problems, such as motor commands and arithmetic. The 269 items are composed of 11 clinical/ability scales measuring motor abilities, rhythm sense and reproduction, tactile abilities, visual abilities, receptive speech, expressive speech, writing, reading, arithmetic abilities, memory function, and intelligence. Three additional scales provide information as to the presence of pathognomonic signs, left hemisphere damage, and right hemisphere damage. Administration of the Luria-Nebraska Neuropsychological Battery is approximately 2 to 3 hours (substantially less than the Halstead- Reitan Battery).

Although authors of the Luria-Nebraska Neuropsychological Battery have published numerous articles in support of its reliability and validity, other investigators have not been able to replicate these results.^[21] The inadequate validity and reliability of the Luria-Nebraska Neuropsychological Battery are owing primarily to the lack of any theoretical model used in its development. Whereas the strength of Luria's original work was his ability to generate hypotheses about brain-behavior relationships and methods to tests these hypotheses, the developers of the Luria-Nebraska Neuropsychological Battery were unable to emulate this strength.

INDIVIDUALIZED TESTING APPROACH

The main advantage to the battery approach is that it allows for the collection of massive amounts of information on the status of cognitive functioning in a highly standardized manner. This advantage is contrasted with numerous disadvantages: the time required for a complete assessment is often excessive and fatigues the patient; the batteries

often include assessment measures that are not necessary for a given patient, and, conversely, the batteries do not provide comprehensive assessments of all cognitive functions. By recognizing these limitations, most neuropsychologists use an individualized approach to testing.

An individualized approach allows the neuropsychologist to use pertinent information to guide test selection. For example, if neuropsychological assessment is requested for a patient with diagnosed Alzheimer's disease, the neuropsychologist knows that trying to complete a Halstead-Reitan Battery would not only be unfair to the patient but would also provide little useful information. Instead, the examiner may choose to use a number of shorter tests with lower performance ranges to allow for extremely low scores. Using this approach, the neuropsychologist chooses tests (either from existing batteries or tests designed to assess specific deficits) that assess cognitive functions relevant to a given patient. Thus, examination time is shortened, and the specificity of the testing results is increased. Inevitably, however, the selection of tests introduces a certain bias, and some domains of good or bad function may be missed.

Neuropsychologists have a vast array of tests from which to choose when using the individualized approach. Over 700 tests of cognitive functioning are available, assessing such complex functions as intelligence and such basic functions as primary motor speed. Although a detailed description of all of these neuropsychological tests is well beyond the scope of this chapter, the next section provides a brief description of the most commonly used tests and their role in assessing specific cognitive domains. This review is limited to the most commonly used tests in neuropsychological assessments of adults.

27.9 NEUROPSYCHOLOGICAL TESTS

27.10 Orientation, Attention, and Vigilance

Impairments in orientation, attention, and vigilance are common sequelae to brain damage, and regardless of the localization of brain pathology, these abilities are often compromised. When a patient is disoriented and unable to attend to ongoing events, there is usually severe pathology. In addition, inability to attend to ongoing stimuli makes the interpretation of neuropsychological tests of higher cognitive functions, such as intelligence or memory, difficult. Therefore, the assessment of orientation, attention, and vigilance is an integral part of all neuropsychological assessments and usually is performed first.

ORIENTATION TESTS: PERSONAL, TEMPORAL, AND SPATIAL

Standard bedside mental status examinations always assess orientation to person, time, and place. Usually this information is gathered from interviewing the patient in an open manner, and is not part of a standardized test. Many tests of cognitive function include questions assessing orientation, although they may not provide selective scores for orientation. Specific tests with orientation questions, or tests designed to assess orientation, are listed here.

Mini-Mental Status Examination (MMSE).^[22] The MMSE includes questions that assess orientation to time ("What is today's date?" "Month?" "Day of the week?" "Year?") and orientation to place ("Where are you now?" "What state are you in?" "County?" "City?" "What is the name of this place?"). Each item is scored as pass or fail. Although the orientation section of the MMSE does not provide a separate score, a failure of two or more items is reflective of impaired performance.

Wechsler Memory Scale-Revised (WMS-R).^[22] Although the majority of this test's items assess memory function, there is a subset of questions assessing orientation to person, place, and time. Failure of two or more items is considered impaired.

Temporal Orientation Test (TOT).^[24] The TOT is designed to specifically assess orientation to time. The questions include knowledge of current hour and minutes, date, day of the week, month, and year. Errors are assigned negative scores depending on the amount of disorientation. The error score is subtracted from 100 and any score less than 95 is reflective of impaired performance.

Money Road Map Test (MRMT).^[25] The MRMT assesses the ability of the patient to identify left and right directions at different orientations. The patient views a map on which the examiner traces a route. At each turn, the patient has to identify whether the examiner made a left or right turn. In order to correctly perform this test, patients must be able to mentally reorient to the perspective of the examiner and to different orientations of the route. If a patient makes more than 10 errors (out of 32 turns) his or her performance is considered impaired.

Finger Localization Test.^[26] This test of personal orientation requires the patient to identify which finger has been stimulated by the examiner under visual guidance, and in the absence of visual input. A variant of this test is found in the Halstead-Reitan Battery, which assigns numbers to each finger of each hand, and requires the patient to identify which hand and which finger number has been stimulated in the absence of visual input.

Left-Right Orientation Test.^[27] This test of left-right orientation requires the patient to display lateralized body parts (e.g., "show me your left hand"), identify laterality of the examiner's body (e.g., "point to my left hand"), and touch lateralized body parts of the examiner (e.g., "touch my left hand"). In order to correctly perform this task, the patient must be able to reverse personal orientation when confronted with identifying laterality of the examiner. The normative data for this test are very limited, but a cutoff score of four errors is suggestive of impaired left-right orientation.

MENTAL STATUS TESTS

Mental status tests are used to assess overall level of cognitive functioning. These tests are brief to administer and not very comprehensive. They tend to include a few questions on orientation, attention, memory, language, and sometimes praxis. Although mental status testing provides basic information on the integrity of most cognitive functions, the tests tend to lack sensitivity to detect mild cognitive impairment. In addition, most tests of mental status do not have normative data, so the effects of various demographic

variables (e.g., age, gender, education) are not known. Despite these limitations, the tests provide useful information, and some form of mental status testing should be a part of all neuropsychological assessments.

Mini-Mental Status Examination (MMSE).^[22] In addition to the orientation questions listed above, the MMSE includes items assessing registration of information, recall of three words, attention and sequencing abilities (serial sevens, or spell word backward), naming, repetition, following spoken commands, writing, and copying. The test provides a general summary of cognitive function, but does not assess any cognitive domain in depth. The maximum score for the MMSE is 30, and a cutoff score of 24 is considered to indicate impaired performance.

Although the MMSE is the most commonly used mental status test, it has a number of problems. First, one must accept the basic limitation of any screening exam. Since the test has a limited number of questions, adequate testing of cognitive function is not possible. Practically, however, the MMSE score is used as an indicator of intact or impaired performance. The cutoff score of 24 is associated with relatively high false-negative rates (test indicates absence of impairment when impairment is present) and relatively high false-positive rates (test indicates impairment when no impairment is present). Additionally, MMSE score is affected by education, race, and gender. Despite these limitations, the MMSE provides a "quick-and-dirty" assessment of overall cognitive function, and in most contexts a score of 22 or lower is considered an accurate mark of clinically significant cognitive impairment.

Mental Status Questionnaire (MSQ).^[28] The MSQ is composed of items assessing orientation to time and place and ability to name the current and past presidents of the United States. The maximum score of the MSQ is 10 errors, and individuals making more than 2 errors are considered moderately impaired. This cutoff score suffers from the same limitations as the MMSE.

Short-Portable Mental Status Questionnaire (SPMSQ).^[29] The advantage of the SPMSQ over the MMSE and MSQ is that normative data have been gathered to aid in interpreting performance. This represents a major advantage to the SPMSQ. However, the test still suffers from problems with false-positives and false-negatives (particularly in patients with mild cognitive impairment).

TESTS OF ATTENTION AND VIGILANCE

Testing attention involves assessment of the ability to attend to stimuli, the ability to focus attention on selected stimuli, and ability to inhibit attention to inappropriate stimuli. Tests of vigilance also require the active updating of information in an ongoing display requiring attention. All of these abilities are essential to intact cognitive function. Information on attention and vigilance should be reported in all neuropsychological assessments

Simple Reaction Time (SRT). SRT tasks require the patient to respond, as quickly as possible, to a stimulus. The time the patient takes to respond (RT) is usually measured in milliseconds. Slowed RT is one of the most sensitive measures of impaired cognitive functioning, but individual data are difficult to interpret owing to the large inter- and inpatient variability.

Choice Reaction Time (CRT). There are many measures of CRT, but all follow a basic paradigm: the patient is required to respond to one stimulus but to not respond to another. An example of this is the Continuous Performance Test, in which the patient is asked to respond, as quickly as possible, to a rare stimulus that is embedded in a stream of ongoing similar stimuli. These tests assess the patient's ability to maintain attention and vigilance for the target stimulus and the ability to inhibit responses to the nontarget stimuli. Individual differences are difficult to interpret owing to large inter- and inpatient variability.

Span Tests. Tests of span capacity are a more standard form of assessing attention and vigilance than reaction time measures. In addition to assessing attention, span tests also require some form of short-term memory. However, forward span tests (discussed below) are thought to be more reflective of attentional abilities. When backward span (repeating a sequence heard in the reverse order of presentation) is used, different cognitive processes are required, including working (or

short-term) memory, so that the test is no longer a pure measure of attention.

The most commonly used span measures are the Digit Span tests from the WAIS-R and the Wechsler Memory Scale-Revised (WMS-R).^[23] In these tests, patients listen to random sequences of numbers presented in increasing length, and immediately repeat each sequence. Two trials at each span length are presented, and maximum span is the number of digits the patient can correctly repeat on at least one trial. Average performance on this measure is considered to be between five and nine digits.^[30] A variant of this task uses letters instead of digits. The interpretation of letter span performance is nearly identical to digit span performance.

Both digit and letter span are measures of verbal ability. A nonverbal span measure is the Corsi Block Test.^[31] In this test the patient is presented with an array of nine blocks arranged in a random order. The examiner touches blocks in sequences of increasing length. The patient is required to reproduce the sequence at each length. As in the digit span test, two trials are given at each sequence length and maximum span is the number of blocks the patient taps in the correct order on at least one trial. Average performance on this test is similar to digit span.

Attention/Concentration Subtest of the WMS-R.^[23] One subtest of the WMS-R (discussed below) is the Attention/Concentration Index. This composite measure of attention and concentration includes test performance on digit span, visual span (a variant of the Corsi Block Test), and three measures of speeded performance. One major advantage to the use of this measure is that it has good normative information (see WMS-R description later) and is converted to age-adjusted standard scores with a mean of 100 and a standard deviation of 15. The use of these standard scores allows for comparisons across many different neuropsychological tests (e.g., WAIS-R).

Paced Auditory Serial Addition Test (PASAT).^[32] The PASAT is a test requiring attention and vigilance. In this test, the patient listens to a tape recording of digits presented one at a time. The task for the patient is to add each number to the one immediately preceding it. For example, the recording might present the numbers 1, 7, 5, 4. The patient adds the first two numbers (1 + 7) and

responds with the number 8. The patient then adds the second two numbers (7 + 5) and responds with the number 12. The patient then adds the third two numbers (5 + 4) and responds with the number 9. This continues for a total of 61 numbers presented in a random order. The test can be given at different rates of presentation ranging from a slow rate of one number every 2.4 seconds to the fastest rate of one number every 1.2 seconds. This test assesses attention and vigilance because the patient is required to not only attend to the relevant stimuli (numbers) but also be vigilant to changes in the ongoing presentation. This is an extremely sensitive measure of vigilance. However, the test also involves working or short-term memory because the patient must "hold" in short-term memory the preceding number while formulating a response. Although this is a sensitive test, the norms for interpretation are limited.

Digit Symbol.^[16] This subtest of the WAIS-R presents the patient with a row of numbers one through nine, each paired with nonsense symbols (e.g., inverted T). Below this key are empty boxes with numbers above each box. The patient is required to transcribe the symbol corresponding to the number above the box as quickly as possible. This measure requires focused attention and switching behavior between the key and the target boxes. One advantage of this test is the extensive WAIS-R norms available on performance expectations. This test also requires motoric speed and may not be appropriate for patients with marked motor impairment. A variant of this test is available that requires a verbal response only, thus decreasing motoric demands.^[33]

Trail Making Test.^[34] There are two forms to this test: Trail Making Tests A and B. Trail Making Test A provides an assessment of complex attention. This test requires the patient to connect randomly positioned numbered circles in numeric order as quickly as possible. Form B presents the patient with numbered circles and circles with letters. The patient is required to connect the circles in numeric and alphabetic order as quickly as possible, alternating between numbers and letters. Both Forms A and B require focused attention for successful performance. In addition, Form B requires the patient to switch cognitive sets between numbers and letters. Both forms of the Trail Making Test are highly dependent upon motoric speed, and may not be appropriate for patients with marked motor impairment (e.g., Parkinson's disease).

Cancellation Tests. Another useful test of attention and vigilance is that which requires the patient to seek a selected stimulus out of a background of similar stimuli. One such measure is the Letter Cancellation Test^[35] where the patient is required to cancel selected letters, designs, or words from a background of nontarget letters, designs, or words. Because cancellation tasks are timed measures requiring motoric responses, they may not be appropriate for patients who have marked motor impairment.

CLINICAL SITUATIONS FOR TESTING ORIENTATION, ATTENTION, AND VIGILANCE

Neuropsychological data on orientation, attention, and vigilance abilities are useful in defining dysfunction in all levels of neurological functioning. Such tests are particularly useful in cases of toxic and metabolic abnormalities (see [Chapter 38](#) and [Chapter 39](#)), which affect level of consciousness (see [Chapter 1](#)), sleep/wake cycles (see [Chapter 2](#)), and memory functioning (see [Chapter 5](#)). In addition, attentional testing is essential for patients who evidence neglect or dyspraxia (see [Chapter 4](#)). Useful information on patients with psychiatric presentations is also provided when attention is assessed ([Chapter 3](#)). When requesting neuropsychological assessment of orientation, attention, and vigilance, it is important to request testing on all aspects of attention and vigilance including simple attention, focused attention, and set-shifting.

27.15 Intellectual Abilities

Intelligence is considered to be the culmination of cognitive abilities. The testing of intelligence involves assessments of attention, reasoning, memory, language, perception, and construction. Intelligence tests should provide an overview of cognitive function integrity. Most tests of intelligence do not adequately assess all cognitive abilities, however.

INTELLIGENCE QUOTIENTS

These tests are the current gold standard in intelligence testing and include the Wechsler Adult Intelligence Scale- Revised (WAIS-R), Wechsler Intelligence Scale for Children-III (WISC-III), and Wechsler Preschool and Primary Scale of Intelligence-Revised (WPPSI-R).^[16],^[36],^[37] Each Wechsler test is used for different age ranges: the WPPSI-R test is for ages 3 years to 7 years and 3 months; the WISC- III test is for ages 6 years to 16 years 11 months; and the WAIS-R test is for ages 16 years to 74 years 11 months. Because the different Wechsler tests are similar in construction, interpretation, and psychometric concerns (standardization, norms, reliability), only the WAIS-R will be discussed.

In keeping with the idea that intelligence is the culmination of cognitive function, the WAIS-R is composed of different subtests, each assessing different cognitive functions ([Table 27-1](#)). Because of this, you will find the various subtests listed under different subheadings in this chapter. In addition, since the WAIS-R assesses many different cognitive functions, it is often the framework for neuropsychological assessment, and provides an overview of the integrity of cognitive abilities. Results for subtest performance often guide further (and more extensive) testing of selected functions.

The WAIS-R provides three summary measures: Verbal IQ, Performance IQ, and a Full Scale IQ. The IQ score represents an age-adjusted scaling of an individual's intellectual performance. This provides a standard measure that can be compared across individual patients or within a given patient over chronological age. Due to the extensive norms for the WAIS-R (discussed above) these measures may be generalized to the population of the United States. The Wechsler tests have been translated into many different languages, and adequate norms exist for most of these modifications. The characteristics of the standardization

TABLE 27.9.15-27 -- SUBTESTS OF THE WECHSLER ADULT INTELLIGENCE TEST-REVISED AND COGNITIVE FUNCTIONS THEY ASSESS

Wechsler Adult Intelligence Scale-Revised	
Verbal Scales (Verbal IQ)	Cognitive Function Assessed
Information	General fund of information

Digit span	Attention/concentration Short-term memory
Vocabulary	Vocabulary knowledge Semantic memory
Arithmetic	Attention/concentration Executive function Processing speed Calculations
Comprehension	Reasoning, problem solving, concept formation Executive formation
Similarities	Reasoning, problem solving, concept formation Executive function
Performance Scales (Performance IQ)	Cognitive Function Assessed
Picture completion	Reasoning, problem solving, concept formation Executive function Processing speed
Picture arrangement	Reasoning, problem solving, concept formation Executive function (sequencing) Processing speed
Block design	Construction Praxis Spatial reasoning Motor function Processing speed
Object assembly	Construction Praxis Spatial reasoning Motor Function Processing speed
Digit symbol	Attention/concentration Executive function (sequencing) Motor function Processing speed

Sum of Verbal IQ and Performance IQ constitutes Full Scale IQ.

sample of IQ scores (Verbal, Performance, and Full Scale) are a mean performance of 100, with a standard deviation of 15. In addition, individual subtest performance can be converted to standard scores with associated variability. Thus, the clinician is able to classify individual performance for both summary IQ measures and individual subtest performance against these values and provide a relative ranking of performance.

The summary IQ scores are extremely useful in educational settings. They are highly correlated with educational attainment in adults (with an approximate correlation of .79), and are often used to predict academic abilities in children. Although these scores are useful, care needs to be exercised in their use. Because IQ scores represent the culmination of cognitive abilities, they are extremely susceptible to brain damage. The presence of a potentially reversible impairment in one of the basic elements of cognitive function (e.g., attention/vigilance) will provide artificially low IQ performance. Therefore, IQ scores need to be interpreted in the context of a complete neuropsychological examination.

One particularly difficult issue in intellectual performance is the diagnosis of profound intellectual impairments, or mental retardation. First, this diagnosis has major consequences for an individual. Once assigned with the label of mental retardate, educational and occupational opportunities are limited. The individual is guided away from mainstream educational settings and provided with specialized training. Second, there are no universally accepted diagnostic criteria for mental retardation. The usual criterion is IQ performance greater than two standard deviations below the mean (e.g., an IQ score of less than 70 on the WAIS-R). Because the performance level for mental retardation is so low, however, statistical reliability of the standardization sample is also low. As seen in [Figure 27-1](#), as the scores decrease (or increase) toward the tail of the distribution, the number of sample scores drops dramatically. The representativeness of cases at these extreme levels is limited and hence it is problematic to generalize the results to the population of interest. Because of these issues, it is incumbent on the examiner to base the diagnosis of mental retardation on multiple assessments of intellectual performance and not on a single measure.

The use of IQ scores in neuropsychological assessments is limited to providing a basic measure of cognitive functional integrity. Comparison of Verbal IQ performance to Performance IQ performance has been suggested to provide an assessment of dominant (verbal) and nondominant (performance) hemispheric function. Actuarial studies of this Verbal IQ/Performance IQ comparison, however, have not supported its use in this capacity. Verbal IQ measures do provide some indication of dominant hemispheric integrity, but Performance IQ measures do not reliably indicate nondominant hemispheric integrity. This lack of reliability is due to basic differences between verbal and performance measures. Whereas most subscales comprising Verbal IQ are not timed, all Performance IQ subscales are. This difference adversely affects the Performance IQ scores of individuals with compromised motor and cognitive speed (e.g., patients with basal ganglia damage). In addition, there are basic differences in sensitivity to brain damage between verbal and performance subscales. The subtests of Verbal IQ tend to require overlearned abilities such as vocabulary knowledge and general information. These abilities are, in general, less affected by brain damage. The subtests of Performance IQ tend to require novel abilities, such as reproducing visual patterns using colored blocks. These abilities are, in general, more affected by brain damage. This difference between overlearned and novel abilities is evident in aging, and reflected in the performance of the standardization sample.

In contrast to the use of summary IQ scores for neuropsychological assessment, the analysis of subscale performance is very useful. As shown in [Table 27-1](#), each subscale assesses specific (and overlapping) cognitive abilities. The pattern of performance on the subtests can provide useful information in forming hypotheses as to possible impairment in various cognitive abilities. These hypotheses can then be tested with additional, more focused, assessments. The use of subscale performance patterns has resulted

in various interpretative methods for specific neuropsychological use.

PREMORBID ESTIMATES OF INTELLECTUAL FUNCTION

In order to provide useful information on general cognitive functioning, current measures of intelligence need to be compared with premorbid level of functioning. Because neuropsychological testing results are typically not available for the period prior to neurologic trauma, neuropsychologists are forced to estimate premorbid

abilities.^[39] There are three basic approaches to estimation of premorbid intellectual functioning: estimates derived from life history variables believed to be correlated with measures of cognitive functioning (e.g., years of education); measures of best current cognitive functioning, or "present abilities," which are used to estimate a minimum level of premorbid functioning; and comparison of an individual's test results to population-based estimates of normal performance (norm-based comparisons as discussed above). Each of these approaches has associated error that needs to be considered in the interpretation of neuropsychological testing data.

The first method, estimates based on life history variables, offers a potential wealth of information that is thought to be related to the cognitive performance. Estimates derived from life history variables may include basic demographic information such as age, education, and gender but may also include information from developmental history, medical history, occupational history, and academic history. The application of these data to an estimate of premorbid functioning can be accomplished in either qualitative or quantitative methods. The qualitative approach allows the examiner to form a "best-guess" of premorbid functioning.^[39] For example, the estimated premorbid functioning for an individual with a normal developmental history, outstanding academic history, a college degree, and an occupational attainment of CEO of a major corporation would be higher than an individual with a normal developmental history, poor academic history, a high school diploma, and an occupational attainment of sales clerk. Although this information may be helpful, it does not provide an actual estimate of premorbid functioning.

The quantitative approach to the use of life history information typically uses demographic information such as age, education, and gender to provide an estimate of the range of premorbid test scores for a given individual.^{[40], [41]} This approach is useful because specific ranges of test scores may be generated to be compared with current scores, but typically does not take full advantage of nonquantifiable information such as developmental and medical history.

The second method of estimating premorbid cognitive abilities, the "present abilities" approach, uses current test scores to provide a lower-bound estimate of prior functioning. The theory underlying this approach is that neurologic damage does not affect all cognitive abilities equally and that an individual's highest test score on current testing is most likely to reflect intact performance. Therefore, that highest test score can be used to provide an estimate of overall premorbid cognitive functioning. For example, if an individual is scoring at the below average range of performance on tests of verbal memory, verbal comprehension, and verbal fluency but is performing at the average range on a test of visual-spatial skills and nonverbal reasoning, the examiner may assume that the individual was performing at least at the average range on all measures. Of course, this estimate is only meant to provide an interpretative guide, as other explanations for a given pattern of intact and impaired performance are possible.

A more standardized method than the "present abilities" approach for estimating premorbid IQ is found in tests such as the National Adult Reading Test (NART)^[42] and its variants. These tests rely on current performance of reading ability or vocabulary knowledge to estimate premorbid abilities. Both reading ability (particularly reading of phonically irregular words such as *debt*) and vocabulary knowledge tend to be less affected by brain damage than other cognitive abilities. By using these abilities to estimate premorbid IQ, the examiner is able to get an estimate of a lower-bound to previous IQ.^[43] All of these approaches to premorbid IQ estimation are subject to many caveats. First, the range of scores provided by the quantitative approaches is limited. With these measures, it is not possible to get very high or very low IQ estimates. Second, these approaches overestimate low IQ performance and underestimate high IQ performance. Third, each approach is associated with differing levels of statistical error, usually measured as the standard error of estimate. For example, the quantitative approaches have standard errors ranging between 7 and 16 points. Since the standard deviation of IQ is 15 points, these estimates can at best provide a range of possible scores equal to or greater than one standard deviation. Therefore, extreme care needs to be applied to the use of these estimates. Most neuropsychologists will use a combination of quantitative and qualitative approaches to the estimation of premorbid IQ.

OTHER INTELLIGENCE TESTS

The Wechsler scales are not the only method for the assessment of intellectual abilities. Due to space limitations we cannot list all tests of intelligence. However, other tests of intellectual abilities tend to follow two different assessment methods: tests of verbal abilities and tests of nonverbal abstraction. The first method, testing of verbal abilities, is represented by tests such as the Peabody Picture Vocabulary Test-Revised (discussed in the section on Perception and Construction Abilities), in which patients are asked to choose which of four pictures best identifies a spoken word. This method is based on the high correlation between vocabulary knowledge and IQ.^[44] The second method, tests of nonverbal abstraction, is represented by the Raven's Progressive Matrices test (discussed in the section on Reasoning and Problem Solving Through Concept Formation), in which patients must abstract general principles and rules from patterns. This method tends to correlate well with the Full Scale IQ from the Wechsler scales.

TESTS OF ACADEMIC ACHIEVEMENT

Tests of academic achievement typically assess standard academic skills such as reading, writing, arithmetic skills,

and spelling. The scores derived from these measures provide important information on neuropsychological and educational abilities. They allow comparisons of an individual patient's educational development to normative expectations. They also help identify specific areas in need of remediation. Finally, academic achievement tests provide important information in the diagnosing of specific learning disabilities. The presence of learning disabilities is suggested when there is a large discrepancy between measures of intellectual ability and measures of academic achievement. Additional testing is required to formally assign a diagnosis of learning disabilities. The most commonly used tests of academic achievement are the Peabody Individual Achievement Test-Revised (PIAT-R)^[45] and the Wide Range Achievement Test-Revised (WRAT-R).^[46] Both of these tests assess reading, arithmetic, and spelling. The PIAT-R has additional scales assessing the patient's fund of general information and reading recognition. Both tests provide information as to an individual patient's academic achievement in terms of grade level, standard score, and standing.

CLINICAL SITUATIONS FOR TESTS OF INTELLECTUAL ABILITIES

Intellectual assessment is very important for patients presenting with impairments of higher cognitive functioning such as memory, language, and reasoning. Because these higher cognitive functions are highly correlated with intelligence, intelligence assessment allows the examiner to interpret scores of memory, language, and reasoning performance in light of basic intellectual abilities. Intellectual assessments are not particularly helpful in patients with disturbances in level of consciousness (see [Chapter 1](#)), disrupted sleep/wake cycles (see [Chapter 2](#)), or neglect and dyspraxia (see [Chapter 4](#)). Additionally, the comparison of intellectual abilities and academic achievement is helpful in identifying patients who may have learning disabilities. In children with developmental or neurodegenerative disorders affecting the cortex or subcortex (see [Chapters 28](#), [33](#), and [34](#)) and those with chromosome alterations, enzyme defects, or storage abnormalities (see [Chapters 30](#), [31](#), and [32](#)), these assessments help in tailoring educational efforts and expectations. When intelligence testing is requested, the referring physician should ask for a reporting of subscale performance as well as summary IQ scores.

27.21 Reasoning and Problem Solving Through Concept Formation

Reasoning and problem solving are highly related to intellectual functioning. Similar to intellectual function, these abilities tend to be impaired following damage to the CNS. Specific location of injury appears to be less important to reasoning impairments, as does the presence of CNS disturbance. Impairments in reasoning and problem solving result in difficulties in all areas of daily functioning. Patients may not be able to form generalizations from a given situation and interpret events concretely. Tests of reasoning and conceptualization usually assess verbal or nonverbal abilities.

TESTS OF VERBAL REASONING AND CONCEPT FORMATION

Comprehension.^[16] This subtest of the WAIS-R is a test of verbal conceptualization. Patients are required to answer questions or interpret proverbs that require problem solving (e.g., "What does 'a rolling stone gathers no moss' mean?"). Scoring is based on partial credit on most items for concrete responses and full credit on responses reflecting abstraction of general principles. One advantage of this test is the extensive WAIS-R norms available on performance expectations.

Similarities.^[16] This subtest of the WAIS-R requires the patient to identify the common elements between seemingly uncommon stimuli. The test begins with simple problems (e.g., "How are an orange and banana alike?"), and progress to more difficult problems (e.g., "How are praise and punishment alike?"). Scoring awards full credit for complete abstractions, partial credit for concrete responses, and no credit for incorrect responses. One advantage of this test is the extensive normative data from the WAIS-R standardization sample.

Arithmetic.^[18] This subtest of the WAIS-R presents the patient with progressively more difficult arithmetic word problems. The test is timed so the patient must attempt to complete each problem as quickly as possible. In addition, bonus points are given for some of the difficult problems when the patient responds very quickly. Since this test is a subtest of the WAIS-R, it benefits from extensive normative data.

TESTS OF NONVERBAL REASONING AND CONCEPT FORMATION

Category Test.^[18] The Category Test is part of the Halstead-Reitan Battery and tests visual concept formation. In this test, patients see slides with four stimuli and are required to identify the concept presented on each slide. The principle remains the same in each of six different sets of slides, but changes between sets. A final set of slides presents pictures viewed in previous sets as a test of memory for the solution. This test can be very frustrating for patient and examiner alike, but is one of the more sensitive measures in the Halstead-Reitan Battery.

Raven's Progressive Matrices.^[47] These tests (Coloured Progressive Matrices, Standard Progressive Matrices, and Advanced Progressive Matrices) measure visual concept formation and problem solving. Patients are presented with multiple designs that are linked by a common conceptual pattern. The final design is missing, and the patient must choose which of six to eight alternative final designs is correct. The range of abilities this test assesses is very large, from the concrete to extremely abstract. Extensive normative data are available for British norms, and adequate norms are available for U.S. norms.

Wisconsin Card Sorting Test (WCST).^[48] This test of visual concept formation adds cognitive set-shifting to concept formation. Patients are presented with four "target" cards with simple colored designs that can be sorted by three concepts. The patients match probe cards with identical colored design to the target cards according to whatever concept they generate. The only feedback to the

patient after each trial is whether his or her response is correct. The order of sorting concept is fixed, but unbeknown to the patient, changes after a set number of correct responses. Thus, patients must be able to switch the concept they were using for the previous trials.

CLINICAL SITUATIONS FOR TESTS OF REASONING AND PROBLEM SOLVING THROUGH CONCEPT FORMATION

Because reasoning and problem-solving abilities are closely associated with intellectual functioning, testing should be requested in those situations that require intelligence testing.

27.25 Verbal Function

Disturbances in language function are one of the most noticeable impairments in cognitive abilities. They can be the result of generalized cognitive deterioration, as in dementing conditions (see [Chapter 33](#)), or confusional states (see [Chapters 38](#), [39](#), [40](#), and [55](#)). Likewise, they may be due to specific lesions, as in transcortical aphasia (see [Chapter 6](#)) or psychiatric conditions (see [Chapter 3](#)), as in psychotic word salad or neologisms. Most assessments of verbal function include testing of expressive abilities (spontaneous speech, naming, repetition of words and phrases, writing) and receptive abilities (comprehension of speech, comprehension of written material).

APHASIA BATTERIES (see [Chapter 6](#))

Boston Diagnostic Aphasia Examination (BDAE).^[49] This battery is a comprehensive assessment of verbal function. It provides information on 12 areas of language abilities using 34 subscales. Assessments include verbal comprehension, written comprehension, writing to dictation, naming, articulation, spontaneous speech, repetition, reading, following simple and complex commands, speech fluency, and prosody. The test provides an overall severity rating score and a profile of subtest performance. This test is very useful in providing a comprehensive assessment of verbal function, but because of the number of items, testing time is quite long. Therefore, this battery is mostly used for specific diagnosis and rehabilitative planning of aphasic patients. Because of scoring and normative information, separate subtests can be given independently for a more focused (and shorter) examination of specific areas of verbal function.

Multilingual Aphasia Examination (MAE).^[50] This test is similar to the BDAE in that it provides a comprehensive assessment of language function. The administration time is shorter, however. MAE tests were taken from the Neurosensory Center Comprehensive Examination for Aphasia. An advantage to the MAE is that alternate forms are provided, so repeated testing can be conducted without contamination of practice effects. Subtests of the MAE can also be given independently of the complete battery.

Neurosensory Center Comprehensive Examination for Aphasia (NCCEA).^[51] This battery provides detailed assessments of reading, writing, articulation, visual abilities, and tactile abilities. The battery has 20 subtests measuring visual naming, description of use of objects, tactile naming, digit repetition forward and backward, sentence construction, identification of objects, oral reading for single words and sentences, visual naming of objects, written naming of objects, writing to dictation, writing from copy, and articulation. In addition, four "control tests" are provided. These tests are given if the patient makes errors on the tactile naming, visual naming, or reading tests. Extensive norms are provided for each subtest, so they may be used independently. Administration time is usually under 2 hours, which makes this battery practical in everyday clinical use.

APHASIA SCREENING TESTS

Because most aphasia batteries require extensive time for administration, screening measures have been developed. These screening tests have variable reliability, sensitivity, and specificity to language impairments.

Aphasia Screening Test.^[18] This test is part of the Halstead-Reitan Battery and is composed of 32 items testing reading, articulation, spelling, repetition, naming, calculations, and construction. Administration time is brief (approximately 15 to 30 minutes). Each ability is tested with one or two items, so the range of abilities is not great. In addition, studies of the diagnostic utility of this test have been disappointing.^[52]

The Token Test.^[53] This test is extremely sensitive to impairments in verbal functions. It does not provide specific information as to type of verbal disturbance, however. The patient is presented with tokens of different shapes (i.e., circles, squares, triangles), sizes, and colors. The patient is required to perform certain acts with the tokens, such as point to selected tokens, touch them, pick them up, and place one token on top of another. Administration and scoring are very simple and the testing time is brief (approximately 15 minutes). Because this test requires comprehension of detailed information, it is sensitive to patients with disturbances of attention and vigilance. This test is particularly useful in identifying the presence of verbal function disturbances and whether additional, more detailed testing is required.

INDIVIDUAL TESTS OF VERBAL SKILLS

The most commonly used individual tests of verbal skills come from the batteries discussed above. Because of the common use of these individual tests, a few will be presented below.

Naming Test.^[50] This test comes from the MAE. Patients are required to name common and uncommon objects depicted in line drawings.

Boston Naming Test.^[54] This naming test is not part of any battery, but is often added to the BDAE. Patients are required to name 60 objects depicted in line drawings. The objects range from simple and common objects such as a tree to complex and uncommon objects such as an abacus. If a patient is unable to name an object, he or she is given a phonemic cue and a semantic cue.

Controlled Oral Word Association Test.^[50] This test measures verbal fluency and comes from the MAE. Patients are required to generate as many words as possible, as quickly as possible, to a given letter. Proper nouns, numbers, and the plural form of a produced word are not allowed. The patient is given three 1-minute trials using three different letters. A variant of this test also requires the patient to generate exemplars from different categories (e.g, four-legged animals, things found in a grocery store, parts of a building).

Sentence Repetition.^[50] This test is part of the MAE and requires the patient to repeat spoken sentences. The first item is simple, composed of three syllables, and the last item is complex, composed of 24 syllables. In addition to testing repetition, this test assesses verbal memory.

CLINICAL SITUATIONS FOR TESTS OF VERBAL FUNCTION

Assessment of language function is necessary for all neuropsychological examinations. Not only do these tests provide information about verbal function, they also assess basic skills needed to complete other neuropsychological tests. Usually, requests for administration of aphasia batteries are limited to patients with documented verbal impairments. Screening tests or individual tests of naming, comprehension, verbal fluency, repetition, reading, and writing should be requested for all referrals. In the assessment of patients with vascular disease (see [Chapter 22](#) and [Chapter 45](#)), cortical developmental (see [Chapter 28](#) and [Chapter 30](#)), or degenerative processes (see [Chapters 31 32 33 34 35](#)), language testing can help in identifying deficits and tracking verbal decline or improvement.

27.30 Memory (See [Chapters 5](#) and [33](#))

The ability to record, retain, and reproduce information constitutes memory functioning. Memory is not a unitary phenomenon, however. There are different forms of memory ([Table 27-2](#)) including memory requiring awareness (explicit memory) as well as memory that occurs in the absence of awareness (implicit memory) (see [Chapter 5](#)). All standard clinical assessments of memory test explicit memory. Even within explicit memory there are different forms. Semantic memory represents the ability to learn information about the world in general. Episodic memory represents memories that are tied to specific episodes. For example, the knowledge that a bicycle has two wheels, pedals, a seat, and handlebars represents semantic memory; it is not possible to identify when this information was acquired. The memory of the first time one rode a bicycle is an example of episodic memory; the events surrounding that first ride are part of the memory trace. Most clinical neuropsychological tests of memory test a combination of semantic and episodic explicit memory. There are many different memory tests, both batteries and tests of single abilities.

Wechsler Memory Scale-Revised (WMS-R).^[23] The WMS-R is a memory assessment battery composed of 13 subtests (see [Table 27-2](#)). The 13 subtests include

TABLE 27.9.30-2 -- SUBTESTS OF THE WECHSLER MEMORY SCALE-REVISED THAT FORM THE SUBSCALES AND THE MEMORY FUNCTIONS THEY ASSESS

Wechsler Memory Scale-Revised	
SUBSCALES	Cognitive Function Assessed
Verbal Memory Index	
Logical memory I	Verbal long-term memory Verbal learning Executive function (?)
Verbal paired associates I	Verbal long-term memory Verbal learning
Visual Memory Index	Cognitive Function Assessed
Figural memory	Nonverbal long-term memory Nonverbal learning
Visual paired associates I	Nonverbal long-term memory Nonverbal learning
Visual reproduction I	Nonverbal long-term memory Nonverbal learning Construction
Attention/Concentration Index	Cognitive Function Assessed
Mental control	Attention/concentration Processing speed Calculations
Digit span	Attention/concentration Verbal short-term memory
Visual memory span	Attention/concentration Spatial short-term memory
Delayed Recall	Cognitive Function Assessed
Logical memory 11	Verbal delayed memory Verbal learning Executive function (?)
Verbal paired associates 11	Verbal delayed memory Verbal learning
Visual paired associates II	Nonverbal delayed memory Nonverbal learning
Visual reproduction II	Nonverbal delayed memory Nonverbal learning Construction

The sum of Verbal Memory Index and Visual Memory Index form the General Memory Index.

- Information/Orientation
assessing general personal information and orientation to person, place, and time;
- Mental Control
assessing speeded performance for reciting the alphabet, counting backward, and counting forward by three's;
- Figural Memory
assessing memory for nonverbal designs;
- Logical Memory I
assessing recall of a story presented orally;

Verbal Paired Associates I
assessing recall memory for the second words of pairs that had been previously learned;
Visual Paired Associates I
assessing recall memory for color-design pairs that had been previously learned;
Visual Reproduction I
assessing ability to reproduce difficult-to-verbalize designs after a brief exposure;
Digit Span
assessing forward and backward digit span;
Visual Memory Span
assessing ability to reproduce increasingly longer spatially separated sequences of taps made by the examiner;
Logical Memory II
assessing ability to recall information from the stories in Logical Memory II after a 30-minute delay;

Visual Paired Associates II
assessing ability to recall associations from Visual Paired Associates I after a 30- minute delay;
Verbal Paired Associates II
assessing ability to recall associations from Verbal Paired Associates I after a 30- minute delay; and
Visual Reproduction II
assessing ability to recall the designs presented in Visual Reproduction I after a 30- minute delay.

Twelve of these subtests (all except Information/Orientation) contribute to five indices, namely Verbal Memory Index, Visual Memory Index, General Memory Index, Attention/Concentration Index, and Delayed Memory Index. The standardization sample for the WMS-R follows the same method as that used in the WAIS-R (although with a smaller standardization sample size), so good normative data are provided for each subtest as well as the index scores. Although this test is well normed, there are some limitations to the interpretations of the index scores. First, the nonverbal measures (visual paired associate learning, visual reproduction, figural memory, and visual memory span) are easy to encode verbally. In addition, factor analytic studies have consistently identified only three factors. The first, and most reliable, factor is composed of the items from the Attention/Concentration Index. The second and third factors appear to be composed of items for immediate memory and delayed memory. Therefore, confidence that the Visual Memory Index measures nonverbal memory is decreased. Despite these limitations the WMS-R still provides extremely useful information on memory abilities.

Rey Auditory Verbal Learning Test (RAVLT).^[56] This test of verbal memory presents the patient with multiple trials of learning a list of 10 words. Following each presentation of the study list, the patient is asked to recall as many words as possible. Following the fifth repetition of this study list, a new study list is introduced followed by a recall trial. Following this recall, the patient is asked to recall as many of the words from the first list as possible. Finally, a recognition test is given if delayed recall is defective. This test provides information on immediate verbal memory, rate of learning, occurrence of retroactive and proactive interference, delayed recall, and recognition.

California Verbal Learning Test (CVLT).^[56] This variant of the RAVLT increases the number of words on each list to 16 and uses words from four categories of foods. The testing procedure is also modified to provide a cued recall where the categories are provided to the patient to aid recall.

Rey-Osterrieth Complex Figure.^[57] In this nonverbal test of memory, patients are presented with a difficult-to- verbalize complex line drawing. They are first asked to copy the figure, with no mention of being required to remember the design for later recall. After a brief delay (approximately 3 minutes) the patient is asked to reproduce the design. Delayed memory is tested again in 30 minutes. One potential difficulty with this test is that most of the elements that make up the complex design can be assigned a verbal label (e.g., a square on top of a triangle with a flag on top), so some verbal memory contamination can occur. This difficulty is common to most nonverbal tests of cognitive abilities.

CLINICAL SITUATIONS FOR MEMORY TESTS

Because memory is a basic ability of higher cognitive function, some assessment of memory ability should be conducted for most patients. Memory assessment is particularly important for patients with suspected dementing illnesses (see [Chapter 33](#)), toxic and metabolic conditions (see [Chapters 38](#) , [39](#) , [40](#) , and [55](#)), and possible depression (see [Chapter 3](#)). When requesting memory assessment, information on form of memory tested should be provided.

27.32 Perception and Construction Abilities

The ability to perceive stimuli is one of the basic requirements for the assessment of cognitive function. Therefore, tests of visual, auditory, and tactile perception are common in neuropsychological assessments. Certain alterations in perception, such as neglect, are diagnostically informative.

VISUAL PERCEPTION AND CONSTRUCTION

Tests of visual perception typically assess color perception, object recognition, visual organizational abilities, visual scanning, and differentiation of figure from ground. Most neuropsychological assessments will assess color perception informally. The Color Vision Screening Inventory ^[58] is occasionally used by examiners, however. This test provides a screening measure of color blindness.

Peabody Picture Vocabulary Test-Revised.^[59] This test is discussed in the section on Tests of Verbal Function; it can be used to assess ability to visually recognize objects.

Benton Facial Recognition Test.^[60] This test of visual object recognition uses faces as stimuli. Patients are presented with a target face on one page and six faces on the adjacent page. One of the six faces matches the target face. The test progresses in difficulty from easy (a duplicate of the target face is presented in the six faces) to hard (the matching face differs from the target face in orientation and lighting). Since both the target and matching face are seen together, memory requirements are minimized.

Judgment of Line Orientation (JLO).^[61] This test assesses ability to match lines of different orientation to target lines. Difficulty increases on this test by varying the length of the matching lines. Since both target and matching lines are seen together, memory requirements are minimized.

Hooper Visual Organization Test (HVOT).^[62] This test presents the patient with 30 easily recognized objects that have been decomposed into parts and randomized. The patient is required to identify each object. Successful performance on this test requires the patient to mentally reorganize the decomposed images into the complete shape. There have been a number of normative studies of performance on the HVOT, but none is fully adequate.

Picture Arrangement.^[63] This subtest of the WAIS-R requires the patient to rearrange a series of pictures that, when placed in the correct order, tell a story. One advantage of this test is the extensive normative data generated for the WAIS-R.

Letter Cancellation Test.^[35] This visual scanning test is discussed in the section on Tests of Attention and Vigilance. When systematic errors occur on this test, such that the patient completes only one side of the page, the possibility of visual neglect is raised.

Line Bisection Test.^[63] This test presents the patient with lines drawn in different locations on a page. The patient is required to draw a perpendicular line through the lines on the page. Visual scanning is required to locate all the lines on the page. As with the cancellation tests, if systematic errors occur, where the patient does not

bisect the line on one side of the page, the possibility of visual neglect is raised.

Embedded Figures Test.^[64] This test differentiates figure from ground and consists of 16 line drawings of figures on one page, and a complex figure that contains the target figure and overlapping figures. The patient is required to trace the target figure in the complex figure. Scoring is on a pass-fail basis, with extra credit given for fast performance.

Rey-Osterrieth Complex Figure.^[57] This test of visual construction is discussed in the section on Memory. Information on visual construction can be found from performance on the copy portion of this test.

Clock Drawing Test.^[65] This test of visual construction in which the patient is required to draw a clock with all the numbers and "set" the clock at 20 minutes to four o'clock. Clock drawing has been a part of bedside mental status testing for a long time, but scoring had been somewhat arbitrary. The addition of explicit scoring criteria has improved interpretation.

Developmental Test of Visual-Motor Integration (VMI).^[66] This visual construction test was originally developed for the assessment of children. It is also useful in assessing adult visual constructional abilities, however. The patient is required to copy 24 geometric designs ranging from simple (a single line) to complex. Adequate norms for children exist for this test, and its range of performance can be extended to adults.

Three-Dimensional Block Construction.^[67] This test assesses constructional abilities in three dimensions. Patients are presented with 29 blocks of different shapes in a prearranged order. A model is shown to the patient, who is told to use some or all of the blocks to re-create the model. In all, three models are presented to the patient. A maximum of 5 minutes is allowed to complete each model. Adequate norms exist for this test.

AUDITORY PERCEPTION

Auditory perception is tested for acuity, perception of organized sounds, and rhythms.

Sensory Examination.^[18] This test is part of the Halstead-Reitan Battery and assesses auditory perception to single and simultaneous stimulations. The examiner stands behind the patient and gently rubs two fingers together next to each ear. This tests auditory perceptual problems in each ear, and also the presence of extinction to double- simultaneous stimulation.

Speech-Sound Perception Test.^[18] This test is part of the Halstead-Reitan Battery. Patients listen to 60 nonsense syllables on a tape and must choose among four options of printed versions of the sounds. One problem with this test is that individuals who have high-frequency hearing loss tend to perform poorly.

Seashore Rhythm Test.^[18] This test is part of the Halstead-Reitan Battery. Patients listen to two sets of tape- recorded rhythms and are required to judge whether the rhythms are the same or different. The test includes easy items with a few beats and complex items with many beats. Because the patient must remember the first rhythm and must attend to rapidly changing stimuli, this test also measures memory and attention.

TACTILE ABILITIES

Testing of tactile abilities in most neuropsychological assessments is limited to the hands. This information is particularly important for assessing the effects of tactile deficits on test performance.

Sensory Examination.^[18] This test is part of the Halstead-Reitan Battery. The tactile ability assessment includes Fingertip Number Writing, where the examiner traces a number on each finger and asks the patient to report the number without visual guidance, and Tactile Finger Recognition (discussed in the section on Tests of Attention and Vigilance), where the patient must identify which finger has been touched by the examiner without visual guidance.

Face-Hand Test.^{[18], [68]} This is a test of single and simultaneous stimuli on either side of the patient's hand, face, or both. Information from this test is helpful in identifying the presence of tactile inattention.

Tactile Form Perception.^[69] This test requires the patient to recognize geometric forms placed in one hand hidden from view, and identify a drawing of the object in a multiple-choice format. Adequate norms are provided for this test. A variant of this test is found in the Halstead- Reitan Battery, which uses three-dimensional forms and requests verbal responses as opposed to multiple-choice responses.

CLINICAL SITUATIONS FOR TESTS OF PERCEPTION AND CONSTRUCTION ABILITIES

Assessment of perception and construction abilities is very important, not only to aid in diagnosis of inattention (neglect) and constructional apraxia, but also to assess the competency of basic skills required for adequate testing. Most of the tests presented also can assess attention and vigilance. Testing is appropriate for all patients except perhaps for those with alterations in level of consciousness (see [Chapter 1](#)), or dementia (see [Chapter 33](#)).

27.37 Executive Function and Motor Performance

EXECUTIVE FUNCTION

Traditionally, executive functions have been ascribed to the frontal lobes. They involve the ability to assess ongoing stimuli for relevance to specific goals, the formation of goals, planning action to achieve goals, ability to evaluate

plans for efficacy, and executing plans. According to this description, executive functions involve many processes associated with reasoning and intellectual performance. Indeed, the Digit Symbol subtest of the WAIS-R (discussed in the section on Tests of Attention and Vigilance), Category Test, Wisconsin Card Sorting Test, Raven's Progressive Matrices (all discussed in the section on Tests of Reasoning and Problem Solving Through Concept Formation), Rey- Osterrieth Complex Figure (discussed in the section on Memory), and tests of visual scanning (discussed in the section on Perception and Construction Abilities) can all be used to assess executive function. A few additional tests are listed below.

Proteus Mazes.^[70] This test of planning requires the patient to trace a path through progressive difficult mazes without entering any blind alleys. Scoring is based on number of errors (entering a blind alley) and on time to complete the mazes. Both of these measures have been found to be sensitive to patients with frontal-lobe damage.

Design Fluency.^[71] This test of mental flexibility requires the patient to create as many designs as possible that are not objects or shapes in 5 minutes. Next, the patient is required to make as many designs as possible using only four lines (straight or curved) in 4 minutes. Adequate norms exist for this test.

Stroop Word-Color Interference Test.^[72] This test of inhibition has three trials. The first trial requires the patient to read the color names printed in black ink as quickly as possible. On the second trial, the patient is required to name the color of colored dots as quickly as possible. The third trial requires the patient to name the color of ink of color name words. The color name does not match the color of the ink. Forty-five seconds are allowed for completion of each trial. Scores for each trial indicate the number of correct responses. An interference score can be generated, which quantifies the patient's ability to inhibit the inappropriate response of reading the color name as opposed to the color of ink used to print the name in the third trial.

MOTOR PERFORMANCE TESTS

Assessment of motor performance is particularly helpful in identifying integrity of each hemisphere and subtle motor performance. Tests of motor performance include

simple motor speed, strength, and complex motor/dexterity abilities.

Finger Tapping Test.^[73] This is a test of primary motor speed of the index finger of each hand. Patients tap a finger as quickly as possible for five consecutive 10-second trials. Because fatigue may affect performance, a rest period is given between each trial. Large differences between left and right finger speed may reflect lateralized hemispheric dysfunction. Adequate norms are available for this test.

Hand Dynamometer.^[18] This test measures grip strength in each hand. Patients are given three trials with each hand, the first considered practice. Large differences between left and right grip strength may reflect lateralized hemispheric dysfunction. Adequate norms are available for this test.

Purdue Pegboard Test.^[74] This test of finger dexterity requires patients to place pegs in vertically arranged holes. They perform the task using each hand separately and then using both hands. Each trial last 30 seconds. Large differences between left and right performance in comparison to performance using both hands may reflect lateralized hemispheric dysfunction. Adequate norms are available for this test.

CLINICAL SITUATIONS FOR TESTS OF EXECUTIVE FUNCTION AND MOTOR PERFORMANCE

Assessment of executive function is very important for patients presenting with impairments of higher cognitive functioning such as memory, language, and reasoning. Because these higher-cognitive functions are highly correlated with planning, inhibition of inappropriate responses, and goal execution, executive function assessment also aids the examiner in interpretation of tests assessing memory, language, intelligence, and reasoning performance. Assessment of executive function is also helpful in patients with disturbances in level of consciousness (see [Chapter 1](#)), disrupted sleep/wake cycles (see [Chapter 2](#)), and neglect and dyspraxia (see [Chapter 4](#)).

27.41 Emotional Functioning

Most assessments of emotional functioning are conducted during the interview with the patient. This information can be gathered in a standardized or nonstandardized format. Tests of emotional functioning ought to be used to generate hypotheses as to the presence of dysfunction with follow-up of these hypotheses occurring during the interview (see [Chapter 3](#)). There are two general formats to tests of emotional functioning: objective tests and projective tests. Only objective tests will be presented in this section.

Minnesota Multiphasic Personality Inventory-2 (MMPI-2).^[75] This self-report test is an objective measure of personality function composed of 567 true-false questions. The questions were chosen based on their ability to differentiate emotionally impaired individuals from nonimpaired individuals. The MMPI-2 has 10 clinical scales and 4 validity scales. Profiles of the clinical scales can suggest the presence of many different emotional disorders, ranging from mild depression to psychotic conditions. This test has acceptable norms, although the standardization sample was limited in racial diversity. Care needs to be exercised in the interpretation of the MMPI-2 when applied to patients with brain damage, because many of the symptoms elicited by MMPI-2 questions are common to neurological patients.

Beck Depression Inventory.^[76] This objective self-report measure assesses the presence of depressive symptoms experienced by the patient within the past week. It is composed of 21 questions. Each question is scored on a 4-point scale ranging from no impairment (0) to severe impairment (3). The maximum score is 63; a cutoff score indicative of mild depressive symptoms is greater than 10 and for severe depressive symptoms is greater than 30.

One problem with the use of the Beck Depression Inventory with brain-damaged patients is that many of the items reflect somatic concerns and social changes associated with neurologic damage.

Geriatric Depression Scale.^[77] This objective self-report measure of depression was designed for use in elderly patients. The test consists of 30 yes or no questions. A cutoff score of 13 is recommended as an indication of depression.

CLINICAL SITUATIONS FOR TESTS OF EMOTIONAL FUNCTION

The assessment of emotional functioning is important for three reasons. First, emotional disturbance often follows or accompanies CNS damage. Examples include cerebrovascular disease (see [Chapter 22](#) and [Chapter 45](#)), neurodegenerative disorders (see [Chapters 33](#), [34](#), [35](#), and [36](#)), and metabolic, nutritional and drug-induced encephalopathies (see [Chapters 38](#), [39](#), [40](#), and [55](#)). Not only do patients face adjustments to physical function, they also often must make social adjustments that can affect emotional functioning. Second, emotional disturbances can affect cognitive functioning. Although the diagnosis of pseudo-dementia, or dementia related to depression, does not appear to be real dementia, severe depression can cause impairments in attention, vigilance, and motivation, which may affect performance on memory tests. Third, assessment of emotional functioning is required to differentiate functional from neurological disorders.

27.43 PRACTICAL ISSUES

In order to serve the patient best, neuropsychological assessments need to be a cooperative effort between the neuropsychologist and the referring neurologist. The neurologist needs to be as specific as possible when formulating the referral questions. Any pertinent patient information, such as current and past medical status, current medications, brief description on the history of the present illness, and a brief review of physical and neurologic examination results should also be provided. This information helps guide the neuropsychologist in the selection of testing materials and approach to the patient. If testing is to be conducted in the hospital, the patient's schedule needs to include blocks of time when no other clinical tests are scheduled (e.g., radiology, discharge planning) so that the patient may be tested without interruptions and when maximally alert and attentive. The neuropsychologist needs to communicate with the neurologist before testing to discuss the assessment plan, including which cognitive abilities will be tested, the approximate length of testing, and when the neurologist can expect the written report. After the assessment is completed, but before submitting the written report, the neuropsychologist generally contacts the neurologist to provide preliminary feedback. The written report, delivered shortly thereafter, should be brief but complete, including a listing of the tests administered, some form of score report, usually a percentile or standard score for each test, a summary of the findings, and an interpretation of these findings. The brevity of the report depends on the nature of the referral and the questions the neurologist has posed.

This chapter focuses on the major structural malformations and associated problems related to the central nervous system (CNS) and surrounding structures. Although hydrocephalus is not a specific structural disorder, it is discussed in the first section because of the importance and frequency with which hydrocephalus occurs in many of the disorders that follow in the chapter. Furthermore, the evaluation and diagnosis of hydrocephalus plays a pivotal role in clinical management of many CNS malformations. Following hydrocephalus, disorders of development are discussed according to estimated gestational timing of the pathogenesis. Of course the developmental timing for many disorders is not known or only speculative, and therefore, disorders have also been grouped into major categories.

HYDROCEPHALUS

Hydrocephalus is one of the most common manifestations of developmental disorders. A fundamental understanding of the principles, evaluation, and management of congenital and neonatal hydrocephalus is essential for physicians involved in the care of infants with developmental structural disorders of the CNS. Hydrocephalus, in the strictest definition, denotes an increased volume of cerebrospinal fluid (CSF) within the skull, most frequently in the ventricles. Unfortunately the use of various definitions in a wide variety of clinical presentations and pathological abnormalities has resulted in confusion surrounding the definition and meaning of the term hydrocephalus. In this chapter, hydrocephalus is defined as an increase in the volume of CSF within the ventricular system independent of the actual head circumference. So-called normal-pressure hydrocephalus (NPH) is generally not considered a developmental anomaly and occurs mainly in adults; however, the condition is discussed in this chapter in order to complete the discussion of hydrocephalus in a homogenous context.

Developmental Hydrocephalus

Pathogenesis and Pathophysiology. In contrast to normal CSF physiology, which is discussed in [Chapter 26](#), hydrocephalus is the result of a disturbance in the normal CSF fluid dynamics. Two terms frequently used when discussing hydrocephalus are obstructive (noncommunicating) and nonobstructive (communicating) hydrocephalus. These terms were first coined by Harvey Cushing to describe the results of injection of air (pneumoencephalography) into the subarachnoid space or dye into the ventricles. If the air was found to move into the ventricles or the dye out to the subarachnoid space, the cause of the hydrocephalus was considered nonobstructive. If no communication between the spaces was found, the cause of the hydrocephalus was considered obstructive. These terms were used to help define the pathophysiological mechanisms underlying the hydrocephalus. Although it is conceptually appealing, the value of this distinction has been challenged, because increased pressure leading to hydrocephalus is virtually always a result of blockage, ^{1,2} whether it is along the

pathway of CSF flow or at the site of resorption. Overproduction of CSF, as reported in rare cases of choroid plexus papillomas, is not likely to represent a common, if even plausible, cause of hydrocephalus. Thus, the entities included in this section, with the exception of the destructive lesions, are discussed, when known, in reference to where the blockage occurs ([Table 28-1](#)).

Hydrocephalus associated with congenital malformations and disruptions of development is associated with flattened gyri and reduced sulci. If hydrocephalus develops in utero, the cerebral hemispheres may show an abnormal gyral pattern characterized by multiple complex small gyri. This abnormal gyration has been called microgyria, polygyria, or stenogyria. It is important to distinguish this gyral abnormality from polymicrogyria (see later). The primary basis for this distinction relies on the abnormal cortical lamination in polymicrogyria and the normal cortical cytoarchitecture in hydrocephalus-related gyral abnormalities. Of course, it is equally important to remember that true polymicrogyria and hydrocephalus may co-exist in certain malformations.

When hydrocephalus occurs as a function of increasing intracranial CSF fluid volume, intracranial pressure will begin to increase as well. In an attempt to relieve the increased intracranial pressure, the child's head circumference will begin increasing by widening of the sutures. Although the cranial sutures begin fusion by 2 years of age, they can often be split open if the intracranial pressure

TABLE 28-1 -- OVERVIEW OF THE DIFFERENTIAL DIAGNOSIS OF CONGENITAL HYDROCEPHALUS

Etiology	Specific Causes*	Mechanism of Hydrocephalus
Tumors	Most types, benign and malignant	Blockage of CSF pathway
Malformations	Many:	
	Chiari II malformation	Unknown
	Dandy-Walker syndrome	Unknown
	Aqueductal anomalies	Obstruction of CSF flow at the level of the cerebral aqueduct
	Forking/stenosis	
	X-linked hydrocephalus	
Infectious/postinfectious	Abscess	Obstruction by a mass lesion
	Meningitis/ventriculitis	Obstruction of CSF resorption and/or obstruction due to fusion of ventricular wall
	Congenital infections CMV	Adhesions and fusion of ventricular wall
	Toxoplasmosis	Ex vacuo or mass lesion
Vascular/hemorrhagic	Vascular malformation	Mass lesion of posthemorrhage
	Posthemorrhagic	
	Germinal matrix origin	Intraventricular blood obstructs CSF flow
	Choroid plexus origin	
Destructive secondary	Hydranencephaly	Ex vacuo
	Porencephaly	Ex vacuo
	Perinatal leukomalacia	Ex vacuo

*The entities listed are only a partial list and are not meant to reflect a complete differential diagnosis.

CMV, cytomegalovirus; CSF, cerebrospinal fluid.

rises before the age of complete skull ossification (8 to 10 years). At the same time, the fontanelles, if still open, will become tense and bulging. The majority of conditions that are discussed in this chapter result in hydrocephalus before fusion of the cranial sutures; thus, an enlarging head occurs concurrently with the hydrocephalus.

Clinical Features and Associated Findings. Signs and symptoms of postnatal hydrocephalus depend on the expandability of the skull. Before fusion of the sutures, the skull is able to expand, resulting in an enlarging head circumference and tense fontanelles. In addition to the finding of a tense or bulging fontanelle, the separation of sutures can give rise to the so-called cracked pot sound on percussion of the skull. The scalp veins may be prominent, especially frontally. The absolute head circumference cannot be used as a strict diagnostic guide. Instead, it is important to follow the growth of the head circumference over a brief period of time. Any crossing of percentiles over a few weeks is potentially relevant and requires urgent investigation. Clinical signs and symptoms may be minimal or completely absent. ³ When present, irritability, frequent crying, unexplained vomiting (especially in the morning), and persistent or increasing headaches may all signal hydrocephalus. Alternatively, there may be developmental delay, disinterest in the environment with a dull affect, endocrine dysfunction, unsteady gait, and increased tone in the legs. ⁴ In the newborn period, bradyarrhythmia and apneic spells may be the only clinical sign of overt hydrocephalus.

Ophthalmological signs often occur early and are important to recognize. Disturbances of extraocular movements include a supranuclear upgaze paresis underlying the setting-sun sign in infants. In this condition, the eyes appear driven downward and the white of the sclera is seen above the iris. This phenomenon is probably related to aqueductal distention with compression of periaqueductal structures, or by pressure on the quadrigeminal plate by a dilated third ventricular subpineal recess. Unilateral or bilateral abducens or trochlear nerve paresis can occur. Swelling of the optic nerve head (papilledema) occurs before closure of the sutures only with very rapidly progressive hydrocephalus. On the other hand, chronic and longstanding hydrocephalus can lead to optic atrophy, so that papilledema would no longer be apparent. In neonatal hydrocephalus, stretching of the optic radiations and cortices can also result in a clinical picture of cortical blindness. Another unusual neurological manifestation of hydrocephalus is the so-called bobble-head doll syndrome, in which the patient has rhythmical to-and-fro movements of the head in the upright position. It is related to obstructive lesions in and around the aqueduct as well as to cystic lesions of the third ventricle.

Longstanding untreated hydrocephalus has been associated with a neuropsychological profile referred to as the cocktail-party syndrome. ⁵ Characteristic manifestations include a fluent and profuse speech pattern that lacks content and is pragmatically deficient. Chronic hydrocephalus may also result in precocious

puberty. Earlier detection, primarily as a result of improved imaging of the CNS, along with advances in treatment and management, have resulted in these manifestations of chronic hydrocephalus being relatively rare.

A special case in the pathogenesis of hydrocephalus occurs in the case of familial aqueductal stenosis, most frequently inherited as an X-linked trait. Mutations in the gene for L1-CAM, a neuronal surface glycoprotein implicated in neuronal migration and axon fasciculation^[1] are identified in one form (linked to chromosome Xq28). How mutations in this gene result in aqueductal stenosis is unclear. In the case of Xq28-linked familial aqueductal stenosis, mental retardation, spastic paraparesis, and adducted thumbs in about 50 percent of affected males may become apparent later in life even without the presence of overt hydrocephalus.

Differential Diagnosis. Hydrocephalus does not necessarily imply an enlarged head, although an enlarged or enlarging head can be the presenting feature. The converse is also not necessarily true--an enlarged head (macrocephaly) is not always equivalent to hydrocephalus. Several metabolic, hamartomatous, and other genetic conditions can be associated with macrocephaly independent from hydrocephalus.^[2] Examples include Alexander's disease, Canavan's disease, several of the gangliosidoses, glutaricaciduria type I, neurofibromatosis type I, and several of the overgrowth syndromes such as Sotos' syndrome. If the brain itself is enlarged without a significant component of hydrocephalus, the term megalencephaly is appropriate. Malformations and disruptions with enlarged ventricles without CSF flow obstruction have to be differentiated by careful imaging. Holoprosencephaly and hydranencephaly provide examples. A special case is raised by the differential diagnosis of an isolated patient, often a newborn, with aqueductal stenosis. In the newborn, congenital infections, especially toxoplasmosis, must be considered, as does the possibility of preceding intracerebral hemorrhage. Space-occupying lesions around the midbrain, tectum, and pineal region have to be ruled out by appropriate imaging.

Evaluation. Fetuses and infants with hydrocephalus often have an increased head circumference, tense and bulging fontanelles, and widened sutures. Plain radiographs of the skull may show an irregular, shallow scalloping of the inner bone table.

The diagnosis of hydrocephalus relies on the application of neuroimaging techniques combined with the clinical features outlined in the beginning of this section.^[3] Although hydrocephalus is obvious on a computed tomographic (CT) scan or cranial ultrasound, precise anatomical definition of the level of blockage can best be achieved by magnetic resonance imaging (MRI). Assessment of the cerebral aqueduct in the sagittal plane, including evaluation of a CSF flow void through the aqueduct, is also possible via this technique. Evaluation must take into account whether the cranial sutures are open or closed. The ventricular size with an expandable skull versus a fixed-volume skull can be dramatically different even with an equal increase in intraventricular pressure. In the case of open sutures, even moderate increases in pressure can expand the ventricles enormously and the surrounding brain may appear compressed to a thin band. A dramatic reconstitution of the cerebral mantle may be seen after shunting, sometimes with reversion of some preexisting neurological deficits, in particular impaired visual function. On the other hand, in the fixed-volume skull, even enormously elevated intraventricular pressures may give rise to only moderate expansion of ventricular size, especially with so-called communicating hydrocephalus. On CT or MRI, transependymally extruded CSF in the periventricular white matter may be apparent.

Arrested, or inactive, hydrocephalus with apparently normal pressure measurements may pose a special problem for management decisions, because spot check measurements of CSF pressure by lumbar puncture may not accurately reflect chronic CSF dynamics. Longer continuous monitoring of intracranial pressure using an epidural or subepidural device has been advocated for such cases. Obviously, these investigations are not without risk for the patient and are not universally recommended. Meticulous attention to clinical details in order to decide whether or not the hydrocephalus is symptomatic should guide treatment decisions.

Early prenatal detection of hydrocephalus is possible. It should be kept in mind, however, that hydrocephalus may still develop after 16 to 18 weeks' gestation. Of paramount importance is the detection of additional CNS and extracerebral malformations, because these problems may significantly influence the prognosis (see later).

Management and Prognosis. Shunting of the CSF from the ventricles is the mainstay of therapy for hydrocephalus.^[4] The predominant shunt systems currently in use are ventriculoperitoneal shunting (VP) devices with pressure-controlled valves under the scalp, close to the burr hole. The major complications associated with shunt treatment can be broken down into mechanical problems, shunt-related infections, and functional problems. Signs of increased intracranial pressure with headache, lethargy, and vomiting are apparent in the case of shunt malfunction. Functional overshunting can also occur, albeit less frequently. Again, headache is the most common clinical symptom, but in contrast to the headache associated with increased intracranial pressure, headache resulting from overshunting tends to be relieved when the patient is placed in the recumbent position. Shunt infections are a serious complication and are most often caused by *Staphylococcus aureus*. Unexplained fever or frank meningitis usually is the presenting feature. The condition is treated with penicillinase-resistant antibiotics, but culturing the pathogen for determination of drug susceptibility should be attempted in all cases. Replacement of all hardware is frequently necessary. Abdominal complications of VP-shunting include peritonitis, perforation of an abdominal organ, peritoneal cysts, and the development of hydroceles in boys. Seizures, especially during the first year after shunting, occur in approximately 5.5 percent of patients. The incidence of developing seizures declines after the first year. In the Xq28-linked familial aqueductal stenosis, VP-shunting is indicated as well. Unfortunately, the development of mental retardation and spastic paraparesis appears to be independent of the ventricular dilatation per se and does not improve with the treatment.

Under certain circumstances such as neonatal posthemorrhagic hydrocephalus, in which some patients may show resolution of the hydrocephalus without intervention, temporizing measures may be useful. Daily lumbar punctures removing substantial amounts of CSF have been used and are under further clinical investigation. Possible pharmacological intervention consists of a combination of high-dose acetazolamide with furosemide, which can reduce CSF

production considerably. Careful monitoring for the development of nephrocalcinosis (a problem particularly in premature infants treated with this combination of drugs) and electrolyte imbalances is essential. The management of neonatal posthemorrhagic hydrocephalus is very complex and beyond the scope of this chapter (see reference 10 for a review).

The detection of a fetal ventriculomegaly by ultrasound has created a new problem in the management of hydrocephalus that requires insight into the natural history of fetal ventriculomegaly.^[5] The prognosis is strongly influenced by the co-existence of major neural and extraneural abnormalities. In one large series,^[6] 50 percent of diagnosed fetuses died in utero or the pregnancy was electively terminated, mainly because of the detection of major additional anomalies. From the remaining 50 percent, only a small percentage of fetuses were found to develop progressive ventriculomegaly in utero on follow-up investigations. These infants were shunted immediately after delivery and had relatively good outcomes. In an even smaller percentage of infants, the ventriculomegaly resolved, also with a favorable outcome. Of those who were unchanged on follow up in utero, a little more than half remained stable postnatally, their ultimate prognosis again being dependent on the presence of additional neural abnormalities. The other group developed postnatal progression of the hydrocephalus, requiring shunting. The outcome was good in the infants without additional anomalies. The same conclusion holds true for hydrocephalus detected at birth.^[7] Given the importance of additional anomalies for the ultimate prognosis, once fetal ventriculomegaly is identified, a complete workup should be conducted at an experienced center. At present, no definite benefit to intrauterine shunting has been conclusively demonstrated.

Normal-Pressure Hydrocephalus

Pathogenesis and Pathophysiology. NPH is the result of an imbalance between production and resorption of the CSF, usually around the brain convexities. Whereas there is full communication between the ventricles and the subarachnoid space (communicating hydrocephalus), the communication between the subarachnoid space and the arachnoid villi and granulations is not intact, so fluid is not transferred efficiently to the superior sagittal sinus. Subarachnoid hemorrhage, meningitis, head trauma, and elevated levels of CSF protein all cause thickening of the arachnoid or obstruction of the subarachnoid space. A relatively large number of patients do not have an identifiable cause for hydrocephalus, and, pathophysiologically, their lesion best fits with reduced resorption of CSF, based on studies of increased resistance to CSF outflow.^[8] Less frequently, intracranial tumors, stenosis of the aqueduct of Sylvius, and arachnoid cysts (causes mainly discussed in the previous section) can cause NPH due to obstruction within the ventricular system, and normal pressure is maintained as a result of apparent compensations.

In spite of its name, it appears that intracranial pressure in NPH is not always normal. Physiological experiments suggest that a transient elevation of pressure may increase ventricular size and a new fluid balance is reached with normal pressure but with a higher force, based on Pascal's law of pressure in fluids. Other mechanisms may include abnormal ventricular distensibility, increased CSF pulse amplitude, and increased transmante pressure gradients between the

intraventricular and subdural spaces that lead to expansion of the ventricles.

Epidemiology and Risk Factors. NPH has its highest prevalence in the late middle-aged and elderly groups, and is rare in patients younger than 60 years of age. On the other hand, neonates, infants, children, adolescents, and young adults can develop primary or secondary NPH. It accounts for 5 percent of demented patients in the older age group, but its prevalence in the general population is unknown.

Clinical Findings and Associated Disorders. The triad of progressive dementia, gait disturbance, and urinary incontinence was originally described by Adams and colleagues.^[15] In most instances, gait disturbance is the first sign, followed by dementia, and, later, urinary dysfunction. The gait is slow, unsteady, and wide based. Steps are usually short, and patients have difficulty picking their feet off the ground to ambulate (so-called magnetic gait). Turning is difficult and takes several steps. On examination, there is bradykinesia, and the legs may be spastic with increased reflexes. Patients may have difficulty in handwriting and dressing, and may appear to be mildly parkinsonian, but their tremor, if present, is usually postural, not resting. One particular feature is the discrepancy between leg function during walking and simulated walking when sitting. Patients can usually move their legs well and imitate walking while in a chair, but they become awkward and severely impaired as soon as they attempt to walk. This dyspraxia for gait eliminates a pyramidal lesion.

Cognitive decline is clinically multidimensioned and involves impaired attention, poor memory, and poor executive function.^[16] Apathy and bradyphrenia are common, whereas aphasia and upper extremity limb dyspraxia are uncommon.

Neuroanatomically, the gait dysfunction and urinary impairment are believed to relate to the stretched fibers innervating the legs and sphincters that project through the vicinity of the frontal horns of the ventricular system. Compromised microcirculation, due to increased intraparenchymal pressure, may contribute to the cognitive impairment. Positron-emission tomography (PET) data suggest that glucose utilization defects are widespread in NPH and involve subcortical and cortical regions.

Evaluation and Differential Diagnosis. Because the clinical picture of NPH is not specific, especially in the younger patient, several diagnostic tests play a crucial diagnostic role. CT or MRI scans are important to establish the presence of hydrocephalus. The diagnosis of NPH is supported when the anterior ventricular horns measure greater than 30 percent of the diameter of the cranial cavity and the inferior horns are wider than 2 mm. On T₂-weighted MRI, increased signal in the periventricular areas occurs due to presumed transependymal exudation of CSF. Other findings can suggest alternate diagnoses: for example, a normal-sized fourth ventricle with dilated third and lateral ventricles usually indicates aqueductal stenosis.

Clinically, dementing illnesses of all types must be differentiated

'''

from NPH (see [Chapter 33](#)). Alzheimer's disease is not associated with marked gait dysfunction, and a patient with multi-infarct dementia or Binswanger's disease may have a similar clinical presentation to a patient with NPH but has MRI signs of multiple strokes. In younger patients, in whom the classic clinical triad may not be met, the differential diagnosis is wider.

A lumbar puncture usually reveals normal CSF pressure. Furthermore, removal of 20 to 50 ml of CSF may cause clinical improvement in cognitive and gait dysfunction supporting the diagnosis of NPH. Intermittent pressure B-waves detected by intracranial monitoring devices suggest decreased brain compliance and NPH. Radioisotope cisternography is used most often but is not particularly specific. Whereas in normal subjects isotope injected intrathecally can be seen around the brain convexity within 48 hours, reflux into the ventricles and stasis beyond 48 hours are often seen with NPH. However, this finding has relatively low predictive accuracy in the diagnosis of NPH and the response to therapy by shunting procedures.^[17]

Management and Prognosis. The primary treatment is large-volume lumbar puncture and eventual ventricular shunting. However, selection of patients for shunting is controversial; most reports agree that dementia of less than 2 years' duration and typical gait and urinary dysfunction should be considered for shunting as long as there is no evidence for a multi-infarct state on MRI scans. Medical management can include acetazolamide or digoxin to decrease CSF production. The rate of complications of CSF-diverting procedures is approximately 30 percent, with 5 percent being serious with long-term sequelae.^[18] Subdural hematomas, intracranial infections, stroke, and failure of the shunt are the major complications. The proportion of patients who experience long-term benefit from this treatment range from 25 to 80 percent.

NEURAL TUBE DEFECTS

Defects in the formation of the neural tube account for 0.001 to 1 percent of all human malformations, depending on the reference population, making this group of disorders among the most common major malformations. Neural tube closure defects are also among the oldest recorded malformations. For example, it was determined that a mummy from ancient Egypt, investigated by Etienne Geoffroy Saint-Hilaire, was determined to have anencephaly. A curious observation in the 16th century of a child with a froglike head and face, now believed to represent anencephaly, who was born to a woman who had a frog placed on her hand during a febrile illness is the first indication that neural tube closure defects may result from environmental factors.^[19] This example of maternal impression, a theory widely postulated for many centuries as the cause of some congenital anomalies, including the Elephant Man, is noteworthy because of the now recognized association of maternal hyperthermia and neural tube closure defects.^[20]

Pathogenesis and Pathophysiology. The prevailing theory on the pathogenesis of neural tube defects is that they result from a failure of the neural folds to come together to form the neural tube as opposed to the reopening of a closed neural tube. Experimental models and studies in humans have supported this hypothesis. Although monoallelic disorders are occasionally associated with neural tube closure defects,^[21] most data implicate a multifactorial etiology for the occurrence of neural tube closure defects. Neural tube closure defects are common in animals, including mice, in which mutant strains have been invaluable in identifying many genes important for neural tube closure. Strain differences in the susceptibility to neural tube closure defects have been recognized, consistent with the multifactorial model. Similarly, environmental factors have been identified that result in neural tube closure defects. Recent data also indicate that at least in the cranial region, neural tube closure occurs not in a single continuous closure but at multiple sites and in a coordinated pattern. Each defined site may be under the control of different genes and be susceptible to different environmental factors ([Fig. 28-1](#)).^[22], ^[1]

Given that several of the known risk factors could be controlled, it is important to appreciate the embryonic timing of neural tube closure and, therefore, the gestational age at which these defects are believed to arise. Closure of the neural folds begins on approximately day 20 after fertilization and is complete by approximately day 28 after fertilization. This is approximately 1 to 2 weeks beyond the time a woman is expecting her normal menstrual cycle. Thus, during this critical time of development for the nervous system, a woman is frequently unaware that she is pregnant.

Epidemiology and Risk Factors. The past decades have witnessed an overall decline in the incidence of neural tube closure defects, although the etiology for this decline remains elusive. Epidemiological and experimental investigations into potential environmental risk factors, particularly in Wales and Ireland, have failed to identify an obvious source. Several environmental factors have been linked to neural tube closure defects, including maternal diabetes, maternal hyperthermia, and some anticonvulsants (valproic acid and carbamazepine in particular)^[24]; however, the elimination of some of these minor risk factors is not sufficient to explain the overall declining incidence.^[25] Vitamin supplementation, particularly folate, has been linked to a reduced risk for having a second child with a neural tube closure defect.^[26], ^[27] Preliminary data indicate that similar supplementation may also reduce the primary risk for all mothers.^[28] The mechanisms by which vitamin supplementation prevents neural tube closure defects are poorly understood.

As alluded to already, many factors likely play a role in the causation of neural tube closure defects, and the actual etiology is usually multifactorial. Genetic factors certainly play an important role in at least conferring a predisposition to having a child with a neural tube closure defect. The genetic and environmental factors are likely to act synergistically with a woman's risk for having a child with a neural tube closure defect.

Clinical Features and Associated Disorders. Neural tube defects can be conveniently divided into cranial and caudal types, although occasional cases may involve both (e.g., encephalocele in conjunction with myelomeningocele). The terminology of a neural tube closure defect often provides a description of the type and location of the defect. *Anencephaly* strictly means absence of the head;

Figure 28-1 Neural tube closure defects located at multiple sites along the neuroaxis. A CT scan (A) and clinical photograph (B) of a patient with a frontal (nasal glioma) encephalocele. An encephalocele or anencephaly isolated to the occipital region (C). This case showed an open defect at the top of the encephalocele, with extensive loss of neural tissue placing this case in the category of anencephaly (D). A model of neural tube closure defects (from Reference 93). A lumbosacral myelomeningocele (E) with an intact membrane over the defect that involved the spinal cord. Defects in closures III, IV, and I may account for the examples shown A, B, C, and E, respectively. (A, B, Courtesy of Dr. D. Vander Woude.)

however, it practically refers to an absence of the brain and the calvarium covering the brain. Although some cases have partial sparing of supratentorial or, more commonly, the infratentorial structures, the vast majority of cases show a complete absence of most of the brain. The anterior pituitary, eyes, and brainstem are usually spared. Although the tissue fated to become the brain is present in the embryo, it is generally believed that direct contact between the neural epithelium and the amniotic fluid results in degeneration of the neural epithelium. The remaining tissue covering the basal cranium is a highly vascular and friable membrane referred to as the area cerebrovasculosa. *Rachischisis* refers to cases of anencephaly with a contiguous spinal defect involving at least the cervical spine region and extending for varying degrees down the spinal column. In the majority of cases, there is associated polyhydramnios and a significant proportion are stillborn; infants who are born alive do not survive. Neurological function is primarily limited to brainstem and spinal reflexes, although seizures, at times resembling infantile spasms, have been observed in some infants.

Encephaloceles and *cranial meningoceles* are distinguished from anencephaly because encephaloceles and cranial meningoceles have an epidermal covering over the cranial neural tube closure defects. Both entities are associated with a defect in the skull and with protrusion of the meninges either alone in the case of meningoceles, or with meninges and underlying brain in encephaloceles. Occasionally, no clear bony defect or attachment to the underlying brain can be identified, particularly for those located in the frontonasal region. This form of a frontal encephalocele is sometimes called a nasal glioma, although the term is misleading because nasal gliomas are not neoplasms. These lesions may not be immediately obvious on external examination, and may present as an intranasal mass, a pharyngeal obstruction, or with recurrent meningitis. Hypertelorism, median cleft lip, or hypothalamic dysfunction can be associated with these lesions. The size of the encephalocele can vary from a barely visible bulge to those larger than the infant's head. The location of an encephalocele can be helpful in the diagnosis of specific syndromes. For example, the Meckel-Gruber and Walker-Warburg syndromes are frequently associated with occipital encephaloceles, whereas anterior encephaloceles are found more commonly in Robert's syndrome and as isolated malformations are more commonly seen in southeast Asia. Parietal encephaloceles are less common. The extent of the cortex that is herniated into the defect frequently correlates with the neurological deficits. In addition, the malformed cortex within or adjacent to the defect can give rise to seizures.

Neural tube closure defects involving the spinal cord can involve the meninges alone (*meningocele*) or the meninges and underlying spinal cord (*myelomeningocele*). Most caudal neural tube closure defects occur in the lumbar region, followed by the lumbosacral regions, but can also be located in cervical, thoracic, or sacral regions. The terms *spina bifida occulta* and *spina bifida cystica* are also used to describe variations of these defects and encompass bony changes of the vertebral column. *Spina bifida occulta* is

defined as a defect in the posterior bony components of the vertebral column without involvement of the cord or meninges. These defects are often found incidentally on radiographic studies or are picked up because of a subtle clinical finding such as a tuft of hair or a cutaneous angioma or lipoma in the midline of the back marking the location of the defect. On rare occasions, a sinus tract may communicate from the skin to the underlying dura. The clinical presentation is largely dependent on the level and content of the defect. Pure meningoceles may be asymptomatic. Neurological disability is greatest in patients with myelomeningoceles. Infants with defects at or above L2 are more likely to have skeletal deformities, including kyphosis and scoliosis, dislocated hips, and clubfeet (see later). The degree of motor paresis is equally dependent on the level of the neural tube closure defect and is discussed in more detail under management and prognosis. Involvement of the kidneys, urinary tract, and bladder with various forms of incontinence and reflux is very common and depends on the level of the lesion as well (see later).

Other disorders frequently included in spinal neural tube defects are *tethered spinal cord*, *spinal lipomas*, and *sacral teratomas*, although these entities do not arise as a result of failed neural tube closure. Nonetheless, spinal dysraphism is occasionally associated with these defects. The etiological relationship between these disorders remains unclear. Tethering of the cord due to a short and thick filum terminale can present late and insidiously with progressive gait disturbances, atrophy of various muscle groups or the entire limb, loss of reflexes, loss of sensation in particular in the sacral dermatomes, and sphincter disturbances.^[29] The gait abnormality results from weakness and lower extremity spasticity. Pain in the gluteal, perianal, and other pelvic areas as well as the limbs associated with cramping can occur in particular with later presentation. Early and seemingly fixed deformities, as well as sudden and dramatic deteriorations, can also be seen. Deteriorations may occur, particularly during periods of rapid growth. *Diastematomyelia* can give rise to a similar picture; however, the symptoms may be more strictly unilateral.

Myelomeningoceles, particularly those arising in the lumbosacral regions, are frequently associated with other defects along the neuroaxis and the surrounding mesoderm. The cranial bones may show regional thinning resulting in radiographic and transilluminative lucencies. These defects, also known as *luckenschadel*, are present in far greater than 50 percent of term infants with myelomeningoceles but are rarely found after 2 years of age. Although these bony lucencies frequently occur in patients with myelomeningoceles, especially in the presence of hydrocephalus, they are not specific for this disorder. They may be found incidentally or in association with hydrocephalus. The base of the skull is also abnormally flattened (*platybasia*) in most patients with myelomeningoceles, resulting in a shallow angle between the clinoid process and the foramen magnum.

The cerebral hemispheres may show malformations that are not clearly linked to the neural tube defect. The associated anomalies range from those that are found infrequently, such as agenesis of the corpus callosum, polymicrogyria, and pachygyria, to frequent findings like an enlarged *massa intermedia*. The most common finding associated with myelomeningocele is the *Chiari II malformation*, referred to by some authors as the Arnold-Chiari malformation. The Chiari II malformation is present in more than 95 percent of children with myelomeningoceles. Although a broad spectrum of findings are part of the Chiari II malformation,^[29] the change found in virtually all cases includes displacement of the cerebellar vermis (and to a lesser extent the inferior lateral cerebellar hemispheres) over the dorsal aspect of the cervical spinal cord ([Fig. 28-2](#)) within the upper vertebral column. The fourth ventricle, pons, and medulla are similarly elongated and partially located in the spinal canal. The lower medulla may be kinked. Forking of the aqueduct, aqueductal stenosis, or aqueductal atresia may be present. Less common findings include fusion (beaking) of the inferior tectum and anomalies of cranial nerve nuclei. Hydrocephalus is a common complication of myelomeningoceles, and may occur prenatally or postnatally. The etiology of the hydrocephalus is not always clear, although the aqueductal changes could account for some of the cases. Clinically, the Chiari II malformation may present with lower brain stem and cranial nerve dysfunction. Dysphagia leading to feeding difficulties, drooling, nasal regurgitation, stridor, vocal cord paralysis, and life-threatening apneic spells can occur. Cyanotic episodes are ominous, carrying a considerable mortality rate. Nystagmus, retrocollis, and opisthotonos can be seen. In addition, later presentation of the Chiari II malformation may include loss of head control, development of weakness in the arms, and increasing spasticity leading to quadriparesis.

In addition to the dysraphism, other malformations may be concurrently found in the spinal cord.^[30] The two most frequent abnormalities of the spinal cord are hydromyelia (dilations of the central canal) and syringomyelia (a glial-lined cavity within the parenchyma of the spinal cord). They may either occur in isolation, or they may be found together (hydrosyringomyelia). These disorders may be found localized to a short segment of the spinal cord or along great distances. It is also important to recognize that these conditions are not specific to dysraphisms and can even be found post-traumatically. Partial (diastematomyelia) and complete (diplomomyelia) duplications of the spinal cord are occasionally present in association with myelomeningocele. These anomalies are also not specific for dysraphisms of the spinal cord, and each may be found in isolation or with other CNS malformations.

Differential Diagnosis. The diagnosis of a neural tube defect is usually obvious, except in rare cases of small encephaloceles and with *forme fruste* lesions. Examples include dural sinus tracts and possibly some cases of *aplasia cutis congenita*, in which bony skull defects can occur; however, there is no cystic outpouching of components of the CNS. Tumors such as caudal lipomas, teratomas, and dermoids may occasionally mimic a neural tube closure defect. The amniotic band sequence can also disrupt the neural folds or cranium, or both, resulting in a defect resembling a neural tube closure defect.^[26] Disruptions due to the amniotic band sequence are often easily distinguished from neural tube closure defects by the asymmetry, the presence of facial clefts, and the presence of extremity amputations. The signs and symptoms of tethering of the cord and related anomalies have to be differentiated from

Figure 28-2 Examples of several posterior fossa anomalies. A midsagittal MRI scan(A) and photograph of a brain(B) with Dandy-Walker malformations. The cerebellar vermis is rotated anteriorly, and there is a cystlike dilation of the fourth ventricle. A Chiari I malformation(C) is characterized by a tongue of cerebellar tonsils extending over the cervical spinal cord. The cerebellar vermis is intact and shows no displacement. The Chiari II malformation(D) is characterized by the cerebellar vermis extending as a tongue of tissue into the cervical spinal canal. The inferior vermis is white, corresponding to the extreme gliosis usually seen in this disorder. Note the beaking of the inferior tectum, and the elongated and distorted pons and medulla with the kinking of the lower medulla. (A, Courtesy of Dr. R. Robertson)

other types of progressive spinal cord disease including tumors, multiple sclerosis, spinal cord infarction, and progressive spastic paraparesis.

Evaluation. The diagnosis of anencephaly is readily made upon examination of the affected infant. The evaluation of children with less dramatic neural tube defects is more complex. Occipital encephaloceles may be part of a syndrome with important genetic and prognostic implications. For example, the Meckel-Gruber syndrome and the Walker-Warburg syndrome, both mentioned earlier, are autosomal recessive disorders with a poor prognosis. A special case is the frontonasal encephalocele. Clear (CSF) rhinorrhea following the removal of a nasal polyp requires immediate evaluation, with imaging and prophylactic antibiotic treatment instituted before surgical repair. A careful endocrine evaluation is particularly important in sphenoidal encephaloceles. In general, careful imaging, preferably using both MRI and CT scanning, is important for the evaluation of encephaloceles to outline their content and anatomical relationships for treatment planning.

In the evaluation of the infant with spinal dysraphism, particularly the lumbosacral forms, it is important to be aware of the commonly associated Chiari II malformation, as well as of the possibility of coexisting hydrocephalus. Myelomeningoceles outside of the lumbosacral region have a less consistent association with hydrocephalus.

At present, it is recommended that every child with a myelomeningocele be screened for the presence of hydrocephalus with at least transfontanelle ultrasound because the development of signs and symptoms may be delayed. Careful morphological and functional urological assessment is of major importance in children with myelomeningoceles. Only in very low lesions at S3 will there be a flaccid and, therefore, relatively easy to manage bladder. Higher lesions are often associated with incoordination of the detrusor and external urethral sphincter.

In suspected occult dysraphism and the other closed malformations of the spinal cord, careful MR imaging is essential in establishing the diagnosis. Particular attention needs to be paid to a low-lying conus medullaris and thickened *filum terminale* in order to recognize the presence of a tethered spinal cord.

Management and Prognosis. In anencephaly, the prognosis for survival without maximal support for these infants is dismal, and a significant proportion of infants are stillborn. Survival of liveborn infants can be prolonged with the assistance of life support systems, creating controversy over the use of anencephalic infants as organ donors.

The management for dysraphic disorders begins with the planning of an atraumatic delivery. The avoidance of labor by prelabor cesarian section significantly improves neurological outcome in children with myelomeningoceles.^[31] Larger encephaloceles are also managed in this fashion. Decisions concerning the surgical management of encephaloceles are dependent on the clinical context in which the encephalocele occurs. This includes the identification of syndromes and other associations important for prognosis and genetic counseling (see reference 22 for a more complete list of associations and syndromes). Most encephaloceles are sporadic, however, so that prognosis and management are based on the extent of the individual defect. Generally, surgical excision is recommended, even if there are significant associated malformations; the goal of surgery in these cases may be to simply improve caregiving for the affected infant. More urgent surgery may be indicated in the case of CSF leaks to prevent meningitis. The prognosis

is significantly better in anterior encephaloceles as opposed to parietal and occipital lesions, particularly those involving the posterior fossa contents (see the discussion of Chiari III malformation later). Frequently, a frontal or occipital sporadic encephalocele can be surgically managed with fairly good outcome.

The surgical treatment of spinal dysraphism in most centers is now directed at closing all but the prognostically worst cases. Although early treatment is preferable, there are no data to support that emergency closure improves outcome. Timely closure does, however, reduce the rate of infectious complications. At present, a planned operation within the first 24 to 48 hours postnatally is the standard of treatment, although some delay of the closure under antibiotic coverage does not seem to affect outcome adversely. Concurrent shunting of co-existing hydrocephalus is often necessary and advisable even for what might appear to be arrested ventriculomegaly. Prevention of meningitis or ventriculitis is extremely important, because intellectual outcome is inversely related to the occurrence of such complications. Therefore, antibiotic prophylaxis is used before and around the time of surgery, in particular with open defects. Surgical management of the Chiari malformation itself may become necessary when prominent brain stem signs persist despite adequate treatment of the hydrocephalus.^[32] In these selected cases, decompression via suboccipital craniectomy and cervical laminectomy can be beneficial. Urological management plays a prominent role in the care of these children.^[33] It is very important to avoid secondary dilatation of the proximal urinary system, which has the potential to cause chronic pyelonephritis and renal damage. Urological complications continue to be a leading cause of morbidity in children with myelomeningocele. Various conservative (intermittent catheterization,

anticholinergic medication) and surgical regimens for bladder management may be appropriate.^[34] Rectal incontinence can often be successfully managed with conservative treatment such as regulated emptying of the bowel. Several late complications of myelomeningoceles can arise. Scoliosis, especially with lesions at or above L2, and traction on the cord, may result from the defect alone. Postsurgical complications include spinal cord infarction, compression of the cord by subarachnoid cysts, and inclusion cysts arising from trapped skin appendages.

The distribution of weakness and deficits on examination is an important predictor for ambulation. In general, involvement above the L3 level creates motor deficits that preclude ambulation; lesions below S1 usually allow for unaided ambulation. If the deficit level falls between S1 and L3, a number of assisting devices may be useful for ambulation.^[35]

Tethering of the cord may also be found as a late complication after meningomyelocele repair^[36] but may also occur as a primary abnormality (see the previous discussion). In all cases, surgical untethering of the cord is recommended. The associated pain responds best to surgical treatment, and ambulation and bladder function may improve as well. However, sphincter dysfunction often remains a permanent problem even after complete release. Given the potential for rapid deterioration with incomplete neurological recovery, even prophylactic surgery in an otherwise asymptomatic child with a tethered cord seems advisable.

At present, primary prevention of neural tube defects focuses on dietary folate replacement around the time of conception. Such a supplementation has been shown not only to reduce the risk for the birth of a second affected child but may also be effective in reducing the primary incidence of neural tube defects. Given the early timing of the failure of neural tube closure, supplementation may be too late when an unplanned pregnancy is noted. The question of general diet fortification with folate is being debated.^[37]

Prenatal detection of neural tube defects has become routine through screening programs using serum and amniotic chemistry and prenatal ultrasound. Elevated serum or amniotic fluid alpha-fetoprotein (AFP) and elevated acetylcholinesterase in the amniotic fluid are found in almost all open neural tube defects. This determination is highly sensitive for open neural tube closure defects but is not always completely specific, because of other possible causes for elevated AFP in the amniotic fluid. If combined with the determination of acetylcholinesterase in the amniotic fluid, the sensitivity of the test approaches 100 percent with much improved specificity. In addition, fetal ultrasonography can provide an additional level of confidence with very high sensitivity in experienced hands at even 14 to 16 weeks' gestation. Indirect signs such as the lemon sign, referring to a symmetrical bifrontal narrowing of the skull, and cerebellar abnormalities are helpful in addition to the often difficult direct demonstration of the defect. Fetal ultrasonography can also assist in dating the pregnancy, an important factor in the calculation of the AFP values, given their dependency on the gestational age of the fetus. The peak of sensitivity for maternal serum AFP levels lies somewhat later than the amniotic fluid determination and is optimal at 16 to 18 weeks' gestation. Before that time, the levels may be normal despite the presence of a neural tube closure defect. The specificity of this test is much lower, so that careful follow-up testing needs to be performed after the determination of an elevated value. This commonly includes a high-level fetal ultrasonography and often amniocentesis.

SEGMENTATION, CLEAVAGE, AND MIDLINE DEFECTS

These disorders are believed to arise from a defect in midline development. The result is a failure of midline structures, like the corpus callosum, to form. Included are also abnormalities in the separation of the neural tube into two hemispheres. This later defect is believed to result in holoprosencephaly and related disorders.

Pathogenesis and Pathophysiology. Completion of neural tube closure is followed by segmentation in the anteroposterior axis. Although these segments were originally defined morphologically, recent data have demonstrated a coordinated expression of a variety of developmentally regulated genes, mostly members of transcription factor families such as the homeobox genes. In more general terms, these data have suggested that the segmental organization of the nervous system is established through a combinatorial regional expression and regulation of specific

Figure 28-3 Semilobar and alobar holoprosencephaly. In semilobar(A) and lobar holoprosencephaly there is an apparent midline sagittal (interhemispheric) fissure (coronal section of brain). However, coronal sections reveal the cerebral cortex to be continuous across the midline. Furthermore, no corpus callosum is present. The thalamus is abnormally shaped, with marked midline fusion. Alobar holoprosencephaly(B) has no indication of a midline fissure on coronal sections or when viewing the brain dorsally. Again there is no evidence of a corpus callosum, only subcortical white matter across the midline.

developmental genes.^[38],^[39] These segments form the progenitors to all structures recognized in the adult nervous system. In addition to the anteroposterior organization of the nervous system, bilateral symmetry arises in the cerebral hemispheres. At approximately 5 to 6 weeks after fertilization, the prosencephalon, the most rostral segment of the nervous system, shows differential growth as two distinct hemispheres. The most anterior point of the neural tube, the lamina terminalis, is the location from which the major crossing fibers between the cerebral hemisphere will arise. Both the anterior commissure and the corpus callosum have their anlagen in the lamina terminalis. From there, the corpus callosum grows back over the top of the third ventricle to form its genu, body, and splenium. Failure of the prosencephalon to grow into two symmetrical hemispheres and defects in the region of the lamina terminalis are believed to give rise to the class of defects commonly referred to as cleavage defects or midline defects.

Epidemiology and Risk Factors. Although several teratogens and maternal factors have been reported as risk factors for the midline defects, these associations are weak and at present no definite causality has been established. On the other hand, holoprosencephaly is sometimes found segregating in families and linkage to specific chromosomal loci has been established. Evidence from this linkage analysis and from deletion mapping indicates that at least chromosomes 2p21, 7q36, 18p11.3, and 21q22.3 may harbor genes responsible for holoprosencephaly.^[40] The gene for autosomal dominant familial holoprosencephaly at 7q36 (HPE3) has been identified by two groups led by Belloni and Roessler as the human Sonic hedgehog homolog, a member of an important family of developmental signalling molecules. In addition to these loci, trisomy 13 is closely linked to midline malformations, including arrhinencephaly, agenesis of the corpus callosum, and holoprosencephaly, and is the single most common chromosomal defect underlying holoprosencephaly. Other cytogenetic etiologies in holoprosencephaly include deletions of 13q, triploidy, and duplications of 3p.

Clinical Features and Associated Disorders. Holoprosencephaly is frequently divided into subtypes according to the extent of cerebral hemisphere involvement, but these distinctions are probably artificial. The most commonly used classification scheme defines three subtypes--alobar, semilobar, and lobar holoprosencephaly.^[41] Alobar holoprosencephaly is the most severe of these ([Fig. 28-3](#)). The brain shows no evidence of a midsagittal fissure. The corpus callosum is absent, and the olfactory bulbs and tracts are almost always absent as well. Varying degrees of fusion of the basal ganglia and thalamus are present. This form of holoprosencephaly is most frequently associated with severe facial malformations (see later). Semilobar holoprosencephaly is characterized by an incomplete fusion of the cerebral hemispheres. The occipital and parietal lobes (see [Fig. 28-3](#)) tend to be more or less separated, whereas the frontal lobes show varying degrees of fusion. Again, the corpus callosum is absent in all cases and the olfactory bulbs and tracts are absent in most. The basal ganglia and thalamus (see [Fig. 28-3](#)) are variably involved but at least partially fused in all cases. In lobar holoprosencephaly, a midline fissure is present over the entire dorsal aspect of the brain; however, in at least the medio-orbital region of the frontal lobe, there is fusion across the midline. The olfactory bulbs and tracts are again absent in the vast majority of cases as is the corpus callosum. The posterior fossa contents are often unremarkable in holoprosencephaly. Only in the most severe cases of alobar holoprosencephaly can anomalous development of the cerebellum occasionally be seen. On the other hand, absence of the corticospinal tracts is a common finding and is believed to be the consequence of the severe malformation of the cerebral cortex with subsequent failure of formation of proper motor projections.

A spectrum of distinctive facial dysmorphisms is part of the holoprosencephalic malformation sequence. These facial abnormalities are expressions of the underlying profound disturbance of midline development, affecting prechordal mesoderm that is important in facial development as well. The facial phenotypes can be ranked in descending order of their severity: (1) cyclopia (the eye and orbits are

fused or in various states of incomplete separation; agnathia may also be present); (2) ethmocephaly (instead of a nose, a proboscis is present and often located above the incompletely separated, or severely hypoteloric, eyes); (3) cebocephaly (the nose now is between and below the hypoteloric eyes, but there is only a single blindly ending nostril); (4) premaxillary agenesis or aplasia of the primary palate, associated with hypotelorism and often midline cleft lip and palate; (5) milder facial dysmorphism with hypotelorism, flat base of the nose, and milder midline or bilateral clefting; and (6) minimal forms such as single central incisor. Although it is generally true in the holoprosencephaly spectrum that the face predicts the brain,^[42] exceptions do occur. In general, the severe facial dysmorphisms of cyclopia, cyclopia with agnathia, ethmocephaly, cebocephaly, and severe hypotelorism with agenesis of the primary palate and a median cleft lip and palate usually go along with the severe alobar form of holoprosencephaly. The correlation of severity of the facial appearance and brain morphology is less pronounced at the mild end of the spectrum of facial phenotypes. Thus, the brain does not necessarily predict the face. Although the full-fledged facial phenotypes seem to be always associated with holoprosencephaly, cases of agnathia (but without cyclopia), for example, or central cleft lip and palate, have been seen in patients with a morphologically normal-appearing brain and also with brains that have malformations distinct from the holoprosencephaly sequence.

The clinical presentation of holoprosencephaly is dependent on the degree of CNS involvement. Infants with severe alobar forms often die shortly after birth. Survivors frequently present with severe mental retardation, seizures (infantile spasms occur early), severe motor impairments, poikilothermia, and endocrine insufficiencies. In the milder forms of holoprosencephaly, longer survival with various degrees of psychomotor retardation is possible. Endocrine dysfunction may become apparent, with diabetes insipidus and growth hormone deficiency having been reported in a number of cases. It should be re-emphasized that only the classic facial phenotypes are predictive of the severe alobar holoprosencephaly with its associated very poor prognosis but that a number of partial facial phenotypes, such as midline cleft lip or midface hypoplasia, are not necessarily associated with the most severe malformations in the spectrum.

The diverse syndromic contexts in which holoprosencephaly can occur are listed in reference 25. In families with autosomal dominant holoprosencephaly, carriers of the gene with minimal expression of the defect (such as hypotelorism or a single central incisor) can be neurologically normal. There may be considerable variability of expression within a given family, with severely involved cases occurring alongside milder ones. Autosomal recessive holoprosencephaly has been reported as well and in some families is associated with heart and limb defects.

Evaluation. Most cases of holoprosencephaly occur sporadically but may also be a feature of one of several malformation sequences or syndromes.^[25],^[40] Therefore, part of the clinical evaluation of a patient with holoprosencephaly should always include a careful workup for additional malformations, because this information may provide the diagnosis of a specific syndrome with potentially far-reaching genetic implications. Because of the associations with some deletion/microdeletion syndromes, high-resolution karyotype analysis (\pm fluorescent in situ hybridization [FISH] analysis) with special emphasis on chromosomes 2p21, 3p, 7q36, 13q,

18p11.3, and 21q22.3 is recommended in all cases of holoprosencephaly. If the affected proband is not available, chromosome analysis in the parents is important to rule out a carrier status for a balanced translocation. Possible misdiagnoses in the severe forms of alobar holoprosencephaly include hydranencephaly and hydrocephalus, as well as large and expanded interhemispheric cysts that sometimes are associated with agenesis of the corpus callosum. Expanded large posterior third ventricular cysts can be mistaken for semilobar holoprosencephaly. Bridging of cerebral cortex across the midline can be missed in very mild cases of lobar holoprosencephaly and is best evaluated on coronal T1-weighted MRI images. The prenatal diagnosis of holoprosencephaly is based largely on ultrasound examination. A first trimester diagnosis is possible based on ultrasound findings of a lack of a midline echo indicative of a monoventricle, cyclopia or marked hypotelorism, a flattened profile of the nose, and microcephaly. Transvaginal ultrasound enhances the visibility of these findings, especially early in gestation. Prenatal diagnosis of mild forms such as lobar holoprosencephaly may be impossible.

Management and Prognosis. The management of a patient with holoprosencephaly depends on the extent of clinical involvement and focuses predominately on seizure control (see [Chapter 52](#)). The prognosis for all liveborn children with severe forms of holoprosencephaly is extremely poor. The rare cases associated with true hydrocephalus due to CSF flow obstruction need to be differentiated from ventriculomegaly as a feature of the malformation itself and treated with VP shunting. Prognosis similarly parallels the ability to control the seizures. Mental retardation may be mild in the least severely affected individuals but is almost always profound in the more severely affected individuals. In cases of holoprosencephaly with less complete CNS involvement, surgical correction of the craniofacial malformations, such as cleft lip or palate, may be appropriate. Endocrine dysfunctions respond to hormone replacement therapy.

OTHER SEGMENTATION AND CLEAVAGE DISORDERS

Septo-optic dysplasia is pathologically defined as absence of the septum pellucidum and hypoplastic optic nerves. This clinical constellation of symptoms and signs has also been referred to as de Morsier's syndrome. Other abnormalities are variably reported, suggesting considerable heterogeneity underlying this phenotype. Clinically, there are optic nerve hypoplasia resulting in visual impairment, endocrine abnormalities resulting from hypothalamic-pituitary insufficiency, and frequently seizures, especially in cases in which there has been disruption of cortical development as well. The degree of visual impairment can vary from blindness, with the development of amaurotic nystagmoid eye movements after a few months, to normal vision in a few cases. The endocrine insufficiencies can lead to

symptomatic hypoglycemia and diabetes insipidus; later, growth hormone deficiency may become apparent. These endocrine insufficiencies can and should be treated by standard endocrine replacement protocols. Although retardation of cognitive development occurs especially in patients with obvious concomitant cortical anomalies, a number of cases with normal cognitive development are on record. Most cases of septo-optic dysplasia have been sporadic; however, there are two observations in sibs and in cousins suggesting the existence of a form with autosomal recessive inheritance. It is an important consideration in the differential diagnosis in children presenting with optic hypoplasia. [43]

Agenesis of the corpus callosum can be found as an isolated malformation or in association with other malformations. [29] A growing number of inborn errors of metabolism also include agenesis of the corpus callosum. In complete agenesis of the corpus callosum, the cingulate gyrus is altogether absent and sulci are found radiating down the medial aspect of the brain from the dorsal surface to the high-riding roof of the third ventricle (Fig. 28-4). Coronal sections or images often reveal slightly dilated ventricles with an irregular batwing-like contour (see Fig. 28-4). A white matter tract, known as the bundle of Probst, can frequently be found running anteroposterior just above the lateral ventricle, where the fibers of the corpus callosum would normally collect into the commissure. Partial agenesis is recognized by the absence to variable degrees of the posterior corpus callosum, with sparing of the rostrum and genu (see Fig. 28-4). In cases of partial agenesis of the corpus callosum, the cingulate gyrus is present only to the extent that the corpus callosum exists. The anterior commissure, also derived from the lamina terminalis, may be absent in cases of complete agenesis of the corpus callosum, although it is usually spared with partial agenesis of the corpus callosum.

Isolated agenesis of the corpus callosum is sometimes discovered incidentally either on imaging studies that were obtained for other reasons, such as trauma, or at autopsy. In isolation, the abnormality clinically is largely silent and deficits may be discovered only on careful neuropsychological assessment. Findings resembling disconnection syndromes have been described in some patients; however, this is by no means a constant feature and in the majority of patients this characteristic cannot be demonstrated. Patients with agenesis of the corpus callosum have a higher incidence of seizures and mental retardation, partially reflecting the slightly higher incidence of neuronal migrational abnormalities also seen in these patients. It should be noted, however, that patients with mental retardation or seizures, or both, are also more likely to undergo CNS imaging, which skews the ascertainment of the clinicopathological correlations in agenesis of the corpus callosum.

Because it can be assumed that the clinical manifestations of agenesis of the corpus callosum most often depend on the associated CNS anomalies rather than on the lack of the corpus callosum itself, careful assessment for such associated malformations is mandatory. Although agenesis

Figure 28-4 Partial and complete agenesis of the corpus callosum. A midsagittal MRI of a patient with complete agenesis of the corpus callosum (A). The medial gyri are seen radiating to the third ventricle. A midsagittal section of the brain from a patient with complete agenesis of the corpus callosum (B). A comparison of (A) and (B) shows remarkable similar findings. A coronal MRI of another patient with agenesis of the corpus callosum (C). The lateral ventricles show the classic batwing form, and dilation is seen in the temporal horns of the lateral ventricles and the third ventricle. A midsagittal section of a brain with partial agenesis of the corpus callosum (D). The partial corpus callosum present (arrowheads) extends from the lamina terminalis posteriorly. The cingulate (partially obscured by the arrowheads) extends the length of the corpus callosum. A sulcus (arrow) extends from the dorsal surface of the brain to the third ventricle only posterior to the formed corpus callosum (C). Courtesy of Dr. R. Robertson

of the corpus callosum can be diagnosed on a CT scan (high riding third ventricle, parallel configuration of the lateral ventricles, and colpocephaly), MRI is far superior in diagnosing associated structural abnormalities. Partial agenesis is also seen very clearly on sagittal MRI images. Midline cysts not associated with agenesis of the corpus callosum, holoprosencephaly, and extreme hydrocephalus without agenesis of the corpus callosum need to be considered in the differential diagnosis. In secondary disruption of the corpus callosum, developmental features, such as lack of the cingulate gyrus and presence of a bundle of Probst, are not found. The potential of an underlying metabolic disorder (e.g., nonketotic hyperglycinemia, infantile lactic acidosis associated with pyruvate carboxylase deficiency, pyruvate dehydrogenase deficiency, and Smith-Lemli-Opitz and Zellweger's syndromes) have to be considered in clinical context. In patients with additional malformations of the brain and/or extraneural structures, a karyotype should be performed as well. A special problem is posed by the prenatal detection of the absence of the corpus callosum on ultrasound. The presence of additional abnormalities and an abnormal karyotype is a poor prognostic indicator for developmental outcome, whereas outcome can be favorable if the agenesis of the corpus callosum is a truly isolated malformation. [44]

Absence of the olfactory bulbs and tracts, or *arrhinencephaly*, is also considered in the midline defects, although the pathogenesis may be distinct. Arrhinencephaly can be found as an isolated malformation or in conjunction with a variety of malformation syndromes. Clinically, bilateral arrhinencephaly manifests as anosmia. Although arrhinencephaly is frequently included in the midline dysplasias and can represent a mild manifestation of the holoprosencephaly spectrum, it would be incorrect to conclude that every isolated case of arrhinencephaly belongs with this spectrum. Possibly, arrhinencephaly can result from a number of independent mechanisms. One example of a non-holoprosencephaly-sequence syndrome associated with arrhinencephaly is Kallmann's syndrome. This syndrome is characterized by a combination of arrhinencephaly, resulting in anosmia, and hypogonadotropic hypogonadism, resulting from gonadotropin-releasing hormone

Figure 28-5 Lissencephaly type I and type II (A). A brain from an 8-month-old infant with Walker-Warburg syndrome demonstrating type II lissencephaly. Note the smooth surface of the brain; slight irregularities of the cortical surface can best be appreciated in areas of light reflection on the specimen (C). A histological section through the cerebral mantle of a 20-week-old gestational age fetus with the Walker-Warburg syndrome. One half of the thickness of this section is taken up by the totally disorganized cortical plates (white bar). In addition, there are subcortical heterotopias pointed out by the arrow (D) shows an age-matched control. Here the cortical plate (white bar) takes up only a fraction of the whole thickness of the mantle (E and F are examples of type I lissencephaly, as can be seen in the Miller-Dieker syndrome (B) is a coronal section stained for myelin that demonstrates the four layers of this type of lissencephaly: 1 corresponds to the molecular layer, 2 is a cellular layer with mostly large neurons, 3 is a layer containing myelinated fibers, and 4 is a broad heterogeneous cell-rich layer. Note that the cortical plate takes up more than half of the total thickness of the cerebral mantle (E). Courtesy of Dr. R. Robertson

deficiency. [45] Other neurological features may be associated. The syndrome can be inherited in an autosomal dominant, recessive, or X-linked recessive pattern. The gene for the X-linked form has been identified; it shares homology with neural cell adhesion molecules, and the developmental defect has been linked to the failure of gonadotropin-releasing hormone (GnRH)-producing neurons to reach the hypothalamus. [45]

NEURONAL MIGRATION DEFECTS

Pathogenesis and Pathophysiology. Anomalous cerebral cortical development is generally characterized as a cortical migrational abnormality, although an actual defect in migration has yet to be conclusively demonstrated. Rorke^[46] has hypothesized a variety of factors that must be considered in the pathogenesis of cortical migrational abnormalities. Among the various components of development, cellular proliferation, cell death, postmigrational intracortical growth and development, and extracellular matrix abnormalities can each be implicated as a possible pathogenetic mechanism.

The cortical migrational abnormalities can be grouped into three general categories: lissencephaly/pachygyria, polymicrogyria, and heterotopia. Lissencephaly and pachygyria are thought to represent a spectrum of the same basic disorder: lissencephaly referring to a diffuse bilateral abnormality of development, and pachygyria being a focal or multifocal abnormality with similar features ([Fig. 28-5](#)). Radiographically and on gross pathological examination, the normal gyral and sulcal pattern is effaced by a smooth agyric surface. The cerebral cortex is markedly thickened with variable preservation of the cerebral white matter. At least two distinct types of lissencephaly exist. Type II lissencephaly (see later) is pathologically characterized by diffuse agyria, although focal polymicrogyria may also be present. Cross sections show the cerebral hemisphere to be approximately one half gray matter and one half white matter (see [Fig. 28-5](#)). The junction between the gray and white matter is usually blurred, and nodules of gray matter heterotopia are commonly seen in the white matter. Type I lissencephaly is classically associated with the *Miller-Dieker syndrome*, although autosomal recessive and X- linked forms have been identified. Type I lissencephaly, independent of the inheritance pattern, shows similar histopathological features. The cortex is extremely thick at the expense of the cerebral white matter, and the cortex is organized into four abnormal layers. The Miller-Dieker syndrome has been mapped to 17p13, and the putative gene cloned by Reiner and colleagues. However, the function of this gene, called LIS1, is not known at this time. In contrast to type I lissencephaly, in which the remainder of the brain is relatively spared, type II lissencephaly is frequently associated with other CNS malformations. Most common are the Dandy-Walker malformation and cerebellar cortical dysplasia. The diffuse, thick nature of the pachygyria/lissencephaly malformation suggests a failure of neurons to migrate completely through the developing white matter. Similar assumptions can be made about cerebral heterotopia, where groups of neurons fail to migrate fully

Figure 28-6 Polymicrogyria. The border of polymicrogyria and normal cortex. The border is extremely well delineated. The polymicrogyria is characterized by fusion of layer I, continuity of layer IV, and extensive undulating folds of cerebral cortex.

to their cortical destination, remaining in the developing white matter or periventricularly. Thus, the pathogenesis of these malformations is believed to be early in cortical neurogenesis, probably beginning around 10 to 12 weeks of gestation or earlier.

Polymicrogyria is frequently recognized as a fine stubbling on the surface of the brain (described as similar to Moroccan leather in appearance). By MRI and gross examination of brain sections, the cerebral cortex shows a complex set of small gyri that appear fused to each other. Microscopic examination confirms the gross impression, highlighting the small, complex gyri and fusion of layer 1 ([Fig. 28-6](#)). Controversy exists as to whether polymicrogyria is a malformation or a disruption of development. The answer is likely to be both. Given that polymicrogyria is almost always present at the margins of disruptions, such as porencephaly, and in the setting of malformations, such as Zellweger's syndrome and triploidy, the conclusion often drawn is that there are multiple pathogeneses for polymicrogyria. Unfortunately, some overlap exists in the microscopic features of polymicrogyria regardless of the presumed pathogenesis. However, unlike lissencephaly and pachygyria, the border between polymicrogyria and normal cortex is distinct, and layer 6 in adjacent normal cortex and the deepest layers of the malformed polymicrogyric cortex are contiguous (see [Fig. 28-6](#)). Based on the pathological features of polymicrogyria, the timing is later in neocortical development, generally believed to arise from defects occurring between 17 to 18 weeks' and 24 to 26 weeks' gestation.

Cerebral heterotopia are collections of disorganized gray matter in inappropriate places ([Fig. 28-7](#)). Heterotopia in the cerebral hemispheres can take on one of many patterns. They may occur as focal, isolated anomalies found incidentally on imaging or at autopsy, or they may have clinical manifestations, as described later. Occasionally, an isolated heterotopia or multifocal cerebral heterotopia are associated with an overlying cortical malformation. Another pattern is that of bilateral subcortical heterotopia, which may

Figure 28-7 Periventricular nodular heterotopia(A). An MRI from a patient with extensive periventricular heterotopia(A, Courtesy of Dr. C. Walsh.) The heterotopia are the same signal intensity as the cerebral cortex and scallop the margin of the ventricular surface. Histological sections from a normal fetus(B) at 20 weeks' gestation and a similar age fetus with periventricular heterotopia(C). The germinal tissue normally present around the angle of the lateral ventricle is replaced by several nodules of maturing grey matter (heterotopia).

be strikingly symmetrical. Islands of subcortical laminar heterotopia separated from the malformed cortex by a band of white matter create the entity known as double cortex. In addition to white matter heterotopia, glial and neuroglial heterotopia are often found in the leptomeninges overlying a cortical anomaly or around the base of the brain. The displaced tissue can form a radiographically and grossly identifiable plaque over the surface of the brain.

Another group of anomalies of cerebral cortical development that is being recognized with increasing frequency are the focal *cortical dysplasias* or *cortical migrational anomalies*([Fig. 28-8](#)). The increasing practice of surgery in the management of intractable seizures has resulted in the recognition of a variety of cortical malformations in a significant number of cases.^[47] Although polymicrogyria and pachygyria have been seen in many cases, the most frequent anomaly has been labeled focal cortical dysplasia. This disorder is characterized by a disruption in the lamination pattern, and by maloriented neurons in inappropriate layers including layer 1 and in the cerebral white matter. Their pathogenesis is unclear.

Epidemiology and Risk Factors. The incidence of disorders resulting from neuronal migrational abnormalities is unknown. Most of the cortical migrational disorders, particularly the diffuse ones, show a variety of inheritance patterns. Other cases show no clear inheritance and appear to be sporadic. A variety of environmental risk factors, including retinoic acid, methylmercury, and radiation, have been associated with the development of neuronal migrational disorders. In utero infections, particularly viral, are also known to result in cortical migrational abnormalities. The pathogenesis for viral induced migrational disorders remains unknown, although a destructive process is speculated to underlie the defect.

Clinical Features and Associated Disorders. The most striking clinical context in which type I lissencephaly is seen is the Miller-Dieker syndrome. Classic facial features include bitemporal hollowing, a rather short nose with a broad bridge and upturned nares, long and thin upper lip, small chin, and mildly low-set and posteriorly rotated ears. Although this constellation is referred to as the Miller-Dieker facial dysmorphism, the findings can be rather subtle. Most individuals with type I lissencephaly present in the neonatal period with marked hypotonia.

Figure 28-8 Focal cortical dysplasia. An axial MRI scan from a patient with focal cortical dysplasia. The left hemisphere shows a normal cortical ribbon; however, in the right hemisphere, in the posterior frontal lobe the cortical ribbon is abnormally thickened and the sulcal pattern is lost. The underlying white matter may be slightly th(Courtesy of Dr. R. Robertson.)

Later, a spastic quadriplegia dominates the picture. Seizures are a constant part of the clinical picture; they can start as neonatal seizures but more commonly present as infantile spasms with myoclonic and tonic seizures that later lead to Lennox-Gastaut syndrome with the additional occurrence of atonic seizures. The electroencephalogram typically shows fast alpha- and beta-activity admixed with high-amplitude slow activity. Mental and psychomotor retardation are usually profound. Cardiac anomalies occur in 20 to 25 percent of patients, and there can be genital anomalies in about 70 percent of males.

Type II lissencephaly occurs in a group of disorders associated with congenital muscular dystrophy, often involving the eyes as well. The Walker-Warburg syndrome, the Finnish muscle-eye-brain disease (MEB), and Fukuyama congenital muscular dystrophy (FCMD) are entities within this group. The Walker-Warburg syndrome (WWS) is the most severe of these, and the syndrome has a high proportion of neonatal lethality. The brain malformation often is complex with hydrocephalus, cerebellar hypoplasia (and occasionally Dandy-Walker malformation), and sometimes an occipital encephalocele associated with the cortical malformation. Clinically, it is characterized by profound hypotonia in the neonatal period due to the combined muscle and CNS involvement. The eyes can be affected in a number of ways, of which retinal dysplasia is the most consistent. Anterior chamber malformations, cataracts, choroidal colobomata, optic nerve hypoplasia, and microphthalmia can occur. Serum creatine kinase levels are elevated. Arthrogryposis may be present, and contractures may develop later. This condition is inherited in an autosomal recessive fashion, and as yet, no gene or genetic localization has been defined.

MEB of Santavouri has many features that resemble WWS; the disorder is prevalent predominantly in Finland.^[49] This condition presents at birth or the first few months of life with hypotonia and weakness. Serum CK levels are consistently elevated after 1 year of age and often earlier. Subsequent psychomotor development is markedly delayed; however, many patients will acquire the ability to stand and walk. Mental retardation and seizures are common. The EEG is usually abnormal and progressively so after about 6 to 7 years of age. Most patients show a progressive motor deterioration, increasing spasticity, and contractures by 5 years of age. The eye abnormalities consist of high myopia, retinal degeneration, and optic atrophy. Congenital glaucoma and juvenile cataracts may also be present. The visual evoked potentials tend to be progressively delayed and of abnormally high amplitude, with an abolished electroretinogram at the same time. Neuroimaging often reveals less severe but comparable findings of MEB syndrome to WWS. Hydrocephalus is seen frequently, and patchy white matter abnormalities can be seen on T2-weighted MRI images.

FCMD is the second most common muscular dystrophy in Japan;^[50] only Duchenne muscular dystrophy is identified more frequently. It appears to be extremely rare outside of Japan. In contrast to the MEB and WWS, eye involvement is generally less frequent and less severe. Patients show considerable psychomotor retardation and progressive muscular weakness and contractures. Seizures occur in about 50 percent of patients. When present, ocular findings include myopia and optic atrophy. MRI of the brain demonstrates the areas of pachygyria as well as polymicrogyria. Areas of abnormal T2 signal on MRI can be seen in the white matter. The cerebellum is only mildly affected, and hydrocephalus is rare. Linkage to chromosome 9q31 has been established for this autosomal recessive disorder; however, at the time of writing, the responsible gene had not been isolated.

Polymicrogyria has a less heterogenous clinical presentation than does lissencephaly. For all practical purposes, the different forms of polymicrogyria, independent of their syndromic or etiological context, present with often focal seizures. The various syndromic associations of polymicrogyria are discussed later under differential diagnosis.

Heterotopia can be sporadic, inherited as a simple Mendelian trait, or be part of a more complex syndrome. When heterotopia appears in isolation, the main presenting feature is seizures of various kinds, although by no means are they obligatory. Onset of the seizures can be from childhood (most commonly) to adulthood. Focal, multifocal, and generalized seizures can occur. Infantile spasms and the Lennox-Gastaut syndrome are seen at the severe end of that spectrum. Other neurological problems such as motor impairments and mental retardation may co-exist. The risk for these additional manifestations is lowest when the abnormality is localized to the periventricular region, higher in white matter heterotopia, and highest in diffuse subcortical band heterotopia. However, even in diffuse subcortical band heterotopia, normal psychomotor development can be seen, although it is infrequent.

The initial presentation of cortical dysplasia is most commonly the onset of various types of seizures. With this presentation, there are no clear signs or symptoms that predict cortical dysplasia versus another cortical lesion. The age of seizure onset tends to be in childhood, but can be delayed into adulthood and can be as early as infancy.^[51] When the condition appears in infancy, the clinical picture can vary from clearly focal-appearing seizures to infantile spasm with relatively minimal or no focal clinical features. Later, the seizures may also include tonic seizures as well as drop attacks. Onset during the first few days of life as an Early Infantile Epileptic Encephalopathy (EIEE) has also been described.^[52] EEG findings can be variable.^{[51], [53]}

Differential Diagnosis. Among the conditions with lissencephaly type I, the Miller-Dieker phenotype is distinguished from the isolated lissencephaly sequence (ILS) by the lack of distinctive facial features in ILS. However, bitemporal hollowing and a small chin can be seen in ILS as well. Furthermore, FISH analysis has demonstrated 17p13.3 microdeletions in a significant number of ILS cases.^[54] However, other probes appear to distinguish between the two entities, suggesting a difference in the physical extent of the deletions, potentially accounting for the additional anomalies in the Miller-Dieker syndrome like the loss of contiguous genes. Other cases of ILS could possibly result from mutations in other genes.

The differential diagnosis of the lissencephaly II syndromes can be difficult. These difficulties are reflected in the many essentially synonymous designations of these syndromes, including the MEB syndrome; *hydrocephalus, agyria, retinal dysplasia, ± encephalocele (HARD±E)*; and *congenital ocular dysplasia/muscular dystrophy*

(CODM) syndromes. Although there is no difference in principle between WWS and MEB syndromes beyond the degree of severity, this does not automatically prove that they are allelic variants at the same gene locus. The short survival of the WWS patients does not allow for a careful longitudinal analysis of the kind that has been conducted in MEB patients, potentially obscuring clinically relevant differences. Clearly, this question awaits the genetic assignment of both phenotypes. However, it now appears clear that MEB disease is genetically distinct from the related FCMD. FCMD maps to chromosome 9q, from which MEB has been excluded. Fukuyama muscular dystrophy, despite many similar features, usually does not include the severe eye and brain anomalies found in the WWS.

Many other syndromes and associations may show variable forms of lissencephaly, pachygyria, and polymicrogyria as features and many cases are not easily classified into any particular syndrome ([Table 28-2](#)).^[55] Discussions of these rare disorders have been reviewed.^[46] A number of metabolic conditions can also be associated with pachygyria and lissencephaly. The most frequent syndrome to show such an association (along with polymicrogyria) is Zellweger's syndrome.^[56] This is a disorder of peroxisomal biogenesis that is characterized by marked neonatal hypotonia, facial dysmorphism, wide open fontanelles, and renal and hepatic abnormalities. Neonatal adrenoleukodystrophy and bifunctional enzyme deficiency are also peroxisomal disorders that may show migrational abnormalities. Glutaricaciduria type II, pyruvate dehydrogenase deficiency, nonketotic hyperglycinemia, and sulfite oxidase deficiency/molybdenum co-factor deficiency are examples of other metabolic disorders that occasionally include a cortical dysplastic malformation as one of the manifesting features.

The differential diagnosis of conditions with polymicrogyria also is rather extensive,^[46] reflecting the nonspecific nature of the malformation. In addition to the lissencephaly type II conditions discussed already, Aicardi's, Neu-Laxova, Zellweger's, and Smith-Lemli-Opitz syndromes could be mentioned as monogenic conditions. Polymicrogyria can also occur with a variety of chromosomal abnormalities. As outlined earlier, disruptive and destructive disorders can have polymicrogyria associated with them. The most common association is with congenital cytomegalovirus infection, and the timing of this malformation is probably similar to the disruptions of porencephaly and hydranencephaly. In fact, both of these disorders have been reported with congenital cytomegalovirus infection, as well as other congenital infections. Extensively fused polymicrogyria can be difficult to differentiate from pachygyria on imaging.

Periventricular as well as subcortical band heterotopia can occur as X-linked inherited conditions, mapping to different regions on the X chromosome.^[57] In familial band heterotopia, affected females present with the heterotopia and often seizures, whereas affected males show more severe brain malformations, including lissencephaly. This factor may be due to random X-inactivation in females preventing full expression of the defect, and it also raises the possibility that a spectrum of developmental disturbances, from focal heterotopia to lissencephaly, exists with a common pathogenesis.^{[54], [58], [59]} In X-linked familial periventricular heterotopia, affected male family members also have a more severe malformation and clinical phenotype than affected female siblings.^[59] Again, a number of syndromes include neuronal heterotopia with some regularity. For example, in Aicardi's syndrome, heterotopias are as constant a feature as agenesis or hypoplasia of the corpus callosum. Retinal lacunae, cerebellar abnormalities, and hemivertebrae may also be found in this syndrome. Aicardi's syndrome is probably an X-linked dominant male lethal condition, so that only girls are affected clinically. The presentation is with severe early seizures (infantile spasms) and profound psychomotor retardation. An interesting addition to the list of metabolic conditions associated with heterotopia, in which the peroxisomal disorders again are represented, is the Smith-Lemli-Opitz syndrome (type II), diagnosed by an elevated level of plasma 7-dehydrocholesterol.

The differential diagnosis of polymicrogyria versus focal cortical dysplasia can be difficult because of the similar clinical presentation with focal seizures. Imaging is

the instrument that is most often used to differentiate the two (see later). The so-called benign focal epilepsies of childhood are important to differentiate from fixed cortical malformations, because their prognosis and management are different.

Evaluation. The diagnosis of the Miller-Dieker syndrome and also the isolated lissencephaly sequence is based on the finding of a smooth brain surface with widely open sylvian fissures on neuroimaging studies, an appearance that has been called the [figure 8](#) sign. The broad cortex in relation to the extremely narrow white matter can be seen on MRI. Cytogenetically visible deletions of the critical chromosomal region 17p13.3 are seen in about two thirds of clinically convincing cases. ^[54] More than 90 percent of

TABLE 28-2 -- SUMMARY OF MAJOR SYNDROMES WITH CORTICAL MALFORMATIONS

Disorder	Cerebrum	Cerebellum	Hydrocephalus	Eye	Muscle	Other

MDS, Miller-Dieker syndrome; ILS, isolated lissencephaly sequence; WWS, Walker-Warburg syndrome; MEB, muscle-eye-brain disease; NL, Neu Laxova syndrome; NRS, Norman-Roberts syndrome; DWS, Dandy-Walker malformation; A, agyria; P, pachygyria; E, encephalocele; +, affected; -, unaffected.

patients show loss of this critical region when FISH analysis is employed.

Type II lissencephaly has an appreciably different MRI appearance, with a gray to white matter ratio of 1:1. Here, as well as for all of the other disorders of neuronal migration, careful evaluation of the morphology of the cortex by MRI is essential. In cases of type II lissencephaly/pachygyria, especially in the presence of associated CNS malformations or abnormalities of the eyes, the congenital muscular dystrophies with associated eye abnormalities have to be considered. Determination of serum creatinine kinase levels, and muscle biopsy may become necessary. Once the diagnosis of a congenital muscular dystrophy with structural brain abnormalities has been made, the differential diagnosis between the individual conditions should follow the considerations outlined earlier. Prenatal diagnosis of WWS by ultrasound is possible, although not always easy. The posterior fossa anomalies and demonstration of retinal detachment are helpful.

The workup for focal cortical abnormalities of migration also relies heavily on extremely high-quality MRI, because some of these lesions can be very hard to detect. Clinical suspicion must remain high and hints, such as delayed myelination underneath a cortical region, may be valuable in defining the location of the abnormality. The value of functional imaging techniques such as positron-emission tomography, single photon emission computed tomography, and perfusion-diffusion MRI at this point cannot be generalized. These techniques are under active development. Several special MRI techniques, such as three-dimensional surface rendering, are also being evaluated for this purpose and appear promising. At a minimum, high-resolution imaging with thin cuts and optimal gray to white matter resolution for the age of the patient is essential. On EEG, focal very high amplitude rhythmical activity is characteristic of cortical dysplasias; however, this activity is recorded in less than half of the cases. Other EEG patterns, such as focal abnormal fast activity, have no predictive value for a focal dysplasia. At times, the surface EEG can be normal or appear to show primary generalized spike and wave discharges. An additional diagnostic problem is the question of whether the underlying lesion is unifocal or multifocal. Multifocal discharges on the EEG do not necessarily mean multifocality of the dysplasias, although they can. Conversely, electrographical evidence for only one focus does not exclude the existence of additional foci. Long-term video-telemetry monitoring may be helpful in evaluating these questions. In cases in which seizures are resistant to medical management and there is a high degree of suspicion for a focal cortical abnormality but lack of noninvasive evidence, intraoperative electrophysiology may prove useful. Resected pathological material often shows features of cortical dysplasia.

Management and Prognosis. In general, the prognosis for patients with Miller-Dieker syndrome and WWS is very poor, and many patients do not survive infancy. Very little psychomotor development, if any, takes place. Insertion of a gastric tube may be necessary to provide adequate nutrition, prevent aspiration, and facilitate care. Treatment of the often prominent seizures follows general guidelines.

In the congenital muscular dystrophies with structural brain abnormalities, the brain malformation may require surgical intervention for the hydrocephalus or sometimes for the encephalocele in WWS. If the hydrocephalus is due to aqueductal stenosis and a Dandy-Walker anomaly is present, shunting of both the lateral ventricles and the posterior fossa cyst may become necessary. The prognosis is better in the Finnish MEB disease, and although patients often acquire the ability to walk, there may be secondary deterioration because of increasing spasticity. In this condition, ophthalmological management becomes important: high myopia, cataracts, glaucoma, and retinal detachment may require intervention.

The epileptic syndrome in migrational abnormalities is often medically intractable, surgical extirpation of the lesion is often desirable, and earlier surgical intervention may improve the overall developmental prognosis. For an isolated focus of polymicrogyria or cortical dysplasia presenting with intractable seizures, extirpation can be curative; however, multifocality is not an automatic contraindication against the surgery, because extirpation of a major focus may result in overall improvement of seizure control. The presurgical and intraoperative evaluation is essential for success of the surgery and is dealt with in detail in reference 60. For isolated epileptogenic heterotopias, surgical excision also is an option; the drop attacks that can be seen in the diffuse bilateral band heterotopias may respond to callosotomy.^[61]

OTHER DISORDERS OF NEURONAL MIGRATION AND CORTICAL FORMATION

Ulegyria is another distinct cortical anomaly. Ulegyria is best characterized as a fusion of layer 1 at the depths of sulci with relative sparing of the crests of the gyri. The fusion is frequently associated with gliosis in the cortex, neuronal loss, and obliteration of the cortical lamination. The scarring at the depth of a sulcus and sparing at the surface of the brain results in a mushroom appearance when the gyrus is viewed on cross section. These lesions have very well-defined borders and discrete islands of preserved neurons within the lesion. The histology and location, frequently in an arterial zone, have led to the contention that ulegyria arises late in gestation or in early neonatal life as a vascular injury to the immature cortex, possibly related to hypoperfusion. Ulegyria may be clinically silent or manifest as seizures, similar to those of polymicrogyria discussed earlier.

An enlarged brain volume, or *megalocephaly*, can be sporadic, autosomal dominant, autosomal recessive, or part of a recognized syndrome or disease ([Table 28-3](#)).^[1] Generalized megalencephaly shows a diffuse broadening of the cerebral gyri with an increased white matter and gray matter volume and frequently normal-sized ventricles. The brain is usually microscopically normal, although several reports have suggested an increased cell volume. In the familial form of megalencephaly with autosomal dominant inheritance, the majority of cases are neurologically normal. Hydrocephalus and extracerebral fluid collections have to be ruled out by imaging in all cases.

Hemimegalencephaly ([Fig. 28-9](#)) may occur in isolation or may be associated with a specific syndrome, the most

widely recognized of which are Beckwith-Wiedemann syndrome and the linear sebaceous nevus syndrome. The abnormally large cerebral hemisphere shows regions of broad and fused gyri. Cross sections of the hemisphere reveal regions of thickened cerebral cortex and frequently heterotopia in the cerebral white matter. Microscopically, the hemisphere shows marked disorganization with regions resembling pachygyria. In other regions, the neurons of the malformed cortex are abnormally spaced and disorganized in orientation. The clinical presentation of hemimegalencephaly is variable.^[62] One clue to the possible existence of hemimegalencephaly is the identification of body asymmetries, especially of the skull and face, or the recognition of other features of a syndrome associated with hemihypertrophy. Most patients with hemihypertrophy present during the first year of life with frequent, focal seizures or infantile spasms. Some infants show asymmetries of motor development that can be subtle or present as frank hemiparesis. The EEG is variable, showing a fast rhythmical pattern in the alpha to beta range, burst-suppression patterns, spike-wave or repetitive triphasic complexes, or both. Some authors assign a poor prognosis to repetitive triphasic complexes. Mental retardation is frequently associated with hemimegalencephaly and appears to be correlated to some extent with the severity of the epilepsy. Patients with normal development and intelligence or well-controlled partial seizures have been reported. The association of hemimegalencephaly with Wilms' tumor of the kidney is important to recognize. Given the difficulties of medical seizure control in the majority of cases, and the adverse effects that ongoing seizures potentially have for developmental outcome, early modified hemispherectomy has been repeatedly advocated and successfully performed in these children.^[63]

Microcephaly is defined by the head circumference being two standard deviations below that predicted by the body size. This definition does not provide any indication of the nature of the brain abnormality. The etiology of microcephaly is complex ([Table 28-4](#)) and includes conditions that restrict brain growth (such as the craniosynostosis), destroy formed brain substance before completion of brain growth (examples include hypoxic-ischemic insults and some infections), or intrinsically impair brain growth. Intrinsically impaired brain growth can be the result of a metabolic insult (exogenous or inborn), or a defect of brain formation itself (as is assumed to be the case in the so-called primary genetic microcephalies, the chromosome breakage syndromes, and also in the majority of syndromes associated with microcephaly). It should be kept in mind that a small head circumference at birth does not rule out metabolic conditions, nor does a normal head circumference at birth rule out primary genetic causes of microcephaly. Microcephaly is a manifestation of many syndromes and is very common in syndromes that have mental retardation and cortical migration abnormalities as a component. Jones^[21] has compiled 39 syndromes that have microcephaly as a frequent component and an additional 21

syndromes in which microcephaly is occasionally present. One hundred and seventy six syndromes have been

Figure 28-9 Hemimegalencephaly. An axial T2-weighted MRI scan demonstrates the moderately larger right hemisphere compared with the left. The cerebral cortex is poorly defined on the right side, and the T2-imaging highlights the abnormal signal intensity of the cerebral white matter on the same side.

reported, with at least one case of documented microcephaly.^[22] Patients who appear to have a primary form of significant microcephaly, meaning that it is not associated with other malformative features, are sometimes referred to as having microcephalia vera. This heterogeneous condition (autosomal recessive and X-linked forms have been identified) shows a striking reduction of head circumference up to 5 standard deviations below the mean. No distinct facial dysmorphism is associated with this condition. These individuals are severely mentally retarded and have no recognizable speech but are often described as having a relatively preserved personality. Although patients often have a somewhat lumbering gait, there is a paucity of other neurological findings. Skull films at birth show that the sutures are present. The brain is usually small, less than 300 g (normal 1200 to 1500 g) and shows a primitive gyral pattern. The cortex is thickened and disorganized without clear lamination. Isolated microcephaly can also be transmitted as an autosomal dominant trait. In this circumstance, the degree of microcephaly usually is not as pronounced, and intelligence is relatively preserved. Given the preponderance of genetic conditions presenting with isolated microcephaly, Tolmie and colleagues^[64] calculated an empirical recurrence risk of 19 percent after a single affected proband.

POSTERIOR FOSSA ANOMALIES

Pathogenesis and Pathophysiology. The development of the brain stem and cerebellum has been extensively investigated at the anatomical, cellular, and molecular levels.^[4c] The cerebellum is entirely derived from the rhombic lip, a dorsal ridge of the developing neural tube located at the junction between the midbrain and hindbrain (rhombencephalon). Proliferation and migration at the rhombic lip results in caudal growth of the cerebellar anlagen, with the cerebellum forming the roof of the fourth ventricle. Aplasia of the cerebellum is an extremely rare condition, and most such cases are believed to represent secondary disruptions of normal development, primarily on a vascular basis.

In the 1890s, Chiari described a group of malformations of the posterior fossa, each characterized by a displacement of the cerebellum.^[65] Chiari II malformations, also known as the Arnold-Chiari malformation, have been described previously in this chapter (see the discussion of neural tube defects). *Chiari I* malformations are distinguished from Chiari II malformations by the displacement of the cerebellar tonsils (as opposed to the vermis in cases of the Chiari II malformation) over the cervical spinal cord (see [Fig. 28-2](#)). The Chiari I malformation is occasionally equated with herniation syndromes involving pressure coning and necrosis of the cerebellar tonsils. These two entities should remain distinct, since Chiari I represents a malformation and the other entity a result of increased pressure within the posterior fossa. Occasionally, hydromyelia or syringomyelia may be associated with the Chiari I malformation, as with the Chiari II malformation. However, myelomeningoceles are not associated with Chiari I malformations.

The rare *Chiari III* malformation represents a displacement of the cerebellum into an occipital encephalocele. Occipital encephaloceles can involve either the occipital lobes of the cerebral hemispheres or the posterior fossa elements. As mentioned previously, encephaloceles involving the posterior fossa elements, and the cerebellum in particular, frequently carry a poor prognosis.

The *Dandy-Walker malformation*, by the strictest definition, includes a dilated fourth ventricle, an anteriorly rotated cerebellar vermis that is partially or completely absent, and an enlarged posterior fossa with an elevated tentorial insertion.^[66] The Dandy-Walker malformation is not a true cyst of the fourth ventricle but a cystlike dilation of that ventricle (see [Fig. 28-2](#)).

Absence or partial absence of the cerebellar vermis is also a characteristic of *Joubert's syndrome*. This syndrome can be distinguished neuropathologically from the Dandy-Walker malformation by the absence of a cystically dilated fourth ventricle. Relatively few brains of patients who have been clinically diagnosed with Joubert's syndrome have been studied pathologically. One problem related to understanding the pathological findings in this syndrome is the lack of a clearly defined clinical spectrum. Patients described

as having Joubert's syndrome show a broad spectrum of clinical findings (see later), including variation between families, suggesting the possibility of more than one etiology.

Focal deficits primarily involving the sixth and seventh cranial nerves, whether unilateral or bilateral, have been variably classified as *Mobius' syndrome*. Although disagreements exist as to the definition of this syndrome, at the very least, bilateral deficits of the sixth and seventh cranial nerves justify the designation of Mobius' syndrome. Whether unilateral deficits involving one or multiple cranial nerves should be designated Mobius' syndrome as well remains controversial. Although very few cases have been studied pathologically, most data agree that destructive lesions, frequently assumed to be vascular in origin, are the basis for most cases of Mobius' syndrome. Whether congenital absence of cranial nerve nuclei exists as a distinct entity is likely but unknown.

Several clinical syndromes are believed to result from a form of miswiring in the nervous system that is derived from the establishment of aberrant neural connections. Duane's syndrome is one form and is discussed later. Another example of this phenomenon is the *Marcus Gunn syndrome*, in which patients present with activation of the levator palpebrae upon use of the muscles of mastication, such as suckling in an infant. Often there is congenital ptosis on the affected side. This syndrome is believed to result from misdirected neuronal connections between the third, fifth, and other cranial nerves.

Epidemiology and Risk Factors. Given the diverse group of anomalies that afflict the posterior fossa, it is impossible to give a concise estimate for the incidence or prevalence of this group of disorders. Some of the anomalies are found in almost constant association with other malformations. For example, the Chiari II malformation (discussed earlier with myelomeningoceles), is almost uniformly associated with lumbosacral spinal neural tube closure defects and thus the incidence parallels the incidence of myelomeningoceles. Other anomalies, like the Dandy-Walker malformation, may be found either as an isolated malformation, in conjunction with other malformations (e.g., cardiovascular), or as part of a syndrome (e.g., Meckel-Gruber syndrome and WWS). Risk factors also vary depending on the malformation in question. Mobius' syndrome, for example, is found more frequently among children born with congenital heart malformations than in isolation. Dandy-Walker malformations have been associated with maternal exposure to retinoic acid and warfarin. A complete discussion of the risk factors and associated syndromes involving the posterior fossa has been compiled.^[22]

Clinical Features and Associated Disorders. The cerebellum may be diffusely small (hypoplasia) or absent (aplasia). These conditions are relatively rare, especially cerebellar aplasia. *Cerebellar hypoplasia* and *aplasia* may present with any combination of hypotonia, motor delays, cognitive delays, ataxia, head and truncal titubations, irregularities of speech rhythm, and nystagmus. However, clinically asymptomatic cases of cerebellar hypoplasia or even aplasia are well documented in the older literature.

The *Dandy-Walker* malformation is clinically heterogeneous, as alluded to earlier. Some cases exhibit other CNS abnormalities, such as agenesis of the corpus callosum, brain stem anomalies, and migrational abnormalities. Mental retardation is also variable and frequently correlates with the presence of associate anomalies. Patients without associated anomalies may have relatively normal intelligence and development.^[67] Therefore, the evaluation of an individual with the Dandy-Walker malformation requires a careful search for such associated abnormalities. Ataxia and brain stem dysfunction are often the presenting features and are believed to result from local pressure effects on the brain stem and cerebellum. Owing to pressure fluctuations in the posterior fossa, these symptoms can occur intermittently. The initial presentation may occur as late as adulthood, with headache and progressive neurological deterioration. Although hydrocephalus is often included in the definition of the Dandy-Walker malformation, hydrocephalus is often not present at birth and may present in the first year of life as a secondary event. Although occasionally clear etiologies for the hydrocephalus, such as aqueductal stenosis, are identified, most cases show no clear obstruction of CSF flow. Lack of patency of the foramen of Magendie and the foramina of Lushka, once considered the pathogenesis of the malformation, is rare and unlikely to be the etiology of the hydrocephalus in most cases.

Joubert's syndrome is an autosomal recessive condition that presents with abnormalities of respiratory rate control in infancy (particularly episodic tachypnea and also respiratory pauses), rhythmical tongue protrusion, abnormal eye movements, ataxia, and mental retardation.^[68],^[69] Structural eye abnormalities such as chorioretinal colobomata have been described. The degree of developmental delay can be variable and is not necessarily as severe as initially thought.

The clinical spectrum associated with the *Chiari I malformation* has broadened in recent years with the increasing use of MRI, the imaging modality of choice for the diagnosis of this condition. As opposed to the Chiari II malformation (see the previous discussion of neural tube closure defects), the Chiari I malformation usually becomes symptomatic in teenage to early adult years, although the initial presentation can also be in an infant or older adult. The initial complaint is often neck pain, at times presenting with torticollis or retrocollis. If cervical spinal cord *syringomyelia* co-exists, symmetrical, asymmetrical, or even totally unilateral arm pain can be the initial complaint. Neurological symptoms and signs also are dependent on the neural structures involved. Predominant impairment of the brain stem and cerebellar tonsils by either compression at the level of the foramen magnum or by extension of the syrinx into the brain stem (syringobulbia) can lead to a variety of brain stem and cerebellar signs. In the very young age group, sleep apnea, stridor, and feeding difficulties may be the presenting symptoms. Eye movement abnormalities are relatively common. Oscillopsia is reported by the patient, and a variety of forms of nystagmus can be seen. Downbeating nystagmus, especially when accentuated by lateral downgaze, should alert the examiner to a potential problem at the craniocervical/pontomedullary junction. Torsional nystagmus may also be present, especially in the presence of syringomyelia or syringobulbia. Lower cranial nerve impairment can lead to dysphagia and aspiration, which may first present as late as the eighth decade. When complicated

by syringobulbia, asymmetrical cranial nerve involvement up to cranial nerve V may be present. Imbalance and vertigo with truncal ataxia may indicate impairment of the vestibulocerebellar and spinocerebellar systems. With the co-existence of cervical hydrosyringomyelia, this picture becomes even more complicated. Forty to seventy-five percent of cases of Chiari I malformation have an associated syringomyelia, depending on the series and method of ascertainment.^[70] When the patient is

presenting with symptoms referable to the spinal cord, syringomyelia can be demonstrated in over 90 percent of cases. The most common location of maximal expansion is C4 to C6, though the cavity can expand up and down the entire spinal cord. The cavity often is centrally or slightly asymmetrically located, thus first impairing crossing fibers in the anterior spinal commissure. Because these fibers carry sensory information predominantly for pain and temperature, and the posterior columns can be relatively spared, a dissociated sensory loss may result; pain and temperature sensation may be disturbed in a capelike distribution over the shoulders and down the arms, while light touch and joint position remain relatively unaffected. Compromise of the anterior horn cells may result in patchy weakness, amyotrophy, and loss of reflexes in the arms. These findings are often asymmetrical or even unilateral. With expansion of the cavity, additional symptoms, including long tract symptoms, can become apparent. Another important manifestation of syringomyelia, especially in childhood, is progressive scoliosis, sometimes the earliest sign of a syringomyelia. Skeletal anomalies of the skull base can be associated with the Chiari I malformation as well, most frequently basilar impression (see later). Other skeletal anomalies of the craniocervical junction associated with the Chiari I malformation include the Klippel-Feil anomaly and atlanto-occipital assimilation.

In contrast to these cerebellar syndromes, the brain stem can also be the primary area affected. In its broadest definition, *Mobius' syndrome* refers to a combination of bilateral symmetrical and asymmetrical facial weakness associated with abnormalities of horizontal gaze, most often deficiencies of abduction. Other cranial nerve functions can be impaired as well, especially those of cranial nerves IX, XII, V, and occasionally, III. The impairment of lower cranial nerves can lead to early feeding difficulties, problems with swallowing, and atrophy of the tongue that is frequently unilateral. Neurosensory deafness may also be associated. A variety of somatic anomalies may be present in patients with Mobius' syndrome.^[71] At least 50 percent of patients have limb anomalies. Thirty percent have talipes, and 20 percent exhibit hypoplasia of digits, transverse terminal defects, or syndactyly. The Poland anomaly and the Klippel-Feil anomaly can also be associated with the condition. Concurrent congenital heart disease, urinary tract anomalies, and hypogonadism or hypogonitalism are less frequent. Mild mental retardation is reported in 10 to 15 percent of patients with Mobius' syndrome; however, psychomotor development can also be slowed because of communication and social interaction problems resulting from the cranial nerve palsies. Most cases of Mobius' syndrome appear to occur sporadically and may in some cases indicate a disruptive sequence. The association with Poland anomaly is sometimes referred to as Poland-Mobius syndrome and may be familial.

Another syndrome involving cranial nerve nuclei is *Duane's syndrome*. This syndrome consists primarily of limited abduction with widening of the palpebral fissure on attempted abduction and globe retraction on attempted adduction. It is due to deficient abducens innervation to the lateral rectus with compensatory innervation by the third nerve. Again, most of the cases that have been described have been sporadic; however, familial occurrences have been seen in the context of a number of anomalies such as limb anomalies, eye anomalies, and deafness.^[72] The combination of Duane's anomaly, Klippel-Feil anomaly, and perceptive deafness has been referred to as Wildervanck (cervico-oculo-acoustic) syndrome. It is of uncertain inheritance. The *Marcus Gunn's (jaw-winking) syndrome* consists of unilateral ptosis, with elevation of the ptotic lid to a position higher than the opposite side on opening of the mouth, especially with deviation of the mouth to the opposite side. There are a few families with a suggestion of a dominant mode of inheritance with incomplete penetrance.

Differential Diagnosis. Cases of congenital cerebellar hypoplasia have been reported as autosomal recessive and probably also with X-linked inheritance.^[72] Cerebellar hypoplasia and pontocerebellar hypoplasia have been associated with a number of other syndromes.^[72] Together, these findings indicate that cerebellar hypoplasia is genetically heterogeneous. A recently recognized group of metabolic disorders of protein glycosylation (carbohydrate-deficient-glycoprotein syndromes) can also present with a picture of neonatal olivo-ponto-cerebellar atrophy.^[73] Prenatal cytomegalovirus infection also needs to be investigated in infants with congenital cerebellar hypoplasia or aplasia.

Because the Dandy-Walker malformation is a feature of a considerable number of syndromes,^[72] evaluation of the internal organs, particularly the heart and kidneys, as well as a skeletal and muscular assessment^[74] is essential once a Dandy-Walker malformation is recognized. Differential diagnostic considerations have to include conditions that can cause cystlike expansions in the posterior fossa. These include arachnoid cysts, mega-cisterna magna, and cystic tumors. MRI is the imaging modality of choice given the problems of visualizing the posterior fossa by CT scanning. True cysts, like arachnoid or ependymal cysts, in the posterior fossa may mimic a Dandy-Walker malformation. However, in contrast with the enlarged fourth ventricle associated with Dandy-Walker malformations, the fourth ventricle is compressed in the presence of a true cyst.

In Joubert's syndrome, there is no cystic dilatation in the posterior fossa, so that the cerebellar hemispheres appear to lie closely opposed without an intervening vermis. A similar cerebellar picture of agenesis of the cerebellar vermis without a posterior fossa cyst has been seen in several other syndromes, including the oro-facio-digital syndrome type VI of Papp-Varadi, as well as other syndromes with vermal hypoplasia and agenesis.^[74] Patients with oro-facio-digital syndrome type VI of Papp-Varadi often have an unusual V-shaped partially duplicated metacarpal on hand radiographs and sometimes hamartomatous nodules under the tongue can be found. An unequivocal distinction between these syndromes is not always possible.

The differential diagnosis in the Chiari I malformation

52

with syringomyelia is broad given the protean nature of the possible clinical symptoms. Multiple sclerosis, spinal muscular atrophy, amyotrophic lateral sclerosis, spinocerebellar ataxias, mononeuropathy multiplex, cervical disc and degenerative disease, and a variety of other disorders of the spinal cord and cerebellum can be confused with the condition on clinical grounds. Imaging resolves the majority of these differential diagnostic points. The situation can be more difficult in patients with prominent neurological symptoms but only borderline abnormal findings on imaging. Alternative diagnoses have to be considered seriously in that scenario. A cavity in the spinal cord can also have a traumatic (hematomyelia), inflammatory (necrotizing myelopathy), metabolic (Leigh's disease), or neoplastic (astrocytoma and ependymoma) basis. Of the neurocutaneous disorders, neurofibromatosis type 1 and von Hippel-Lindau disease can be associated with a syrinx. Demonstration of a flow void within the cavity by MRI can be helpful to show continuity with the CSF spaces.

Mobius' syndrome must be differentiated from neuromuscular diseases with a prominent component of facial weakness, especially those with involvement of the extraocular muscles. Centronuclear myopathy in particular should always be considered because of the congenital presentation in the X-linked form. Mitochondrial myopathies, myasthenic syndromes, and, given facial involvement alone, myotonic dystrophy and facioscapulohumeral dystrophy as well as some of the structural congenital myopathies need to be considered. In cases in which the time of onset symptoms is unclear, a multitude of acquired causes for multiple cranial nerve palsies has to be considered. These causes may include trauma to the skull base and cranial nerves; infection of the meninges, skull base, and cavernous sinus; inflammation of the nerves, brain stem, or cavernous sinus; and tumors of the skull base and meningeal neoplastic spread.

Moebius' syndrome is distinguished from Duane's syndrome, in most cases, by the sparing of the face and lower cranial nerve nuclei in patients with Duane's syndrome. Duane's syndrome itself needs to be differentiated from other causes of abducens palsy in childhood, in which the elaborate co-innervatory phenomena of Duane's syndrome usually are not seen. More bizarre associated eye movement abnormalities can be seen in Duane's syndrome and may confuse the picture. The globe retraction can sometimes be difficult to appreciate, especially in infants.

Evaluation. Imaging the posterior fossa is best done with MRI. The relationship between the cerebellar vermis and fourth ventricle and cisterna magna needs particular attention. Diagnosis of cerebellar and/or pontine hypoplasias can be difficult in mild cases and, strictly speaking, requires age-matched controls. As mentioned earlier, for any unusual posterior fossa anomaly, screening for additional malformations may lead to a syndrome diagnosis. Ultrasound of the heart and internal organs, a skeletal radiographic survey, and an ophthalmological evaluation are recommended. In cases of young patients with Joubert's syndrome, an overnight sleep study may alert the physician to respiratory irregularities and apnea spells. In cases of hydrocephalus associated with the Dandy-Walker malformation, evaluation should follow the guidelines outlined in the section on hydrocephalus.

Diagnosis of the Chiari I malformation as well as of syringomyelia relies on clinical suspicion as well as on adequate imaging. As mentioned earlier, the imaging modality of choice is MRI, especially sagittal images. The now routine inclusion of these images in any MRI study of the head has led to the discovery of a number of asymptomatic Chiari I malformations and asymptomatic cases of syringomyelia. It has also become apparent that the clinical picture is broader and more varied than the classic clinical syndromes described. The question frequently arises about the significance of low-lying tonsils that are discovered incidentally on a cranial MRI examination. The tonsils normally retract upward with age, so their location must be interpreted in an age-dependent context. The cut-off in the first 10 years of life appears to be 6 mm below the level of the foramen magnum; from 10 to 30 years, it would be 5 mm; and after that, 4 mm. Herniations greater than 12 mm are almost invariably symptomatic. On the other hand, about 30 percent of individuals with significant displacements of 5 to 10 mm are asymptomatic.^[75] Similarly, syrinx cavities can be large with minimal clinical symptoms.

A patient with one of the brainstem syndromes needs to be evaluated in an effort to rule out disorders that may mimic the syndrome (see differential diagnosis), and also to define the extent of the abnormalities and establish the presence of any associated malformations. In patients with Mobius' syndrome, this may require (in addition to a careful neurological and ophthalmological examination) brain stem auditory evoked responses; creatine-kinase determination; imaging of the brain,

posterior fossa, and skull base by MRI; a skeletal radiographic survey; and echocardiography.

Management and Prognosis. Treatment of the Chiari I complex consists mainly of decompressing the structures trapped in the foramen magnum. Surgical approaches for pediatric^[76] and adult^[77] patients are comparable. Most often, a suboccipital craniectomy, with or without dural patch grafting, and cervical laminectomies are performed, but anterior approaches may become necessary in selected cases to achieve satisfactory decompression. Occasionally, very large syrinx cavities require drainage by fenestration or shunting into the subarachnoid space. In general, the decompressive surgery at the foramen magnum is the more successful of the two,^[77] and co-existing syrinx cavities may even shrink or resolve postoperatively without further intervention. Signs and symptoms referable to brain stem compression respond better to surgery than symptoms related to the spinal cord, even when syrinx decompression is included in the operation. Major pre-existing sensory or motor deficits are poor prognosticators for functional recovery.^[76]

Treatment of the Dandy-Walker malformation is also treated surgically by shunting of the hydrocephalus and the posterior fossa cyst via a double ventriculoperitoneal and cystoperitoneal shunt.^[78] This intervention may allow for normal mental development in the absence of additional CNS malformations.

The respiratory abnormalities associated with Joubert's syndrome usually improve after infancy. If significant and life-threatening apneic periods occur, home ventilation may be used successfully during the initial high-risk period. In

case of severe feeding difficulties, the placement of a gastric tube may be appropriate.

Although disabilities resulting from the Mobius' syndrome can initially be very significant, including feeding difficulties and speech impairments, these problems tend to improve with time. Therefore, temporary placement of a feeding tube may be indicated in severe cases. The facial immobility can cause a significant social handicap and needs to be addressed in the management plan for such patients.

[PreviousNext](#)

ABNORMALITIES OF THE SKULL AND SPINE

Craniosynostosis

Pathogenesis and Pathophysiology. Craniosynostosis refers to the premature fusion of one or more of the cranial sutures. The premature fusion of one or more sutures results in abnormal and often asymmetrical growth of the cranium with resulting effects on both the underlying brain and the outward appearance of the head. In patients with craniosynostosis, the brain may show a nonprogressive hydrocephalus. Intracranial pressure may be elevated even in the absence of hydrocephalus and also in cases in which the absolute intracranial volume may, in fact, be increased (such as can be the case in sagittal synostosis). Significant advances in the pathogenesis of craniosynostosis have recently emerged by the identification of mutations in members of a family of receptors for fibroblast growth factors. Point mutations in the fibroblast growth factor receptors (FGFR) were first recognized in the *FGFR2* gene in Crouzon's syndrome and then also in Apert's, Jackson-Weiss, and Pfeiffer's syndromes. *FGFR1* was also found to be mutated in Pfeiffer's syndrome. These findings have clearly linked these genes to the development of craniosynostosis.^[79] Many of these syndromes have overlapping defects in other parts of the musculoskeletal system and other organ systems that are likely to result from the pleiotropic expression of the FGFRs. Mapping of the mutations in the FGFRs has shown that mutations in different parts of these receptors, including the intracellular, the extracellular, and the transmembrane domains, account for some of the variation in clinical expression. At present, the reason why mutations in different regions of these genes have such unique phenotypes is speculative. Some of the mutations render the receptor constitutively active, explaining the dominant inheritance. Several syndromes associated with a dwarfed stature can also result from mutations in an FGFR. Specifically, thanatophoric dysplasia and achondroplasia or hypochondroplasia result from mutations in *FGFR3*.^[79] Some cases of thanatophoric dysplasia include a cloverleaf skull, a severe form of craniosynostosis (see later). It is already clear that other genes are also involved in the development of craniosynostosis.^[80] For example, mutations in the homeobox gene *MSX2* have been linked to the Boston type of craniosynostosis^[81] but appear to be rare. In addition to these now molecularly characterized syndromes, there are many cases of craniosynostosis that are of unknown etiology, and others arise from apparently nongenetic causes such as the amniotic rupture sequence.

Clinical Features and Associated Findings. In 1988, Cohen^[82] reviewed all the syndromes with craniosynostosis as one of the features. He found 64 described syndromes; over the subsequent years, many more have been added. About 80 to 90 percent of all cases of craniosynostosis are sporadic and not part of a recognized syndrome. The sagittal suture is most often affected, leading to an elongated appearance of the skull with a normal face. This skull shape is referred to as *scaphocephaly* or *dolichocephaly*. Girls are affected slightly more often than boys, and there are usually no neurological deficits associated with this type of craniosynostosis. Although the biparietal diameter is low, the actual head circumference is usually above the 95th percentile, so that the actual intracranial volume is normal or even increased and impairment of brain growth usually does not occur, although the intracranial pressure may be elevated in some cases. Premature closure of the coronal sutures can occur in an asymmetrical fashion (*plagiocephaly*) or symmetrically (*brachycephaly*) (Fig. 28-10). Both conditions occur more commonly in boys. Brachycephaly, in particular, has a higher incidence of neurological complications. Optic atrophy with resulting visual impairment can be due to traction of the chiasm and optic nerves due to upward displacement of the chiasm in the foreshortened skull. Increased intracranial pressure may also develop in this condition and lead to optic atrophy as well as to more diffuse neurological damage. The incidence of mental retardation in brachycephaly is higher even in cases in which there is no increase in intracranial pressure after adequate surgical treatment. *Metopic craniosynostosis* is rare and often occurs in a syndromic context such as the Opitz trigonocephaly syndrome (C syndrome) or in conjunction

Figure 28-10 Craniosynostosis. A three-dimensional CT reconstruction from a patient with Apert's syndrome. The coronal sutures are prematurely closed, and the sagittal suture is abnormally (Courtesy of Dr. D. Vander Woude)

with holoprosencephaly. Asymmetrical closure of the lambdoid suture leads to another form of plagiocephaly. These single-suture synostoses can be very mild phenotypically. A particularly severe situation can result from the combined closure of the coronal and sagittal sutures (*oxycephaly*). Here, microcephaly and crowding of the intracranial content may result. In the most severe form, the sagittal, coronal, and lambdoid sutures are affected, resulting in the *cloverleaf*, or trilobed, skull (*kleblattschadel*). Patients with the cloverleaf skull anomaly show a bulging forehead, proptotic eyes, and severe neurological impairment.

Syndromic craniosynostosis accounts for only about 15 percent of cases of craniosynostosis. The two most common conditions are Crouzon's and Apert's syndrome; they account for about two thirds of syndromic craniosynostosis cases. In *Crouzon's syndrome*, synostosis of the coronal, sagittal, and lambdoid sutures is the most common. Ocular proptosis resulting from shallow orbits is a constant feature. Visual impairment occurs in about half of the affected patients.^[83] Traction and compression in the optic canals lead to optic atrophy in 22 percent of patients and legal blindness in 7 percent.^[84] Conductive hearing loss is common and occurs in about 55 percent of patients.^[84] Headaches are a concern in about one third of the patients, and seizures have been reported in up to 12 percent of patients.^[84] Mental deficiency is rare. This disorder follows autosomal dominant transmission. *Apert's syndrome* (acrocephalosyndactyly) is an autosomal dominant disorder characterized by coronal synostosis (see Fig. 28-10) in conjunction with a malformed and short cranial base, resulting in a short and high skull (brachyturriccephaly). Platybasia is often associated. In infancy, there is a wide and gaping defect in the region of the sagittal and metopic sutures (see Fig. 28-10). Again, visual impairment is common.^[83] Optic atrophy and conductive hearing loss can also occur in Apert's syndrome. Mental deficiency is common in this condition; in one series, half of the patients had an IQ below 70.^[85] However, normal or above average intelligence can certainly be noted among these patients. The CNS can be affected in a number of ways, the most frequent includes agenesis or hypoplasia of the corpus callosum, migrational anomalies, and gyral abnormalities. Ventriculomegaly does not necessarily mean hydrocephalus, which is uncommon in Apert's syndrome. Hand anomalies in Apert's syndrome consist of fused middle fingers involving at least digits 2, 3, and 4. For most of the more severe craniofacial syndromes with craniosynostosis, upper airway obstruction can become a problem requiring surgical management.^[86]

Differential Diagnosis. As noted earlier, craniosynostosis is a defining feature of many syndromes.^[22] Metabolic conditions that can lead to a premature fusion of cranial sutures include hyperthyroidism, hypercalcemia, and hypophosphatasia. Asymmetries of the skull are also seen in nonsynostoses such as hemimegalencephaly, hemiatrophy, and unilateral destructive lesions of the brain that result in a marked size difference between the two cerebral hemispheres. The amniotic band rupture sequence can also give dramatic alterations in skull shape. A small head per se does not mean premature closure of the sutures; retarded brain growth as a primary abnormality has to be considered. Earlier closure of the sutures can be seen under these circumstances. Severe constraint in utero can have the same effect. A number of other position-dependent asymmetries of skull shape can be seen, especially in hypotonic infants, or infants with other external restrictions of skull growth. Finally, there exists a long list of syndromes that include unusual skull configurations not based on premature fusion of cranial sutures.

Evaluation and Management. Although skull films were traditionally the modality of choice for the evaluation of craniosynostosis, CT with three-dimensional reconstructions are now the method of choice for the evaluation of the cranial skeleton and planning of management. The goal of evaluation should not only be the delineation of the various anatomical abnormalities but also an attempted specific diagnosis in a given case of craniosynostosis. Direct mutation analysis of the *FGFR* genes may be appropriate in selected cases.

Treatment for the craniosynostosis is surgical and involves excision of the fused suture and separation of the bony margins by an implanted matrix. Good results can usually be obtained,^[87] especially when surgery is performed before 6 months of age. With the demonstration of potentially elevated intracranial pressure in single-suture synostosis, the indication for repair has moved away from purely cosmetic indications. For the kleeblattschadel deformity, early subtotal craniectomy is the only reasonable attempt at correction, although the severity of the overall condition may prohibit invasive treatment. The acrocephalosyndactyly syndromes may require surgical approaches to the associated hand malformations, particularly polydactyly and syndactyly. Careful attention needs to be paid to vision and hearing in patients with craniosynostosis. Hearing aids may be necessary for adequate communication and language development. Shunting for hydrocephalus is rarely necessary.

Other Disorders of the Skull and Spine

DWARFISM

Although dwarfism is primarily a defect of the musculoskeletal system, central and peripheral nervous system manifestations are encountered in a variety of these disorders. The most frequent neurological manifestations are a result of impingement of the nervous system as a result of narrowing of bony foramina. For example, in some dwarfism syndromes, such as achondroplasia, narrowing of the foramen magnum can obstruct CSF flow and result in hydrocephalus. In achondroplasia, the development of clinical symptoms usually requires a narrowing of the foramen magnum to under -3 to 4 SD (standard deviations are available in radiology texts). *Thanatophoric dysplasia*, which is due to mutations in the same genes as achondroplasia (see earlier), has a unique neuropathology.^[88] The temporal lobes are

distorted by deep radial fissures arranged as spokes of a wheel ([Fig. 28-11](#)). Microscopically, the temporal lobes, particularly medially, are disorganized, often showing polymicrogyria. Polymicrogyria may also occur outside the temporal lobes.

The diagnosis of thanatophoric dysplasia is important for management decisions and for the purpose of genetic

535

Figure 28-11 Thanatophoric dysplasia. A ventral view of the brain from a 20-week-old fetus with thanatophoric dysplasia. Radially oriented, deep fissures in the medial temporal lobe replace the normal smooth surface at this age and are pathognomonic for this disorder.

counseling. Clinically, there are short limbs, a narrow thorax with short ribs, a short spine with flat vertebral bodies, and a large-appearing cranium with a flat nasal bridge. There are two subtypes: the more common variety (type 1) with bowed bones but rarely a cloverleaf skull, and a second form (type 2) with straight bones but with a complex craniosynostosis giving rise to the cloverleaf skull. Hydrocephalus is common with the second type of craniosynostosis. Both forms are associated with mutations in *FGFR3*.

Achondroplasia can be associated with a number of neurological complications.^[90] Stenosis at the level of the foramen magnum can cause a high cervical or lower medullary myelopathy. In case of lower medullary myelopathy, apneic spells or respiratory insufficiency can result; high cervical myelopathy can give rise to long tract symptoms, including frank quadriplegia. Stenosis of the spinal canal with myelopathy or radiculopathy can occur at any level. Careful assessment for lower extremity hyperreflexia, clonus, and Babinski's sign is important for the early recognition of a myelopathy. Surgical decompression may become necessary in these cases. The development of hydrocephalus in achondroplasia is possible due to stenosis at the level of the foramen magnum, although this occurrence is not very common. A milder degree of hydrocephalus has been postulated to be due to impaired CSF resorption because of diminished venous return from the cranial compartment. A degree of macrocephaly, however, is normal in achondroplasia, and head circumference measurements should be compared with head circumference charts specifically corrected for achondroplasia. The large number of skeletal dysplasias, many of which have secondary neurological complications, are beyond the scope of this chapter. The reader is referred to reference 90 for a complete discussion.

SKULL BASE AND NECK

Malformations and deformities of the skull base can be part of a number of conditions, including the craniosynostosis syndromes (short and steep cranial base), neurofibromatosis I (aplasia of the sphenoid wing), Chiari types I and II (platybasia, flat cranial base), osteogenesis imperfecta (basilar impression, invaginated cranial base), and Hajdu-Cheney syndrome (basilar impression), as well as other disorders. They can also occur in isolation or in a familial context. Other conditions such as Paget's disease, rickets, rheumatoid arthritis, and hypoparathyroidism have to be considered in the differential diagnosis. Nuchal pain and vertigo may be early and nonspecific complaints. If they are present, the primary position downbeating nystagmus of craniocervical junction origin may give a diagnostic lead in this situation. The neurological syndrome of *basilar impression*, including platybasia and the more extreme convexobasias, can begin insidiously with increasing spasticity in the lower extremities, ataxic gait, and loss of proprioception also in the upper extremities. In addition, lower cranial nerve function may become impaired late in the course, including dysphagia.^[91] The neck may be short and cervical motility impaired; in conjunction with the nuchal pain, the presentation may be neck stiffness or torticollis. Symptoms and signs of associated conditions such as the Chiari malformations and syringomyelia can complicate the picture. Sagittal CT reconstruction plus sagittal MRI is the optimal imaging modality combination to confirm the diagnosis. Surgical decompression at the foramen magnum is the treatment of choice, occasionally requiring additional laminectomies of C2 and C3 with cervico-occipital fusion. Platybasia (defined as the angle between planes of the anterior cranial fossa and the clivus being greater than 140 degrees) in isolation is generally asymptomatic.

Congenital fusion of the cervical vertebrae is known as the *Klippel-Feil anomaly*. Presumably this reflects a failure of segmentation rather than a secondary fusion. This anomaly can be part of a number of syndromes (such as Turner's, Noonan's, and Wildervanck's syndromes) but can also occur sporadically or be inherited in isolation as an autosomal dominant or autosomal recessive trait. Vertebral fusions can extend beyond the cervical spine, but most commonly they are restricted to levels C2 and C3 or C5 and C6. Clinically, there is a short neck, low posterior hairline, and limitation of neck movements, particularly rotation and bending to the sides. Atlanto-occipital anomalies are frequently associated, and one of the major reasons for associated morbidity. Kyphosis and scoliosis are often associated, as is spina bifida occulta in some cases.^[92] Many patients also have a variety of genitourinary anomalies, including unilateral renal agenesis.^[92] Hearing impairment can be noted in about 20 percent of patients. Other skeletal malformations such as Sprengel's deformity can be associated. The main neurological complications result from craniocervical instability with the possibility of spinal cord compromise. It has also been noted that patients with the Klippel-Feil anomaly may have mirror movements on neurological examination^[93]; the reason for this observation is not clear.

Occipitalization of the atlas or assimilation of the atlas refers to the fusion of the anterior arch and ring of C1 with the foramen magnum. A Chiari type I malformation, Klippel-Feil anomaly, achondroplasia, or syringomyelia may be associated. Atlantoaxial instability (atlas-dens interval greater than 3 mm) can occur in rheumatoid arthritis and also in a number of genetic conditions and syndromes,

536

most notably Down's syndrome. It is recommended to screen trisomy 21 patients at 5 and 10 years for atlantoaxial instability and, if the condition is present, restrict potentially harmful physical activities.

HISTORY AND DEFINITIONS

A variety of neurological disorders result from abnormalities of bones, ligaments, muscles, and other mesenchymal tissue that compress the nervous system. In many instances the result is a focal disorder of nervous system function such as a mononeuropathy, a root syndrome, or the compression of intracranial contents by abnormalities of the skull. Much of our clinical knowledge of the peripheral system is derived from these kinds of lesions--for instance, the dermatomal map, which every student of the nervous system carries in his or her black bag, is in part derived from the study of patients with a herniated disc and root compression. Much of the standard neurological examination of the sensory system is derived from studies carried out by Henry Head 80 years ago in patients (including himself) who had lesions of individual peripheral nerves.

DEGENERATIVE STRUCTURAL DISORDERS

Degenerative Disc Disease

Pathogenesis and Pathophysiology. The vertebral disc is composed of the inner gelatinous nucleus pulposus and the surrounding annulus fibrosus. Vertebral disc herniation refers to rupture of the annulus with displacement of the central nucleus. In youth, the disc is highly elastic. With the passage of time, the direct vascular supply to the vertebrae and discs decreases, and they undergo the accumulated effects of axial loading. The resulting decreases in water and oxygen content, and metabolic efficiency lead to a disc that is more compressible, less elastic, and more prone to tear and rupture. Disc rupture and herniation can cause pain by several mechanisms. The periosteum of the bony spine, the ligaments, the outer fibrous annulus of the vertebral discs, and the dura are all innervated by nociceptive afferents from the spinal nerves. A ruptured or torn fibrous disc may generate local pain owing to mechanical stress on these pain-sensitive structures. Also, the exposed disc material has a direct toxic effect and elicits a local inflammatory response, both of which may promote increased pain sensitivity. In addition to these local effects, the mass of the herniated disc material may compress the spinal roots by protruding into the lateral recess or the neural foramen, or it may protrude into the spinal canal, compressing the spinal cord in the cervical or thoracic region or the cauda equina in the lumbosacral region. Details of the mechanisms by which compression causes neurological dysfunction are complex and probably include mechanical alteration of axonal membranes, impaired axonal flow, and ischemia due to compromise of the microcirculation with resultant edema and eventual demyelination. Finally, regional muscle spasm may accompany other effects, adding to the pain and disability.

The accumulation of degenerative lesions in the lumbosacral spine may compromise the area of the central canal available to the cauda equina enough to cause symptomatic lumbar spinal stenosis with or without discrete disc herniation. Most commonly, these lesions include degenerative discs that bulge posteriorly, a hypertrophied ligamentum flavum that bulges anteriorly, and hypertrophied facet joints that crowd into the bony canal posterolaterally ([Fig. 29-1](#)). Less common lesions may contribute to the problem, hastening significant stenosis: congenitally short pedicles, spondylolisthesis without spondylolysis, or abnormal angulation of the bony spine.

Epidemiology and Risk Factors. Vertebral disc degenerative changes are a universal accompaniment of aging.

Figure 29-1 Lumbosacral spinal stenosis. L4 vertebra in cross section. Posterior bulging of the intervertebral disc, hypertrophy of degenerated facet joints, and hypertrophy of the ligamentum flavum crowd into the central canal to cause lumbar spinal stenosis.

Teenagers rarely develop symptomatic disc herniation. The peak incidence of symptoms occurs between the ages of 30 and 50. Patients often describe the onset of low back pain, usually remittent and without specific features, in their twenties, perhaps after identifiable trauma, and the onset of more specific symptoms that leads to the diagnosis of disc herniation is often not preceded by further trauma. Probably the accumulation of degenerative changes to the annulus and the preservation of the expansile gelatinous nucleus, overlapping with a period of life when job and sports-related activities increase the amount of mechanical stress on the body, account for this peak in the incidence of disease. The incidence then falls off in the older population, probably due to the lack of mobility of the desiccated disc and the relative lack of physical activity. Women and men are affected approximately equally.

There is a tendency toward disc herniation in some families, such as those with congenital spinal anomalies, including fused and malformed vertebrae and lumbar spinal stenosis due to short pedicles. Patients with increased weight and tall stature are at increased risk for this condition. Also, acquired spinal disorders, such as common degenerative arthritis and ankylosing spondylitis, predispose to disc degeneration. Various behaviors that increase risk include sedentary occupations, physical inactivity, motor vehicle use, vibration, and smoking. In younger women, pregnancy and delivery are associated with lumbosacral herniation, and new symptoms of cervical disc herniation may occur in part because of the bending and lifting involved in child rearing.

Clinical Features and Associated Disorders. The most common site of disc herniation in the cervical region is the C6-C7 level, followed by C5-C6, C7-T1, and C4-C5. Patients typically develop some local pain in the neck that radiates to the shoulders or the interscapular region. In the most common lateral herniations, radicular symptoms ensue. These symptoms include pain in the shoulder and arm, which may follow a dermatomal pattern but more typically is deep and aching and only roughly corresponds to the involved dermatome. At the cervical levels, the roots emerge laterally to exit through the neural foramina above the correspondingly numbered vertebral bodies. Because the spinal cord and bony vertebral levels are roughly aligned in the neck, the level of herniation corresponds to the level of root irritation. Hence, C6-C7 herniation affects the C7 root ([Fig. 29-2](#)). Pain may be exacerbated by coughing or straining. Numbness is more likely to supply reliable localizing information than pain. Compression of the C6 root typically causes numbness in the thumb and index finger, and compression of the C7 root typically involves the index and middle fingers. When compression is severe, myotomal weakness, reflex loss, and, with time, fasciculations and atrophy may ensue. With C6 compression, the biceps, brachioradialis, pronator teres, and radial wrist extensors may be weak, and the brachioradialis and biceps reflexes may be diminished or lost. With C7 weakness, the wrist and finger extensors and the triceps are typically weak. The triceps reflex may also be diminished or lost. With C8 compression, there is often interscapular pain and pain in the medial aspect of the arm and hand with weakness of the hand intrinsic muscles. The finger flexor reflex may be lost. Lesions above C6 are less common and are associated with correspondingly more proximal sensory symptoms and weakness. Lesions of the C5 root may cause shoulder pain and pain and numbness in the lateral aspect of the upper arm. Many muscles can be used to test the C5 root, including the infraspinatus, supraspinatus, deltoid, biceps, and supinator. Lesions above this level may cause neck pain and sensory loss in the neck, supraclavicular area (C3), and acromioclavicular area (C4) of the shoulder. Lesions involving the spinal cord or roots above C4 may paralyze the diaphragm and cause respiratory compromise ([Table 29-1](#)).

In the lumbosacral region, the most common site of

Figure 29-2 Cervical disc herniation. At the cervical levels, roots emerge from the spinal cord near their level of exit. Each root emerges above its corresponding vertebra, with C8 emerging between C7 and T1. Posterolateral herniation at this level causes compression of the exiting root (horizontal hatching). Hence, C6-7 herniation causes C7 compression, and so on. A large central herniation in this region can compress the spinal cord and cause a cervical myelopathy (vertical hatching).

TABLE 29-1 -- CERVICAL RADICULOPATHIES

Root	Muscle Weakness	Action	Location of Pain	Reflex Change
C5	Deltoid	Shoulder abduction (15-90 degrees)	Lateral shoulder	Biceps
	Biceps	Elbow flexion	Lateral upper arm	
	Supraspinatus	Shoulder abduction (0-15 degrees)	Lateral epicondyle	
	Infraspinatus	Humerus external rotation		
C6	Brachioradialis (C5-C6)	Elbow flexion in semipronation	Posterior shoulder	Brachioradialis
	Pronator teres (C6-C7)	Pronation	Lateral forearm	
	ECR (C6-C7)	Radial wrist extension	Thumb and index finger	
C7	Triceps (C6-C8)	Elbow extension	Posterior shoulder	Triceps
	ECR (C6-C7)	Radial wrist extension	Medial forearm	
	ED (C7-C8)	Finger extension	Index and middle fingers	
C8	Flexor pollicis longus	Thumb flexion	Interscapular medial forearm	Finger flexors
	FDS, FDP	Finger flexion	Little finger	

T1	Interossei Abductor digiti minimi	Finger abduction Little finger abduction	Medial forearm Medial epicondyle	None
----	--------------------------------------	---	-------------------------------------	------

herniation is the L5-S1 level, followed by the L4-L5 level and then higher levels. Symptoms of lumbosacral herniation often follow lifting or twisting injuries, or they may result from accumulated low-level trauma. Pain typically occurs in the parasacral area and radiates to the buttocks. Below C8, the roots exit through the neural foramina *below* the correspondingly numbered vertebral bodies. In patients with the most common posterolateral herniation, dermatomal radicular pain typically occurs at the level below the emerging root, which usually escapes entrapment above the protruding disc. Hence, L4-L5 herniation affects the L5 root (Fig. 29-3). With posterolateral L5-S1 herniations and S1 root entrapment, the pain radiates to the posterior aspect of the thigh and, especially when the root is stretched, into the posterolateral lower leg, lateral heel, and sole. This pattern can be demonstrated by straight-leg raising, in which the smaller the angle of elevation required to elicit pain, the greater the suggestion that root compression is responsible. Characteristic pain on elevation of the opposite leg may be even stronger evidence of root compression. Some patients with symptoms that are exacerbated by root traction avoid full weight bearing on the heel of the involved side, standing with the knee flexed and the heel off the floor. When pain is less severe, symptoms may be elicited by having the patient walk on the heels. Numbness is felt in the posterolateral leg, lateral aspect of the heel, and the sole of the foot. The gastrocnemius and hamstrings may be weak, and the ankle jerk may be diminished or lost. More lateral herniation of the L5-S1 disc or herniation of the L4-L5 disc may entrap the L5 root. Here the pain may be similar, with adjustment of the findings to fit the L5 dermatome and myotome. Numbness is most marked on the dorsum of the foot. Weak muscles include the foot elevators (tibialis anterior group), evertors (peronei), and invertors (tibialis posterior), and the toe extensors (extensor hallucis longus). Herniations at higher levels in the lumbosacral region cause pain and deficits that correspond to the roots involved (Table 29-2).

In addition to these radicular syndromes, patients with central herniations in the cervical or thoracic region may develop pain and acute myelopathic symptoms with spasticity and quadriplegia or paraparesis, sensory loss at or below the segmental dermatome of the lesion, hyperactive reflexes, and Babinski's signs. Soon after an acute lesion develops, the reflexes may diminish because of spinal

Figure 29-3 Lumbosacral disc herniation. The most common posterolateral herniation compresses the nerve root traveling downward to emerge one level below the level of the exiting root. Hence, L5-S1 herniation most commonly compresses the descending S1 root (horizontal hatching). More lateral herniation may compress the root exiting at the level of hernia (diagonal hatching). A large central herniation may compress multiple bilateral descending roots of the cauda equa (vertical hatching).

TABLE 29-2 -- LUMBOSACRAL RADICULOPATHIES

Root	Muscle Weakness	Action	Location of Pain	Reflex Change
L1	Iliopsoas (sometimes, but mainly L2-L3)	Hip flexion (mainly L2-L3)	Inguinal crease	None

shock. Patients with lumbosacral central herniation may develop acute compression of the cauda equina. This causes radicular pain, paresthesias, and sensory loss referable to multiple bilateral roots, bilateral leg weakness, and loss of the lower extremity reflexes. Bowel and bladder dysfunction may occur early. When subtle, this dysfunction may be limited to asymptomatic bladder retention noted only on postvoid catheterization. When dysfunction is more severe, there may be perianal and perineal sensory loss, loss of anal tone and reflexes (the reflex anal sphincter constriction due to perianal skin stimulation or anal wink and the bulbocavernosus reflex), and fecal and urinary retention and incontinence.

Degenerative herniations in the thoracic region are uncommon, and symptoms and findings at these levels should raise a suspicion of other underlying lesions, such as tumor or abscess. Disc herniations at this level may cause radiating dermatomal pain resulting from root compression; more frequently, they progress to spinal cord compression.

The symptom most suggestive of lumbar spinal stenosis is neurogenic claudication. Low back pain radiates to the buttocks and thighs and may extend more distally along the lumbosacral dermatomes. This pain is brought on by walking. Unlike vascular claudication, rest in the upright position does not relieve the pain, but rest while seated or forward bending, such as leaning on a shopping cart, may provide relief. Pain is exacerbated by spinal extension, such as downhill walking. When spinal stenosis is severe, patients bend forward while walking. Symptoms and signs may be either mechanical, due to bone, ligament, and joint involvement, or radicular, due to compromise of the lateral recesses or neural foramina.

Proximal compression resulting from root entrapment may increase the vulnerability of nerves to dysfunction due to distal entrapment. This double crush phenomenon is presumed to be a result of disturbed axoplasmic flow and disrupted architecture of the neurofilaments. Therefore, when surgical repair of a distal entrapment fails to provide the expected relief, a contributing radiculopathy resulting from degenerative disc disease should be considered.

Differential Diagnosis. Disc herniations must be differentiated from other causes of acute and chronic neck, back, and extremity pain, radiculopathy, and myelopathy. Malignant and benign tumors affecting the spine, infection, epidural hematoma, various arthritides, including rheumatoid arthritis, ankylosing spondylitis, and Reiter's syndrome, and other spondyloarthropathies may present with similar early symptoms and signs. Various anomalies, such as conjoined spinal roots and multiple roots emerging through a single foramen, may also be confused with disc disease. Degenerative arthritis of the spine can cause symptoms by many mechanisms, including disc herniation, and the various lesions that are causing symptoms in a particular person should be differentiated as clearly as possible to allow directed therapy.

Evaluation. A careful history and physical examination are critical in the evaluation of disc herniation. It has been well established with all imaging modalities that

asymptomatic patients have a high incidence of anatomical lesions. To properly detect clinically relevant illness, it is therefore essential to establish the closest possible clinical correlation of the symptoms and signs with the anatomical findings of the various imaging studies. The initial history should screen for problems that raise a suspicion of severe underlying disease. All patients should be questioned about trauma, cancer, infections, recent fever, and the use of anticoagulant medications. The underlying family history and risk factors for tumor, infection, hematoma, and various disorders that predispose to disc disease should be sought. The physical examination, likewise, is undertaken to seek evidence of other severe underlying disease and to localize and classify the pain and any deficits as mechanical, radicular, or myelopathic. It is most important immediately to establish the presence of major deficits that demand rapid diagnosis and treatment. These include the cauda equina or conus syndrome, acute or progressive myelopathy, and severe radicular motor deficits. If, on the other hand, the findings are consistent with a ruptured disc and either no deficit or a mild to moderate one, it is reasonable to temporize before pursuing a workup to fully evaluate the

cause. If plain radiographs of the affected area reveal no evidence of unexpected lesions, conservative therapy for disc herniation may be tried before further imaging is performed. This approach is justified by the good prognosis for spontaneous recovery of patients with acute radiculopathy with mild to moderate deficits. When the clinical examination leaves doubt about the localization of the lesion, electromyography (EMG) can supplement the diagnosis of radiculopathies and suggest other localizations, such as plexopathies and neuropathies. Electromyography is more sensitive if it is delayed until at least 10 to 14 days after the onset of a new deficit.

The tests available for imaging include plain radiographs, computed tomography (CT), myelography with or without CT, and magnetic resonance imaging (MRI). X-ray studies can be used to screen for unexpected infection, tumor, or deformity of the bony spine. Radiographs cannot show the neural tissues or the disc itself, but loss of disc space height and other degenerative changes may provide some indirect diagnostic information. Interpretation of plain radiographs must be tempered by an awareness of the high frequency of degenerative findings in asymptomatic populations. Plain radiographs taken under conditions of flexion and extension can also be used to assess spinal stability. Myelography is invasive, indirect, and nonspecific; however, it retains certain advantages in the era of MRI. It can visualize the entire length of the spine and best defines the root sleeves. Although myelography alone cannot distinguish between osteophytes and a herniated disc compromising a foramen, when combined with CT, it provides the best visualization of lateral pathology and small osteophytes. It is now most commonly used to answer specific questions that remain after the MRI examination. CT is superior to MRI in distinguishing soft tissue from bone. MRI has emerged as the preferred imaging choice in most cases. It demonstrates bone and soft tissues directly, easily allows multiplanar visualization, and is suited to the visualization of multiple levels. The high contrast of epidural fat and the cerebrospinal fluid (CSF)-filled thecal sac allows accurate assessment of subtle compression in most cases.

Lumbar spinal stenosis is evaluated by CT or MRI. MRI best demonstrates the relationship of the bony and neural structures. CT best demonstrates lateral recess stenosis. Although the dimensions of the bony canal can be used as guidelines, diagnosis must ultimately be based on the correlation of stenosis with the clinical findings. The transverse interfacet dimension should be greater than 16 mm. A dimension of less than 10 mm indicates severe stenosis. An anteroposterior dimension of less than 12 mm suggests stenosis; however, this finding is less sensitive in patients with symptomatic disease. A lateral recess of 3 mm or less suggests stenosis.

Management. The crucial initial step in management of patients with disc herniation syndrome is to identify those lesions that merit further evaluation and immediate therapy. In the remaining cases, the good prognosis for early recovery justifies a trial of conservative therapy before definitive imaging is done. Conservative therapy includes rest in a position of comfort followed by early remobilization, gentle exercises, and analgesics for pain as needed. Nonsteroidal anti-inflammatory agents probably provide little relief in most cases. For severe pain, judicious time-limited use of narcotics should be considered. Oral and epidural corticosteroids can be helpful. Many other modalities are available, but there are few reliable data about their effectiveness in populations: medical and physical measures (e.g., ice, heat, massage, and ultrasound) that address secondary muscle spasm, transcutaneous electrical nerve stimulation (TENS), acupuncture, exercise, and traction. If improvement within the initial 4 to 6 weeks is not satisfactory, it is helpful to confirm the diagnosis by imaging. This may provide a diagnosis of an unsuspected condition, localization for epidural steroid injection, or information about suitability for eventual surgery.

Clear indications for surgery include the presence of acute myelopathy, cauda equina syndrome, severe or progressive motor deficits, and intractable pain. When conservative measures fail to provide a satisfactory response within 6 to 12 weeks, surgery should also be considered. Studies comparing the outcome of surgical therapy with conservative care suggest that early recovery occurs more often with surgery. Although the benefits of surgery are lost with prolonged follow-up periods, it is important to point out that in an often cited study, patients in the conservative therapy group who had not responded to this therapy received surgery. Newer microsurgical techniques allow shorter hospitalization and rehabilitation periods but have not been shown to improve long-term outcome. The success rate of chymopapain chemonucleolysis has not reached that of surgery in most hands, and this treatment carries significant risks. Percutaneous nucleotomy has also been disappointing and should not be pursued given the current level of experience.

For patients with lumbar spinal stenosis, initial therapy is symptomatic, with analgesics, pain-modulating medications, and physical and occupational therapy. When significant disability and pain remain despite conservative measures, referral for surgical decompression should be considered.

Prognosis and Future Perspectives. The prognosis for the relief of pain and a full functional recovery is good. With bed rest alone, Weber found that 70 percent of patients experienced decreased pain and improved function within 4 weeks, and 60 percent had returned to work. Seventy percent were functionally unrestricted at 1 year. With selective surgery, 90 percent of patients should have a good functional recovery within a year. Patients with psychosocial problems tend to do worse with either therapy, but those with appropriate indications respond better to surgery. Sensory dysfunction does not recover as fully as motor function, and a large proportion of patients retain some sensory deficits. Patients in whom relapse occurs should be re-evaluated for new lesions that are potentially addressable by surgery; however, the success rate of surgery declines with follow-up procedures, and a significant proportion of patients with disc herniation experience relapse with chronic low back pain.

Research into the mediators and biomechanics of pain may further elucidate the mechanisms of pain in disc disease and provide other conservative therapies. Improved imaging techniques may further refine the selection of patients for surgery. It is hoped that improved surgical

selection and further refinements in surgical technique may continue to improve outcome and shorten the period of disability.

Cervical Spondylosis

Pathogenesis and Pathophysiology. Degenerative changes of the spine universally accompany aging, and the accumulation of such degenerative changes in the cervical spine constitutes cervical spondylosis. These spondylotic changes become clinically important when they cause pain or neurological dysfunction. Aging leads to desiccation and shrinkage of the intervertebral discs. The resultant loss of vertebral height narrows the intervertebral foramina. The weakening of the containing fibrous annulus allows bulging of the desiccated discs, which may then form transverse bars that protrude posteriorly, compromising the spinal canal. Their protrusion more laterally into the foramina may further compromise this space. Osteophytes and hypertrophic osteoarthritic changes of the facet and uncovertebral joints may further impinge on the spinal canal and foramina. Hypertrophy of the ligamentum flavum, which runs longitudinally along the posterior wall of the spinal canal, may compromise this space even more (Fig. 29-4). Intuition suggests that compression of the cervical spinal cord and nerve roots by the stenosis of the spinal canal and foramina is responsible for the myelopathy and radiculopathies characteristic of cervical spondylosis. However, a finer understanding of the pathogenesis of this disorder has been elusive. Proposed explanations of the neurological deficit include (1) direct compression by stenosis adequate to compromise the cord and roots, (2) rubbing of the spinal cord and roots on protruding skeletal structures that may not themselves be severely compressive, and (3) arterial or venous compromise. All of these factors may play a role. Pathological study shows the presence of distorted and flattened spinal cords that correspond to spondylitic bars. Demyelination of the lateral columns

Figure 29-4 Cervical spondylosis. C5 vertebra in cross section. Posterior osteophytes of the vertebral endplate and hypertrophy of the ligamentum flavum compromise the cervical spinal canal and cause flattening of the spinal cord.

occurs at the stenotic site and caudally and of the posterior columns rostrally. This demyelination corresponds to the sites of rubbing: anteriorly and inferiorly with neck flexion and posteriorly and superiorly with extension. In the central gray matter ischemic changes with neuronal loss are seen. Sometimes syringomyelia can be found. Root sleeves may be thickened and rootlets adherent.

Epidemiology and Risk Factors. The major risk factor for cervical spondylosis is aging. Although trauma may contribute, there is usually no history of significant

trauma. Screening of asymptomatic patients shows a high frequency of spondylotic changes that increases with advancing age. By age 59, 70 percent of women and 85 percent of men have changes on radiographs, and by age 70, the number increases to 93 percent of women and 97 percent of men. ⁴³ Up to 75 percent of these patients have abnormal neurological findings by age 65, but fewer have symptoms of spondylosis. ⁴⁴ Heavy labor and especially occupations that expose the patient to vibration probably increase the risk of spondylosis.

Clinical Features and Associated Disorders. The major clinical features are the symptoms and signs referable to cervical myelopathy and radiculopathy. Patients may complain of neck pain and pain radiating into the arms. There may be weakness of the legs and sensory loss, especially of position sense. The weakness or sensory loss may be discovered when an elderly patient presents for gait problems or falls rather than as a direct complaint. Bowel and bladder dysfunction are uncommon complaints accompanying advanced cervical myelopathy. Most commonly, the onset of symptoms is insidious; however, occasionally an elderly patient with spondylosis presents with catastrophic onset of quadriparesis or paraparesis after a fall.

Typically, there is some limitation of neck mobility. Examination of the cranial nerves should be normal, although the jaw jerk may be increased in some cases. Weakness is common in the lower extremities, especially in the iliopsoas, hamstrings, and extensors of the feet and toes. Tone in the lower extremities is spastic, and Babinski's sign may be present. Sensory loss to light touch, vibration, and joint position is sometimes found. The major deficits in lower extremity function are determined by the degree of myelopathy. Findings in the upper extremities vary depending on the level of central canal stenosis and the degree of cervical root involvement. Patients may have mild weakness with brisk reflexes. When roots are compromised, especially in the lower cervical myotomes, atrophy, weakness, and fasciculations may be found, at times mimicking the signs of amyotrophic lateral sclerosis. Sensory loss in the upper extremities may also be seen, following a simple radicular pattern or, more commonly, a patchy distribution, presumably due to multiple root and cord involvement.

The main associated features are those of disorders that compromise the cervical spine and predispose to osteoarthritis. These include prior trauma, prior disc herniation, various congenital anomalies of the cervical spine, and underlying systemic arthritic disorders.

Differential Diagnosis. The issue of differential diagnosis is particularly important when one is dealing with a condition that is commonly present as an asymptomatic radiological finding. When a patient presents with a combination of radicular signs and symptoms accompanied by

cervical myelopathy, the diagnosis of spondylotic disease is not difficult. However, this clinical presentation is not common, and most patients have either myelopathy resulting from central protrusions or radiculopathy resulting from lateral protrusions, but not both. The differential diagnosis must therefore cover conditions that cause pure myelopathy, motor neuron disease, and combined myelopathy and radicular or neuropathic lesions.

The syndrome of slowly progressive spastic weakness of the extremities, worse in the lower than in the upper extremities, may be produced by a variety of pathological causes. Some of these are listed here along with clues that may help to distinguish them from spondylotic myelopathy.

Multiple Sclerosis (see [Chapter 48](#)). Age of onset, gender, and types of neurological findings do not reliably distinguish chronic spinal multiple sclerosis. Early onset of bladder symptoms, visual complaints, and mental status changes should be sought. Cranial MRI may demonstrate periventricular bright lesions on T2-weighted images in the majority of patients with multiple sclerosis. Visual evoked responses and oligoclonal bands in the CSF, if abnormal, are helpful.

Amyotrophic Lateral Sclerosis (see [Chapter 36](#)). In most patients with amyotrophic lateral sclerosis, lower motor neuron signs are evident from the beginning, but spasticity predominates in a few. The finding of atrophy of muscle and increased reflexes in the same myotome strongly suggests amyotrophic lateral sclerosis. Bulbar symptoms or signs should be carefully sought on examination and should be evaluated with EMG. The sensory loss from radicular or long tract involvement, common in cervical spondylosis, should be absent. In one recent series, 5 percent of patients with amyotrophic lateral sclerosis underwent a cervical laminectomy in the hope of arresting progressive spasticity, emphasizing how commonly the two conditions coexist.

Primary Lateral Sclerosis. A few patients with a slowly progressive, purely spastic condition are found to have a degenerative disease allied to amyotrophic lateral sclerosis, but without lower motor neuron features.

Subacute Combined Degeneration of the Spinal Cord (see [Chapter 40](#)). Vitamin B₁₂ deficiency should never be overlooked. A low serum B₁₂ level, hypersegmented polymorphonuclear leukocytes, and macrocytic anemia are some of the abnormalities found in early cases. The lesions of B₁₂ deficiency begin in the cervical or thoracic cord, and deficits are often primarily sensory, which is quite uncommon in patients with cervical spondylosis.

Dural Arteriovenous Fistula. Several decades ago it was believed that spinal arteriovenous malformations presented either as subarachnoid hemorrhage or as the lumbar syndrome of painful cauda equina deficit. It is now known that small arteriovenous fistulas in the spinal dura can cause myelopathy with either a stepwise progression or abrupt onset. Most malformations are seen on MRI or myelography; however, some require selective angiography of the segmental arteries that supply the cord for definitive diagnosis.

Myelopathy Associated with AIDS (see [Chapter 44](#)). A subacute vacuolar change in the spinal cord may develop in patients with human immunodeficiency virus (HIV) infection, usually in those with frank acquired immune deficiency syndrome (AIDS) and a history of multiple opportunistic infections. Most patients are younger than the average patient with spondylosis. The clinical findings often emphasize an ascending sensory disorder.

HTLV-I Myelopathy (see [Chapter 41](#)). A slowly progressive spastic paraparesis with early bladder involvement in a patient from a region endemic for human T-cell leukemia-lymphoma virus (HTLV)-I infection should prompt suspicion of this infectious cause. Patients typically have milder spasticity of the upper extremities. Diagnosis can be made by identifying the presence of antibodies to HTLV-I in serum.

Familial Spastic Paraplegia. These patients can be recognized by their family history, usually that of an autosomal dominant disorder. No direct DNA testing is available.

Syringomyelia. Cervical syringomyelia may occur in isolation or in association with the Chiari malformation, trauma, or tumor. Patients typically have lower motor neuron signs in the upper extremities due to involvement of the central gray matter and upper motor neuron signs in the upper and lower extremities due to involvement of the descending corticospinal tracts. The segmental loss of spinothalamic modalities of sensation and the neuropathic quality of the accompanying neck, back, and extremity pain as well as the context of an associated underlying problem suggest the diagnosis. MRI demonstrates the syrinx.

Compressive Lesions at the Craniocervical Junction. The Chiari malformation may cause myelopathy, vertigo, and ataxia. There may be an associated syringomyelia. Basilar impression due to instability of the atlanto-occipital joint or atlantoaxial instability, as in rheumatoid arthritis, may cause slowly progressive myelopathy. These lesions often occur in the context of spondylotic lesions, and it is very important to clarify the source of progressive findings. Certain tumors, such as meningiomas and schwannomas, at the craniocervical junction may also mimic the signs of cervical spondylosis. Often the history suggests a loss of function on one side followed by progression of signs to all four extremities. Down-beating nystagmus suggests the localization. Imaging high enough to demonstrate the craniocervical junction is crucial before cervical myelopathy is attributed to spondylotic lesions.

Evaluation. Evaluation begins with a careful history and examination. This is especially important because of the known high rate of radiological spondylotic abnormalities in asymptomatic populations. It is very important to establish the best possible correlations between the clinical findings and the imaging abnormalities. Available imaging modalities include plain radiographs, CT myelography, and MRI. Plain films can show many of the degenerative changes of bony elements; however, they do not reveal the relationship of these to the neural structures. Simple flexion and extension films performed with care can also demonstrate spinal instabilities that are not apparent on MRI or CT myelography. MRI is the easiest noninvasive means of diagnosis. MRI can demonstrate the dimensions of the spinal canal and foramina and distortion of the spinal cord and roots caused by the impingement of bony structures. Gadolinium enhancement can demonstrate the presence of various alternative lesions that may be under consideration. CT myelography can be used to answer any questions that remain after MRI. The myelogram may fail

to show complete block even when significant spondylotic myelopathy is present.

Management. Conservative management of cervical spondylosis includes immobilization with a cervical collar and the use of non-narcotic, nonsteroidal medications for pain. The symptoms and signs in most patients stabilize with this therapy; that is, the myelopathy does not progress, and in some patients it improves. Yet controlled studies evaluating the benefit of immobilization have not been done. When radicular pain is the major problem demanding further intervention, epidural steroid injections can be effective. We refer patients for neurosurgical evaluation and surgical therapy when their myelopathy progresses despite these conservative measures, after careful consideration of other diagnostic possibilities as listed earlier. There has been no documentation of long-term benefit from surgery, although many series have shown evidence of benefit in the short term.^[9] Posterior decompressive laminectomy is the procedure that has the longest history. However, unless it is performed over many levels, it will not relieve multilevel compression. Wide decompression performed over a number of segments may be complicated in later years by a swan neck deformity owing to the loss of posterior supporting elements. The anterior approach with interbody fusion is especially suitable for patients with single level nerve root compression. Its benefits for cord compression are less well defined. When radicular symptoms are due to bony osteophytes, foraminotomy may relieve the symptoms and signs of root compression. Although the benefit of surgery has not been systematically validated, and many patients improve spontaneously or with immobilization by a collar, clinical experience with individual cases suggests that selected patients do benefit and show marked improvement shortly after decompressive surgery.

Prognosis and Future Perspectives. The natural history of cervical spondylosis is not known. Although the course of the disease is progressive and most patients have chronic symptoms, the large majority remain stable for many years and do not require surgical intervention.

MRI has greatly advanced the precision of diagnosis while sparing most patients the discomfort and risk of myelography. Future advances in imaging may further facilitate diagnosis. Rowland has pointed out our great lack of knowledge of the natural history of cervical spondylosis as well as the need for controlled trials to demonstrate the effects of surgery and clarify surgical indications.^[9] Such studies, if they are done, will require a cooperative effort and careful definition of clinically relevant questions.

Ankylosing Spondylitis

Ankylosing spondylitis (AS) is one of the group of seronegative forms of arthritis, which also includes Reiter's syndrome and psoriatic arthritis. There is a close association with the HLA-B27 type, and the disease is more than three times more common in men than in women. In many patients, the disease seems to progress slowly for years, primarily with back pain, and then stabilizes without much disability. In some cases the disease progresses to total spinal fusion, producing a typical bamboo spine on x-ray criteria. In all patients, the presence of sacroiliac joint disease on radiographs is required to make the diagnosis. There are two major neurological complications of AS: a cauda equina syndrome of unclear etiology, and several types of cervical spinal cord compression due to dislocation or deformity.

Ankylosing spondylitis is less common in black populations and in people of Japanese ancestry, in parallel with the lower expression of HLA-B27 in these groups. There is a considerable familial incidence of AS. Approximately 20 percent of patients with AS have joint disease in the peripheral joints, not in the vertebral column or pelvis, and it is in this group that the neurological complications seem to be most frequent.

Patients with the cauda equina syndrome of AS^[9] have a gradual and relatively symmetrical loss of function in the L5, S1, and S2 roots. Both motor and sensory fibers are affected. Foot drop, weakness of plantar flexion, and perianal sensory loss are typical. Nearly all patients develop bladder and bowel incontinence. The cervical spine disorder most often associated with AS is instability at the craniocervical junction because of ligamentous laxity at the level of the odontoid process.^[10] Some patients have stepwise subluxation of the cervical spine, resembling that seen in seropositive rheumatoid arthritis. In either case, myelopathy may develop, often with significant sensory loss in the hands, as well as quadriparesis. As in rheumatoid arthritis, there may be marked instability of the cervical spine or craniocervical junction with much local pain, sudden changes in neurological symptoms with postural change, and eventual requirement for surgical fusion. Patients with AS may have uveitis or cardiac disease. Fractures of the fully or partially fused spine, especially if osteopenia exists, are common.

The cauda equina syndrome can be confused with lumbar disc disease, but the distinguishing features of the former are symmetry and early loss of bladder function. The craniocervical instability of AS produces a myelopathy that may be insidious and difficult to distinguish from general weakness, myopathy, nerve entrapment, or generalized neuropathy.

The diagnosis should be confirmed radiologically; there are specific criteria for the diagnosis of AS.^[11] Cauda equina syndrome is accompanied by a distinctive radiological change, consisting of a wide patulous distention of the subarachnoid space in the sacral region, often with erosion of the overlying sacral bone. The cause of this distended space is unknown, nor is it clear how this distention contributes to nerve root dysfunction.^[12] CSF examination does not suggest an arachnoiditis. The cervical spine should be fully visualized by MRI, and the position of the odontoid should be carefully noted. In rheumatoid arthritis patients, asymptomatic widening of the space between the odontoid and the arch of C1 (normally 3 mm or less) is observed. In AS, unrecognized fracture, odontoid dislocation, or atlantoaxial dislocation can occur.

Unfortunately, no specific therapy is available for patients with the cauda equina syndrome. A scattering of case reports indicate that some authors have attempted decompression of the thecal sac. Decompressive laminectomy

is of no value. Fractures or cervical dislocations may require fusion.

COMPRESSIVE STRUCTURAL DISORDERS

Fibrous Dysplasia

Pathogenesis and Pathophysiology. Our understanding of the pathogenesis of fibrous dysplasia has advanced greatly in recent years. Several investigators have identified a point mutation in the gene that codes for the alpha subunit of the G-protein, Gsa, in affected bone and other tissues in patients with fibrous dysplasia. The absence of this mutation in non-affected tissues in patients with the disease suggests that a somatic mutation occurs early in embryogenesis to create a genetic mosaic. The mutated Gsa proteins activate adenylate cyclase and increase signaling through the cyclic adenosine monophosphate (cAMP)- protein kinase A pathway.^[13] Recent work suggests that the resultant phosphorylation of transcription factors enhances transcription of the proto-oncogene *c-fos* and translation of *c-fos* protein in affected tissues.^[14] These findings surely represent only part of the molecular story, and it is likely that enhanced production of other oncoproteins is yet to be discovered.^[15] These molecular changes result in a gain of function that probably underlies the bony and endocrinological lesions characteristic of fibrous dysplasia. The functional result is a disorder of lamellar bone remodeling and repair. The pathological result is a replacement of normal bone and marrow elements by a vascular fibrous tissue composed of whorls of proliferating fibroblasts with haphazardly arranged trabeculae of metaplastic bone and fluid-filled cystic areas lined by multinucleated giant cells. The appearance is similar to that of osteitis fibrosa cystica due to hyperparathyroidism but is distinguished by the absence of osteoblasts. The abnormal bone originates from the medullary cavity and grows outward thinning the bony cortex.^[16] The high prevalence in puberty, the accelerated expansion of lesions during pregnancy, and the association with precocious puberty in females in the McCune-Albright syndrome^[17],^[18] suggest a hormonal influence that is, so far, poorly understood. Estrogen and progesterone receptors have been identified in affected bone.^[19] Patients with fibrous dysplasia have an accelerated turnover of bone, and many have elevated serum alkaline phosphatase levels, reflecting increased osteoblastic activity. Those with extensive disease also have elevated urinary hydroxyproline, reflecting increased turnover of collagen, a measure of the activity of osteoclasts. Serum calcium and inorganic phosphorus remain normal, reflecting compensatory increases in bone formation and resorption. Fibrous dysplasia is generally considered to occur sporadically. Sassin and Rosenberg found no positive family histories among 50 cases with cranial fibrous dysplasia.^[16] This result is consistent with the current hypothesis that the disorder results from a somatic mutation early in embryological development.

Epidemiology and Risk Factors. The age of onset is variable, but the disorder most commonly presents in childhood, especially during the period of most rapid bone

TABLE 29-3 -- FREQUENCY OF SKULL BONE INVOLVEMENT OF SKULL BONE BY FIBROUS DYSPLASIA

Bone	Number of Cases (N = 50)
Frontal	28
Sphenoid	24
Frontal and sphenoid	18
Optic canal involved	10 (3 bilateral)
Temporal	8
Parietal	6
Occipital	2

Adapted from Sassin JF, Rosenberg RN: Neurological complications of fibrous dysplasia of the skull. Arch Neurol 1968;18:363-369.

growth. However, in one series of 50 patients with fibrous dysplasia of the skull, over half came to medical attention after age 18. There is no difference in incidence based on race or sex for the most typical forms.^[16] However, the McCune-Albright syndrome occurs more frequently in females. As noted earlier, the bony lesions may expand at an accelerated rate during pregnancy.

Clinical Features and Associated Disorders. About 70 percent of patients have the monostotic form involving a single bone. The remainder have the disseminated polyostotic form, which is often predominantly unilateral. Sites of involvement vary, the ribs and long bones being the most common sites. The skull is involved in about 50 percent of polyostotic cases and in 10 to 27 percent of monostotic cases.^[16] Most of the clinical manifestations that prompt neurological evaluation are due to skull involvement (Table 29-3). Patients may present with a variety of focal neurological findings secondary to the compressive effects of the involved bone (Fig. 29-5). Visual impairment

Figure 29-5 Fibrous dysplasia. Sagittal T1-weighted MRI scan of the head. Fibrous tissue is seen replacing bone of the occiput and skull base. This patient presented with acute hoarseness that was presumed to be due to compression of the accessory nerve in the skull base.

followed by hearing loss and tinnitus are the most common presenting neurological deficits. Although various other cranial neuropathies may occur as a result of the compressive effects of involved bone, these are rare enough that none were seen in two large studies of cases involving the skull.^[16],^[20] Optic nerve compression with visual symptoms is common when the frontal and sphenoid bones are involved. A proptotic and downward displaced eye is often seen when these bones are involved and should prompt questions about visual symptoms and a radiological evaluation of the optic canal. Patients with stenosis of the optic canal may complain of decreased acuity or blurring of vision, scintillating scotoma, flashing light, or graying of vision when pressure is applied to the globe. Optic atrophy may be seen on fundoscopic examination. The visual symptoms may be slowly progressive, and they have often been present for some time when the patient presents. Patients may also have progressive facial asymmetry and deformity resulting from facial nerve involvement. Patients with hearing deficits typically have conductive loss due to stenosis of the external canal and middle ear by the involved temporal bone. A nonthrobbing headache may be a common complaint as well. Sassin and Rosenberg's patients also had an increased incidence of seizures (6 of 50), confirming the findings of prior reports.^[16] The reason for this association is not known.

Fibrous dysplasia has been associated with various other disorders. Cutaneous pigmentation occurs in over 50 percent of those with the polyostotic form. The McCune-Albright syndrome consists of polyostotic fibrous dysplasia, usually largely unilateral, with cafe(c) au lait spots, and various forms of endocrine hyperfunction, especially precocious puberty in females.^[17],^[18] Rarely, other endocrine abnormalities, including hyperthyroidism, acromegaly, Cushing's syndrome, hyperparathyroidism, and diabetes mellitus, may occur. Some patients may have a progressive diffuse facial deformity called leontiasis ossea; however, this facies may be caused by other disorders as well, including Paget's disease and craniometaphyseal dysplasia.^[20] Malignant transformation to sarcoma occurs in about 0.5 percent of patients with fibrous dysplasia and 4 percent of those with the McCune-Albright syndrome.^[21] This tumor is rare in the skull.^[20]

Differential Diagnosis. Fibrous dysplasia must be differentiated from benign and malignant neoplasms, including meningioma with adjacent hyperostosis, sarcomas or fibromas replacing bone, bone cysts, and various orbital masses, including eosinophilic granuloma, Hand-Schuller-Christian disease, and orbital pseudotumor.^[20],^[22] In addition, other metabolic diseases of bone must be considered, including Paget's disease, hyperparathyroidism, hyperostosis frontalis interna, osteopetrosis, and craniometaphyseal dysplasia (Pyle's disease). In general, age of onset, other clinical features, and radiological features easily distinguish these disorders. Rarely, the cranial hyperostosis found in hematological disorders causing bone marrow hyperplasia or cyanotic heart disease may cause confusion.

Evaluation. Evaluation should seek to distinguish fibrous dysplasia from other tumors or metabolic diseases and to assess the presence of deficits that require follow-up or surgical intervention. Plain x-ray films, CT, and MRI can distinguish fibrous dysplasia from tumors and characterize other metabolic disorders. Meningioma with adjacent hyperostosis is distinguishable on CT and MRI by its typical enhancement and its extension into the cranial cavity. Fibrous dysplasia expands into the outer table, leaving the inner table and cranial contents undisturbed.^[20] Imaging dedicated to the optic foramina should be done when the frontal and sphenoid bones are involved. Skeletal survey and increased uptake on bone scintiscanning can identify asymptomatic areas of involvement. Serum alkaline phosphatase levels are often elevated, but serum calcium and inorganic phosphorus are normal, helping to differentiate hyperparathyroidism. When following patients with frontal and sphenoid involvement who have not had surgery, photographs of the head, quantitation of proptosis, documentation of acuity and visual fields, and fundoscopic examinations for optic atrophy should be performed along with radiological views of the optic canal. These parameters may then be followed every 3 to 6 months until it is clearly established that no progressive visual loss has occurred. The onset of pain, increasing alkaline phosphatase levels, rapid growth, or invasion into cortical bone should

raise a suspicion of possible malignant transformation. Biopsy may be needed to distinguish progression of fibrous dysplasia from malignant transformation.

Management. Treatment is indicated when clinical function is significantly threatened. When visual symptoms are present in patients with a small or diminishing optic canal, surgical decompression by unroofing the optic canal can in most cases arrest progression. Such treatment rarely leads to significant return of function; therefore, patients at risk for visual loss must be closely followed. The lesions are highly vascular, and intraoperative bleeding and intrabony hematomas may complicate surgery. Radiotherapy is contraindicated because it greatly increases the risk of malignant transformation. Because lesions may progress more rapidly during pregnancy, careful follow-up, especially for visual symptoms, must be maintained. Decisions about surgery during pregnancy should be based on the neurological status of the patient.

Prognosis and Future Perspectives. The course in most cases is benign. Leeds and colleagues followed 15 patients for 6 to 39 years and found that radiological progression was slight or equivocal in all except two patients.^[20] Yet although the lesions become less active after skeletal maturation, progression does not necessarily stop with bone growth, and the lesions may reactivate during maturity. Recent success in elaborating the molecular mechanisms of intracellular signaling and their alterations in fibrous dysplasia and other diseases opens a rich field in which our understanding of the pathogenesis of fibrous dysplasia can be deepened. The elaboration of this work is likely to clarify the endocrinological manifestations of fibrous dysplasia. A better understanding of the molecular pathogenesis may eventually produce effective therapies, as it has in Paget's disease of bone.

Paget's Disease

Pathogenesis and Pathophysiology. Paget's disease (osteitis deformans) is a metabolic bone disease of un

known etiology characterized by increased osteoclast size and activity that results in resorption of bone followed by reactive new bone formation. This process produces areas of bone resorption with new bone laid down in an abnormally dense mosaic pattern. The osteoclasts in affected bone contain nuclear and cytoplasmic virus-like inclusions, and evidence has been presented of an association with various paramyxoviruses, including measles virus, respiratory syncytial virus, and canine distemper virus. It has been speculated that the disorder represents the late effect of viral infection on osteoclasts or their precursors and that affected osteoclasts tend to form multinucleated syncytia, which have increased resorptive activity. Normal osteoblasts may then be stimulated by the primary pathological osteolytic disorder.

Epidemiology and Risk Factors. Paget's disease is the second most common metabolic bone disease in the elderly population, after osteoporosis. It is most common in patients of northern European ancestry and is uncommon among Asians and Africans. Males predominate slightly. The prevalence in the elderly population of the United States is 1 to 3 percent, with 0.1 to 0.2 percent of patients having significant symptoms.^[23] The risk is increased in relatives of those affected, but pedigrees do not support direct inheritance.

Clinical Features and Associated Disorders. The disease typically begins in middle age or later and varies from limited asymptomatic involvement of a single or few sites to widespread symptomatic disease. The femur, pelvis, and spine are most commonly affected, although any bone may be involved. Skull involvement is also common. The most typical presenting symptoms are focal progressive bone pain, deformity due to expansion of bone, and structural failure such as vertebral compression fracture or bowing of weight-bearing long bones. Enlarging hat size due to progressive skull expansion is a classic symptom. Other typical facial changes include enlarged and coarsened orbits and prognathism. Patients may also notice focal increases in skin temperature due to increased blood flow at affected sites. The most common neurological symptoms are headache, deafness, and problems resulting from spinal disease. The cause of the deafness is unclear. Both auditory nerve compression and involvement of the middle ear ossicles have been suggested as mechanisms; however, autopsy studies have not borne out either hypothesis.^[23], ^[24] The main mechanisms presumed to cause neurological symptoms are compression of neural and vascular structures by overgrowth of bone into limited spaces, traction on neural structures displaced by bony deformity, and possibly a vascular steal phenomenon resulting from the local high blood flow demand of pagetic bone ([Table 29-4](#)). Involvement of the skull may cause basilar impression with consequent problems, including headache, ataxia, hydrocephalus, myelopathy, or cranial neuropathies. Patients may develop intradiscal lesions with spinal stenosis and, rarely, extramedullary hematopoiesis. These lesions may cause back pain or may progress to cause spinal cord and nerve root compression. Yet compressive symptoms due to spinal disease are uncommon, and when they occur in patients with Paget's disease, the possibility of sarcomatous degeneration should be considered. High-output heart failure due to the highly vascular shunts is rare.

TABLE 29-4 -- NEUROLOGICAL COMPLICATIONS OF PAGET'S DISEASE

Deficit/Localization	Proposed Mechanisms of Injury
Hearing loss	
Conductive	Involvement of middle ear ossicles
Sensorineural	Compression/traction of auditory nerve
Spinal cord and root involvement	Compression of central canal and foramina
Radiculopathy (esp. lumbosacral)	Compression, traction
Myelopathy (esp. thoracic)	Compression, vascular compromise (?steal)
Cranial nerves and brain stem	
Olfactory nerve	Sphenoid thickening compromising lamina cribosa
Optic nerve	Optic canal stenosis, orbital compression, ?vascular steal
Oculomotor nerves	Superior orbital fissure stenosis, ?vascular steal
Trigeminal nerve	Foraminal compression, ?vascular steal
Facial nerve	Facial canal stenosis, ?vascular steal
Lower cranial nerve, brain stem, cerebellum	Foraminal stenosis, basilar impression, platybasia, and vertebral artery compression from compression within foramina transversaria

Major categories are listed in order of decreasing relative frequency. Among cranial nerve deficits, those of the lower cranial nerves are most common.

From 1 to 5.5 percent of patients with Paget's disease develop osteogenic sarcoma.^[25] Other tumors, such as giant cell tumor of bone, are less common. The pagetic osteogenic sarcoma is osteolytic, and pathologic fracture is the most common presentation. Malignant degeneration should also be suspected when a rapid increase in pain or growth is noted or when compressive spinal findings emerge. About 5 percent of patients have hyperparathyroidism, but the mechanism of this association is not known. A complex array of vitamin D-related disorders may also accompany Paget's disease.

Differential Diagnosis and Evaluation. The differential diagnosis includes primary and metastatic bony tumors, especially prostate cancer, and other metabolic bone disorders that produce lytic lesions and hyperostosis. Degenerative arthritis may cause confusion, especially when one is trying to determine the source of symptoms when the two diseases coexist.

Plain radiographs of affected bones are still the primary means of diagnosis. The bones are expanded, often with thickening of the cortex. There may be a peripheral edge of lytic fronts and a small intracortical lytic area. It is common to find lytic lesions predominating in the skull. The most striking feature is typically osteosclerosis, which may have a fluffy appearance. The sclerosis is often intermixed with lytic disease. Uniformly sclerotic ivory vertebrae may be seen. Radionuclide scanning demonstrates greatly increased uptake and is the most sensitive test to establish the extent of involvement. Computed tomography can be used to distinguish osteolytic lesions missed on plain radiographs and can identify soft tissue masses ([Fig. 29-6](#)). In this regard, it may be an important adjunct in the differentiation of benign lesions from tumor. The urinary

Figure 29-6 Paget's disease of bone. Head CT bone windows show thickening of the bony calvarium with osteosclerotic and lytic lesions.

hydroxyproline-creatinine ratio is elevated, reflecting increased bone resorption. Greatly elevated bone alkaline phosphatase levels reflect increased osteoblastic activity and are characteristic. The relative elevations of these values reflect the predominance of either lytic (early) or blastic (late) disease. Serum calcium is usually normal unless some other factor, such as immobilization, tips the balance in favor of resorption and hypercalcemia. Inorganic phosphorus is normal or slightly elevated. When malignant degeneration is suspected, as in a patient with a pathological fracture, early biopsy should be pursued.

Management. The management of Paget's disease has changed in recent years. Both bisphosphonate and calcitonin attack the underlying metabolic disorder by inhibiting bone resorption. Although there is no consensus on the best therapy, both are now being applied to prevent the development of long-term complications. Etidronate, the first bisphosphonate available, provides definite benefit by inhibiting osteoclast activity. However, it interferes with the normal mineralization of new bone. The newer bisphosphonates, such as pamidronate, are similarly effective without impairing mineralization. These agents may be given in short courses intravenously or chronically by mouth. The urinary hydroxyproline level begins to fall within days of an intravenous dose, and the serum alkaline phosphatase declines later and more gradually. These substances remain in bone for a long time and may promote prolonged remissions. Subcutaneous or nasally administered calcitonins also inhibit osteoclasts. Symptomatic relief follows; however, the effect is short-lived, and the agents must be continued to maintain this effect. A loss of effect during therapy may be due to the formation of neutralizing antibodies, which occurs in about one fourth of those treated. The cytotoxic plicamycin used for hypercalcemia of malignancy causes a rapid improvement but is more toxic than the bisphosphonates or calcitonins. Gallium nitrate has antiosteoclastic activity, but data on its clinical use do not yet support its use outside of controlled trials. The goals of treatment are to normalize metabolism as evidenced by biochemical markers and to relieve symptoms. Most patients obtain relief from bone pain. Reversal of neurological deficits and stabilization--and rarely improvement--of hearing often follows therapy. There has been radiological evidence of healing of osteolytic lesions. Malignant lesions should be treated aggressively with radical resection for best results. Chemotherapy has not yet been shown to be effective. Early detection is currently the only available way to improve survival. Patients require life-long surveillance for tumor recurrence. With the currently available array of effective therapies for Paget's disease, it is most important that patients be properly referred for expert care.

Prognosis and Future Perspectives. Many patients remain asymptomatic. Newer drug therapies can now address bone pain and other rarer symptoms and may offer long-term remission. However, as noted previously, prevention or early detection of neurological deficits is essential to avoid loss of function, since therapy is more likely to arrest than to reverse them. The prognosis after malignant degeneration has occurred, however, remains poor, with only about 10 percent of patients surviving 5 years.^[26] Research in Paget's disease has produced advances in the understanding of the possible underlying etiology, the metabolic processes that promote the disorder, and the application of several new therapies. Further clarification of the viral hypothesis, development of improved diagnostic metabolic markers, and refinement of management with antiosteoclastic agents are expected in the future.

Other Compressive Disorders

Numerous other less common structural disorders are occasionally associated with compressive neurological signs and symptoms, including hyperostosis frontalis interna, anomalies of the craniocervical junction, congenital and acquired abnormalities of the spinal cord, generalized skeletal abnormalities, and such miscellaneous disorders as arachnoid diverticula. The clinical signs and symptoms of these disorders are summarized in [Table 29-5](#).

Compressive Neuropathies

COMPRESSIVE DISORDERS OF THE MEDIAN NERVE

Pathogenesis and Pathophysiology. The median nerve is subject to compression at the wrist, where it accompanies the flexor tendons as they pass beneath the volar carpal ligament. This region, the carpal tunnel, is a closed space within which pressure may rise. Studies with recording wicks placed in the canal show that flexion or extension elevate the canal pressure and that thickening of tendon sheaths or encroachment by other structures leads to a sustained rise in pressure within the canal.^[27] Compression of the median nerve at the wrist then leads to the carpal tunnel syndrome (CTS), the most common of the

TABLE 29-5 -- OTHER STRUCTURAL DISORDERS AND ASSOCIATED NEUROLOGICAL SYNDROMES

Disorder	Neurological Syndrome
Hyperostosis frontalis interna	Headache
Anomalies of the craniocervical junction region	
Basilar impression	Brain stem, cerebellar, and cranial nerve compression
Chiari malformations	Brain stem, cerebellar, and cranial nerve compression
Atlantoaxial subluxation (e.g., congenital, rheumatoid arthritis, Down's syndrome)	Cord and lower brain stem compression
Congenital and acquired abnormalities of the spinal cord	
Klippel-Feil syndrome	Cord and root compression
Scoliosis	Cord and root compression
Kyphosis	Cord and root compression
Generalized skeletal abnormalities	
Achondroplasia	Spinal stenosis, disc disease, basilar impression
Mucopolysaccharidoses	Cord and root compression, basilar impression
Down's syndrome	Atlantoaxial subluxation, basilar impression
Osteoporosis	Cord and root compression
Osteoporosis	Brain stem and cord compression
Osteomalacia	Cord and root compression, basilar impression
Osteitis fibrosa cystica (hyperparathyroidism)	Basilar impression
Osteogenesis imperfecta	Basilar impression
Miscellaneous disorders	
Arachnoid diverticula	Cord and root compression

entrapment neuropathies.^[28] Although nonspecific tenosynovitis is the most common cause of rising canal pressure, other causes may be relevant: amyloidosis may infiltrate the tendon sheaths, rheumatoid arthritis may cause synovial tissue to invade the canal, or hypothyroidism may cause tissue edema.

The median nerve is subject to compression at proximal sites near the elbow by a hypertrophied pronator teres muscle, by a vascular anomaly, or by trauma ([Fig. 29-7](#)).^[29] The symptoms and signs of proximal median neuropathy differ from those of CTS because the entire median nerve, including the motor branches to the flexors of fingers and thumb, is affected.

The archetypal motor and sensory loss anticipated with a lesion of the median nerve at three different levels is summarized in [Table 29-6](#). Not all listed muscles are

always affected, and EMG testing is more sensitive than manual muscle testing.

Epidemiology and Risk Factors. The degree to which CTS is an occupational disorder is still disputed. [30] Reported work- and trauma-related disorders of the upper extremities have increased tenfold in the past two decades, although only a small proportion relate to CTS. There is no consistent agreement about the diagnostic criteria, particularly whether the diagnosis requires confirmation by nerve conduction velocity (NCV) testing. In a Mayo Clinic retrospective chart review, using both NCV and clinical criteria, the prevalence of CTS was 125 per 100,000. [31]

It is estimated, based only on clinical criteria, that half of the cases of CTS seen in the United States are work- related. Motions of the wrist that require frequent rotation or flexion-extension, especially with force, seem to produce the highest incidence of disease. Carpenters, butchers, office workers who use keyboards, dental assistants, and musicians have a high incidence of CTS. Many workplaces have made ergonomic redesign a priority because of the rising medical costs of overuse syndromes, including CTS. Other overuse syndromes include tendinitis, tenosynovitis, local arthritis, vasospastic conditions due to vibration, and functional thoracic outlet syndrome. The last of these is discussed subsequently.

Symptoms of CTS are common in the latter months of pregnancy, probably because of rising tissue pressures due to fluid retention. In the majority of instances, the symptoms

TABLE 29-6 -- MEDIAN NERVE COMPRESSION

Location	Muscles Affected	Action	Sensory Loss
At the wrist	Abductor pollicis Opponens pollicis	Abduction Opposition	Palmar and dorsal surfaces of thumb, index, middle fingers

Figure 29-7 Median nerve diagrammed in relation to the volar aspect of the right forearm. A, Compression within or near the pronator teres muscles, fibers of which are shown. B, Anterior interosseous nerve. C, Median nerve at the wrist, beneath the volar carpal ligament, which is shown.

promptly resolve with delivery. Women are more likely to be diagnosed with CTS than men by a ratio of 60:40. In patients with occupational CTS, this ratio may be reversed. The higher frequency in women may reflect smaller wrist circumference, which correlates with CTS in some studies, or the different work conditions experienced by women.

Clinical Features and Associated Disorders. Patients with classic CTS report nocturnal distal pain and paresthesias. Pain may be present throughout the arm up to the level of the shoulder, but tingling is typically felt more distally. Some patients can detect the location of the tingling in the index and middle fingers, but many find it more difficult. Typically, patients rub and shake the hand because it feels asleep. On examination, patients in the early stages of disease have slight weakness of thumb abduction (away from the plane of the palm) and slight sensory loss, which is sometimes best detected on the dorsum of the index and middle fingers. There may be paresthesias into the palm with tapping over the wrist crease (Tinel's sign) and with forced wrist flexion for 30 seconds (Phalen's sign). In the later stages, patients have visible thenar atrophy and marked weakness of thumb abduction and opposition. Atypical forms of CTS exist, and one may observe marked autonomic dysfunction, acute onset, marked sensory loss, or unexpected neurological findings due to anatomical variations.

Patients with proximal median neuropathy may have partial or confusing deficits. Often the diagnosis is suspected because deep palpation over the course of the median nerve is painful and causes paresthesias.

In about 75 percent of patients, CTS is accompanied by nonspecific tendinitis in the flexor tendons. Hypothyroidism, atypical mycobacterial infection, diabetes, rheumatoid arthritis, and acromegaly are also associated with CTS. Pregnancy accounts for about 1 percent of CTS cases. In half the patients with symptomatically unilateral CTS, NCV in the opposite extremity is delayed. Additional ulnar nerve compression, cervical radiculopathy, bursitis, tendinitis, and osteoarthritis often occur in CTS patients, as well as an array of rheumatological complaints.

Differential Diagnosis. Cervical radiculopathy is a common diagnostic issue when the diagnosis of CTS is under consideration. Patients with radiculopathy are more likely to report neck pain, radiating pain with coughing or sneezing, and daytime (as opposed to nocturnal) paresthesias. With C6 or C7 radiculopathy, the biceps or triceps tendon reflex may disappear. Sensory loss proximal to the wrist is not characteristic of median neuropathy. A theory that proximal compression of a nerve root will worsen distal entrapment by impairing axonal transport (the so-called double-crush syndrome) has not been proved. [32] Most investigators believe that in patients with two sites of compression, for instance, C6 radiculopathy plus CTS, the disabilities are purely additive.

Large vessel vascular disease, leading to hemispheric transient ischemic attacks (TIAs), must be considered because the paresthesias of CTS may be brief enough to suggest TIAs. However, TIAs are rarely nocturnal and are not painful or unpleasant. Furthermore, hand tingling in a person with a TIA is usually associated with other neurological signs.

Diffuse peripheral neuropathy is a diagnostic problem with respect to CTS; it may complicate the electrophysiological investigation. Diabetic axonal neuropathy is the commonest coexisting neuropathy.

Evaluation. A diagnosis of CTS is usually evident from the history, and the neurological examination should focus on excluding other possible diagnoses. Tinel's and Phalen's signs are present in about half of patients with CTS and may be helpful. Electrophysiologic testing is important for the diagnosis of CTS [33] and should be carried out in nearly every instance prior to surgical release. If the clinical picture is straightforward and no therapy is planned other than conservative measures, electrophysiological testing can be omitted. Testing depends on the measurement of sensory action potentials from median innervated digits, especially the index finger, and comparison with other sensory potentials in that hand, such as radial or ulnar. Comparison with the opposite hand is usually done, but the results are limited by the high frequency of bilateral nerve conduction abnormalities. In a typical patient with mild CTS, the size of the median sensory action potential is maintained, but demyelination causes delay when it is measured at the wrist. In more advanced cases the compound muscle action potential is also delayed.

When the findings are not clear-cut, other comparisons can be made, and sequential recordings over the nerve as it passes through the palm can demonstrate the actual site of sensory delay when that is necessary. EMG recordings from abductor pollicis brevis and comparison with other intrinsic hand muscles can be made to be certain that only the muscles innervated by the median nerve are affected; this is especially helpful when cervical root disease is being considered. There are numerous pitfalls provided by anatomic variations, such as the Martin-Gruber anastomosis, in which nerve fibers destined to innervate the thenar muscles are found in the median nerve at the elbow but join the ulnar nerve in the forearm and pass the wrist in the ulnar nerve, giving the electrophysiological appearance of a marked loss of motor potential with stimulation of the median at the wrist. When median neuropathy near the elbow is being considered, the EMG pattern is most helpful because nerve conduction tests show diagnostic changes in no more than a third of cases. ^[29]

Management. Many patients with CTS are managed successfully by conservative means, ^[30] with reduction of any activity that may exacerbate tenosynovitis, use of a wrist splint, and oral nonsteroidal anti-inflammatory drugs (NSAIDs), such as ibuprofen 1600 mg/day or naproxen 750 mg/day. The splint should hold the wrist in a few degrees of extension ^[35] and may be worn at night or during wrist use. Prolonged or continued wrist splint use may lead to reduced range of motion and should be discouraged.

Steroid injection within the carpal canal is a time-honored technique and may be helpful diagnostically. After local anesthesia of skin and subcutaneous tissue, 15 to 30 mg of a depot preparation of methyl prednisolone is injected. The needle should be introduced 2 to 3 cm proximal to the palm itself and to the ulnar side of the palmaris longus tendon; injection into the nerve is to be avoided. No more than three injections should be done, since damage to the tendons may occur with frequent use of local steroids. Injection may provide relief of symptoms for several months, but symptoms recur in over 80 percent of patients. Injection is particularly suitable for pregnancy-related CTS. ^[36]

Patients who have persistent symptoms following conservative management should be referred for surgical release, and those with sensory or motor deficits normally require surgery. Advanced disease, especially in the elderly, will not improve motorically, so the only reason for surgery is to provide relief from pain. The degree of slowing of NCV is not a good predictor either of the need for surgery nor for outcome. The results of surgery are generally excellent. Forty percent of patients are asymptomatic following surgery, and another 40 percent have only trivial residual symptoms. Long-lasting incisional pain, slight weakness of the wrist, and a small number of patients who are neurologically worse after surgery are found in 10 percent of surgical outcome studies. ^[37]

Prognosis and Future Perspectives. In general, the prognosis for CTS is good. The condition is not disabling unless there are compounding problems such as compensation issues, psychological impairment, reflex sympathetic dystrophy, or an occupation requiring great strength or precise control of the digits (as in instrumental musicians).

Surgical techniques are under constant review and modification. Several procedures for endoscopic carpal tunnel release have been introduced. Overall, these seem to have efficacy that is about equal to that achieved with standard release procedures, as judged by randomized trials reported thus far. ^[38] There have been reports of hemorrhage within the palm, ulnar nerve compromise, and other complications that do not occur with standard release. The endoscopic procedure needs further evaluation.

In many industries, major efforts have been made to avoid the risk of occupational CTS, along with other overuse syndromes, by undertaking ergonomic redesign of work stations and tools. These efforts will continue in the future, since the economic consequences of these conditions can be very severe. In fact, within the last 2 years, premiums for worker compensation insurance have fallen slightly in many parts of the United States, possibly signaling a change in incidence of overuse and CTS in the workplace.

COMPRESSIVE DISORDERS OF THE ULNAR NERVE

Pathogenesis and Pathophysiology. The ulnar nerve is subject to entrapment at the elbow and, less commonly, can be traumatized in the palm or at the wrist. The common site of compression is at the cubital tunnel, which consists of the edge of aponeurosis of the flexor muscles, beneath which the nerve must pass ([Fig. 29-8](#)). This area is located about 3 to 5 cm distal to the medial epicondyle. Compression within the cubital tunnel is increased by elbow flexion. Less commonly, the nerve can be compressed externally at the elbow groove (for instance, during anesthesia), or by synovium in rheumatoid arthritis patients, or by callus following a fracture.

Epidemiology and Risk Factors. The prevalence of ulnar nerve disorders is unknown. Based on the apparent frequency of abnormalities in routine EMG/NCV studies, asymptomatic or minimally symptomatic ulnar neuropathy is very common, approaching the range of incidence of CTS.

Risk factors for ulnar neuropathy are poorly defined. Arthritis of the elbow may be a contributing cause. Persons who habitually rest the flexed elbow on a table or chair, specifically those with chronic pulmonary disease, can compress the nerve. There is a much lower incidence of ulnar neuropathy as an occupational disorder compared with CTS, but musicians who use one arm in a flexed position (cellists, violinists) commonly develop ulnar neuropathy. In baseball pitchers, particularly those who employ the slider and curve ball pitch are more at risk than fast ball pitchers. Other than these exposures, ulnar neuropathy is more common in the nondominant side, suggesting that repeated elbow flexion is more important etiologically than is repeated muscular usage. Ulnar neuropathy at the elbow is the most common anesthesia-related compressive neuropathy.

Ulnar neuropathy at the wrist can be caused by ulnar artery thrombosis at that site, by lacerations or ganglia. The ulnar nerve lies outside the carpal tunnel adjacent to the ulnar artery. The first occupational focal neuropathy described was observed by Ramsay Hunt, who reported compression of the ulnar nerve at the wrist in telegraph operators, who used the proximal palm to tap the key.

Figure 29-8 Ulnar nerve. Diagrammed in relation to the volar aspect of the right forearm. A, Compression at the cubital tunnel, by the aponeurosis of the flexor group. The branch innervating FCU is seen above the compression, and the branch innervating FDP to the digit V is below it. B, Compression at the wrist (Guyon's canal).

Clinical Features and Associated Disorders. The first symptoms in the majority of patients with cubital tunnel syndrome involve intermittent hypesthesia in the ulnar distribution. This is often associated with elbow flexion and dissipates with elbow extension. These symptoms may vary during the day and from day to day, disappearing for a period of time. Pain around the elbow, tenderness over the cubital tunnel, or radiating pain traveling into the palm may also be present. The amount of pain and paresthesia vary, and for some individuals the sensory loss is not bothersome. Although most patients present with sensory complaints, motor dysfunction, including weakness of intrinsic hand muscles and decreased grasp or pinch, or a loss of dexterity, can occur. An early motor symptom can include a loss of control of the fifth digit due to weakness of the third palmar interosseous muscle. In other patients, no early symptoms are noted, and the patient eventually presents with marked muscular atrophy and weakness. (See [Table 29-7](#) for individual muscles and sensory distribution.)

Diabetes mellitus may be a comorbid illness and seems to predispose to ulnar neuropathy, possibly by impairing the microvasculature of the nerve. Rheumatoid arthritis may cause synovial overgrowth and compress the ulnar nerve.

Differential Diagnosis. Neurogenic thoracic outlet syndrome, due to an aberrant ligament or band compressing the inferior trunk of the brachial plexus, is described later. The clinical findings may resemble those of ulnar neuropathy. This entity can be detected by finding weakness in median innervated muscles as well as ulnar innervated muscles and by the presence of sensory loss on the medial forearm. The same anatomical features pertain to metastases or a primary tumor within the brachial plexus or to radiation plexopathy. Cervical spondylosis affecting the C8 nerve root is quite rare; most radiculopathies affect the C6 or C7 root. Symptomatic thoracic outlet syndrome, in which the plexus is compressed by elevated arm positions or by muscular spasm, does not cause sustained neurological abnormalities.

Evaluation. The sensory examination is important, particularly in cases of early disease, in which sensory abnormalities may be the only findings. Sensory loss with ulnar neuropathy typically stops at the wrist creases. If the ulnar neuropathy is at the level of the wrist, the dorsum of the hand will be spared. Clinical evaluation should include a careful study of the pattern of weakness. Ulnar neuropathy causes weakness of adduction and abduction of all fingers, and adduction of the thumb. Importantly, flexion of the terminal phalanx of the fifth (or fourth and fifth) digit is carried out by the flexor digitorum profundus IV and V, a muscle that is located in the

forearm. If this is the only flexor found weak, cubital tunnel syndrome is very likely.

With lesions of the ulnar nerve above and at the elbow, there can be atrophy and flattening of the hypothenar eminence and interossei. The hand may demonstrate a "claw-hand" deformity (*main en griffe*), with the fifth, fourth, and, to a lesser degree, the third fingers hyperextended at the metacarpophalangeal joints and flexed at the interphalangeal joints. The hyperextension at the metacarpophalangeal joints results from paralysis of the interossei and ulnar lumbricals. This results in the unopposed action of the long finger extensors; the flexion at the interphalangeal joints is due to tension from the long finger tendons. Ulnar paresis or paralysis also affects extension at the interphalangeal joints of the second to fifth fingers, adduction and abduction of the second to fifth fingers, and abduction and opposition of the fifth finger. Froment's prehensile thumb sign (*signe du journal*) may be present as a result of adductor pollicis weakness. This sign occurs when a sheet of paper, grasped between the thumb and index finger, is pulled; the proximal phalanx of the thumb is extended, and the distal phalanx is flexed.

Electrophysiological testing focuses on the demonstration of slowing of motor and sensory fibers at the elbow.^[39] Sometimes it is possible to show that only the ulnar nerve is affected but not to localize the disorder well. This happens particularly when there is significant axonal loss in patients with long-standing neuropathies.

Management. Conservative management consists of reducing occupational exposure, if any, using NSAIDs, and using a half-splint held in place with a wrap, so that the elbow is maintained in gentle extension. Such a splint can be worn at night as well as during the day. Steroid injections

TABLE 29-7 -- ULNAR NERVE COMPRESSION

Location	Muscles Affected	Action	Sensory Loss
At elbow (cubital tunnel syndrome)	Flexor digitorum profundus V	Flexes little finger, distal joint	Medial side of hand and fingers to wrist crease
	Interossei	Adducts and abducts	
	Flexor pollicis brevis	Adducts thumbs	
	Opponens V	Adducts little finger	
At wrist	Interossei	Adducts and abducts	Palmar and medial hand and finger
	Flexor pollicis brevis	Adducts thumb	
	Opponens V	Adducts little finger	

have no role in the treatment of patients with the cubital tunnel syndrome.

The decision to refer patients for surgery should be based chiefly on the presence of a demonstrated worsening deficit, even if mild.^[40] Many ulnar neuropathies stabilize and remain mild. Pain may be a significant problem and may force an early decision for surgery. The choice of a procedure is not without controversy. Many surgeons prefer a simple cubital tunnel release, by sectioning the taut aponeurosis. Others remove the medial epicondyle, which forms the medial wall of the ulnar groove, in order to decompress the nerve. Mobilization of the nerve and moving it to a position above the epicondyle and beneath the flexor muscles produces a definitive decompression. Attention to arm position during anesthesia will help to cut down on perioperative neuropathy. In many patients the condition stabilizes at a mild or moderate degree of nerve dysfunction.^[41]

COMPRESSIVE DISORDERS OF THE RADIAL NERVE

The radial nerve is subject to compression at several sites ([Table 29-8](#)).^[42] An acute compression can occur at distal parts of the brachial plexus, in which the nerve is compressed against the humerus, usually when the patient falls asleep with the arm draped over a chair; this is the so-called Saturday night palsy. Fractures involving the shaft of the humerus can damage the nerve, since it is closely applied to the bone through much of its course. There is a radial tunnel located beneath the extensor carpi radialis, 3 to 4 cm distal to the lateral epicondyle. Finally, the radial sensory branch, supplying the dorsum of the wrist and hand, is subject to laceration or contusion ([Fig. 29-9](#)).

Persons subject to acute intoxication from alcohol or drugs are those most likely to develop an acute radial nerve compression. The radial tunnel syndrome is usually chronic and is associated with anatomical variations near the elbow that have no predictable risk factors.

Radial nerve palsy causes wrist drop with paralysis of finger and thumb extension. Because the intrinsic hand muscles are weak in this position, apparent palsy of finger abduction is seen; this can be corrected by supporting the fingers. In patients with acute Saturday night palsy, the brachioradialis is weak, but the triceps muscle is usually only partially affected. Sensory loss is usually slight. The radial tunnel syndrome affects the posterior interosseous nerve, so that wrist extension can be spared because the extensor carpi radialis is above the level of the compression. Local pain and a Tinel's sign at the site of the radial tunnel help to identify this uncommon syndrome.

Radial tunnel syndrome can resemble the signs of a C7 radiculopathy, but the weakness of the finger flexor muscles seen with the C7 deficit soon leads to correct localization. Acute radial palsy is usually painless, but the pattern of weakness, including pseudo-weakness of intrinsic, is readily recognizable. Focal motor neuropathy, which is probably a variant of chronic inflammatory neuropathy, often affects the radial nerve at the region of the elbow; usually other nerves are affected too. Radiological studies are usually not required. If there is a question of hematoma or fracture, plain films or ultrasound examination will suffice.

Figure 29-9 Radial nerve diagrammed in relation to the dorsal aspect of the right forearm. Compression at the radial tunnel. The branch innervating the ECR is seen above the point of compression.

TABLE 29-8 -- RADIAL NERVE COMPRESSION

Location	Muscles Affected	Action	Sensory Loss
At elbow (posterior interosseus syndrome)	Extensor carpi ulnaris	Extends wrist	None
	Extensor digitorum communis	Extends fingers	
	Extensor pollicis	Extends thumb	
	Abductor pollicis	Extends, abducts	
Below elbow (sensory radial branch)	None		Lateral side of forearm and hand

If nerve conduction studies are carried out acutely, they will show conduction block because the acute disorders are demyelinating in most instances. Electromyographical studies in patients with radial tunnel syndrome can be very helpful in locating the exact site of nerve compression.

If an acute radial palsy lasts for more than a few days, the patient should be referred for physiotherapy and for occupational therapy to allow fitting of a spring-loaded brace for finger and wrist extension. Radial tunnel syndrome patients may require surgical exploration; the two indications for surgery are pain and established or progressing weakness.^[43] Acute radial palsy patients usually recover completely within 4 to 6 weeks. Even after severe injury to the nerve, full late recovery can occur. With bracing, acceptable use of the hand can be maintained.

THORACIC OUTLET SYNDROME

True neurogenic thoracic outlet syndrome (TOS) is due to an aberrant band or ligament crossing the brachial plexus, usually between the transverse process of the C7 vertebra and the sternum or first or second rib. The inferior trunk of the plexus, consisting of fibers derived from C8 and T1 nerve roots, is compressed. The syndrome is very rare.^[44] Symptomatic, or secondary, TOS does not involve an identifiable anatomical structure causing nerve compression and is believed to be due to an abnormal shoulder posture or to muscle spasm. It is most often diagnosed with certainty in persons who use one or both arms above the head or in instrumental musicians. Sometimes there is a preceding history of minor cervical or shoulder trauma precipitating muscle spasm or a change in shoulder or neck posture. Some patients are tall, slender, and more round-shouldered than average ("droopy shoulder syndrome"). In addition, vascular types of compression can occur within the thoracic outlet, usually affecting the subclavian artery. Surprisingly, neurogenic and vascular compression do not usually coexist, most patients demonstrating one pattern or the other, but not both. There are no known risk factors for vascular TOS. Since some patients develop thrombosis of the subclavian or innominate artery, a thrombotic disorder would be a risk factor.

The diagnosis of true neurogenic TOS requires an anatomical abnormality, which is presumably congenital. Symptomatic TOS may be occupational. There may be an overlap with overuse syndrome or with other nerve entrapments, and if the clinical findings are slight, a firm diagnosis may not be possible. True neurogenic TOS causes a stereotyped clinical picture. Patients complain of numbness and pain in the affected arm. There is weakness of all intrinsic muscles of the hand, corresponding to the C8 and T1 myotomes, and often starting with the thenar muscles. Sensory loss, if present, is located on the ulnar side of the hand and forearm. With further compression of the plexus, extensors of the thumb and index finger and pronator quadratus are affected.

Symptomatic TOS causes positional numbness and pain without demonstrable neurological deficit. There may be pain on palpation over muscles or nerve trunks. The radial pulse may diminish with arm abduction, but the value of this observation is much reduced by the fact that it is present in 15 percent of normals.

Alternative diagnoses center around other conditions that affect the lower plexus. These include metastatic cancer, radiation injury, syringomyelia, and, rarely, lower cervical disc herniations. Nerve conduction testing is important, mainly to exclude atypical median or ulnar neuropathies. The plexus injury in true neurogenic TOS is axonal in type, so that reductions in ulnar sensory action potentials, accompanied by EMG findings in the C8 and T1 myotomes, are to be expected. An MRI scan of the plexus and cervical spine is advisable to exclude tumor. Many tests of pulse volume in various arm positions have been described in the past, but they have little role in modern medicine. If there is a suspicion of subclavian stenosis or occlusion, angiography or MR angiography should be carried out without delay.

Symptomatic TOS is treated by physiotherapy, consisting of a program to strengthen the muscles and improve cervical and periscapular strength and posture. Neurogenic TOS may require surgical release; for proper visualization, a retroclavicular approach is best, although an extensive literature describes transaxillary first rib removal, an unproven procedure that has many described complications.^[45] The prognosis of patients with symptomatic TOS depends on proper management through physiotherapy. The prognosis of those with neurogenic TOS is unknown owing to the marked rarity of the disorder.

COMPRESSIVE DISORDERS OF THE SCIATIC, PERONEAL, AND TIBIAL NERVES

The sciatic nerve and its branches are resistant to entrapment, and there is no consistent area in the lower extremity where entrapment occurs. Compression of the sciatic nerve can occur in situations in which there is variation in the course of the sciatic nerve between parts of the piriformis muscle, or by a myofascial band in the distal portion of the thigh between the biceps femoris and the abductor magnus. The sciatic nerve can be acutely compressed or injured by retroperitoneal bleeding in the setting of anticoagulant therapy. Surgical trauma from hip replacement, gunshot wounds, fractures of the hip or femur, and infarction are

some of the causes of sciatic nerve lesions. Such compression may occur following fractures or other acute traumatic lesions. Forcible inversion of the foot, which results in stretching of the nerve and damage at the level of the fibular head, may cause peroneal dysfunction. Other causes of peroneal damage include improperly applied casts or tight garters, bandages, or stockings. Some patients may be susceptible to peroneal compression including those who were unconscious from drugs, anesthesia, or illness with coma. Excessive weight loss in the presence of chronic illness may also predispose the patient to peroneal compression. Certain occupations including those that require prolonged sitting, squatting, or kneeling may provoke peroneal dysfunction. Finally, ganglia or tumors of the nerve or neighboring structures may be associated with compression of the peroneal nerve. Tibial nerve dysfunction resulting from tarsal tunnel syndrome consists of entrapment of the posterior tibial nerve at the level of the medial malleolus. This syndrome is quite rare and usually occurs after ankle fracture or in patients with rheumatoid arthritis. Any or all of these divisions of the posterior tibial nerve may be affected.

The risk factors for peroneal or sciatic mononeuropathy are those associated with any acute compression, namely, local trauma, fracture, or prolonged unconsciousness. Peroneal nerve compression can occur with prolonged squatting and has been seen in vegetable or fruit pickers working in fields.

Diabetes is a risk factor for sciatic or peroneal neuropathy, probably because it contributes to vascular insufficiency and predisposes to nerve infarction or conduction failure if the nerve is compressed.

The sciatic nerve innervates the knee flexors and all the muscles below the knee. Therefore, complete palsy of the sciatic nerve leads to marked instability of the foot and to a severe impairment of gait. A complete palsy of the sciatic nerve is extremely rare and would not be expected from sciatic nerve entrapment. The entire foot except for a small region supplied by the saphenous nerve over the medial malleolus is supplied by the sciatic nerve. With entrapment, pain or paresthesia may radiate into these territories.

Peroneal palsy is usually acute and is the result of external pressure applied to the nerve in its vulnerable fixed position against the fibula. Loss of eversion (if the superficial division is involved) or of dorsiflexion of the toes and ankle (if the deep division), or both, are found. Sensory loss is much more apparent with lesions of the superficial division, and such loss involves the lateral calf, the lateral malleolus, the dorsum of the foot, and the medial three or four toes up to the interphalangeal joint. With lesions of the deep division, the sensory loss is smaller and involves the small area between the first and second toes and the web space and the adjacent portion of the dorsum of the foot. In common acute compressive peroneal lesions, pain is not a typical complaint, and there are few or no sensory symptoms. With entrapment or chronic lesions, patients may experience radiating pain and slowly progressive motor and sensory disturbances.

The primary symptom of tarsal tunnel syndrome is a burning, unpleasant pain in the sole of the foot. This pain may become worse during rest or while sleeping at night. Pain and sensory disturbances over the entire plantar surface of the foot may occur. With involvement of one or two divisions of the posterior tibial nerve, these findings may be restricted to only a portion of the plantar surface.

Lesions of the sciatic nerve must be distinguished from herniated lumbar disc disease. Most patients with sciatic pain due to lumbar disc disease have monoradicular symptoms. Thus, pain radiating to the lateral side of the foot and small toe is associated with S1 lesions; pain radiating to the dorsum of the foot with L5 lesions; and pain radiating to the medial part of the calf with L4 lesions. Marked weakness of both the anterior tibial and gastrocnemius muscles suggests sciatic neuropathy. Other disorders to be considered in the clinical setting of sciatic nerve dysfunction include lumbar spinal stenosis (see earlier discussion) and vascular (diabetic) neuropathy (see [Chapter 38](#)). In patients with progressive sciatic deficits with pain as the initial symptom, intraspinal carcinoma, lymphoma, and myeloma should be included in the differential diagnosis.

L5 radiculopathy may resemble peroneal dysfunction, yet in most patients there is accompanying back pain or sciatic pain. In these cases, weakness of both eversion and inversion and the loss of sensation above the midpoint of the calf of the outer surface, together with the greater weakness of the extensor hallucis than of the anterior tibial muscle, suggest an L5 radiculopathy.

In distinguishing tarsal tunnel syndrome from other disorders, the examiner should consider the varied causes of foot pain. These include plantar fasciitis, stress fractures, bursitis, and trauma to the plantar nerve distal to the tarsal tunnel. Diabetic neuropathy causing burning painful feet may also be difficult to distinguish from bilateral tarsal tunnel syndrome.

Electromyography and NCV testing are very helpful in the diagnosis of disorders of the sciatic nerve and its branches.^[46] Focal slowing at the fibular head, implying a demyelinating process, is usually found in patients with acute or chronic peroneal mononeuropathies. Sometimes in those with severe lesions, there is enough axon loss to obscure this important finding. Many sciatic lesions of diverse causes result in marked axon loss, and no demonstrable area of focal slowing will be found even

though the lesion is anatomically focal. In these situations, reliance on the pattern of EMG abnormality is still very helpful. Computed tomography or MRI scanning of the lumbar spine, the retroperitoneal space, and the course of the nerve may be needed to establish an exact anatomical diagnosis. Spontaneously arising and progressive mononeuropathy in the lower extremity always presents the possibility of unrecognized tumor.

Management of these lesions depends entirely on their cause. Pain control with sciatic lesions is best achieved by pharmacological means. In patients with peroneal palsy, a fitted brace (ankle foot orthosis [AFO]) should be used to protect against ankle joint damage and improve gait unless the muscle paresis is mild. Even in patients with acute lesions, the prognosis of sciatic or peroneal neuropathy is at best, fair. Too often there is extensive axon loss and a resulting lasting deficit.

OTHER COMPRESSIVE DISORDERS OF THE LOWER EXTREMITIES

There are other uncommon compressive neuropathies of the lower extremities including those involving the femoral,

TABLE 29-9 -- OTHER NERVES IN THE LOWER EXTREMITY AND ASSOCIATED COMPRESSIVE SYNDROMES

Nerve	Muscles Affected	Reflex Changes	Sensory Loss	Compressive Causes	Etiological and Anatomic Differential Diagnosis
Femoral	Hip flexors Knee extensors	Reduced knee reflex	Anterior thigh, medial calf	Idiopathic, iatrogenic by surgery, retroperitoneal, hemorrhage, tumor	Infarction trauma radiculopathies
Lateral femoral cutaneous	None	None	Lateral thigh	Entrapment	
Saphenous, ilioinguinal and iliohypogastric	None None	None None	Medial calf, low abdomen	Iatrogenic surgery, scar after surgery	Trauma, infarction

The storage diseases are characterized by pathological reactions that lead to the intracellular accumulation of abnormal material in the nervous system. They include disorders that may affect the entire nervous system, primarily the gray or white matter. Most, but not all, are pediatric conditions, but adult variants are being recognized more often. This discussion deals primarily with the neurological aspects of these diseases.

[PreviousNext](#)

NEURONAL CEROID-LIPOFUSCINOSES

Neuronal ceroid-lipofuscinoses (NCLs) are a group of diseases characterized by neurological symptoms and the accumulation of autofluorescent waxy lipopigments within the lysosomes of neurons and other cells. The disorders are linked to a number of celebrated names in neurological history, including Batten, Jansky, Bielschowsky, Santavuori, and Kuf, each of whom described clinical variants of these multidimensional disorders. The conglomerate term neuronal ceroid-lipofuscinoses was coined by Zeman and Dyken in 1969 to emphasize the neurological involvement, clinically and pathologically. ^{1,2} In 1995, a classification of seven forms of NCLs was developed to consolidate earlier clinical and genetic descriptions ([Table 30-1](#)).

Pathogenesis and Pathophysiology. In the NCLs, waxy lipopigments, composed of ceroid, lipofuscin, and excessive amounts of a protein identified as "subunit c," accumulate in neurons and non-neuronal tissue. All subsequent symptoms are based on this accumulation, which activates cellular dysfunction and death in differently maturing groups of neurons (see [Table 30-1](#)). It has been speculated that cellular death is apoptotic. ³ A combination of metabolic and mechanical factors also lead to the dysfunctional state. The lipopigments accumulate first in the larger neurons and tend to cluster around the axonal hillock. Inert lipopigments and debris progressively accumulate in an area rich in inhibitory synapses. Thereafter, the waxy pigments gradually spread to other parts of the neuron, ultimately involving the rest of the cell body while sparing the dendritic tree. Progressive swelling of the neuron occurs, followed by cellular death, subsequent disruption of the cell membranes, extracellular extrusion of debris, and its accumulation within scavenger cells. By this time, smaller neurons are involved as well as glia, endothelium, and fibrocytes. Lipopigments accumulate to a mild extent in almost all cells of the body, including lymphocytes, eccrine cells, fibroblasts, endothelial cells, ganglion cells of the rectum, and conjunctival cells. This observation permits detection of the "diagnostic" cytosomes without the need for brain biopsy. It must be emphasized, however, that the absence of such material in non-neuronal sites does not exclude the diagnosis, and the presence of similar osmophilic bodies does not establish it.

The slow process of waxy pigment accumulation first in the axonal hillock may account for the epileptogenesis that is often present, particularly in the late infantile (NCL 2)

TABLE 30-1 -- NEURONAL CEROID-LIPOFUSCINOSES

Type	Name	Enzyme Deficiency	Prominent Cytosome	Genetics	Age of Onset	Major Signs
NCL 1	Batten's(juvenile chronic form)	Not known	Fingerprints	Autosomal recessive	4-12 yr juvenile	Blindness, seizures, dementia; mixed pyramidal and extrapyramidal signs
NCL 2	Bielschowsky's (acute late infantile)	Not known	Curvilinear	Autosomal recessive	Infants	Seizures, followed by acute decline in motor and mental functions with vegetative state in 2 years
NCL 3	Santavuori's (acute infantile)	Not known	Granular	Autosomal recessive	Infants, 3-12 months	Fulminating psychomotor deterioration, seizures
NCL 4	Kuf's (adult recessive)	Not known	Granular	Autosomal recessive	Adult	Chronic motor, cerebellar, or extrapyramidal signs and mental deterioration, seizures
NCL 5	Boehme's (adult dominant)	Not known	Granular	Autosomal dominant	Adult	Seizures, no retinopathy
NCL 6	Lake's (early juvenile)	Not known	Curvilinear	Autosomal recessive	Early juvenile, 4-5 yr	Mixed pattern of signs of NCL 1 and 2
NCL 7	Atypical	Not known	Variable	Autosomal recessive	Variable	Retinopathy, mental and motor deterioration

and juvenile (NCL 1) forms. It is speculated that classic seizures are precipitated by an overriding glutaminergic state caused by cancellation of the inhibitory influences at the axonal hillock. Hyperglutaminergic states may also lead to more rapid loss of other neurological functions.

All NCLs are autosomal recessive except for the adult autosomal dominant or Boehme form of the disease. It is notable that the proposed gene defects are different for the different forms of the disorder. In NCL 1, a genetic defect exists in chromosome 16p12; the early juvenile, or NCL 6, form is carried on chromosome 13 (13p31-32); the infantile form (NCL 3) is carried on the first chromosome (1q32); and the genetic defect for Bielschowsky's disease (NCL 2) is not known, but is definitely not located on the first, thirteenth, or sixteenth chromosomes. The loci for the two adult forms (NCL 4 and NCL 5) and the many atypical cases (NCL 7) are not known. Furthermore, it has been shown in some examples of classic juvenile NCL that no abnormalities are present on the sixteenth chromosome. ⁴

Epidemiology and Risk Factors. These genetic diseases are probably present in all ethnic and racial groups around the world. One series in the United States found that NCL 1 was the most common form, followed by NCLs 2, 3, 7, 4, 6, and 5 (see [Table 30-1](#)), in that order. These data agree with experiences in Germany, Britain, the Netherlands, and Sweden. In Poland, on the other hand, the late infantile (NCL 2) form is encountered more frequently. This may possibly hold true for the other Eastern European countries as well. In Finland, the more common type is the acute infantile Santavuori form. It is so common there and so rare elsewhere that it is often called the Finnish form. In Saudi Arabia, the vast majority of NCL patients suffer from a form that is relatively uncommon in the United States, the early juvenile NCL 6.

Clinical Features and Associated Disorders. The most frequent of the many syndromes is NCL 1 or Batten's disease, the classic juvenile chronic form. Onset, which includes neurological dysfunction, usually occurs between the ages of 5 and 15 years. ⁵ The patient may be referred initially to an ophthalmologist or psychiatrist. By age 10, the patient is most often referred to a neurologist. The obvious behavioral symptoms have progressed from a learning deficiency to frank dementia. Likewise, visual dysfunction has usually progressed to blindness. There is a slow and steady progression of neurological symptoms. Three stages of clinical deterioration occur. The first phase involves visual and behavioral disturbances, and the middle phase consists of seizures and motor dysfunction related to a mixture of pyramidal and extrapyramidal symptoms. In the terminal phase the preceding symptoms may become much worse, and there may be changes in affect and motor signs including myoclonus. The three phases are steadily progressive and form an overall monophasic illness that distinguishes NCL 1 from the other disorders described in this chapter.

As a general rule, phase one lasts from 6 months to 5 years, phase two from 2 to 10 years, and phase three from 1 to 10 years. This results in a life expectancy that ranges from 3 to 25 years after the initial visual-neurological symptoms are noted. The course of the disease is generally directly proportional to control of the seizures. Once seizures become refractory and frequent, the course proceeds rapidly downhill to a vegetative state.

The rather slowly progressive course of NCL 1 is quite different from the more rapidly progressive NCL 2 (Bielschowsky's disease). In this acute, late infantile form, the period from the initial neurological symptoms to a severe vegetative state is seldom longer than 2 years. In NCL 2, on average, the first symptom seldom appears after 2 years of age. ⁶ This condition's hallmark is a seizure disorder that begins precipitously, progresses rapidly, and ultimately becomes refractive to all anticonvulsant medications. The initial seizures are usually described as drop attacks, myoclonic, partial, or generalized seizures, although nearly all types of seizure often occur within a short period of time. In this rapidly developing disorder, severe intellectual and mental deterioration is seen. The child becomes nonambulatory, usually in the first year of the disease. During this time, vision is progressively lost, yet because of the general loss of neurological function, such an isolated sign is often not recognized. Compared to patients with the juvenile form, a characteristic retinopathy occurs with striking retinal artery attenuation, patches of retinal atrophy, and symmetrical macular granular degeneration.

The third most frequent form of NCL in the United States is the rapidly progressive infantile form. The onset occurs within the first year of life, after a symptom-free period between birth and 3 months of age. Then a sudden and dramatic psychomotor collapse occurs with loss of neurological and visual functions. The collapse may or may not be associated with drug-refractory seizures or severe myoclonus.

Kuf's adult-recessive form of NCL (NCL 4) has two major clinical presentations. ^[1] One begins with late-onset epilepsy and subsequent subacute loss of mental functions but relative preservation of motor functions. Another clinical form of NCL 4 is marked by predominant motor dysfunction. This dysfunction may become manifest as pure cerebellar ataxia or progressive rigidity.

In contrast to other NCLs, Boehme's disease (adult- dominant NCL 5) is transmitted by autosomal dominant inheritance. Onset of symptoms usually begins around age 30, and this form can be practically indistinguishable from the epileptic form of NCL 4. The NCL 5 syndrome is associated with epilepsy in all instances, and it is important to emphasize that neither NCL 4 nor NCL 5 shows retinal disturbance. This adult-onset condition remains stable for a short time and then becomes progressively worse until seizures become refractory. The syndrome is associated with progressive behavioral and mental dysfunction eventually ending in dementia. The ability to ambulate is lost because of the combination of pyramidal and extrapyramidal dysfunction. Both NCL 4 and NCL 5 are characterized pathologically by excessive amounts of aging lipofuscin and osmophilic granular material in the neurons and ganglion cells in non-neuronal tissues. ^[2]

The early juvenile form of NCL, (NCL 6), formerly considered a transitional form, ^[3] has clinical features that overlap those of the late infantile and juvenile forms. There may be fewer retinal abnormalities than in NCL 1 or NCL 2, but other features characteristic of both the juvenile and late infantile forms are seen. Onset occurs between 4 and

8 years of age, and the course is subacute compared to the chronic juvenile and acute late infantile forms of the disease.

Differential Diagnosis. The most important step in the differential diagnosis is to identify the order of the characteristic symptoms, taking into account the fact that the retinal picture may be of greatest importance. This evaluation separates the retinal NCLs (NCL 1, 2, 3, 6, and some 7) from the nonretinal NCLs (NCL 4, 5, and some 7). The differential diagnosis for the group includes all neurodegenerative diseases characterized by epilepsy, blindness, motor failure, and dementia, including the gangliosidoses and sphingomyelinoses.

Evaluation. A battery of laboratory tests is important in the workup of NCL patients. Neuroimaging studies show abnormalities characteristic of the type and stage of disease and demonstrate that most NCLs are ultimately atrophic poliodystrophies involving the cerebral cortex. Certain unique types such as the spinocerebellar form show selective involvement of the cerebellum in which autofluorescent storage material accumulates in Purkinje cells. ^[4] In NCL patients with epilepsy, electroencephalography (EEG) shows epileptogenic patterns. Electroretinograms are decreased or absent in patients with the retinal NCL types. Particularly in NCL 2 (and NCL 6), exaggerated evoked potential responses are seen, especially following tactile or somatosensory stimulation. Evoked potential exaggeration also occurs in some other NCLs.

Clinical and histopathological evaluations are essential to make the specific diagnoses. Ultrastructural cellular cytosome alterations are seen on electron microscopy in extracerebral tissue such as ganglion cells in the rectal submucosa, in eccrine cells and fibrocytes of the skin, in endothelial cells in vessels, in lymphocytes in the peripheral blood, and in conjunctival cells. Extracerebral evaluation may not be entirely infallible. Many current diagnostic problems stem from confusion about the cytosomes themselves. Osmophilic inclusions occur frequently as an artifact of tissue preparation for electron microscopy and do not always represent the diagnostic inclusion of the NCL. Four suggestive cytosomes are important, and two of these are diagnostic. The osmophilic fingerprint cytosomes are highly characteristic as lymphocytic inclusions in NCL 1. The second diagnostic osmophilic cytosome is the curvilinear body, which characterizes NCL 6 and many forms of NCL 7. These are not seen in NCL 4 or NCL 5. The third important ultrastructural cytosome is the granular cytosome or GROD, which is encountered in all forms of NCL but is the dominant cytosome in NCLs 3, 4, and 5. The least diagnostic cytosome is the classic lipofuscin body.

A large proportion of the storage material involved in NCL consists of the mitochondrial protein called subunit c. This material is found in very high quantities in NCL 2 but is also seen in increased amounts in NCL 1 and NCL 6. Urinary dolichols are also increased in the NCLs but are higher than normal in many other conditions as well.

Management. Symptomatic treatment, particularly proper anticonvulsant therapy, is important in all NCL disorders. Sodium valproate has been used with success. Antioxidants may improve the symptoms in some cases, and trials of these medications have been undertaken in patients with NCLs 1, 2, 3, and 6. It has been suggested that long-term antioxidant treatment and vitamin E may delay loss of intellectual and motor function and may be helpful in seizure control as well. Extrapyramidal symptoms such as dystonia and myoclonus are treated symptomatically, and behavioral modification techniques may be useful, particularly in the chronic forms. If the symptomatology is of long standing, palliation of the symptoms may be extremely useful in supporting a long and often useful life for the patient. School placement and modified educational programs are important in patients with the chronic forms of disease.

LIPIDOSES

Gangliosidoses

As a group, the gangliosidoses ([Table 30-2](#)) are characterized by central ganglioside accumulation, autosomal recessive inheritance, psychomotor retardation, often organomegaly, and they may show cherry-red spots.

Pathogenesis and Pathophysiology. All the gangliosidoses are characterized by storage of abnormal gangliosides in neurons and other parts of the nervous system (see [Table 30-2](#)). The storage of the ganglioside material results from the absence or inaction of a cleaving enzyme that normally promotes lipid breakdown. ^[9] The enzyme itself may be absent, or the enzyme may be present but the protein necessary to activate it is deficient. In all of the gangliosidoses, there is a dramatic accumulation of lipid that distends the neuronal cell body; the resulting mechanical factors interfere with metabolic function and ultimately destroy the cell. Different neuronal populations are involved and produce different symptoms. The storage is primarily neuronal and tends to occur mainly in the polioencephalon in large neurons. The weight and volume of the affected brain increase markedly during the second year of life; it can often weigh well over twice the normal amount for age and sex. Thereafter, cystic degeneration of the remaining cortex and subcortex occurs. The neuropathological process is not limited to the brain, and motor neurons of the anterior horn cells of the spinal cord are also affected. Pathological examination of these disorders reveals distorted and ballooned neurons. Fusiform swelling of the axons, termed torpedoes, occurs, and astrocytic proliferation is seen. White matter degeneration occurs secondary to the neuronal dysfunction and cell death. Electron microscopic studies show the gangliosides usually tightly packed within the individual cells. In most gangliosidoses, these cytosomes, or membranous cytoplasmic bodies, are osmophilic and often take on a loosely "whorled" form.

Epidemiology and Risk Factors. These exclusively autosomal recessive genetic disorders are globally distributed. Because intermarriage among relatives increases gene frequency, there are often pockets of these diseases in certain sequestered populations. Thus, type I GM₂-gangliosidosis, or Tay-Sachs disease, has a high frequency among Ashkenazi Jews. Although this disease was once considered rare in black populations, it has been recently noted to occur in the southern United States in areas with a history of consanguinity. ^[10] In Saudi Arabia, which has high consanguinity and reproduction rates, there is also a high gene

TABLE 30-2 -- GANGLIOSIDOSES

Type	Name	Enzyme Defect	Storage Product	Genetics	Age at Onset	Primary Clinical Features
GM ₁ -gangliosidosis type I	Infantile form	Beta-galactosidase	GM ₁	Autosomal recessive	Birth	Cherry-red spot in 50 percent, edematous face, hepatosplenomegaly, seizures mental and motor retardation
GM ₁ -gangliosidosis type II	Juvenile form	Beta-galactosidase	GM ₁	Autosomal recessive	5-15 yr	As above, but slower in evolution
GM ₁ -gangliosidosis type III	Adult form	Beta-galactosidase	GM ₁	Autosomal recessive	Adult	Prominent extrapyramidal signs without hepatosplenomegaly
GM ₂ -gangliosidosis type I	Tay-Sachs disease; infantile form	Hexosaminidase A	GM ₂	Autosomal recessive	Infants	Hyperexcitability, blindness, cherry-red spot
GM ₂ -gangliosidosis type II	Juvenile form	Hexosaminidase A	GM ₂	Autosomal recessive	5 yr	Seizures, dementia, pyramidal and extrapyramidal motor signs
GM ₂ gangliosidosis type III	Adult form	Hexosaminidase A	GM ₂	Autosomal recessive	Adult or adolescence	Variable pictures, including myelopathic, motor neuron, or extrapyramidal signs
GM ₂ -gangliosidosis: activator factor abnormality		Hexosaminidase A deficiency due to activator factor dysfunction	GM ₂	Autosomal recessive	Childhood	Similar presentation to Tay-Sachs disease
GM ₂ -gangliosidosis	Sandhoff's disease	Hexosaminidase A and B	Globoside and GM ₂ ganglioside	Autosomal recessive	Infants	Clinically similar to Tay-Sachs with hepatosplenomegaly
GM ₃ -gangliosidosis	Hematoside sphingolipodystrophy	Not known	GM ₃ (hematoside)	Autosomal recessive	Infants	Respiratory difficulties, seizures, with delayed motor and mental retardation

frequency of the GM₂-gangliosidosis known as Sandhoff's disease. ^[11] None of the gangliosidoses result from other types of genetic transmission.

Clinical Features and Associated Disorders. Generalized gangliosidosis, first reported by Norman and colleagues in 1959, ^[12] affects the brain and organs outside the central nervous system. ^[13] There are clinical similarities between children with these diseases and those with both Hurler's disease and Tay-Sachs disease. In *type I GM₁-gangliosidosis*, affected subjects appear abnormal from birth. Nonpitting edema of the face and extremities produces a dull, heavy-appearing facies with frontal bossing, depressed nasal ridge, low-set ears, and large maxilla. The gums and tongue may be large. Ocular signs include a cherry-red spot in about 50 percent of such patients, but corneal clouding is unusual. Hepatomegaly and splenomegaly occur often. Intellectual and motor development are retarded from birth, and children eat poorly, gain weight slowly, and are generally weak and incoordinated. Joints tend to be enlarged, and the long bones are wide in the center and tapered at the ends; kyphoscoliosis and breaking of vertebrae are usual. Myotactic hyperreflexia, hypertonus, and flexion contractures occur. Seizures usually occur late in the disease, and affected children, blind and in respiratory failure associated with infection, die by the age of 2 years.

Type II GM₁-gangliosidosis (juvenile form) follows a more prolonged course and shows a less precipitous decline in activity. Onset of symptoms occurs between 5 and 15 years of age, and the affected patient may appear normal through the first years of life.

Type III GM₁-gangliosidosis (adult type) is characterized by a slowly progressive course with predominant extrapyramidal signs of dystonia and postural reflex impairment. Rigidity is common, and speech disturbances and increased muscle tone are frequent additional features. Neuronal ganglioside storage occurs in the basal ganglion, ^[14] and, in contrast to the infantile and juvenile forms, no visceral or skeletal changes occur. Magnetic resonance imaging (MRI) demonstrates symmetrical high-intensity lesions in the putamen on T2-weighted images. It has been suggested that the putaminal lesions may be primarily responsible for the dystonia. ^[15] In adult-type GM₁-gangliosidosis there is a structural mutation of the gene for beta-galactosidase that is allelic with the mutations seen in type I GM₁-gangliosidosis.

The symptoms in *type I GM₂-gangliosidosis (infantile form, or Tay-Sachs disease)* are uniform in type and timing of development. The first clinical manifestations occur within 6 months of birth, yet the infant appears normal for the first 3 months. Initially, excessive hyperexcitability and irritability develop, and infants have a heightened startle reflex to noises and tactile stimuli. Hypotonia and a delay in motor and mental development are characteristic. During the first 6 months of life the child's visual acuity is usually deficient and continues to deteriorate to the point of blindness by 1 year of age. The early blindness is thought to be retinal in origin, since the GM₂-ganglioside storage lesion is within the ganglion cells of the macula, and normal pupillary responses persist. The macular cherry-red spot, appearing in all cases within the first 3 months of life, is highly characteristic, although it tends to disappear late in the disease owing to total retinal atrophy. The color of the macula has little pathophysiological significance compared to the milky, whitish halo found around the macular region. This finding is a result of the buildup of opaque gangliosides. Because of this macular lesion, the baby has fixation defects and searching conjugate eye movements. At times, the extreme hyperexcitability and reactivity suggest frank seizure activity. If seizures occur, they are of a myoclonic character that closely resembles infantile spasms (see [Chapter 52](#)). The

progression of symptoms continues through the second and sometimes third year of life, and most children die before the age of 4. Megalocephaly is predominant even in the terminal stages.

A *juvenile variant of type II GM₂-gangliosidosis* follows a much different course. These children first become ill after 5 years of age, and death occurs within 10 years following a course of seizures, progressive dementia, and cerebellar, pyramidal, extrapyramidal, and spinal dysfunction as well as optic atrophy.^[16] Such patients have a partial deficiency of hexosaminidase-A in spleen, liver, and brain in assays performed with the natural substrate for the ganglioside. This form of the disease may present as a progressive pure form of dystonia and dementia that begins before 5 years of age. These cases differ from the classic form of GM₂-gangliosidosis in the regional preferences of the storage process.^[16]

Adult-onset type III GM₂-gangliosidosis has been reported with a number of phenotypic patterns, and the clinical picture may vary within families. Adults between 16 and 28 years of age, who have had very mild symptoms in childhood, develop pronounced motor symptomatology. The adult form may be associated with a partial deficiency of hexosaminidase-A, and in such cases, spinal and cerebral degeneration is usually predominant.^[17] These individuals do not have seizures, fundoscopic abnormalities, or dementia. Other adult patients may show predominant extrapyramidal abnormalities with dystonia and choreoathetosis,^[18] motor neuron,^[19] or pure neuropsychiatric signs.^[20]

Sandhoff's disease results in the storage of GM₂-ganglioside, globoside, and asialo-GM₂-ganglioside in visceral tissues. These storage materials are biochemically distinguishable from those of Tay-Sachs disease. The disease is a result of a deficiency of both hexosaminidase-A and hexosaminidase-B activity.^[21] Patients with Sandhoff's disease have clinical symptoms that are similar to those characteristic of Tay-Sachs disease, with hyperacusis, decreased vision, a cherry-red macular spot, decerebrate rigidity, and megalencephaly. In contrast to Tay-Sachs disease, hepatosplenomegaly is seen, and the tubular epithelial cells of the kidneys are filled with sphingolipids. Cardiomyopathy and mitral insufficiency may be present, and death usually occurs between 2 and 4 years of age.^[21] There are some variants of Sandhoff's disease, including a juvenile form in which patients are normal until 5 years of age, when they develop ataxia, slurred speech, intellectual deterioration, and progressive hyperreflexia and hypertonia. Fundoscopic examination may be normal.

A few cases have been reported of infants with severe neurological and systemic problems that have been traced to excessive accumulation of *GM₃-ganglioside (hematoside)* in tissues^[22] without GM₁ or GM₂. In these cases, there is a decrease in the enzyme *N*-acetylgalactosaminyl transferase, which is important in the synthesis of GM₁ and GM₂ from GM₃. These infants have pronounced respiratory difficulties in the first weeks of life, when generalized

seizures become prominent. Poor motor and mental development is typical, and dysplastic features such as an enlarged tongue, high-arched palate, inguinal hernia, and loose skin are found. The hands and feet are broad, and there is marked hirsutism. Generalized muscle hypotonia, poor responses, and diminished reflexes develop, but the optic fundi are normal, and the liver and spleen are minimally enlarged. Because of dysphagia and difficulty in feeding, death usually occurs within the first few months of life. On autopsy, spongy degeneration in the brain stem and diencephalon is evident, and intracytoplasmic bodies are seen in astrocytes.

Differential Diagnosis. The other group of degenerative disorders that should be considered in the differential diagnosis is the cerebroretinal syndromes. In patients with some variant forms, such as the neuronal ceroid-lipofuscinoses, primary movement disorders and spinocerebellar degeneration must be considered.

Evaluation. The full workup for these disorders includes a detailed clinical evaluation, neuroimaging, electroencephalography, cerebrospinal fluid analysis, and tissue histology. EEG studies show hypsarhythmoid patterns. Neuroimaging demonstrates a deep cortical zone associated with decreased white matter volume and ventricular dilatation. The gray matter may be disproportionately large. In some cases, a small cerebellum and brain stem are seen. Specific diagnosis rests with evaluation of the accumulated stored material or specific enzymatic deficiency assays. Electromicroscopic studies reveal cytosomal lipid bodies in a variety of tissues depending on the type of disease.

Special testing is warranted for populations at particular risk. Since approximately 80 percent of patients with Tay-Sachs disease are of Jewish ancestry, massive population screening studies of white blood cell enzymes to detect the carrier state have been successful. Amniotic fluid removed early in pregnancy and chorionic villi may also be studied to determine whether the Tay-Sachs disorder is present. Several pitfalls should be avoided in diagnosing patients with gangliosidosis. For example, there is often confusion between Sandhoff's disease and Tay-Sachs disease because of similar clinical and biochemical results. DNA testing, coupled with enzyme analysis, provides a good level of sensitivity and specificity. Pseudodeficiency has been reported in a non-Jewish patient; the diagnosis can be confirmed by DNA testing.^[22]

Management, Prognosis, and Future Perspectives. Definitive treatment is not available for patients with most of the gangliosidoses, but some experimental approaches may be effective. Enzyme replacement therapy with multiple laminar lysosomes coated with human IgG has not been effective.^[23] Bone marrow transplantation is being used, but the attendant risks of radiation to the brain and chronic immunosuppressive therapy are worrisome. Palliative therapies are helpful. The prognosis remains dismal. Future research with enzyme replacement, inhibitors, and activators, identification of new enzyme activators, and genetic counseling are all indicated.

Sphingomyelinoses

As a group, the sphingomyelinoses, which are disorders of autosomal recessive inheritance, are marked by prominent organomegaly and delayed motor and mental development. Sphingomyelin is a molecule containing a ceramide, a phosphoric acid ester, and choline.

There are four types of sphingomyelinoses or Niemann-Pick disease (types A, B, C, D, and E), all of which have neurological involvement except types B and E. Approximately 50 percent of affected patients belong in the type A group, characterized by severe neurological symptoms. Although type C disease involves moderate neurological signs, often extrapyramidal in nature, type D has only mild neurological sequelae that appear later in the course. Type B has no neurological signs. All of the sphingomyelinoses are transmitted as autosomal recessive traits ([Table 30-3](#)).

In all cases, generally the first observed clinical abnormality is hepatosplenomegaly. In addition to the systemic organopathy, patients develop progressive neurological deterioration with motor and mental decline. Macular degeneration occurs, and a cherry-red spot appears in about 25 percent of patients with type A disease,^[24] usually in the first year of life. Seizures may develop, and as the disease progresses, children become inexorably obtunded and difficult to feed. Recurrent infection is often a major problem, and death occurs before 2 years of age. In some cases, peripheral nervous system involvement is detected with slow nerve conduction velocities. In type C disease, the childhood or adult form, deterioration occurs more slowly, and the patients usually seem normal until 2 years of age or even young adulthood. They often develop dystonia with selectively swollen cells in the basal ganglia. In such patients, foamy histiocytes can be found in bone marrow and spleen, and hepatic cells show small clusters of histiocytes that resemble sea-blue histiocytes.^[24] In type D disease, neurological difficulties usually begin between the second and fourth years of age, related predominantly to hepato-splenopathy.^[25]

The differential diagnosis rests with the other storage diseases, but in the absence of neuronal ceroid-lipofuscins and ganglioside, hepatosplenomegaly should strongly suggest the sphingolipidoses. Most confusion in diagnosis involves the cerebrosidoses. Definitive diagnosis is based on identifying excessive amounts of sphingomyelin and the foamy cells. Antenatal diagnosis of types A and B disease can be made. Most histological information has been obtained from studies of the infantile or type A form. Very often the central nervous system of these patients is gliotic, small, and atrophic. The gray matter shows necrotic changes with large neurons that are distended and ballooned with apparent storage of sphingomyelin. In some patients, there are extensive abnormalities in the spinal cord, midbrain, and cerebellum. The white matter is rarely affected. Changes in retinal cells similar to those in the brain are seen. Biochemical assay of membranous cytoplasmic bodies reveals large amounts of sphingomyelin and cholesterol.

Cerebrosidoses

Cerebroside is composed of a ceramide and hexose molecule. There are three forms of cerebrosidosis or Gaucher's disease: type I (adult), type II (infantile), and

TABLE 30-3 -- SPHINGOMYELINOSES (NIEMANN-PICK DISEASE) AND CEREBROSIDOSES(GAUCHER'S DISEASE)

Type	Name	Enzyme Defect	Storage Product	Genetics	Age at Onset	Primary Clinical Features
SPHINGOMYELINOSES						
Type A	Classic Niemann-Pick	Sphingomyelinase	Sphingomyelin	Autosomal recessive; prenatal detection available	Infants	Hepatosplenomegaly, Niemann-Pick cells in bone marrow Prominent neurological findings, motor and mental retardation, cherry-red spot in 25 percent
Type B	Non-neurological variant	Sphingomyelinase	Sphingomyelin	Autosomal recessive; prenatal detection available	Chronic progressive	No neurological signs and massive hepatosplenomegaly
Type C	Childhood or adult	Sphingomyelinase	Sphingomyelin	Autosomal recessive	2-4 yr; chronic and progressive or adult onset	Hepatosplenomegaly, Nieman-Pick cells in bone marrow Prominent neurological findings, especially dystonia
Type D	Nova Scotian variant	No defect yet identified	Sphingomyelin	Autosomal recessive	2-4 yr; chronic and progressive	Clinically similar to type C. Most neurological signs may be secondary to hepatosplenopathy
CEREBROSIDOSES						
Type I	Classic Gaucher's, chronic, non-neuropathic form	Glucose cerebrosidase	Glucose cerebroside	Autosomal recessive	Adults	Chronic disease involving viscera and blood-forming tissues, non-neurological
Type II	Infantile or neurological Gaucher's disease	Glucose cerebrosidase	Glucose cerebroside	Autosomal recessive	Infants	Prominent neurological signs with early opisthotonos, severe mental and motor retardation and death by 2 yr
Type III	Juvenile	Glucose cerebrosidase	Glucose cerebroside	Autosomal recessive	Juveniles	Hepatosplenomegaly and moderate neurological signs of motor and mental retardation

type III (juvenile) (see [Table 30-3](#)). Gaucher's disease is the most frequently reported of the lysosomal storage disease, and particularly frequent among Ashkenazi Jews.^[21] It is the result of inherited defects in acid beta-glucosidase metabolism and accumulation of the substrate glucosylceramide in cells of monocytic-macrophage origin.

Type I disease, so-named because it was first described by Gaucher, is the chronic, non-neuropathic form.^[23] This form is usually found in adults and is a predominantly chronic disease involving the viscera and blood-forming tissues. Type II, on the other hand, is an acute neuropathic disease found in infants. It is almost always apparent by 6 months of age but may present as early as the newborn period, frequently with hyperextension or opisthotonic posturing of the head. The posturing is believed to be due to Gaucher's cells in the meninges at the base of the brain. Affected babies have early strabismus or heterotropia, generalized hypertonia, and difficulty in swallowing, a fairly consistent neurological clinical triad. Profound psychomotor retardation develops, and laryngospasm, myoclonus, bulbar impairment, and seizures may be evident. Rapidly progressive central nervous system (CNS) deterioration occurs combined with splenomegaly, and most patients with this form of cerebrosidosis die by the age of 2 years. The course of disease is similar in many respects to the fulminating course of type A sphingomyelinosis. The infantile neuronal form of Gaucher's disease does not have a proclivity toward Jewish ancestry. Type III cerebrosidosis, most often found in juveniles, is heterogeneous, usually associated with hepatosplenomegaly, bone marrow containing Gaucher's cells, and neurological difficulties including hypertoxicity, opisthotonos, and mental decline. These patients may also have myoclonus, and the diagnosis should be considered in children with the progressive myoclonic epilepsies (see [Chapter 52](#)). Although this classification of Gaucher's disease into three entities is accepted, exceptions to it do occur,^[26] such as a rare non-neuropathic form occurring in early infancy and a neuropathic form seen in adults.

In all forms of Gaucher's disease, although the spleen is greatly enlarged, it is not tender. Hypersplenism may occur. Anemia, thrombocytopenia, and leukopenia are frequent findings. Hepatomegaly is usually present, and there is laboratory evidence of hepatic malformation. There may be pulmonary infiltrates. Bony fractures are common, possibly due to infiltration of the medullary space by Gaucher's cells, which weaken the bone.

Full clinical assessment includes a careful neurological examination, a detailed funduscopic examination, routine laboratory assessment including a hemogram, bone marrow, and liver assessment, and a family history. Thereafter, a battery of liposomal enzyme and tissue analyses can be used to identify the specific storage defect.

Gaucher's cells, found in the bone marrow and other reticuloendothelial tissues, are the hallmark of the disease. These monocytic-histiocytic cells are large, with an average weight of 20-60 µg, and have a distinctive cytoplasm that appears wrinkled or pleated. The abnormalities are best recognized by a supravital technique and phase microscopy. Histochemistry shows abundant acid phosphatase activity, and on electron microscopy Gaucher's cells show many membrane-enclosed sacs containing long slender tubules. The cells are rare in the central nervous system but occasionally may be seen along vessels. Pathological changes in neurons are most pronounced in the bulbar nuclei, where numbers of neurons are decreased, secondary neuronal phagia by histiocytes and macroglia occurs, and excessive cellular glycoprotein is present.

Mucopolysaccharidoses

Mucopolysaccharides ([Table 30-4](#)) are constituents of connective tissue composed of alternating units of polymerized hexuronic acids and hexose amines. As a group, mucopolysaccharidoses are characterized by somatic dysplasia, slowly deteriorating mentation and motor control, storage of mucopolysaccharide within cellular lysosomes, and urinary excretion of heparin sulfate, dermatan sulfate, or related compounds. It is generally agreed that the causative defect in the mucopolysaccharidoses (MPS) involves lysosomal hydrolysis. Because of faulty breakdown of glycosaminoglycans, these products are stored within the lysosomes, distending the lysosome and the cell body. Mucopolysaccharides represent the major component of the lysosomal storage material, particularly in fibroblasts. Because the brain is also a prime storage site, mental retardation is a prominent feature of all MPS. There are 13 subclasses of MPS (see [Table 30-4](#)).^[27]

The mucopolysaccharidoses are inherited as autosomal recessive diseases, with the exception of Hunter's syndrome, which is sex-linked. The global frequency of the varieties of MPS has not been clearly established. Population studies in the Netherlands indicated that Sanfilippo's syndrome type A is the most common form, with an estimated frequency of 1:24,000 in that population.^[28] In British Columbia, the incidence of Hunter's syndrome was estimated at 1:78,000,^[29] but in Israel its frequency may be higher. Sanfilippo's syndrome type B is seen particularly often in Greece,^[30] and in the Cayman Islands a high frequency of Sanfilippo's syndrome type A has been found, with an estimated carrier frequency of 1:10.

As a group, these diseases are marked by striking somatic dysplasia, slowly deteriorating neurological and systemic symptoms, storage of mucopolysaccharides in the lysosomes, and excretion of mucopolysaccharides in the urine (see [Table 30-4](#)). Although each type has a specific enzyme deficit, the similar spectrum of clinical manifestations in all MPS disorders makes biochemical differentiation essential. For many reasons, Hurler's disease has become the prototypical MPS. Patients who have this syndrome in early infancy may appear reasonably normal, but by 6 months of age it is obvious that a severe disorder is present. The abnormal facial appearance is one of the first signs noted, and hepatosplenomegaly and umbilical and inguinal hernias are soon detected. Affected infants may have chronic rhinorrhea associated with frequent colds, recurrent airway infections, and otitis media. When children with Hurler's disease attempt to sit, a characteristic kyphoscoliosis is often observed, which progresses with time. Ultimately, a frank gibbus deformity, one of the earliest described clinical features of the disease, develops. Vision is often impaired in Hurler's disease because of corneal clouding.

TABLE 30-4 -- MUCOPOLYSACCHARIDOSES AND MUCOLIPIDOSES

Type	Name	Enzyme Defect	Storage Product	Genetics	Age at Onset	Primary Clinical Features
MUCOPOLYSACCHARIDOSES						
1	Hurler's (MPS I)	Alpha L-iduronidase	Heparin sulfate (HS) and dermatan sulfate (DS)	Autosomal recessive	Birth or by 6 months	Abnormal facial appearance, hepatosplenomegaly, kyphoscoliosis, corneal clouding, mental retardation
2	Hurler-Schie MPS V/I	Alpha-L-iduronidase	Heparin sulfate (HS) and dermatan sulfate (DS)	Autosomal recessive	First year	Severe joint involvement, coarse facial features, hepatosplenomegaly, corneal clouding, but near-normal mentation
3	Scheie's (MPS V)	Alpha-L-iduronidase	Heparin sulfate (HS) and dermatan sulfate (DS)	Autosomal recessive	First year	Normal stature and less severe neurological deficits than in types I and 2
4	Hunter's (MPS II)	Iduronate 2-sulfatase	Heparin sulfate (HS) and dermatan sulfate (DS)	x-linked	First year	Similar to Hurler's but without corneal clouding
5, 6, 7, 8	Sanfilippo's A, B, C, D (MPS III)	A: Heparin sulfatase B: N-acetyl-alpha-D-glucosaminidase C: N-acetyl-CoA-acetyl-alpha-D-glucosaminidase D: N-acetyl-alpha-D-glucosamine-6-sulfatase	A: Heparin sulfate B: Heparin sulfate C: Heparin sulfate D: Heparin sulfate	Autosomal recessive	First year	Hepatosplenomegaly and facial coarseness less than in Hunters and Hurler's. Mental and motor retardation, death by age 10. Among the subgroups, C is the most mild. In all subgroups, patients excrete heparin sulfate
9, 10	Morquio's A, B (MPS IV)	A: Acetyl galactosamine-6-sulfatase B: Beta-galactosidase	Keratan sulfate and chondroitin sulfate Keratin sulfate	Autosomal recessive	First year	Skeletal dysplasia with compressive neurological signs (severe in A, mild in B). No or little mental retardation. Corneal clouding 50 percent and organomegaly less prominent compared to other MPS. Survival to middle age
11	Maroteaux-Lamy(MPS VI)	Aryl sulfatase B	Dermatan sulfate	Autosomal recessive	First year	Growth retardation, coarse features, myelopathy
12	Sly's (MPS VII)	Beta-glucuronidase	Dermatan sulfate and heparin sulfate	Autosomal recessive	First year through childhood	Hepatosplenomegaly, psychomotor retardation, and coarse features
13	Multiple sulfatase (A, B, C)	Not known	Dermatan sulfate and heparin sulfate	Autosomal recessive	First year	Variable signs
MUCOLIPIDOSES						
1	Sialidosis (ML, type1)	Neuraminidase	Oligosaccharide, glycolipids	Autosomal recessive	Adolescence	Cherry-red spot, myoclonic seizures, painful neuropathy, mildly coarse facial features
2	Lipomucosaccharidosis (ML 1, type 2)	Beta-galactosidase and sialidase	Oligosaccharide, glycolipids	Autosomal recessive	Infants	More severe than sialidosis. Facial and somatic dysmorphism, progressive mental retardation
3	I-cell disease (ML II)	Multiple lysosomal enzymes-- major marker is mannose-6-phosphate transferase	Oligosaccharide, glycolipids	Autosomal recessive	Infants	Severe disease. Facial and somatic dysmorphism, progressive severe mental retardation, hepatosplenomegaly. Death often by age 10
4	Pseudo-Hurler's (ML III)	N-acetyl glucosamine-1-phosphotransferase	Oligosaccharide, glycolipids	Autosomal recessive	Childhood	Mild in comparison to I-cell. Corneal clouding. Survival to adulthood
5	Berman's mucopolipidosis (ML IV)	Not yet characterized	Oligosaccharide, glycolipids	Autosomal recessive	Childhood	Most patients of Ashkenazi Jewish extraction

Although the infant with Hurler's disease may develop some sitting and walking skills as well as early language skills, these are soon lost. Severe mental retardation becomes apparent, and patients are usually bedridden before the end of the juvenile period.

Patients with Hurler-Scheie disease (type 2) have severe joint involvement, short stature, small thoraces, hepatosplenomegaly, coarse facial features, and corneal clouding. They may have near-normal mental abilities. The small thorax and cardiac involvement in this disease often reflect mitral valve insufficiency.

Scheie's syndrome usually occurs in individuals of normal size, and their neurological deficits are less severe than those seen in patients with types 1 and 2 disease. These patients have only mild hepatosplenomegaly with marked coarseness of the facial features or severe mental retardation. Dysostosis multiplex or bony involvement is also mild, although a common feature is carpal tunnel symptomatology. It is rare for neurological problems to be severe enough to cause early complaints. Generally, ocular involvement, specifically corneal clouding or retinal abnormalities suggesting degeneration, lead to suspicions of an MPS disorder. In most instances, the diagnosis is not made before the age of 10 years, and frequently it is not recognized until age 20 or later.

Two types of Hunter's syndrome have been suggested, one with predominant mental retardation and one not associated with retardation. Children with Hunter's syndrome may have a facial appearance similar to that characteristic of Hurler's syndrome, but the cornea is not clouded in Hunter's disease. In fact, corneal findings are the most important features distinguishing Hunter's from Hurler's disease. Patients with Hunter's syndrome often have a macular skin rash over the arms, shoulders, and thighs that may change in character. Urinary excretion of heparin and dermatan sulfate is similar in Hunter's and Hurler's diseases.

Sanfilippo's syndrome (MPS III, types 5-8) is subgrouped into four types, each with milder dysostosis multiplex, facial abnormalities, and hepatosplenomegaly than the abnormalities seen in patients with Hunter's and Hurler's syndromes. As the child grows older, the liver and spleen may actually resume normal proportions. Hyperactivity, speech delay, and/or frank mental retardation are often the original presenting conditions. In early life, deterioration is slow, but by the end of the first decade, neurological deterioration becomes more rapid. These children are soon bedridden, and death usually occurs by the mid-teens. Sanfilippo's syndrome is a

classic example of a neurodegenerative disease with a monophasic downhill course.

In 1929 Morquio^[31] described a syndrome characterized by severe skeletal dysplasia; two types, severe (type A) and mild (type B), occur. In both forms, mental symptomatology is absent or only mildly present. Neurological symptoms may result from compression of the spinal cord or medulla. The skeletal changes include joint laxity, shortness of stature, pectus carinatum, shortened vertebrae, genu valgum, pes planus, and enlarged joints. The neck is short, and the odontoid process in the cervical region is often underdeveloped, accounting for the atlantoaxial subluxation seen.^[32] Corneal clouding is present in 50 percent of cases, and hepatomegaly is less prominent than in other forms of mucopolysaccharidosis. Cardiac involvement may include aortic regurgitation. Patients usually survive until middle age.

These disorders are most easily confused with the mucopolysaccharidoses and the GM₁-gangliosidosis because of the associated facial and somatic progressive dysmorphism. Full general and neurological assessments are necessary, and even with a full family history, these recessive diseases may not be fully expressed in an immediate family constellation. Important laboratory evaluations include identification of mucopolysaccharides in the urine and assays for enzyme defects in leukocytes and cultured fibroblasts (see [Table 30-4](#)).

The mucopolysaccharidoses remain an essentially untreatable group of disease. Symptomatic palliative therapies are available, but these are slowly progressive diseases, and life expectancy is limited.

Mucopolysaccharidoses

The mucopolysaccharidoses (MPS) are a group of diseases that may be confused phenotypically with the mucopolysaccharidoses (see [Table 30-4](#)). In these rare diseases both lipids and mucopolysaccharides accumulate in tissues.^[33] Each of the five types of mucopolysaccharidoses is an autosomal recessive disease. There is no specific race or ethnic predilection except for the MPS IV type.

The first patients described with sialidosis (type 1) had myoclonic seizures and a retinal-macular cherry-red spot.^[34] Age of onset varies, but older patients who were normal in early life predominate. Most patients remain clinically normal until adolescence. They then show initial neurological manifestations of myoclonus and visual and gait impairments. Once visual pathology is evident, including night blindness or loss of color vision, the disease becomes progressive.^[34] A cherry-red spot is uniformly present. Lens opacities may occur. Myoclonus is typically generalized, and in some cases it may be stimulus-linked. Intellectual deterioration may be a late occurrence. Painful neuropathy, delayed nerve conduction velocity, generalized convulsive seizures, ataxia, and dysostosis multiplex ensue. Facies may be coarse but to a lesser extent than those seen in the mucopolysaccharidoses.

Lipomucopolysaccharidosis (type 2) has a very different clinical picture. The onset of symptoms always occurs early in life. Babies may be born with hydrops fetalis. The somatic and facial features are invariably coarse. Dysostosis multiplex, periosteal cloaking, and hepatosplenomegaly dominate, and contractures of major bony articulations, inguinal hernias, and mild hepatosplenomegaly are common findings. Angiokeratoma corporis diffusum may be more prominent in these patients than in those with sialidosis. Neurological impairment is slowly progressive and is marked by dementia and other signs such as ataxia, hypotonia, reduced muscle mass, and cherry-red spots. Foam cells and vacuolization of lymphocytes are seen in aspirated bone marrow.

Patients with Hunter's syndrome (type 3) have coarse facial and somatic features and severe mental retardation. Mild forms of dysostosis multiplex are seen, but these are much less severe than those seen in patients with Hurler's disease.

...

Umbilical hernias, hepatosplenomegaly, kyphoscoliosis, and lumbar gibbus are all typical features of Hunter's syndrome. These features are seen earlier than they are in patients with Hurler's disease, but they are not as severe. The thorax is usually small, joint movement is restricted, and the tongue is large, often with gingival hyperplasia. Corneal haziness is common, and cardiac involvement includes cardiomegaly and aortic insufficiency. These children are severely ill and frequently die in the first decade of life from cardiopulmonary failure.

Patients with pseudo-Hurler's syndrome have a later clinical onset, usually in childhood, and some may live into adulthood but are mentally retarded. Linear growth is severely affected, corneal clouding and aortic regurgitation are common, and older patients show joint stiffness. Facial coarseness is minimal. In the MPS IV form, severe corneal clouding and psychomotor retardation are seen. Facial dysmorphism is not characteristic.

The mucopolysaccharidoses are most easily confused with the mucopolysaccharidoses. They are biochemically distinguishable by the lack of the mucopolysacchariduria characteristic of the MPS. There are some clinical and biochemical similarities with the GM₁-gangliosidosis. Detailed and skilled clinical evaluation of systemic as well as neurological factors is essential in addition to assays for lysosomal enzymes and mucopolysaccharides in the urine.

GLYCOGENOSES

Pathogenesis and Pathophysiology. The glycogenoses or glycogen storage diseases are lysosomal disorders in which glycogen accumulates within a number of tissues; hypoglycemia usually accompanies the clinical signs.^[35] These diseases are named for the specific enzyme deficiency that occurs in the glycogen metabolic pathway (Table 30-5), and their ordering follows the enzymatic steps involved in glycogen synthesis and catabolism.^[36]^[37]^[38]^[39]^[40]^[41]^[42]^[43]^[44]^[45]^[46]

Epidemiology and Risk Factors. Current knowledge indicates that all the known genetic glycogenoses are inherited as autosomal recessive traits. This has been shown clearly in patients with Pompe's disease, in which the type 3 and 4 variants are possibly related to different alleles.

TABLE 30-5 -- GLYCOGENOSES*

Type 1 Von Gierke's disease (Cori) (glucose-6-phosphatase)
Type 2 Pompe's disease (Cori) (acid maltase)
Type 3 Smith's disease (late infantile) (acid maltase) ^[37] , ^[38]
Type 4 Engel's disease (adult) (acid maltase) ^[39]
Type 5 Forbes' disease (Cori) (debrancher- or amylo-1,6-glucosidase)
Type 6 Anderson's disease (Cori) (debrancher- or amylo-transglucosidase)
Type 7 McArdle's disease (Cori) (myophosphorylase)
Type 8 Hers' disease (Cori) (hepatophosphorylase)
Type 9 Tarui's disease (Cori) (phosphofructokinase) ^[40]
Type 10 Hug's disease (Cori) (hepatic phosphorylase kinase) ^[41]
Type 11 Satoyoshi's disease (phosphohexose isomerase) ^[42]
Type 12 Thomson's disease (phosphoglucomutase) ^[43]
Type 13 Glycogen synthase deficiency
Type 14 Bresolin's disease (phosphoglycerate kinase) ^[44]
Type 15 Tonin's disease (phosphoglycerate mutase) ^[45]
Type 16 Tsujimo's disease (lactate dehydrogenase) ^[46]

*Enzyme deficit in parenthesis.

The gene for human acid alpha-glucosidase is contained on chromosome 7q21-23.^[47] Two types of mutant alleles were identified in one family in which both adults and infants had acid maltase deficiency.^[48] One type resulted in reduced net production of active alpha-glucosidase with partial enzyme deficiency. An infant type of debrancher enzyme deficiency syndrome appears to be transmitted as an autosomal recessive trait. The heterozygous state, however, could not be diagnosed with certainty. Muscle glycogen concentrations appeared to be normal in another patient. Studies have confirmed that an autosomal recessive mode of inheritance occurred in the brancher enzyme disorder. The presence of enzymatic activity in cultured fibroblasts is lower in affected individuals than in normal controls, and the same is true (although less marked) in their parents, strongly suggesting that the trait is autosomal recessive. Tarui's disease is also transmitted in this way. Prenatal diagnosis and genetic research are indicated in further studies of these entities.

Clinical Features and Associated Disorders. In Von Gierke's disease, hypoglycemia causes many of the clinical difficulties seen in patients during the first year of life. In this period seizures are frequent, and long-standing hemiplegia and mental retardation occur. Failure to thrive, xanthomas, and isolated hepatomegaly are common, and excessive subcutaneous fat over the buttocks, breasts, and cheeks develops. Affected children usually have a protruding abdomen due to enlargement of the liver. Patients often have recurrent stomatitis frequent infections and may have isolated chronic inflammatory bowel disease.

The infant with Pompe's disease usually develops normally during the first weeks or several months of life, but hypotonia and associated weakness then occur. Spontaneous movement declines, the cry becomes weak and struggling, and swallowing is dysfunctional. Respiratory difficulty results from the skeletal muscular weakness and inability to handle pooled nasopharyngeal secretions. Massive cardiomegaly develops, and a soft, systemic murmur is often heard at the left sternal border. Ultimately, hepatomegaly appears, and the tongue may be enlarged and protrude awkwardly. Palpation of the muscles reveals them to be small and firm, and muscle stretch reflexes are suppressed. Progressive debilitation occurs, and patients usually die by 1 to 2 years of age.

In the late infantile form of acid maltase deficiency, symptoms and signs may simulate those of Duchenne's muscular dystrophy. In such patients, the gastrocnemius and deltoid muscles are firm and rubbery on palpation. There is accompanying hypertrophy of the gastrocnemius muscles, and Gowers' sign is often present. Toe walking develops with ankle contractures, and the gait is unsteady and wobbling owing to lumbar lordosis. Cardiomegaly is absent. In adults with acid maltase deficiency, weakness of the muscles develops during the third through sixth decades of life. Weakness is more prominent proximally than distally, and the pelvic girdle is involved more than the shoulders. Intercostal and diaphragmatic muscles are involved in many patients. Adults do not show enlargement of the liver, heart, or tongue. Frequently, symptoms suggesting polymyositis or late-onset muscular dystrophy cause confusion in the initial clinical diagnosis.

Three types of debrancher deficiency syndrome have

been identified: infantile, childhood, and adult. In the infantile type, early symptoms are similar to, but less marked than, those typical of Von Gierke's disease, which is associated with hypoglycemia, failure to thrive, and hepatomegaly. Patients with the infantile type are hypotonic and weak and have poor head control. Juvenile-onset debrancher enzyme deficiency begins between the ages of 2 and 15 with exercise intolerance and associated heart failure. These patients are hypotonic and have a protuberant abdomen. Adult patients develop progressive chronic myopathy in middle age.

Clinical manifestations of the infantile brancher deficiency syndrome are generally seen in the first 6 months of life and are related to failure to thrive, hepatosplenomegaly, and frank liver failure with cirrhosis. Such patients have poor motor and mental development, muscular hypotonia, and weakness. Muscle atrophy appears early and is accompanied by hyporeflexia. More benign forms of this variant present later in life with only mild hepatomegaly and elevated liver enzymes.

Children affected with classic McArdle's disease (myophosphorylase deficiency) initially show decreased stamina and easy fatigability. Although onset usually occurs in childhood, neonatal presentations have been reported. Severe cramping pain, usually in the distal skeletal muscles, develops after exercise and is often associated with renal impairment. In adolescence and adulthood, patients may develop persistent weakness and moderate loss of muscle bulk. Patients with Hers' disease have no specific neurological or muscle findings but display varying degrees of growth retardation, hypoglycemia, ketosis, and hepatomegaly. In Tarui's disease, motor development is normal during the first decade, but decreased muscle exercise tolerance, myoglobinuria, and easy fatigability develop in childhood. An unusual infantile syndrome characterized by limb weakness, seizures, cortical blindness, and corneal opacifications occurs; microscopic studies reveal typical findings of neuron axonal dystrophy.^[49]

Mild cases of hepatophosphokinase deficiency (Hug's disease) have been associated with hepatomegaly, attacks of ketonuria with fasting, and intermittent diarrhea. Involvement of muscle with accompanying weakness is reported.

Those with Satoyoshi's disease experience muscle pain and stiffness with exercise. Exercise tolerance is present in childhood with some muscle pain, but the symptoms become more prominent later in life. Muscle contractures do not occur after ischemic exercise.

Numerous episodes of supraventricular tachycardia occurred in an infant with Thomson's disease. The baby developed normally until he was about 18 months old, when he began to walk on his toes. Examination revealed mild weakness and poor muscle development. Calf muscles were bulky and firm, and the Achilles' tendons

were shortened. There was no clinical history of exercise intolerance, muscle pain, or myoglobinuria. Yet another patient had recurrent vomiting, lethargy, and poor weight gain. Metabolic acidosis was profound. In patients with some other glycogenosis defects, such as phosphoglycerate mutase, phosphoglycerate kinase, and lactate dehydrogenase deficiencies, a link between exercise intolerance and myoglobinuria has been found. In patients with the phosphoglycerate kinase deficiency, the defect is sex-linked, and hemolytic anemia, seizures, mental retardation, and exercise intolerance with myoglobinuria have been prominent features. In adults, phosphoglycerate mutase deficiency has been associated with myalgia, cramps, and myoglobinuria following exercise.^[45] Lactate dehydrogenase deficiency has been reported in one patient who suffered from severe myoglobinuria with exercise. In this syndrome there is a lactate dehydrogenase-M unit, which is coated on chromosome 11.

Differential Diagnosis. Most of the glycogen storage disorders must be differentiated from various myopathies and muscular dystrophies. In the former, abnormalities are seldom limited to the muscle. Liver failure problems and other systemic symptoms are often obvious. Because of the liver problems present in most of these diseases, one must always consider other storage diseases such as the mucopolysaccharidoses, mucopolipidoses, sphingomyelinoses, cerebrosidoses, and gangliosidoses in the differential diagnosis.

Evaluation. These diagnoses can usually be made by performing assays of enzymatic activity in the particular tissue most affected, such as the liver, peripheral white cells, muscle, and even brain. Since severe hypoglycemia is the best screening indicator of this class of disease, postprandial and glucose tolerance tests are particularly useful. A variety of other biochemical tests, such as uric acid, cholesterol, fatty acids, triglycerides, lipid profiles, and liver function tests, should be performed, as well as bone studies in specific instances.

Management, Prognosis, and Future Perspectives. Therapy varies depending on the particular syndrome involved. In Von Gierke's disease, small amounts of free glucose can be given to maintain normal glucose concentrations; dietary carbohydrates are also given, but because excessive glucose leads to glycogen storage in the liver and kidneys, small feedings of carbohydrates are the preferred method of treatment. Dietary substitution of medium-chain for long-chain triglycerides has been used, and diazoxide has been beneficial in some cases. Portal caval shunts have been used to bypass the liver. Preoperative intravenous hyperalimentation appears to eliminate some of the metabolic problems that occur following surgery. Liver transplantation has been performed with apparent beneficial results. No practical treatment is available for Pompe's disease. Epinephrine administration has reduced liver glycogen content to normal but not that in muscle. In patients with the late infantile form, muscle glycogen content has been diminished.^[36]

Special preparations of amyloglucosidase from *Aspergillus foetidus* have reduced striated muscle glycogen content, lengthened the PR interval, and decreased ventricular electrical forces. Intravenous administration of deficient enzyme to mice results in uptake into skeletal muscle.^[50]

In the debrancher syndromes, growth failure and hepatic dysfunction, including hypoglycemia, appear to improve with the administration of oral cornstarch. Treatment with a combination of zinc, glucagon, and alpha-glucosidase reduced liver glycogen concentrations in an infant, although the infant died at 11 months of age from an infection.^[51] Orthoptic liver transplantation has been attempted with varying success.

A fat-rich diet in patients with McArdle's disease has

53

shortened the muscle recovery period from an acute physical load. Maximum strength does not appear to be improved by the fat-rich diet, but tolerance for submaximal loads appears to be increased, and recovery from muscle discomfort is accelerated.^[51] Symptoms can be controlled with frequent small carbohydrate meals in Hers' disease. Despite any of these interventions, the prognosis is guarded for patients with all of the glycogenoses.

LEUKODYSTROPHIES

The leukodystrophies (Table 30-6) are genetic diseases that show morphological changes in the white matter of the central nervous system. Each of the leukodystrophies most likely represents an inborn error of metabolism due to a defective gene that produces an enzymatic abnormality and metabolic derangement that affects myelin. Myelin dysfunction is the basic feature of all these disorders, and demyelination or destruction of normally formed myelin can occur as well as loss of defective myelin, called dysmyelination. Simple demyelination is typical of many sudanophilic leukodystrophies. Dysmyelination is related to an underlying genetic or metabolic disturbance, and in this type of leukodystrophy, abnormal lipids incorporated into the defective myelin sheath tend to be metachromatic when stained. Leukodystrophies may be caused by enzymatic defects that produce aberrations in peroxisome function, which induces demyelination, or to enzymatic defects at specific points in the metabolic pathways of the sphingo- lipids.

Pelizaeus-Merzbacher Syndrome

Pelizaeus-Merzbacher syndrome occurs in a particular type of demyelinating sudanophilic leukodystrophy and has many subtypes. [52] In all, sudanophilia is produced when neutral fat stains such as Sudan black react with the neutral fat breakdown products of myelin. Since this breakdown of myelin is the result of a variety of metabolic or acquired insults, sudanophilia provides no useful information about the pathogenic origin of the insult. Most of the early reports were based on the pathological process rather than on the clinical picture, and the common denominator histologically is the presence in the CNS of patches of dysmyelination interspaced with perivascular islands of relatively intact myelin. This pattern produces a striped or tigroid appearance and is the origin of the term tigroid leukoencephalopathy.

Classic Pelizaeus-Merzbacher disease has a strong tendency to be more prominent in males, suggesting but not proving a sex-linked inheritance. Although no chemical abnormality has been identified, there is a proteolipid apoprotein defect in gene Xq22 on the X chromosome. [53] [54] [55] The hallmark of the syndrome is the pathological finding of patchy losses of groups of oligodendrocytes with little sudanophilic demyelination. Axons and neurons are usually well preserved. In some patients there are no myelin sheaths and little evidence of myelin breakdown, raising the question of whether an absence of myelin rather than a breakdown of myelin actually occurs. [54] Attempts at prenatal diagnosis have been made with DNA analysis of chorionic villi samples, but this technique is not yet well developed. The transitional type of disorder (type 3) occurs sporadically. Lowenberg-Hill disease (type 4) shows autosomal dominant transmission.

Classic Pelizaeus-Merzbacher disease usually begins in the first few months of life, heralded by nystagmus and head tremor. Motor development delay occurs, and eventually ataxia, attention tremor, and choreathetosis develop. Other signs include lower extremity spasticity, dysarthria, optic atrophy, and seizures. Motor and ocular impairments are severe compared with the mild degree of dementia. Deterioration assumes an even slower pace after 5 to 6 years of age. Death is usually delayed until the second decade of life or early adulthood. Although not always present, a very characteristic early clinical finding may be a slow, rotary "cogwheel" nystagmus. As the patient becomes older, the nearly diagnostic ocular motility sign changes to a nonspecific movement disorder of the eyes. Jerk nystagmus is invariable.

Among the variants, in the connatal form the neurological features and the rapidity and extent of progressive nystagmus are more severe, and death usually occurs within months to a few years of life. In transitional or type III disease (Seitelberger's disease), the clinical severity falls somewhere between that of the connatal and classic infantile forms. Invariably there is moderately severe mental retardation, and the average age of death is between 5 and 10 years. Lowenberg-Hill disease, the adult form, has a very slow course. In contrast to all other forms, no ocular features are seen, and episodic psychotic events are characteristic.

Abnormalities of the brain stem auditory-evoked responses and sleep EEG are seen in some patients. [56] Cranial computed tomographic (CT) scans in long-standing cases have demonstrated cerebellar atrophy and focal areas of demyelination. MRI demonstrates persistent myelin islands and a reversal of the normal gray-white matter signal relationships consistent with dysmyelination. In addition, low- intensity signals from the lentiform nucleus in the thalamus suggests iron deposition, [57] similar to that seen in Hallervorden-Spatz disease (Chapter 34).

All the leukoencephalopathies, genetic and nongenetic, should be included in the differential diagnosis. There is no specific curative therapy for Pelizaeus-Merzbacher disease, and diligent supportive care is essential for both patients and families. While the search for treatment continues, specific clinical genetic characterization and research into the biochemical basis for the diseases continue.

Cockayne's Syndrome

Cockayne's syndrome (see Table 30-6) is sometimes classified as a variant of Pelizaeus-Merzbacher disease because of the similar pattern of patchy demyelination among preserved islands of myelin. [52] However, in this disease there is pronounced involvement of multiple systems, suggesting a different pathogenic mechanism. The brain is small, and the white matter is atrophic. Calcifications are frequently

TABLE 30-6 -- LEUKODYSTROPHIES

Type	Name	Enzyme Defect	Storage Material	Genetics	Age of Onset	Special Comments
PELIZAEUS-MERZBACHER SYNDROME						
1	Classic	Not known	Sudanophilic material	Possibly X-linked	Infantile	Proteolipid apoprotein in defect in gene Xq22 on X-chromosome
2	Connatal Seitelberger's disease	Not known	Sudanophilic material	Not known	Birth	More severe than type 1
3	Transitional Lowenberg-Hull disease	Not known	Sudanophilic material	Sporadic	Inf'antile	Death by 5-10 yr
4	Adult	Not known	Sudanophilic material	Autosomal dominant	Adult	No ocular abnormalities
5	Variant	Not known	Sudanophilic material	Not known	Variable	
COCKAYNE'S SYNDROME						
6	Classic	Not known	Sudanophilic material	Autosomal recessive	6-12 months	Dwarfism with CNS and PNS signs
ALEXANDER'S SYNDROME						
7	Classic infantile	Not known	Not known	Not known	Infants	Psychomotor retardation, megalencephaly
8	Juvenile	Not known	Not known	Not known	Children 7-14 yr	Prominent bulbar dysfunction with normal mentation
9	Adult	Not known	Not known	Not known	Young adults	Presentation of multiple sclerosis
CANAVAN'S SYNDROME						
10	Classic infantile	Aspartoacylase deficiency	N-acetylaspartate in plasma	Autosomal recessive	Infants	Hypotonia megalencephaly, blindness
11	Neonatal	Aspartoacylase deficiency	N-acetylaspartate in plasma	Sporadic	Newborns	Hypotonia, poor swallowing, death within first weeks of life

12	Juvenile	Aspartoacylase deficiency	N-acetylaspartate in plasma	Sporadic	Children 5-teenage years	Ataxia, tremor, and mental retardation with loss of vision. Endocrine and cardiac disorders
KRABBE'S SYNDROME						
13	Classic, infantile	Galactose cerebrose beta-galactosidase	Galactose cerebroside	Autosomal recessive	Infants	Irritability followed by hypertonicity, optic atrophy, and signs of neuropathy
14	Late onset	Galactose cerebroside beta-galactosidase	Galactose cerebroside	Autosomal recessive	Usually children, but may be adults	Cortical blindness, optic atrophy, and spasticity
METACHROMATIC LEUKODYSTROPHY						
15	Greenfield, classical or late infantile	Arylsulfatase A	Sulfatide	Autosomal recessive	Late infantile--18-24 months	Ataxia, hypotonia, bulbar signs, intellectual decline, peripheral neuropathy
16	Scholz	Arylsulfatase A	Sulfatide	Autosomal recessive	Juvenile 4-10 yr	Gait instability, tremor, ataxia, spasticity
17	Austin	Arylsulfatase A	Sulfatide	Autosomal recessive	Adult	Mental instability and progressive dementia
ADRENOLEUKODYSTROPHY						
18	Multiple peroxisomal enzyme deficiency Zellweger syndrome	Dihydroxyacetone phosphate acetyltransferase	Excessive very long-chain fatty acids	Autosomal recessive	Neonatal	Dysmorphic features. hypotonia, seizures and feeding difficulties, with hepatosplenomegaly
19	Ulrichs disease Neonatal adrenoleukodystrophy (NALD)	Deficient peroxisomal oxidation	Excessive very long-chain fatty acids	Autosomal recessive	Neonatal	Coarse features, seizures, poor mental development and visual impairment
20	X-linked Siemerling-Creutzfeldt disease	Deficient peroxisomal oxidation	Excessive very long-chain fatty acids	X-linked recessive	Childhood onset is classic	Classic form; progressive psychomotor decline; variant can be adrenomyeloneuropathy with slowly developing spastic paraparesis of adulthood

present in the globus pallidus and cerebellum, along with mineralization of small arteries. The brain may contain a diffuse proliferation of astrocytes of bizarre appearance, predominantly in the cerebral cortex. Occasionally, Alzheimer-type neural fibrillary tangles are seen. The peripheral nervous system is also involved, with segmental demyelination with preservation of the axon cylinders. There are no consistently specific biochemical abnormalities in this disease. It is inherited as an autosomal recessive trait and has been reported in several members of one family.

Patients with this syndrome are often normal at birth, but in the first 6 months of life they develop a photosensitive dermatitis. In the second year, growth retardation, dwarfism, and kyphosis become apparent.^[58] A facial rash and a facial-somatic dysplasia with a beaklike nose are part of the early picture. Microcephaly, mental retardation, retinitis pigmentosa, and optic atrophy soon develop. Following infancy, the progressive neurological syndrome is characterized by cerebellar dysfunction and upper motor neuron signs. Reflexes may be difficult to elicit, suggesting a coexisting central and peripheral nervous system involvement. Other typical features are joint deformities, abnormally advanced bone age, dental caries, and renal disease. Ophthalmic findings include retinal involvement, poor pupillary response, lenticular cataracts, corneal opacities, and impaired lacrimation. Normal pressure hydrocephalus has been implicated as a possible mechanism for some of the neurological deterioration seen in these patients, although this has not been a consistent finding.^[59]

Neuroimaging procedures reveal calcification of the basal ganglia and cerebellum, and neurophysiological testing shows nerve conduction velocity. It is probably easier to confuse this syndrome with a dysplastic cytogenetic disturbance than with the pediatric neurodegenerative disorders or other leukodystrophies because central demyelination is one of the least striking clinical manifestations. Case reports indicate that treatment of the normal pressure hydrocephalus, when it occurs, may be beneficial (see [Chapter 28](#)). No specific curative therapy is available, and only supportive treatment may be offered.

Alexander's Syndrome

This degenerative disorder is of unknown origin but is believed to reflect a general abnormality or dysfunction of astrocytes (see [Table 30-6](#)). As a result, there is a global dysmyelination or demyelination of the CNS. Eosinophilic hyaline bodies, which are particularly numerous beneath the pial arachnoid membranes and around the cerebral blood vessels, are found throughout most of the brain. Located in the cytoplasm of the white matter, astrocytes may form characteristic fibers. Hyaline inclusions occur especially in the optic nerves, optic tracts, optic chiasm, cerebral peduncles, and spinal cord. Abnormal astrocytes are also observed in the basal ganglion, thalamus, and hypothalamus. Although the astrocytes become distended, there is no evidence of abnormal storage material within neurons, and no biochemical defect has been detected. It is also possible that the demyelination is a secondary event. The white matter is soft and retracted and shows a variable loss of myelin, which appears more marked and diffuse in infantile cases. Axon cylinders are preserved.

The most frequent form of Alexander's syndrome is the infantile form, which has an average onset at 6 months of age. However, onset may occur at any time from shortly before birth to as late as 2 years of age. The average duration of disease is 2 to 3 years, but it can vary from a few months to several years. Predominant psychomotor retardation exists initially, and progressive spasticity and seizures in the context of megalencephaly, with or without frank hydrocephalus, develop. When hydrocephalus occurs, it may result from proliferation of the ependymal lining of the aqueduct by the propagation of astrocytes containing excessive amounts of eosinophilic cytoplasmic material. The peripheral nervous system is not involved.

In the juvenile form, which is much less common than the infantile form, onset usually occurs between 7 and 14 years of age, and the duration is approximately 8 years. Bulbar and pseudobulbar dysfunction predominates, with dysphagia, dysarthria, nystagmus, ptosis, full facial palsy, and tongue atrophy.^[60]^[61] Generalized spasticity and weakness may also occur, but unlike the severe mental retardation characteristic of the infantile form, mentation tends to remain intact.^[62] The adult form of Alexander's syndrome resembles multiple sclerosis clinically and is characterized by blurred vision, spasticity, nystagmus, dysarthria, and dysphagia.

CT changes include low attenuation in the deep cerebral white matter, most extensively in the frontal lobes and subependymal regions. There is inconsistent abnormal enhancement of the caudate nuclei, anterior columns of the fornix, optic radiations, and periventricular areas.

Since the types of Alexander's disease are phenotypically distinct, the differential diagnosis varies by age. If one encounters an infant with chronically developing megalencephaly or macrocephaly with mild regression in psychomotor milestones in the absence of any other obvious cause, Alexander's syndrome is a highly probable diagnosis. Juvenile leukoencephalopathy must be considered in children and multiple sclerosis in adults.

No specific therapy is available for Alexander's syndrome. Much supportive care, however, is necessary, including good nutrition and generous use of antibiotics and antiepileptics. Despite these measures, the prognosis for infants and children with this disease at present is poor. Recent advances in positron emission tomography (PET) scanning and single-photon emission computed tomography (SPECT) indicate that there is an abnormal flow of spinal fluid through the blood-brain barrier. This may be an important point in fully understanding these disorders and may aid in developing interventions.

Canavan's Syndrome

Canavan's syndrome (see [Table 30-6](#)) is a spongy degeneration of the CNS with abnormalities found particularly in the white matter. Vacuoles accumulate in a variety of brain cells, particularly astrocytes, and produce the spongy appearance. The vacuoles result from excessive fluid accumulation, apparently from metabolic

dysmyelination.^[62] The precise cause of these abnormalities remains uncertain. Recent suggestions include a metabolic error in the *N*-acetylaspartate signal as a result of an aspartoacylase defect.^[64] There are increased levels of *N*-acetylaspartic acid in the urine and plasma and aspartoacylase deficiencies in cultured skin fibroblasts.^[64] In addition, astrocytes have abnormal mitochondria with reduced levels of adenosine triphosphate. The brain in Canavan's syndrome has an increased water content and decreased lipids. Chemical changes are limited to the white matter, notably myelin, and are nonspecific. Demyelination is extensive, but axonal fibers and the oligodendroglia are not extensively affected.

The infantile form appears to be inherited as an autosomal recessive disorder. This disease occurs predominantly in Jewish individuals of northeastern European heritage and in Saudi Arabians.^[63] The neonatal and juvenile forms appear to be sporadic.

The three types of Canavan's syndrome all are marked by spongiform leukoencephalopathy, but the age of presentation distinguishes them (see [Table 30-6](#)). The infantile form, or classic Canavan's syndrome, begins within a few months of birth, and death generally occurs by 3 to 4 years of age. The infant initially is hypotonic and has poor head and neck control. Megencephalopathy is common, and arrested development is consistent. In the second 6 months, hypotonia is replaced by spasticity^[63] and often by decorticate and decerebrate posturing. Some hyperreflexia is precipitated by auditory, visual, and tactile stimuli. Vision deteriorates as optic atrophy and nystagmus develop. Seizures of various types, including focal and myoclonic seizures, are usual, and choreoathetotic or dystonic movements can occur. Dysautonomia in the form of paroxysmal episodes of sweating, hyperthermia, vomiting, and hypotension are terminal manifestations.

The neonatal form of Canavan's syndrome is deadly within a few weeks and is characterized by lethargy, hypotonia, diminished spontaneous movement, and difficulty in swallowing. The rare juvenile form develops after 5 years of age and extends into adolescence. Ataxia, tremor, ptosis, and mental deterioration are characteristic. The course is characterized by progressive cerebellar symptoms, dysarthria, dementia, spasticity, and loss of vision. Other organ systems are sometimes involved, resulting in diabetes mellitus, hyperaldosteronism, and heart block, but there is no correlation between the severity of the morphological white matter changes and the clinical presentation.^[65] There is still no specific curative therapy for Canavan's disease, and symptomatic support includes nutritional therapy and generous use of antiepileptic drugs and antibiotics. Whereas currently the prognosis is poor, future research efforts utilizing cloistered populations with the disease, such as those found in Saudi Arabia, may lead to new discoveries.

Krabbe's Syndrome

In contrast to other leukodystrophies, Krabbe's syndrome appears to be purely neurological. In these patients, there is a deficiency of the enzyme galactocerebroside-beta-galactosidase, and the gene is believed to be located on chromosome 14.^[66]^[67]^[68] Assays of amniotic fluid allows prenatal diagnosis, and enzymatic assays on white cells or serum may detect the carrier state.

The white matter is decreased in mass and is gliotic, firm, and rubbery to palpation. Neurons in the pons, thalamus, and dentate nuclei show varying degrees of degeneration, but the neuronal processes of the cerebral cortex are reasonably well preserved. Globoid cells, found deep in the white matter around and within vessels, are distinctive and are of two types, called epithelioid cells and globoid bodies. Epithelioid cells are round, mononuclear, and of medium size. Globoid bodies, however, are large, varying from 20 to 50 microns; they are irregular in appearance and often multinucleated. Both cell types are probably equally important and may occupy different ends of the morphological continuum. Cytoplasm stains positively with periodic acid-Schiff (PAS) and only faintly with Sudan black. No metachromasia is present. Acid phosphatase stain is positive with pale, usually clearly defined, nuclei. Electron microscopy reveals electron-dense granules within the cytoplasm of the cells. Fine intracytoplasmic filaments in both electron-dense linear or curved tubular profiles is a distinctive sign in Krabbe's disease. In experimental studies, intracerebral injection of galactocerebroside produces both types of tubules seen in Krabbe's disease.^[66] Involvement of the peripheral nervous system varies, and segmental demyelination has been reported.^[67] Globoid cells are not seen in peripheral nerves, but histiocytes with foamy cytoplasm and tubular inclusions have been demonstrated. Krabbe's disease is distributed worldwide and has no gender, racial, or ethnic proclivities.

There are two primary forms of Krabbe's disease, the early-onset or classic form, and the late-onset form. The early-onset type usually appears clinically between the third and eighth months of life, although biochemical and pathological changes are present in the early gestational period. Initially, the patient is irritable and has intermittent fever for no discernible reason. Episodic limb or trunk rigidity may occur, and a heightened startle response to noise, light, or touch may be apparent. Feeding problems and seizures may occur. Macrocephaly is uncommon, and hepatosplenomegaly is absent. By 6 months of age, the infant develops severe hypertonus with obvious opisthotonos and decorticate-decerebrate rigidity. Reflexes may be hyperactive or hypoactive if advanced peripheral neuropathy is present. Babinski's signs are usually present along with optic atrophy. By 9 months of age, the baby is usually blind and deaf. In light of these characteristic clinical features, there is very little confusion between the diagnosis of classic Krabbe's disease and other infantile-onset degenerative conditions.

The late-onset type of Krabbe's disease is extremely uncommon. These patients first develop difficulties later in infancy, in childhood, or even in adult life.^[69] This form is usually characterized by cortical blindness, optic atrophy, and spasticity. Gait becomes impaired, but the rate of regression is relatively slow.

Periventricular hyperdensities demonstrated on CT scans have been reported, particularly in the terminal phases. MRI scans demonstrate white matter involvement of the cerebrum and cerebellum,^[70] and electrophysiological evidence of peripheral nerve demyelination is prominent.

Attempts to enhance enzyme activity significantly with thetic stimulator compounds have proved of little value.^[71] Enzyme replacement with liposomes containing beta-galactosidase was tested experimentally in globoid cell leukodystrophy in the twitcher mouse, but there was no evidence of a clinical response.^[72] Bone marrow transplantation in the twitcher mouse model promoted increased galactocerebroside activity and appeared to be associated with a gradual disappearance of globoid cells. At present, there are no curative treatments.

Metachromatic Leukodystrophies

The metachromatic leukodystrophies (see [Table 30-6](#)), also known as sulfatide lipidoses, are a group of lysosomal storage disorders recognized by the accumulation of excessive amounts of sulfatide. The term metachromatic, as a description of the diseases, derives from the staining properties of the stored lipid sulfatides, which develop a brown or gold hue with toluidine blue rather than the usual blue of myelin. The enzymatic defect involves arylsulfatase-A or cerebroside sulfatase-A. A heat-stable nonenzymatic protein activator is also necessary for the hydrolysis of the sulfatide. The sulfatide is stored in lysosomes of neuronal white matter as well as in other somatic tissues, giving rise not only to signs of the disease in the central and peripheral nervous systems but also to disease in other organs and tissues such as the kidneys, pancreas, adrenal glands, liver, and gallbladder.^[72]

In the classic form of metachromatic leukodystrophy, sulfatide content in the white matter is four to eight times that found in normal controls.^[73] There are three isoenzymes for arylsulfatase, A, B, and C. Decreased arylsulfatase-A activity is present in the late infantile, juvenile, and adult forms of the syndrome.^[74] In another condition, multiple sulfatase deficiency, which is often considered a mucopolysaccharidosis, activity of both arylsulfatase-A and -B is markedly reduced.

Epidemiology and Risk Factors. All forms of metachromatic leukodystrophy are inherited as autosomal recessive traits. Carriers are identified by white cell or fibroblast arylsulfatase determinations using either natural or artificial substrates. They have levels of arylsulfatase that vary from 25 to 50 percent of normal. Heterozygotes have approximately ten times more enzyme activity than patients. According to these assays, the disorders are apparently universal in geographical distribution and have no gender, racial, or ethnic preferences.

Clinical Features and Associated Findings. The late infantile form of metachromatic leukodystrophy usually begins between the ages of 18 and 24 months of age, although onset may occasionally be delayed until as late as age 4 years.^[73]^[74] These children develop a gait disturbance that may appear as ataxia or weakness.^[75] Hypotonia is very prominent during this time. At times, abnormalities in the macula resembling the cherry-red spot may be present.^[76] Thereafter, a rather rapid decline continues over a period of 6 months or more until steady regression persists and bulbar signs become apparent. The hypotonia becomes much worse as the disease continues, and weakness dominates during these phases. Intellectual deterioration occurs reasonably rapidly over a 6- to 12-month period. By the terminal stage, hypotonia has reverted to hypertonia and frank spasticity. Involuntary movements are obvious. Another characteristic of the classic form that distinguishes it from other forms of metachromatic leukodystrophy is the presence of megalencephaly, although this finding is not as striking as it is in the gangliosidoses or in Alexander's

and Canavan's syndromes.

A peripheral neuropathy may exist even in the early stages of this disease when absence of reflexes or hyporeflexia is evident. This is a result of peripheral segmental demyelination and the deposition of sulfatide within the nerve fibers. As the CNS sulfatide deposits increase with disease progression, one can account for the turn-around in muscle tone. The hypotonia is first accentuated because of suprasegmental shock influences. These in turn are altered when suprasegmental release occurs. This is the switching point of the change from clinical hypotonia to clinical hypertonia and its associated phenomena. Patients with the classic form often die by 8 to 10 years of age. Yet other patients reach a vegetative trough and live well into their teens. By this time, such patients are indistinguishable from those with the later-onset forms of the disease.

Onset in the juvenile form occurs between 4 and 10 years of age. The majority of patients show the first symptoms during their early years at school. The first observed symptoms are usually bradykinesia and poor school performance. In the very early periods, daydreaming, confusion, and emotional lability are frequently reported. Unsteadiness of gait, usually because of pyramidal tract involvement, may be noted. Extrapyramidal dysfunction such as postural abnormalities and tremor may develop. Myotactic reflexes are usually increased even in the early stages. The rate of deterioration is usually slow and is much more variable than that of the late infantile form of the syndrome. Patients often are not bedridden even 5 to 10 years after the initial symptoms appear.

In this form usually early motor findings such as spastic gait and ataxia may be the most prominent symptoms; they are secondary to intellectual impairment. There is little tendency for hypotonia to appear. When it is manifest, a greater degree of peripheral neuropathy is evident, although even then brisk reflexes and extensor toe signs are frequently present. In spite of this, nerve conduction times are decreased. Dementia occurs but is slower to develop than in the late infantile form. Decerebrate posturing and generalized convulsions occur, perhaps more frequently than in the late infantile syndrome. When the late infantile form is subacute, the juvenile form is chronic, and patients usually live for 20 years or longer.

Onset of the adult form occurs at any time after puberty. Initial symptoms consist of the personality and mental changes that signal impending dementia. Such symptoms are often misdiagnosed as schizophrenia or manic depressive illness. There are usually no clinical signs of peripheral neuropathy. Disorders of movement and posture appear later. Frank dementia becomes the central feature, occurring most frequently by the third or fourth decade of life. Often these mental symptoms in the adult are accompanied by progressive corticobulbar, corticospinal, and cerebellar changes. Visual and somatosensory evoked

potentials are delayed. Even in this form, nerve conduction velocities are markedly lowered.

Differential Diagnosis. Many variants of metachromatic leukodystrophy as well as other conditions should be considered in the differential diagnosis. Among these are multiple sulfatase deficiency that is not associated with striking leukodystrophy. Also, several subtypes in which there is no clear demonstration of a deficiency in the enzyme but in which there is a defect in the activator protein should be considered. Additionally, all leukodystrophies should be entered in the differential diagnosis. Consideration of other leukodystrophies depends on their phenotypic expression as well as a variety of peripheral neuropathies without prominent central nervous system symptoms. Since manifestations include seizures, dementia, and motor failure, any disorder showing these abnormalities must be considered.

Evaluation. Spinal fluid protein concentration is usually moderately elevated, with concentrations in the 150 to 300 mg/100 ml range. There are no qualitative abnormalities in the protein profile. Demonstration of a deficiency of arylsulfatase-A activity either in urine or in leukocytes confirms the diagnosis in the majority of cases. Decreased gallbladder function may be detected by a simple cholecystogram or ultrasonography examination and may be a useful adjunct in the workup. The presence of metachromatic granules in the urine is of some help and gross inspection of an office urine sample can be suggestive of the diagnosis. Brain stem, auditory, visual, and somatosensory evoked responses show some abnormalities, but the results are variable. The most consistent finding is the characteristic decreased nerve conduction velocities found in almost all forms of metachromatic leukodystrophy.

Management. Promotion of enzymatic activity in the nervous system in patients with metachromatic leukodystrophy has been attempted by means of intravenous infusion of beef brain arylsulfatase-A. This has not produced any obvious benefits. Bone marrow transplantation in patients with late infantile metachromatic leukodystrophy has reportedly arrested the motor and intellectual deterioration. The effectiveness and safety of this therapy need further evaluation.

Peroxisomal Leukodystrophies: Adrenoleukodystrophy

The peroxisomal leukodystrophies (see [Table 30-6](#)) represent a relatively new concept for neurologists. Peroxisome refers to the subcellular organelles in the cell body that are deranged by being absent, malformed, or dysfunctional. These conditions include neonatal disorders such as Zellweger's disease and adrenoleukodystrophy as well as later-onset adult conditions such as Refsum's disease. The pioneering work of Moser and associates on the peroxisomal entities has established the fact that peroxisomal dysfunction does not invariably produce the clinical or pathological features of leukodystrophy. The peroxisome is ubiquitous in its clinical and pathological expression. In an excellent short review of these disorders, Moser^[77] listed 14 major peroxisomal diseases to illustrate the two types of peroxisomal forms. One of these categories was identified as a disorder of peroxisome assembly or biogenesis; the prototypical representatives of this type were Zellweger's syndrome and Ulrich's disease or neonatal adrenoleukodystrophy. Another category encompasses disorders with a single peroxisomal enzyme defect, the prototype being sex-linked adrenoleukodystrophy (XALD).^[78]

In the X-linked adrenoleukodystrophy, the genetic abnormality has been mapped to the Xq28 region, and there seems to be a close linkage to the color vision genes.^[79] Inclusions found in cells of the adrenal cortex and cerebral white matter are cholesterol esters that have a striking excess of saturated unbranched fatty acids, C:26 and C:25 being the most abundant. The capacity to oxidize the C:25 and C:26 acids is reduced in patients with XALD. The ALD protein is encoded by a newly identified gene, and this, perhaps, functions as a peroxisomal membrane transmitter that is directly involved in the ligase. Very long chain fatty acids in plasma and cultured fibroblasts are elevated in all forms of ALD and in Zellweger's syndrome. The enzyme or enzyme group responsible for neonatal ALD is still unknown, but it is inherited as an autosomally recessive disease.^[78] A paroxysmal lignoceroyl-CoA ligase deficiency has been found in the X-linked adrenoleukodystrophy.

Neonatal adrenoleukodystrophy is characterized clinically by early onset, dysmorphic features, and a very protracted course. Occasionally, the symptoms occur at a somewhat later period than expected.^[78] One patient presented at 23 months with frequent emesis and acute mental deterioration, followed very quickly by refractive seizures. A long history of developmental, mental, and motor delay had previously been observed in this child. There tends to be a staggering course, sometimes with developmental stagnation or regression preceded or followed by improvement in stasis, visual impairment, truncal hypotonia, and limb spasticity. Subdural hematoma and its sequelae have been associated with this syndrome.^[79]

Among the variants of adrenoleukodystrophy, the childhood form is usually the more fulminating disorder. Patients are completely normal until 4 to 10 years of age, when behavioral problems such as failure in school become manifest. This first sign is the result of rapid regression of auditory discrimination, spatial orientation, speech, and writing. Seizures occurred in less than a third of the patients reported by Naidu and Moser.^[79] Typically, there is a rapid clinical deterioration to spastic paraparesis, swallowing difficulties, and visual loss, culminating in a vegetative state within 2 years of the appearance of symptoms.

In the adolescent cerebral ALD syndrome, signs and symptoms of cerebral involvement are manifest, yet the onset of disease usually occurs between the ages of 10 and 21. The adult form usually presents with dementia, psychiatric disturbances, seizures, and spastic paraparesis with onset at some time after the age of 21. Such patients have presentations similar to those of other problems such as multiple sclerosis, schizophrenia, and brain tumor. They show a reasonably rapid regression.

Included in the differential diagnosis are most of the leukoencephalopathies and dystrophies as well as other processes, depending on the phenotypic expression of the disorder. All early-onset disorders in which there is degeneration and dysplastic status should be considered.

Probably the presence of very long chain fatty acids and the other biochemical abnormalities noted previously are the major methods of making the diagnosis. However, all evaluations consistent with the severe dysmorphic and degenerative states of such patients are probably indicated.

The potential for therapy is, of course, limited for this disease and is primarily directed toward supportive care. Treatment for liver dysfunction or the prothrombin deficiency with vitamin K is indicated. Rehabilitative approaches are sometimes helpful. One should consider the probability of complications such as subdural

hematoma and its treatment. Attempts to mediate some of the biochemical abnormalities with lipid therapy or dietary restriction of very long chain fatty acids and phytanic acid have been tried, but they do not normalize plasma levels of the fatty acids, phytanic acid, or red blood cell plasmalogens. The clinical effectiveness of these interventions has yet to be determined. Ursodeoxycholic acid has reduced levels of bile acid intermediates and has the potential to prevent liver damage. ^[79] Peroxisomal proliferators such as clofibrate do not induce formation of catalase-containing peroxisomes or improve clinical status.

The most successful therapies for peroxisomal disorders are the dietary treatment prescribed for Refsum's disease and combined liver and kidney transplants for hyperoxaluria type I. Therapy for X-linked adrenoleukodystrophy is under active investigation at this time. Steroid replacement therapy is effective for adrenal insufficiency but does not alter the rate of progression of neurological disability. Dietary therapy with a 4:1 mixture of glycerol triolate and glycerol trierigate (Lorenzo's oil) has normalized levels of very long chain fatty acids and plasma within 4 weeks. The results in symptomatic patients have been disappointing. ^[77] However, administration of the oil to patients who are neurologically intact may reduce the frequency and severity of subsequent neurological disability. An international study is under way to evaluate this hypothesis. Bone marrow transplantation is of benefit to patients with early neurological involvement. ^[77]

OTHER LIPIDOSES

Fabry's Disease

This X-linked lipidosis is characterized biochemically by the accumulation of two glycosphingolipids, globotriaosylceramide and galabiosylceramide. The enzymatic deficiency is alpha-galactosidase A. The molecular structure of the gene encoding the enzyme was first identified as the full-length cDNA clone and is localized to Xq21.33-q22.^[76] Twenty different mutations have been described for this gene and include deletions or duplications. The majority of the glycosphingolipids are synthesized in the liver or bone marrow and thereafter are transported to cells by lipoproteins. The major substrate burden in Fabry's disease appears to be on cellular membranes that depend on glycosphingolipids for their integrity and function. Organ storage occurs presumably because of permeable membranes that permit accumulation of high levels of circulating lipids.

The clinical symptoms begin in late childhood or adolescence with the development of painful neuropathy, which is most pronounced in the extremities, and corneal and lenticular opacities and characteristic skin lesions, known as angiokeratoma. These dermatological features consist of ectatic blood vessels covered by thin skin and appear as discreet, slightly raised, blue or dark red spots that cluster in the groin, umbilical area, and thighs. The neurological signs are usually vascular in origin and include transient ischemic attacks, ischemic strokes, and cerebral hematomas. Storage of glycolipids in the systemic vascular system leads to progressive cardiac and renal involvements in the subsequent two to three decades, leading to potential metabolic and hypoxic encephalopathy. Pathologically, the CNS shows lipid accumulation in the autonomic nervous system neurons and several other regions including supraoptic, preoptic, and paraventricular nuclei. The nucleus basalis, anterior thalamus, and the hippocampus are also characteristically loaded with glycolipid, and when the cerebral cortex is involved, layers 5 and 6 demonstrate the neuronal lipid storage. In the peripheral nervous system, loss of small myelinated and unmyelinated nerves occurs.^[76]

Because the disease is rare, carrier testing is not routinely performed. In affected pedigrees, however, alpha-galactosidase A analysis identifies affected males and often heterozygous females. Affected males cannot pass the disease to their sons, but all daughters are carriers.

The differential diagnosis includes conditions associated with angiokeratoma, including metabolic disorders such as neuraminidase deficiency, galactosialidosis, fucosidosis, and GM₁ gangliosidosis. Drugs that can cause corneal opacification include chloroquine and amiodarone. The treatment of Fabry's disease focuses primarily on abatement of the painful neuropathy, and carbamazepine and diphenylhydantoin, as well as neurotrophin have been used with success.^[80] Renal transplantation has also been used in patients with severe renal failure, but whether these allografts can serve as sources of new enzyme for the patient has not been demonstrated.

Noninfantile Refsum's Disease

This lipidosis, also known as hereditary ataxia polyneuritic form, is a familial disorder characterized clinically by retinitis pigmentosa, peripheral neuropathy, cerebellar ataxia, and high protein levels in the cerebrospinal fluid without pleocytosis. Cardiac involvement and nerve deafness occur in almost all patients as well. The accumulated material is phytanic acid. This condition is distinct from the peroxisomal disorder of infantile Refsum's disease, in which phytanic acid accumulation is not the primary metabolic defect but a secondary result of peroxisome assembly.

In Refsum's disease, the first clinical symptom is usually night blindness and clumsiness. Neuropathy develops slowly and is associated with sensory loss, atrophy, and distal weakness. Electromyographic findings include slowed conduction velocities. Although neuropathy may contribute to some of the cerebellar findings, there appears to be true cerebellar ataxia in this condition. The age of neurological disability onset is highly variable from childhood to the sixth decade but usually occurs in adolescence and young

adulthood. In association, cardiac involvement is of clinical significance, and tachycardia, systolic murmurs, and conduction disturbances occur. Fatal cardiac arrhythmias may be responsible for several cases of documented sudden deaths in untreated patients with Refsum's disease.

Refsum's disease is caused by high tissue levels of phytanic acid, a fatty acid that ordinarily is hydroxylated and oxidized within peroxisomes.^[82] It is most likely that alpha-hydroxylation is the specific impaired step in the metabolic pathway. As a result of impaired degradation, up to 30 percent of total plasma fatty acids in patients with Refsum's disease is phytanic acid. Genetic studies indicate that Refsum's disease is inherited as an autosomal recessive disorder. It must be differentiated from other neurological syndromes with neuropathy and ataxia, such as Friedreich's ataxia and Charcot-Marie-Tooth and their variants. Elevated plasma phytanic acid levels eliminates these diagnoses. On the other hand, phytanic acid accumulation is not unique to Refsum's disease and other peroxisome assembly disorders (e.g., Zellweger's syndrome, neonatal adrenoleukodystrophy, and infantile Refsum's disease) show abnormally high levels of this acid. Therefore, the diagnosis is based on the match between the clinical and biochemical pictures.

Control of dietary sources of phytanic acid and free phytol is essential to the rehabilitation of patients with Refsum's disease. Because the main dietary origins of these products are dairy products and ruminant meats, these foods are systematically eliminated.^[83] Improvement is slow, and plasmapheresis is used as an adjunct to hasten clinical recovery. Retinal damage and nerve damage do not improve, but the other signs may substantially abate over a very prolonged period.

Abetalipoproteinemia (Bassen-Kornzweig Syndrome)

This autosomal recessive lipid disorder develops clinically in the first decade of life with steatorrhea, distal sensorimotor neuropathy, and retinitis pigmentosa. Ataxia, dysarthria, areflexia, and ophthalmoparesis may also develop.^[84] Serum cholesterol levels are low, betalipoproteins are low or absent, and erythrocytes take on the appearance of acanthocytes. The primary metabolic defect relates to the inability to synthesize betalipoprotein, the major protein of chylomicrons and very low density lipoproteins. Because of the reduced chylomicrons, severe deficiencies of fat-soluble vitamins, namely A, K, and E, occur. Systemic signs can include cardiomyopathy. The differential diagnosis includes disorders that have combined neuropathy and ataxia, and include Friedreich's disease and the hereditary sensorimotor neuropathies. Laboratory analysis and EMG studies suggesting axonal neuropathy are helpful in directing the clinician.^[85] The differential diagnosis also includes those disorders with acanthocytes, namely neuroacanthocytosis, although typically the latter disorder has tics and dystonia rather than profound neuropathy and ataxia. Finally, the differential diagnosis includes all conditions associated with vitamin E deficiency because neurological abnormalities in Bassen-Kornzweig disease resemble vitamin E deficiency in other situations.

There is strong evidence, both clinically and in the laboratory, that the neurological findings relate directly to vitamin E deficiency. Vitamin E supplementation can arrest the progression of both retinal and neurological deficits.^[86] Other dietary treatments are important to overall rehabilitation status and include restricted intake of long-chain fats and substitution with polyunsaturated fats to reduce fatty diarrhea and improve nutrition.

An-alpha-lipoproteinemia (Tangier Disease)

This autosomal recessive disorder is associated with a nonspecific peripheral neuropathy that may be motor, sensory, or mixed in type. The neuropathy presents in childhood or adulthood, but the distinctive clinical feature about affected persons is their dramatically enlarged and orange-tinged tonsils due to local storage of cholesterol esters. Serum cholesterol is low because of the absence of alphasipoprotein.

Reviews and Selected Updates

References

A large number of diseases, at least 70, involve the metabolism of organic and amino acids. Some diseases present as repeated episodes of acute metabolic decompensation, and the central nervous system (CNS) involvement is usually secondary to the accompanying acidosis, hypoglycemia, or hyperammonemia or to the elevated concentration of amino acids. Nevertheless, it is the secondary involvement of the CNS that is important and is the main problem requiring management. Another group of these disorders involves the CNS primarily, with the systemic disease being negligible. Such disorders are difficult to label at the time of initial encounter as either an organic or amino acid disorder because there are no episodes of acid-base disturbance or disturbance of glucose or ammonia metabolism. They can only be diagnosed by specialized biochemical tests. The recent advent of tandem mass spectrometry is changing the practice of neurometabolic diseases since it provides a rapid diagnosis.^{[1], [2]} In many instances the child will become neurologically crippled before the diagnosis is suspected and ascertained. A third group of disorders impact both the CNS and peripheral tissues. Likewise, mitochondrial enzyme defects treated later in the chapter can be classified by age of presentation. Childhood disorders can be classified in [Table 31-1](#) according to their main presenting features and age.^{[1], [2]} The porphyrias are primarily adult-onset disorders.

AMINOACIDOPATHIES AND ORGANIC ACIDOPATHIES

Neonatal Disorders

MAPLE SYRUP URINE DISEASE

Pathogenesis and Pathophysiology. In 1962, Menkes and colleagues observed an unusual odor, like that of maple syrup, in the urine of four infants who died of progressive encephalopathy in the first few weeks of life ([Fig. 31-1](#)).¹³ Maple syrup urine disease (MSUD) is a disorder of branched-chain amino acid (BCAA) metabolism, in which the concentrations of L-leucine, L-isoleucine, and L-valine, as well as their corresponding alpha-ketoacids, are elevated

TABLE 31-2 -- DIFFERENT CLINICAL PRESENTATIONS OF AMINO ACID AND ORGANIC ACID DISORDERS ACCORDING TO AGE AND SYMPTOMS

NEONATAL DISORDERS WITH DEVASTATING METABOLIC DISEASE

Maple syrup urine disease (MSUD) (branched-chain aminoacidemia)
Urea cycle diseases
Nonketotic hyperglycinemia
Propionicacidemia, methylmalonicacidemia and isovalericacidemia
Certain phenotypes of 3-hydroxy-3-methylglutaryl-CoA lyase deficiency
Holocarboxylase synthetase deficiency
Pyruvate dehydrogenase and pyruvate carboxylase deficiencies
Cytochrome-c oxidase deficiency
Carnitine/carnitine-acyl translocase deficiency
Long-chain acyl-CoA dehydrogenase (LCAD) deficiency
Medium-chain acyl-CoA dehydrogenase deficiency (MCAD) with early neonatal death
Multiple acyl-CoA dehydrogenase deficiency
Certain phenotypes of 3-methylglutaconicacidurias

LATER INFANCY DISORDERS WITH RECURRENT METABOLIC DECOMPENSATION

Intermittent, or intermediate MSUD
Late-onset urea cycle diseases
Arginase deficiency
Certain phenotypes of 3-hydroxy-3-methylglutaryl-CoA lyase deficiency
Certain phenotypes of propionicacidemia and methylmalonicacidemia
Ethylmalonicaciduria and malonicaciduria
Certain phenotypes of 3-methylglutaconicacidurias
3-Ketothiolase deficiency

LATER INFANCY AND CHILDHOOD DISORDERS WITH PROMINENT NEUROLOGIC MANIFESTATIONS

Classic and bipterin-dependent hyperphenylalaninemia
Homocystinuria due to cystathionine beta-synthase deficiency
Disorders of folate and vitamin B₁₂ metabolism with homocystinuria
4-Hydroxybutyricaciduria
Glutaricaciduria type 1
Certain phenotypes of 3-methylglutaconicacidurias
Carnitine palmitoyl transferase (CPT) I and II deficiencies
Adenosine triphosphate synthetase deficiency
Certain phenotypes of MCAD and LCAD deficiencies
Biotinidase deficiency

in body fluids. The branched-chain alpha-ketoacid dehydrogenase (BCKAD) is deficient, and the disorder is inherited as an autosomal recessive trait. It is a multienzyme complex that contains three major subunits: E1, a decarboxylase; E2, an acyltransferase; and E3, a lipoamide dehydrogenase (dihydrolipoic dehydrogenase). The activity of BCKAD is regulated either by inhibition of reaction products or substrate analogues by reversible phosphorylation/ dephosphorylation of the E1 subunit or by the regulation of gene expression through such hormones as insulin and corticosteroids, or L-carnitine or by glucose. The chromosome location of the genes of the subunits and of complementary DNAs is established ([Table 31-2](#)). Mutations of the subunits from different ethnic groups have been identified.

The severe CNS symptoms of the disease have been attributed to brain edema, caused by elevated BCAAs, particularly L-leucine. The neuropathological finding in patients who die is generalized spongy CNS degeneration, similar to other disorders such as nonketotic hyperglycinemia.

Epidemiology and Risk Factors. The worldwide frequency based on routine screening data from 26.8 million newborns is about 1 in 185,000.¹⁴ The disease is common in consanguineous communities; for example, among the Mennonites of Pennsylvania the incidence is 1 in 176. It is encountered frequently in the Middle East, particularly in the Arabian peninsula, where its frequency may be as high as 1 in 2,000.

Clinical Features and Associated Disorders. The classical form of MSUD usually presents within the first 2 weeks of life and rarely beyond 1 month of age. The prodromal symptoms include refusal to feed, vomiting, increasing lethargy, and seizures, with eventual coma. Because the cerebral peduncles and the dorsal part of the brain stem are the earliest parts of the CNS involved, the patient develops opisthotonus and primitive reflexes are usually absent. The initial clinical diagnosis is commonly meningitis or sepsis; and because such patients frequently have associated sepsis, the primary diagnosis may be missed for many days. Cerebral edema leads to tone disturbances, alternating between increased tone and hypotonia. Seizure activity is usually clonic or myoclonic with eyes rolling upward. Early optic atrophy is usual and recedes only if the therapeutic intervention is prompt. When the presence of disease is not recognized at this stage, or the neonate is not managed appropriately, the infant becomes blind and has severe spastic quadriplegia (see [Fig. 31-1](#)). Undiagnosed patients usually develop apnea and die. When treated appropriately, the symptoms will gradually disappear. In well-managed patients, mild to moderate hypotonia (particularly axial hypotonia) persists during the first year of life; eventually, mild to moderate cerebellar ataxia will remain as the only neurological sequela.

TABLE 31-2 -- CHROMOSOMAL LOCATIONS OF DISEASES

Disease and Enzyme(s)	Chromosome Location
-----------------------	---------------------

Maple syrup urine disease: branched-chain alpha-keto acid dehydrogenase (E1, E2, and E3 subunits)	E _{1alpha} : 19q13/1-q13/2; E _{1beta} : 6p21-p22; E2: 1p31; and E3: 7q31-q32
Propionicacidemia: propionyl-CoA carboxylase	alpha subunit: 13q32; beta subunit 3q13-3q22
Methylmalonicacidemia: methylmalonyl-CoA mutase, hydroxycobalamin reductases, adenosyl transferase and cobalamin A-F groups	Mutase: 6p12-p21.2 Others are unknown
Urea cycle disorders: carbamoylphosphate synthetase (CPS), ornithine transcarbamylase (OTC), argininosuccinic acid (ASA) synthetase, ASA lyase	CPS: 2p OTC: Xp21.1 ASA synthetase: 9q34 ASA lyase: 7cen-p21
Classic PKU: phenylalanine hydroxylase	12q22-224.1
Biopterin-dependent PKU: GTP cyclohydrolase, 6-pyruvoyl tetrahydropterin synthase (6PTS), dihydrobiopterin reductase (DHPR), and 4alpha-carbinolamine dehydratase (PCD) deficiencies	GTP cyclohydrolase: 14q22.1-q22.2 6PTS: cDNA available DHPR: 4p15.3 PCD: 10q22
Homocystinuria: cystathionine beta-synthase	21q21-q22.1
Glutaricaciduria type 1: glutaryl-CoA dehydrogenase	19p13.2
Biotinidase deficiency: biotinidase	3p25

Figure 31-1 Maple syrup urine disease and homocystinuria. Clockwise, from left upper corner. The facial and generalized erythematous, scaly, weeping rash in acute, untreated maple syrup urine disease (MSUD). Spastic quadriparetic posture and increased fat pads in cheeks of an infant with poorly managed MSUD. CT of the brain showing left occipital infarct in patient with homocystinuria. Gangrenous fingertips in homocystinuria.

The symptoms of MSUD reappear as overwhelming illness and coma in patients with disorders that lead to protein catabolism, especially infections and diarrhea. When these conditions are not managed appropriately, they lead to further neurological deterioration or death. Clinical symptoms and the course of the disease are milder in infants who are diagnosed through neonatal screening and treated before the initial metabolic crisis. In contrast, a patient with late-diagnosed MSUD experiences frequent recurrent episodes, requires prolonged hospital care, and poses significant management problems without ever improving.

The odor of infants is that of burnt sugar, or maple syrup. It is easily recognized in the urine, hair, axillae, and perineum or in cerumen; it is best appreciated on the frozen urine, because the smell is caused by compounds with oily characteristics accumulating on the frozen surface.

When the levels of BCCA are not monitored frequently during dietary management, abnormal ratios of leucine/ isoleucine or of valine ensue. This situation manifests as severe dermatitis, described as scalded skin syndrome (see [Fig. 31-1](#)). The dermatitis will resolve when the ratios of amino acids are normalized.

A number of MSUD variants have been described.^[1]

Differential Diagnosis. Clinically, the most important differential diagnoses are other causes of neonatal coma, and many can be differentiated by clinical ([Table 31-3](#)) or by simple laboratory observations ([Table 31-4](#)). In the neonate, MSUD is almost always confused with sepsis or meningitis; and the disease is usually associated with either one. The diagnosis of MSUD is suspected only after the sepsis or meningitis workup reveals normal results. Precious therapeutic time will be lost, causing severe neurological crippling or death. MSUD must always be ruled out in any neonate with lethargy progressing to coma; with alternating tone changes; in the absence of changes in blood pH, glucose, and ammonia; and regardless of the presence of an infection. In variant forms of the disease, the diagnosis is usually reached when either blood amino acids or urine organic acids are studied in a child with periodic coma or in a child with pyramidal or cerebellar signs.

Evaluation. Test findings should be grouped into two age categories: one for neonatal and one for episodes after 6 months of age. In the neonatal period, the disease almost never causes significant hypoglycemia, nor acidosis, ketonuria, or hyperammonemia. Therefore, the presence of coma in a neonate who has nearly normal clinical biochemical findings should immediately suggest MSUD. Definite diagnosis is through determination of amino acids in plasma or in urine, which shows significant elevations of L-leucine, isoleucine, and valine. Leucine concentration in blood is always higher than that of the other BCAAs. BCAAs or BCKAD can be measured either by chromatographic techniques or more rapidly by tandem mass spectrometric determinations. A quick spot test of the BCKA in the urine is a strongly positive yellow flocculation when 2,3- dinitrophenylhydrazine is added. After 6 months of life, when recurrent acute metabolic decompensation occurs, it is accompanied by mild to moderate hypoglycemia, severe acidosis, and ketonuria.

TABLE 31-3 -- DIFFERENTIAL DIAGNOSES OF COMA IN NEONATE: CLINICAL FINDINGS

Disease	Tone	Seizures	Dysmorphia	Liver Disease	Infectious Complications
Maple syrup urine disease (MSUD)	Alternating tone	Myoclonic or clonic	Absent	Absent	Almost always present
MSUD (recurrent crisis)	Not specific	May be present	Absent	Absent	May be present
Urea cycle disorders	Severe hypertonia	Usually myoclonic	Absent	Absent	May be present
Various organic acidemias	Hypotonia (propionic), hypertonia (methylmalonicacidemia and isovalericacidemia)	Myoclonic or clonic	Facial and CNS dysmorphia present in propionicacidemia and pyruvate dehydrogenase deficiency	Present in cytochrome-c oxidase deficiency or oxidative phosphorylation diseases	Almost always present
Fatty acid oxidation disorders	Myopathy or cardiomyopathy	As caused by hypoglycemia	Only type 2 glutaric aciduria	Only type 2 glutaric aciduria	Usually absent
Nonketotic hyperglycinemia	Severe hypotonia, stridor, hiccups	Severe, usually myoclonic	CNS dysgenesis such as absent corpus callosum	Absent	Usually absent
Zellweger's syndrome	Severe hypotonia	Severe, usually myoclonic	Facial, CNS dysgenesis, cysts in organs	Severe liver involvement	Usually absent
Nesidioblastosis	None	As caused by hypoglycemia	None	None	None

The electroencephalogram (EEG) of the newborn with MSUD has a characteristic sharp wave pattern described as comblike rhythm.^[9] After proper management, the EEG may be normal between attacks or there may be a generalized slowing of the background and paroxysmal discharges, indicative of the ongoing metabolic disease. In older patients, leucine loading may lead to EEG abnormalities. Even in well-controlled patients, seizure disorder may appear later during childhood, requiring anticonvulsive treatment.

Neuroimaging is a valuable tool, particularly when amino acid determination is not immediately available. In the neonate, it causes a characteristic appearance of white matter attenuation suggestive of brain edema that appears as early as 9 days of life despite dietary treatment. The MSUD edema initially involves the deep cerebellar matter, the dorsal part of the brain stem, the cerebral peduncles, and the dorsal limb of the internal capsule. Eventually, marked generalized diffuse edema appears in the central white matter and is particularly prominent in the frontal areas. The edema subsides after several months of treatment, with mild to severe atrophy of the brain remaining, as evidenced by enlarged ventricles and prominent sulci. The severity of these findings depends on the stage of the disease at which the treatment is initiated. In well-managed patients the neuroradiological sequelae may be increased cerebellar foliation, cerebellar white matter disease, or cerebellar atrophy supporting the clinical presence of ataxia; this last finding may be the only neurological sequela in such children.

Management. Treatment consists of emergency reduction of increased BCAAs in blood. In patients diagnosed early, peritoneal dialysis or hemodialysis should be attempted. A secure central line must be placed, because intensive parenteral nutrition and antibiotics are used for several weeks to prevent catabolism and prompt anabolism. Specific amino acid solutions without BCAA for parenteral nutrition, in MSUD and other disorders of BCAAs, are available from PharmThera (Memphis, TN).^[7] Insulin drip, using diluted insulin solutions, must be initiated to ensure anabolism. Blood levels of BCAAs must be measured initially once or twice daily to monitor the reduction of the level of BCAAs; this is best done by tandem mass spectrometry. A simple clinical guideline to therapy is to follow weight gain in a nonedematous neonate. The treatment usually leads to daily weight increments for about 10 days, at which time the blood leucine level is reduced below 1000 μM. Oral intake of special mild formulas with restricted BCAAs must then be resumed, and parenteral nutrition must be discontinued gradually. A neonate with MSUD is usually difficult to feed, and either a nasogastric tube or temporary button gastrostomy may be used for this purpose.

Once the acute metabolic decompensation is controlled, the patient is placed on BCAA-restricted formulas such as Ketonex or other MSUD formulas. Chronic management is difficult because it requires provision of BCAAs in amounts that permit growth but that do not cause significant BCAA elevations. This requires frequent amino acid analysis and can be achieved only in tertiary care centers where easy access to high-performance liquid chromatography or tandem mass spectrometry is available. Patients should receive thiamine supplementation and L-carnitine; and, when metabolic decompensation occurs, leucine should be restricted.

Prognosis, Prevention, and Prenatal Diagnosis. Prognosis depends on early detection and treatment. Patients whose disease is diagnosed before the initial metabolic attack will grow as nearly normal children, despite recurrent attacks in later infancy. Successfully managed

TABLE 31-4 -- DIFFERENTIAL DIAGNOSES OF COMA IN NEONATE: LABORATORY FINDINGS

Disease	Blood pH	Blood Glucose	Blood Ammonia	Blood Lactic Acid	Urine Ketones	Special Findings
Maple syrup urine disease (MSUD)	Normal	Normal	Normal	Normal	Trace or absent	Elevated branched-chain amino acids and branched-chain ketoacids in urine
MSUD (recurrent crisis)	Acidosis	Moderate/severe hypoglycemia	Normal	Normal	Moderate/severe ketonuria	As in neonatal period
Urea cycle disorders	Alkalotic or normal	Normal	Rapid elevation	High in argininosuccinicaciduria and citrullinemia	Absent	Citrulline values differentiate various types; high oroticaciduria in certain types
Various organic acidemias	Overt/compensated acidosis w/large-base excess	May be mild/moderately low	Usually elevated	Usually elevated	Trace/strong (+) in various disorders	Urine organic acids, blood acylcarnitines
Fatty acid oxidation disorders	Usually normal	Usually moderately/severely low	Variable, but usually normal	May be elevated	Absent	Urine organic acids, blood and urine acylcarnitines
Nonketotic hyperglycinemia	Normal	Normal	Normal	Normal	Normal	Elevated glycerine in blood and cerebrospinal fluid
Zellweger's syndrome	Normal	Normal	Normal	Normal	Normal	Elevated liver enzymes and very long chain fatty acids in blood; pipercolic acid in urine
Nesidioblastosis	Normal	Low with inappropriately elevated insulin levels	Normal	Normal	Normal	Blood glucose and insulin determined at the same time

patients will have a near-normal IQ and normal school performance.^[9] A neonatal screening should be mandatory in countries where the disease is prevalent. The safety window of classic MSUD is only a few days; therefore, newborns should be screened for this disease at 24 to 48 hours of life. This can be achieved either by a Guthrie test or, more easily, by tandem mass spectrometry. The BCKAD activity can be measured in cultured amniotic cells.^[10] If the mutation is known, this can be achieved by molecular genetic studies.

UREA CYCLE DISORDERS

Pathogenesis and Pathophysiology. Recognized only during the past 40 years, the urea cycle disorders (UCDs) include argininosuccinicaciduria (ASA uria; ASA lyase deficiency),^[11] citrullinemia (ASA synthetase deficiency),^[12] ornithine transcarbamoylase (OTC) deficiencies,^[13] and carbamoylphosphate synthetase (CPS) deficiency (Fig. 31-2).^[14] Ammonia is detoxified through five synthetic enzymes and one enzyme that synthesizes an activator for the initial step. The initial three enzymes are in the mitochondria, and the latter three are in the cytosol. This cyclic process both generates and hydrolyzes L-arginine, which is an essential amino acid in infants and important for normal development of brain. When only one of the activities on this pathway is deficient, hyperammonemia and CNS symptomatology ensue. This usually occurs during the first few days to weeks of life and is one of the major causes of devastating metabolic disease of the newborn.

The UCDs cause hyperammonemia, and the clinical picture is similar in all forms of neonatal UCD. The gene locations of urea cycle enzymes are shown in Table 31-2, and complementary DNA is available for most of them.

When any of the aforementioned enzymes is deficient, ammonia cannot be converted into urea, leading to hyperammonemia within the first week of life. Unlike hepatic coma, in which ammonia is only one of the many putative toxins, in neonatal UCD, ammonia is the only cause of encephalopathy. Blood ammonia

concentrations exceeding 300 μM are highly neurotoxic, particularly when prolonged. Primate models with induced hyperammonemia closely mimic the clinical, neurophysiological, and neuropathological findings observed in human neonatal UCD. In late-onset forms of ASA synthetase and lyase deficiencies, levels of citrulline, ASA, and ASA anhydride are elevated between crises when the patient is asymptomatic. This suggests that the acute neonatal symptoms of these disease are due to hyperammonemia and not to elevated levels of urea cycle amino acids. Support for this theory is the family reported by Issa and associates^[15] in which one neonate with citrullinemia died with hyperammonemia while her twin brother remained asymptomatic with elevated levels of citrulline. This point is of paramount importance for the management and prognosis of UCDs.

The swelling of astrocytes in UCDs is due to hyperammonemia and might be caused by the concomitant elevation of glutamine. When glutamine synthetase is inhibited, cerebral edema caused by hyperammonemia can be prevented. In OTC deficiency, the hyperammonemia encephalopathy

Figure 31-2 Algorithm for approach to neonatal-onset hyperammonemia. Abbreviations: NKHG, nonketotic hyperglycinemia; THAN, transient hyperammonemia of the newborn; CPS, carbamyl phosphate synthetase; OTC, ornithine transcarbamylase; AL, argininosuccinate lyase; AS, argininosuccinate synthetase; NAG, N-acetylglutamate synthetase; ASA, arginosuccinic acid. (Reproduced with permission from Lippincott-Raven Publishers, from Batshaw ML: *Errors of Urea Synthesis*. Ann Neurol 1994;35:133-141.)

is shown to be related to brain glutamine accumulations, as demonstrated by magnetic spectroscopic studies.

Epidemiology and Risk Factors. Fortunately, the UCDs are rare disorders. All, except OTC deficiency, are inherited as autosomal recessive traits. The OTC gene is on chromosome X, and its severe form is encountered only in males. The heterozygote female is discussed among UCDs of late onset. The cumulative frequency of all types of neonatal UCDs in Japan is 1 in 46,000 births; and the frequency for OTC deficiency in Japan was reported to be 1 in 80,000. In the Massachusetts screening program, the incidence of ASA lyase deficiency was 1 in 70,000,^[16] and in a Quebec screening program it was 1 in 77,000.^[17] Approximately 65 cases of ASA lyase deficiency have been reported. The incidence of ASA synthetase deficiency (citrullinemia) in the Quebec program was 1 in 250,000 births.^[17] In the Middle East, the most common forms of neonatal UCD are ASA lyase and synthetase deficiencies and they might occur in 1 in 2000 to 3000 births.

Clinical Features and Associated Disorders. All forms of neonatal UCDs manifest nearly identical clinical symptoms. The infant is usually the product of normal pregnancy and delivery, with normal Apgar scores, and remains normal usually for 24 to 72 hours. Shortly thereafter, however, the infant becomes lethargic and refuses to feed; this quickly progresses to coma and is associated with hypothermia, hyperventilation, and respiratory alkalosis. Because cerebral edema appears early in the acute event, the bulging fontanelle erroneously leads to a diagnosis of meningitis with sepsis or pneumonia. If a coma workup is neglected, the neonate will die within a few days with a missed diagnosis. Brittle hair showing trichorrhexis nodosa in ASA lyase deficiency is encountered later during infancy and is not a prominent feature if the infant is given adequate amounts of L-arginine. Patients with ASA lyase deficiency might also have moderate to severe hepatomegaly. Phenotypical variability is the function of different mutations. Metabolic consequences also depend on the availability of compounds that might serve as an ammonia sink; for example, OTC deficiency is less severe than CPS deficiency and ASA synthesis that proceeds normally from citrulline might serve as a store for waste nitrogen.

Differential Diagnosis. The diagnosis is quickly reached by the uniform clinical presentation of the neonatal UCD. Differential diagnosis for neonatally important organic acidemias is by measurement of blood pH, lactic acid, ketone bodies, and glucose (see [Table 31-4](#)). The hyperammonemia observed in organic acidemias is associated with overt or compensated metabolic acidosis, whereas in UCDs the blood pH is usually normal or alkalotic. Blood glycine and urine ketones are elevated in the major ketotic organic acidemias of the neonate, which is not the case in UCDs. It is important to differentiate various types of UCD from CPS and OTC deficiencies. This differential diagnosis is essentially reached by measurements of specific amino acids in plasma and of orotic acid in the urine. The N-acetylglutamate (NAG) synthetase deficiency may be proven clinically by normalization of ammonia after administration of 250 to 500 mg/kg/day NAG in a suspect case. It is now possible to diagnose citrullinemia and ASA uria rapidly within a few hours in a suspected case by tandem mass spectrometry. The simultaneous measurement of acylcarnitines with amino acids particularly eliminates any confusion arising from other diseases with co-existent lactic acidemia.

Evaluation. Any neonate with coma and devastating metabolic disease should receive a battery of clinical biochemical tests, including a determination of ammonia in addition to blood gases, pH, blood glucose, urea, and lactate (see [Table 31-4](#)). These data provide a provisional diagnosis of a UCD within hours, and a definite diagnosis can be made by the measurement of specific amino acids and orotic aciduria.

Management. Prompt intervention before the emergence of significant hyperammonemia is beneficial. The treatment consists of two phases: (1) rescue of the neonate from hyperammonemic coma and (2) maintenance of normal physical and intellectual growth between metabolic crisis with recurrent hyperammonemia. The essential medications for both phases of treatment in UCD are phenylacetate or phenylbutyrate and L-arginine. These medications bind and remove ammonia through alternate pathways as hippurate (1 M ammonia per mole of benzoate) and phenylacetylglutamine (2 M of ammonia per mole of phenylacetate or phenylbutyrate). In ASA synthetase and lyase deficiencies, L-arginine is used because it is converted into citrulline and ASA, respectively, and thus provides an ammonia sink. To avoid cerebral edema, recurrent episodes of hyperammonemia should be treated vigorously at the earliest clinical sign of decline, such as lethargy, irritability, vomiting, or behavior change, or before the plasma ammonia level increases to three times its normal limit.^[18]

Treatment between episodes of metabolic decompensation provides enough protein to ensure adequate growth but avoids hyperammonemia and elevated plasma glutamine levels. In CPS and OTC deficiencies, during the first 6 months of life, a diet that contains a 0.7-g/kg/day mixture of essential amino acids (using UCD formulas available from Mead Johnson, Princeton NJ, or Milupa, Hillington, Middlesex, UK) together with normal milk protein 0.7 to 2 g/kg/day is given and the plasma amino acids levels are monitored. More recently, orthoptic liver transplantation has been recommended for the definitive treatment of UCD; the rewarding results of this treatment in seven patients with UCD have been reviewed.^[19]

Mortality relates directly or indirectly to the consequences of acute brain edema. Even if this complication is prevented, acute hyperammonemia either initially or intermittently can lead to intracerebral and subdural hemorrhage. No infant with a UCD should be given valproate because it may cause liver failure and death.^[20]

Prognosis and Prevention. Neurological outcome and morbidity depend on early diagnosis and appropriate treatment. Long-term studies suggest that use of phenylbutyrate with diet therapy offers the best chance of survival. Hyperammonemia of acute decompensation in ASA lyase and synthetase deficiencies is easily controlled by intravenous or oral administration of L-arginine; with subsequent use of diet and phenylbutyrate, the survival rate is 90 percent.

The neurological outcome in CPS and OTC deficiencies, even when treated appropriately, is only fair, with an average IQ score of 53 ± 6 .^[21] Spastic gait is the eventual neurological sequela. The relatively poor prognosis in these two diseases is due to the unusual severity of hyperammonemia,

its early onset, and its difficult management with frequent recurrent hyperammonemic episodes. On the other hand, both argininosuccinic aciduria and citrullinemia have a better neurological prognosis if they are identified before the initial acute metabolic decompensation and treated appropriately.

No large-scale study for the neonatal screening of UCD has been reported. The short safety window requires screening procedures that provide rapid results. The method should also have low false-negative results and be able to identify the milder forms of the disease. The newly described tandem mass spectrometry procedure using dried blood spots has been able to identify both citrullinemia and argininosuccinic aciduria before the emergence of hyperammonemia and thus is useful for such mass screening of these two disorders. When the tandem mass spectrometry-based orotic acid screen becomes possible, OTC deficiency should also be screenable. At present there is no possibility of screening for the CPS deficiency. All subsequent newborns in a family with a previous newborn with UCD should be treated as such, until proven otherwise.

PROPIONICACIDEMIA

Of the disorders that present as devastating neonatal metabolic disease listed in [Table 31-1](#), propionic acidemia and methylmalonic acidemia are encountered more frequently than the others.

Pathogenesis and Pathophysiology. Propionicacidemia was first described by Nyhan and associates in an infant with episodic ketoacidosis, elevated plasma glycine (ketotic hyperglycinemia), and protein intolerance.^[22] The disease is caused by the deficiency of propionyl-CoA carboxylase (PCC) and the inheritance is autosomal recessive. Propionyl-CoA is generated through the breakdown of L- isoleucine, valine, threonine, methionine, cholesterol, and odd chain-numbered fatty acids. The enzyme is a polymer composed of nonidentical subunits (alpha and beta), with the native enzyme being a hexamer. Its cofactor is biotin, which is bound to an epsilon-amino group of lysine in the alpha subunit. The chromosomal locations of subunits are known, and complementary DNA is available (see [Table 31-2](#)). The deficiency of either subunit causes propionicacidemia.

Deficiency of PCC results in the accumulation of propionyl-CoA, which passes into circulation as propionylcarnitine or propionylglycine. Alternate pathways generate methylcitric acid, 3-hydroxypropionic acid, and tiglic acid. The toxic effects in CNS, bone marrow, and other tissues may be due to the accumulation of excess propionyl-CoA, depletion of the intramitochondrial free CoA pool, or toxic effects of compounds formed secondarily. Hyperglycinemia may be nonspecific and be due to inhibition of glycine cleaving enzyme. Hyperammonemia might be due to the inhibition of CPS I by the accumulating propionyl-CoA. Hypoglycemia might be due to the inhibition of pyruvate carboxylase or malate shuttle by elevated intramitochondrial propionyl-CoA. Despite the association of severe ketoacidosis during metabolic crisis the mechanism of excess ketone body generation is not clear.

Epidemiology and Risk Factors. The disease may be rare in the United States and Canada, affecting 1 in 250,000 to 500,000 births. However, in the Middle East, particularly in Saudi Arabia, it may be as high as 1 in 1,000 births.

Clinical Features and Associated Disorders. The disease manifests from newborn to late infancy with acute decompensation as seen in other organic acidurias. A prodrome of vomiting and refusal to feed progresses to lethargy and coma within days. The infant becomes quickly dehydrated and may experience clonic, myoclonic, or grand mal seizures. Physical examination reveals severe central hypotonia, both during and in between crises. The oral mucosa, angles of the mouth, and perineal area usually show evidence of candidiasis. Facial appearance is usually typical, with depressed nasal bridge and long philtrum; there may be associated abnormalities of the nipple.^[23] Vomiting may be so severe that the infant might be operated on for pyloric stenosis or intestinal obstruction. Approximately 30 percent of the infants might present with immune deficiency, seizure disorder, or acute extrapyramidal signs such as choreoathetosis and dystonia.^[23]

Differential Diagnosis. Two organic acidemias, methylmalonicacidemia and isovalericacidemia, in the neonate cause severe ketoacidosis, but both show increased muscle tone, whereas the tone in propionicacidemia is severely decreased. Patients with isovalericacidemia in crisis usually have a "sweaty feet" smell known to be associated with the disease. Propionicacidemia associated with immune deficiency might be confused with other disorders with immune deficiency.^[23] The urine and blood in infants with multiple carboxylase deficiency will show other intermediates, such as methylcrotonylglycine or isovaleryl carnitine.

All neonates with organic acidemia, all infants with symptoms suggestive of immune deficiency in association with thrombocytopenia or ketosis, and all infants with idiopathic seizure disorder or acute extrapyramidal tract signs should be tested for propionicacidemia, particularly where its prevalence is high.

Evaluation. In early neonatal form, hyperammonemia is severe, usually exceeding 1 mM; in repeated episodes it is usually moderate, rarely exceeding 300 μM; there is severe acidosis with accumulation of massive amounts of ketone bodies. Lactic acidosis is mild, rarely exceeding 6 mM. Hypoglycemia is usually moderate, rarely decreasing below 2 mM. Propionicacidemia has serious deleterious effects on bone marrow cells; neutropenia and thrombocytopenia are common. The platelet count usually drops several days after the onset of coma, while ketonuria is waning.^[23] If it is not appreciated, the patient will have bleeding, particularly intracranially. Propionicacidemia causes severe depletion of T lymphocytes, and the patient will experience frequent infections and sepsis due to unusual gram-negative organisms or *Candida*.

The diagnosis is made by detecting 3-hydroxypropionic acid, propionylglycine, and methylcitrate in the urine by gas chromatography/mass spectrometry or by estimating elevated glycine and propionylcarnitine and decreased free carnitine levels in blood through tandem mass spectrometry. Propionylcarnitine will be elevated both in propionic- acidemia and methylmalonicacidemia; if desired, PCC activity can be measured in leukocytes and cultured fibroblasts. Biochemical findings of propionicacidemia are also

seen in multiple carboxylase deficiency owing to holocarboxylase synthetase or biotinidase deficiencies.

Management. Treatment of initial or acute crisis is by administration of high amounts of glucose and bicarbonate, together with insulin drip, intravenous L-carnitine (50 to 75/mg/kg every 6 hours), and optimum antibiotic coverage to treat sepsis, if present. When amino acid mixtures with restricted BCAAs are available, they can be added to the total parenteral nutrition. Vomiting during or between crises is controlled by intravenous or oral administration of ondansetron. Platelet count should be monitored daily during acute episodes; and when it decreases below 50,000/ mm³, platelet transfusions should be given. It is advisable to place a gastrostomy with fundoplication during the first few years to manage chronic anorexia and vomiting. Once the patient's condition has stabilized, oral feeding with special propionicacidemia formula restricted in isoleucine and valine should be resumed, together with oral carnitine, 100 to 200 mg/kg/day, and Polycitra solution, 2 to 4 ml/kg/ day. The patient should never be permitted to fast because excessive odd chain-numbered fatty acids stored in the adipose tissue of propionicacidemia patients will mobilize and prompt a crisis. Metronidazole at a dose of 7.5 mg/ kg/day should be used to decrease intestinal sources of propionate. Human growth hormone has been used as an adjunctive treatment. Sepsis, intracranial bleeding, and pancreatitis are dreaded complications.

Prognosis and Prevention. The prognosis in propionicacidemia is usually poor, with 50 percent of the patients dying and at least 25 percent showing mental retardation. Chronic hypotonia causes delayed acquisition of motor milestones. A routine neonatal screening test is not uniformly available. Preliminary results of a tandem mass spectrometry-based procedure indicated its value in detecting the disease within 24 to 48 hours, before the initial crisis.

METHYLMALONICACIDEMIA

Pathogenesis and Pathophysiology. Methylmalonic- acidemia was first described by Oberholzer and co-workers in 1967 in infants critically sick with profound ketoacidosis and accumulation of methylmalonic acid in blood and urine.^[24] The disease is a family of disorders caused by defective activity of methylmalonyl-CoA mutase (mutase [0] or mutase [-] complementation groups) or by defective intramitochondrial processing of vitamin B₁₂ (cblA and cblB complementation groups). Other disorders of vitamin B₁₂ will cause methylmalonicaciduria but are not associated with periodic acidotic crisis of methylmalonicacidemia. They are associated with homocystinuria and are presented in the section on neurological diseases associated with homocystinuria.^[25]

Genetic heterogeneity of the disease is evidenced by some phenotypes being responsive to large doses of vitamin B₁₂ whereas no response is observed in others. The defects in the mutase are either (0) with no, or (-) with little, residual activity. The cofactor of the enzyme is 5-deoxy- adenosylcobalamin, and complementation groups cblA and cblB represent its defective synthesis. The toxic effects of intracellular accumulating methylmalonyl-CoA are similar to those of propionyl-CoA. All variants of methylmalonic- acidemia are determined by autosomal recessive genes. The chromosome location of the mutase is known, and its complementary DNA is available (see [Table 31-2](#)).

Epidemiology and Risk Factors. The incidence of methylmalonicacidemia in the Massachusetts screening program was 1 in 48,000.^[16] The disorder is more common in the Middle East, probably occurring in 1 in 1,000 or 2,000 births.

Clinical Features and Associated Disorders. The usual presentation in the neonate is as a typical organic acidemia with overwhelming illness, similar to the presentation of propionicacidemia or isovalericacidemia. These episodes recur either as a consequence of excessive protein intake or from increased protein catabolism through vomiting or infections. The acidosis is usually so severe that the patient will be admitted in shock and might die. Mucocutaneous candidiasis is common, disappearing with appropriate management. The patient usually has increased muscle tone. Seizures, when present, are clonic or myoclonic. As in propionicacidemia, patients with methylmalonicacidemia are prone to a variety of infections and sepsis by unusual organisms. Facial dysmorphism includes high forehead, epicanthal folds, and a triangular mouth. Between episodes the patient will appear normal, with only mild or no developmental delay.

Patients who are poorly managed, particularly those with vitamin B₁₂ -unresponsive variants, might suffer infarcts (metabolic stroke) in the globus pallidus or internal capsule and may develop hemiplegia and acute dystonia. Failure to thrive and failure of linear growth are common. As in propionicacidemia, anorexia and chronic vomiting are usual. The patient may develop acute pancreatitis.^[26] Poorly managed children with methylmalonicacidemia will develop nephropathy due to

tubulointerstitial nephritis or less often to urate nephropathy.

Differential Diagnosis. Most considerations listed for propionicacidemia are also true for methylmalonicacidemia; both propionicacidemia and isovalericacidemia present with massive ketonuria during crisis, the differential diagnosis of which is given in the previous section on propionicacidemia. The same criteria that are listed under propionicacidemia should be used to evaluate any child for possible methylmalonicacidemia.

Evaluation. The acute episode is characterized by severe acidosis with massive ketone body accumulation. Initial episode in a newborn is always accompanied by significant hyperammonemia, whereas blood ammonia values are only mildly elevated in repeated episodes. Hypoglycemia is usually moderate and rarely below 3 mM. There may be mild elevation of plasma glycine levels. During acute episodes, neutropenia and thrombocytopenia are common. Poorly controlled patients show hyperuricemia. A definite diagnosis of the disease is made by detecting massive methylmalonicaciduria; a neonate may excrete up to 1 g/day (normal adult, <5 mg/day). Plasma concentrations of methylmalonic acid in crisis may be as high as 0.2 to 2.5 mM (normally not detectable). Levels of propionylcarnitine in blood are elevated both during and between crises. Other organic acids in urine are those seen in propionicacidemia. Mutase activity may be measured in a variety of ways in specialized laboratories. The cblA and cblB mutants are

identified by complementation studies. Clinical follow-up is by determination of blood levels of methylmalonic acid.

Management. The treatment of acute metabolic crisis is similar to those measures described for propionicacidemia. Exceptions for methylmalonicacidemia are the use of overhydration with adequate calories and no requirement for insulin drips. A patient with methylmalonicacidemia in crisis should be given excessive amounts of intravenous fluids, to clear the circulation from methylmalonic acid. Acidosis in methylmalonicacidemia is usually more severe than in propionicacidemia, requiring very large amounts of bicarbonate, which might quickly lead to hypernatremia. In such instances, tromethamine (Tham) 40 ml/kg/day in six divided doses may be used for 2 to 3 days. The intravenous use of carnitine shortens the crisis significantly.

All patients with methylmalonicacidemia are restricted in their intake of isoleucine, valine, threonine, and methionine, using the same diet for patients with propionicacidemia. Every patient with methylmalonicacidemia should be tested for response to vitamin B₁₂ by administering daily 1 mg hydroxocobalamin intramuscularly. Patients with cblA, methylmalonicacidemia with mutase (-), and half of the patients with cblB or mutase (0) will respond to vitamin B₁₂. The outcome in the responsive patient is favorable, requiring less stringent control of protein intake. Protein requirement of vitamin B₁₂-unresponsive patients must be individualized, providing a minimal amount of the restricted amino acids that will permit growth but that will not lead to frequent decompensation. Generous amounts of calories are supplied through lipids and carbohydrates. Management of unresponsive methylmalonicacidemia is not easy, requiring enormous effort from physician, dietitian, and parents. Other therapeutic measures include metronidazole, 7.5 mg/kg/d; oral carnitine, 100 to 200 mg/kg/day; Shohl's solution, 2 to 4 ml/kg/day; and intramuscular hydroxocobalamin, 1 mg every other day. Patients with methylmalonicacidemia tend to be short and obese; human growth hormone has been used to increase growth and lean body mass and to decrease adipose tissue.

There is no treatment for renal disease due to interstitial nephritis. Allopurinol may be used in patients with high uricacidemia. Patients with methylmalonicacidemia who have basal ganglia infarcts might have cblC or cblD mutations, and homocystinuria should always be investigated in any patient with methylmalonicacidemia. No therapeutic measures, other than standard supportive therapy, are available for pancreatitis.

Prognosis. The addition of L-carnitine and metronidazole to the management of this disorder has changed the prognosis. Van der Meer and colleagues^[27] have pointed out that although most patients before 1985 died, those after 1985, when these drugs were introduced, survived with improved general health. The lifestyle of a well-managed patient with methylmalonicacidemia will be normal, without mental retardation, developmental or motor delay.

Disorders of Later Infancy with Recurrent Metabolic Crises

LATE-ONSET UREA CYCLE DISORDERS

Pathogenesis and Pathophysiology. Late-onset disease has been described in patients with CPS, OTC, ASA synthetase, AS lyase, and arginase deficiencies. They will appear from the first year of life to adulthood with abrupt episodes of acute hyperammonemia. Initial crisis will occur usually when the infant is weaned from breast milk or from low-protein formulas to cow's milk formulas. Decompensation can also occur when the patient ingests a high protein load or experiences increased catabolism (e.g., infection). These episodes readily abate with cessation of protein intake.

Epidemiology and Risk Factors. Patients with a late-onset UCD are rare. The heterozygote female for OTC deficiency is at risk of developing symptoms; and when a male infant with OTC deficiency is born, the mother has to be instructed for possible late-onset disease. Terheggen and associates, in 1969,^[28] described argininemia in two sisters with spastic paraplegia (arginase deficiency). Arginase deficiency is rare. The mechanism for the toxicity of excess arginine is not known. Whether this is due to impaired neurotransmitter metabolism or to excess nitric oxide production from elevated arginine is not clear. Two forms of arginase are known: A-I and A-II. The A-I isozyme contributes 98 percent of the liver activity and is deficient in patients with argininemia. It is inherited as autosomal recessive.

Clinical Features and Associated Disorders. The symptoms are remarkably similar among various types of late-onset UCD. Sudden hyperammonemia leads to such neurological signs as seizures and apnea. It may be preceded by vomiting and lethargy progressing to disorientation, ataxia, amblyopia, and eventually coma. The late-onset CPS deficiency is rare. On the other hand, OTC deficiency may be mild in a male and may first manifest as early as 6 weeks or as late as 6 years. Since infections trigger hyperammonemia, late-onset OTC deficiency may be confused with Reye's syndrome. In symptomatic heterozygotes or mild OTC deficiency, growth and mental retardation are seen in half of patients. The use of valproate in OTC carriers may also cause liver toxicity. Late-onset OTC deficiency causes high mortality.

ASA synthetase deficiency was first reported in a 9-month-old girl with mental retardation. In Japan, a variant form of this disease is found to occur as late as 48 years of age. The symptoms in such cases are nonspecific and include bizarre behavior, psychotic episodes, delusions, hallucinations, insomnia, and endocrine disturbances, such as delayed menarche. ASA lyase deficiency may also occur late in infancy or adults. These cases present as mental retardation or ataxia, or the patient might be totally asymptomatic. This heterogeneity might be explained by the studies of McInnes and colleagues, which indicated at least 12 allelic mutations leading to extensive genetic heterogeneity.^[29] Immunoblot analysis shows a wide variation in size and amount of enzyme protein in patients. The presentation of arginase deficiency is heterogeneous. Early development is usually unremarkable, but developmental delay and psychomotor retardation will definitely appear by 3 years. Progressive spastic diplegia is by far the most common motor deficit, seen by 5 years.^[30] Seizures are present in half of the patients and are often generalized tonic-clonic. These symptoms improve or regress on dietary restriction of arginine.

Differential Diagnosis. The clinical presentations of all

of late-onset UCDs are alike, because only the laboratory findings will identify exact diseases. Oroticaciduria is a common feature except for partial CPS I deficiency. By definition, the mother of a patient with OTC deficiency is a carrier; the presence of the mutant gene in other females related to the mother must be ruled out by allopurinol testing, provided that other diseases that give a positive result are absent.^[31] Although it is the most common presenting symptom of arginase deficiency, spastic diplegia has many other causes (e.g., periventricular hemorrhage in a premature infant or hypoxic brain injury). In these conditions, spasticity is either static or progresses slowly. When spastic diplegia is progressive, familial spastic paraplegia, worsening of an existing hydrocephalus, spinal cord cysts, or tumors should be ruled out.

Hyperammonemia is encountered in other disorders. Reye's syndrome can be differentiated by the elevated transaminase and high plasma lysine levels. Patients with liver failure usually have elevated plasma methionine and tyrosine levels, which are not observed in UCDs of various types. Patients with valproate toxicity have elevated valproylcarnitine levels and deficiency of free carnitine in studies with tandem mass spectrometry.

Any infant or child who develops sudden lethargy or coma after a high-protein meal, infection, and prodrome of vomiting should be immediately evaluated for changes in blood gases, ammonia, lactic acid, and ketones. Arginase deficiency should be ruled out in all children with spastic diplegia. The definite diagnosis of a UCD, or an

organic acidemia, will be reached by using high-pressure liquid chromatography, gas chromatography/mass spectrometry, and tandem mass spectrometry techniques in blood and urine samples. Any infant or child with psychomotor retardation or seizures with no clear cause, or with progressive encephalopathy, should be studied by measurement of plasma amino acids and in some cases by the study of urinary organic acids.

Evaluation. The laboratory findings are the same as those described for neonatal onset UCD, except the hyperammonemia and elevation of specific amino acid and orotic acid levels are only prominent during the acute metabolic crisis. Both ASA synthetase and ASA lyase deficiencies are readily diagnosed by the plasma amino acid profile during the acute episode. Plasma arginine is elevated 2 to 10 times normal in arginase deficiency, and arginase in red blood cells is deficient. Hyperammonemia is not a constant feature of arginase deficiency but is found during a catabolic event (e.g., an infection or consumption of high protein diet). A urine sample may show oroticaciduria and increased excretion of arginine.

Management. The treatment is approximately the same as that for UCD in the neonatal period: protein restriction, sodium phenylbutyrate, and L-arginine in doses previously described. Such patients should receive low protein diets. No specific treatment exists for arginase deficiency. Reduction of protein intake might lead to improvement of the continued disease progression and at times dramatic resolution of the symptoms. Cognitive dysfunction appears to be amenable to diet therapy, and improvement of spasticity has been observed in 30 percent of patients with arginase deficiency. Late-onset UCDs show the same complications as described for the acute neonatal form.

Prognosis and Prevention. Prognosis depends on rapid identification and adequate management. A survey of 12 patients with late-onset ASA lyase deficiency indicated no eventual impairment in intellectual and psychomotor development. Arginase deficiency may be managed with success and arrest of the disease. All subsequent newborns of a family with UCD should be investigated for the disease. The maternally related female members of the extended family with OTC deficiency must be investigated for the presence of the mutated gene either by molecular genetic studies or by allopurinol loading.

Progressive Diseases of Infancy and Childhood

A large number of amino and organic acid disorders appear primarily with neurological symptoms. Only four disorders, phenylketonuria (classic form and bipterin-dependent variant) homocystinuria, type 1 glutaricaciduria, and biotinidase deficiency are presented here.

DEFICIENCY OF PHENYLALANINE HYDROXYLASE

Pathogenesis and Pathophysiology. Although phenylalanine hydroxylase (PAH) is a liver enzyme, the clinical manifestations of classic phenylketonuria (PKU) relate to the CNS. There are no abnormal metabolites formed in classic PKU but only excessive amounts of normal compounds. Therefore, it is logical to assume that elevated levels of blood phenylalanine are responsible for the toxicity. Both animal models and magnetic spectroscopic studies in human brain indicate that phenylalanine levels exceeding 1.3 mM affect the brain metabolism adversely and account for acute phenylalanine toxicity. The threshold for chronic toxicity may be much lower. Acute and chronic adverse effects of high blood phenylalanine on brain can be prevented by high doses of BCAAs. Because both phenylalanine and BCAA share the same transport system, it is conceivable that mutual competition of neutral amino acids at the L-transport system may account for some of these toxic effects. Some patients diagnosed to have mild hyperphenylalaninemia in the past might have had carbinolamine dehydratase deficiency. Fair features and hypopigmentation are caused by the inhibition of tyrosinase by hyperphenylalaninemia. Location of the PHA gene is given in [Table 31-2](#), and its complementary DNA is available.

Epidemiology and Risk Factors. The disease occurs at varying frequency. The highest frequency is in Turkey with 1 in 2,600 births; it is lower among Japanese at 1 in 140,000. Ashkenazic Jews and Finns each have an incidence of 1 in 200,000 births.

Clinical Features and Associated Disorders. PKU usually manifests after 1 year of age as mental retardation. The late emergence of physical findings is the rationale for screening tests in all newborns. The safety window is approximately 6 weeks; and by 1 year of age, the untreated child might lose 50 percent on IQ measurements. The infant is usually born prematurely and has a fair complexion and eczematoid lesions. Myoclonic seizures might occur as

early as 4 months of age, and developmental delay appears between 6 and 18 months of age. Some patients develop normally until 1 year but then lose the milestones. Despite severe CNS involvement, no pyramidal or extrapyramidal signs are usually detected.

Children with untreated or poorly managed PKU usually end up in institutions. A review of 51 never-treated patients followed for more than 20 years indicated 25 percent had seizures disorders, half were profoundly retarded, and about half were moderately impaired.^[32] Approximately two thirds of untreated patients develop microcephaly. Autistic behavior may also emerge. Aggressive, hyperactive behavior is common in poorly managed patients, which becomes less noticeable on lowering the blood phenylalanine level. In well-controlled patients, ingestion of food with high phenylalanine content, at any time during life, will cause confusion and a clear-cut fall in school performance.

Differential Diagnosis. In neonates with severe liver disease, levels of most plasma amino acids, notably tyrosine and methionine, are elevated; and at times that of phenylalanine may also be moderately high. Occasionally, isolated elevation of the blood phenylalanine level (up to 250 μ M) will occur transiently in a normal neonate. In such infants, a repeat study at 4 to 6 weeks usually indicates normal phenylalanine, and the infant will not develop any signs of PKU later in life. The reasons for this transient hyperphenylalaninemia remain obscure.

Other common causes of childhood mental retardation include hyperprolinemia, homocystinuria, and fragile X- syndrome. Clinically, hyperprolinemia cannot be distinguished from mild PKU except by the amino acid analysis. Patients with a missed diagnosis of homocystinuria will have its classic phenotype, which is not observed in classic PKU. Patients with fragile X-syndrome are mostly males with typical facial features of the disease, severe autism, or mental retardation; molecular genetic studies identify the disease.

Many developing countries do not have a neonatal PKU screening program. Therefore, any infant with seizures, developmental delay, or fair features in a community with dark complexion, and any child with mental retardation, hyperactivity, and aggressive behavior should be evaluated for classic PKU.

Evaluation. The blood phenylalanine level is elevated ($>120 \mu$ M), usually more than 1 mM, and the blood phenylalanine/tyrosine ratio is higher than 2, as determined by high-protein liquid chromatography or tandem mass spectrometry techniques. The green color produced by acidic ferric chloride in the urine of PKU patients is caused by the presence of phenylpyruvic acid. This compound is labile, disappearing from urine stored cold or frozen in 1 to 2 days. This test must be done on freshly collected urine. Computed tomography (CT) or magnetic resonance imaging (MRI) reveals demyelination or dysmyelination in central white matter, disappearing on treatment and reappearing if treatment is discontinued.

Prognosis and Prevention. Well-controlled studies indicate that prognosis is extremely rewarding if treatment is started in the first month of life. The North American Collaborative Study of patients to 12 years of age indicates that the longest treated patients who had phenylalanine values less than 900 μ M had the best IQ and psychological test scores.^[33] Numerous studies indicated deterioration of IQ, deviant electroencephalographic findings, and emergence of demyelination on MRI if the treatment is discontinued at or about school age. It is prudent to continue the treatment as long as possible, well into adolescence. Parents should be warned that a well-treated patient will function normally in daily life but may show significant deficits in conceptual, visuospatial, and language-related tasks, in reading and arithmetic skills, in attention span, and in problem-solving abilities.

Classic PKU was one of the first inborn errors of metabolism for which neonatal screening was applied.^[34] Hyperphenylalaninemia and disturbed ratio of phenylalanine/tyrosine in a neonate with classic PKU may be apparent as early as 24 hours but definitely by 3 to 7 days of life. Given the 6-week safety window, neonatal screening for PKU may be done during the first month. Any positive screening result should be rechecked within 1 month. The conventional procedure for PKU screening is the Guthrie test. The problem of false-positive results and the anxiety created in the family recalled for repeat testing led to the exploration of other techniques. More recently, tandem mass spectrometry-based screening procedures have been described that have less problems with false-negative and false-positive results, because, in addition to phenylalanine estimation, they provide an accurate phenylalanine/tyrosine ratio.^{[1], [2]}

The principle of treatment is to restrict dietary intake of phenylalanine. There are numerous formulas for this purpose that have been in use since the mid-1950s. Treatment should be monitored by monthly or bimonthly measurement of plasma amino acids, to ensure that phenylalanine and other essential amino acids are not

lower than normal. Given the beneficial effects of BCAAs in preventing the adverse CNS manifestations of hyperphenylalaninemia, they may be used to supplement the diet. Patients with PKU should avoid consuming food or drinks that contain aspartame, an artificial sweetener (L-aspartylphenylalanine), because intestinal hydrolysis liberates phenylalanine.

Successful management of many females with PKU has resulted in normal lifestyle, marriages, and child bearing. Infants born to mothers with PKU, however, have numerous congenital defects, such as microcephaly, impaired somatic growth, and heart disease.^[35] Because similar defects are not seen among offspring of fathers with PKU, it is apparent that high blood phenylalanine levels in the mother are the cause. Although no threshold is agreed on, fetal outcome is satisfactory if the maternal blood phenylalanine levels are maintained at less than 600 µM throughout the pregnancy.

BIOPTERIN-DEPENDENT HYPERPHENYLALANINEMIA

Pathogenesis and Pathophysiology. Defective synthesis of biopterin (BH₄) causes disruption in several biochemical functions. Deficiencies of the first two steps, that is, guanosine triphosphate cyclohydrolase (GTP-CH) and 6-pyruvoyltetra-hydropterin synthase (6PTS), are known as synthetic defects. The hydroxylase reacts with BH₄, converting it to its hydroxy form 4alpha-carbinolamine, which is then dehydrated by primapterin carbinolamine dehydratase

(PCD) to quinoid dihydrobiopterin, which is labile and must be reduced back to BH₄ through a reaction that uses reduced nicotinamide adenine dinucleotide (NADH) and is catalyzed by dihydropteridine reductase (DHPR). The deficiencies of the latter two enzymes are known as recycling defects. Because primapterin is excreted in PCD deficiency, the disease is also called primapterinuria. BH₄ is a cofactor for enzymes of the initial step in dopamine and serotonin synthesis; when it is not available, neurotransmitter and autonomic function, both in the CNS and periphery, are disturbed. In addition, BH₄ is a cofactor for the generation of nitric oxide in CNS, which is a neurotransmitter/modulator. Deficiency of BH₄ causes severe autonomic irregularities and mental retardation and, ultimately, is not compatible with life. Severe cardiopulmonary dysrhythmia, fluctuating blood pressure, sleep irregularities, and early unexpected death may be explained by these considerations. Because 4alpha-carbinolamine can be spontaneously dehydrated, PCD deficiency does not cause a severe disease. In BH₄-dependent PKU, neurological manifestations are severe in the presence of mild hyperphenylalaninemia, suggesting that trace BH₄ levels are sufficient to promote the phenylalanine hydroxylase reaction in liver but not high enough for adequate hydroxylation of tyrosine and tryptophan in the CNS. All four diseases are inherited as autosomal recessive. The location of their genes is shown in [Table 31-2](#).

Epidemiology and Risk Factors. Hyperphenylalaninemia due to BH₄ deficiency is rare and accounts for 2 percent of all PKU cases. An international database in 1995 for abnormal BH₄ metabolism indicated the following^[36]: 12 patients with GTP-CH deficiency, 182 with 6PTS deficiency, 87 with DHPR deficiency, and 12 with PCD deficiency. The overall frequency is estimated to be 1 in 10⁶ births. In some parts of the world these defects occur more frequently (e.g., 10 percent in Italy, 15 percent in Turkey, 19 percent in Taiwan, and 68 percent in Saudi Arabia).

Clinical Features and Associated Disorders. The signs seen in this disorder are remarkably similar except for PCD deficiency.^[37] The classic presentation is an infant, usually of low birth weight, who develops normally for 2 to 3 months. Then myoclonic seizures appear approximately at 3 months, probably due to serotonin depletion. Bradykinesia is apparent particularly when the infant is naked. The infant lies expressionless. Initially, there may be hypotonia, but soon after "lead pipe" or "cogwheel" rigidity appears ([Fig. 31-3](#)). These are parkinsonian features caused by deficient dopamine. In fact, extensor posturing of the extremities, opisthotonic arching of the back, and pronation of hands are common. Oculogyric crisis, involuntary dystonic movements, and tremors may be observed. Feeding is difficult owing to difficulties in swallowing, and the patient drools because of inability to manage secretions. Early failure to thrive and fair features of PKU are observed. Development arrests at 2 to 3 months, unless the disorder is treated. The patient suffers from severe bronchopneumonia from respiratory irregularities and is often admitted to an intensive care unit for cardiorespiratory difficulties, usually dying before 5 years of age. Those children who survive remain profoundly

Figure 31-3 Glutaricaciduria, biotinidase deficiency and biopterin-dependent phenylketonuria. Clockwise from left upper corner. Infant with glutaricaciduria type I (GAT I) showing dystonic posture and rigidity in flexion. MRI of the brain showing open operculum sign and frontotemporal atrophy in infant with GAT I. Alopecia in a biotinidase-deficient 9-month-old infant with frequent myoclonic seizures from age 3 months. Infant with biopterin-dependent phenylketonuria due to 6-pyruvoyl tetrahydropterin synthase (6-PTS) deficiency showing dystonic grimacing and fisting of hands and hypotonic pithed frog posture of legs.

retarded. Episodes of hyperthermia without infection, fluctuating high blood pressure, and reversed diurnal rhythm of sleep have been described. Deficiency of DHPR, in general, shows a more severe progression of the disease, whereas GTP-CH deficiency might be milder and missed in some instances. The clinical picture of PCD deficiency is essentially that of a mild PKU, and it is not unusual for such a patient to be classified as having transient hyperphenylalaninemia.

Differential Diagnosis. All infants with parkinsonian signs, myoclonic seizures, unexpected fair features, unexplained failure to thrive, unexplained severe bronchopneumonia or cardiopulmonary arrest, unexplained hyperthermia, and fluctuating blood pressure should be studied for the presence of 6PTS and DHPR deficiencies. Blood amino acids, particularly phenylalanine, should be determined in all children with mental retardation. Even when mild hyperphenylalaninemia is found, BH₄ loading, DHPR activity in red blood cells, and pterin measurement in urine should be performed.

Evaluation. Hyperphenylalaninemia is usually not as severe as in classic PKU. The end products of catecholamine and serotonin metabolism in cerebrospinal fluid and urine, such as 5-hydroxyindoleacetic, homovanillic, and vanillylmandelic acids, are considerably lower than normal. The characteristic findings are in the urinary pterin metabolites. In GTP-CH deficiency both neopterin and biopterin are low in the urine. In 6PTS deficiency the urine neopterin level is very high and that of biopterin is very low or undetectable, leading to a greatly elevated neopterin/ biopterin ratio. The urinary excretion of pterins may range from normal to massively elevated in DHPR deficiency. In PCD, an unusual pterin, primapterin, is detected in the urine. The pterin assay has been adapted to be used with dried urine spots on filter paper.^[38]

Another option is to perform a BH₄ loading dose, given 2 mg/kg IV or 7.5 to 20 mg/kg orally in divided doses. This will lower plasma phenylalanine to within normal limits within 8 to 12 hours if a patient has BH₄-dependent PKU. In 6PTS deficiency the excretion of neopterin will rapidly decrease on BH₄ loading. The BH₄ loading must be done while the patient is on a normal diet. An occasional patient with 6PTS deficiency with normal CSF finding but abnormal plasma and urine phenylalanine and pterin values has been described. This milder form of the disease is called the peripheral type. It is important to measure the red blood cell DHPR activity to rule out DHPR deficiency, because a BH₄ loading test might miss an occasional patient. Levels of prolactin are elevated in various forms of BH₄ deficiency and might provide a rapid clue to the presence of these diseases.

Management. The patients with BH₄ deficiency should be treated with BH₄, which is available from either Milupa, Hillington, Middlesex, UK, or Schirks Laboratories, Jona, Switzerland. The standard therapy is 20 mg/kg/day BH₄ given in three to four equal doses. All patients with proven diagnosis should be immediately placed on neurotransmitter precursors, which do not require hydroxylation. These are levodopa, 15 mg/kg/day and L-5-hydroxytryptophan, 4 mg/kg/day, together with 2- to 4-mg/kg/day carbidopa. The best results are obtained when neurotransmitter therapy is combined with BH₄. Therapeutic results should be followed by plasma phenylalanine, by prolactin, and, when possible, by urine pterins. Additional supplementation of folate is given in DHRP deficiency because it results in reduction of synthesis of tetrahydrofolate.

Prognosis and Prevention. Certainly the majority of the patients with 6PTS deficiency will respond well to the therapy and will grow as normal children. However, prognosis in all BH₄-dependent PKU is guarded, particularly in DHPR deficiency, because many patients have neurological impairment despite vigorous and early therapy. The hyperphenylalaninemia of various forms of BH₄ deficiency can be identified in routine screening tests; however, the diagnosis in a patient with GTP-CH deficiency was missed in the neonatal screening. Prenatal diagnosis has been achieved in DHPR and 6-PTS deficiencies.

HOMOCYSTINURIA: CYSTATHIONINE beta-SYNTHASE DEFICIENCY

Pathogenesis and Pathophysiology. Two important groups of diseases involving methionine metabolism are (1) homocystinuria due to the deficiency of

cystathionine beta- synthase (CBS) and (2) homocystinuric syndromes with abnormalities of folate or vitamin B₁₂ metabolism with or without methylmalonic aciduria.^[39] CBS deficiency, commonly known as homocystinuria, was reported in 1962.^[40] The recognition of homocystinuric syndromes is more recent.^[41]

The primary metabolic consequence of CBS deficiency is intracellular homocysteine accumulation. The cells then excrete the compound to plasma where the elevated levels exist either as free or as oxidized to homocystine, to mixed disulfides with cysteine, or with other sulfhydryl groups in proteins. When homocysteine is elevated in plasma, homocystine is excreted through the urine. Homocysteine is located at the crossroads of important biochemical reactions.

Homocysteine is an end product of biochemical reactions that utilize methylation. Biological methylations are achieved by activated methionine, S-adenosylmethionine. Once the methyl group is transferred, remaining S-adenosylhomocysteine is hydrolyzed into homocysteine and adenosine. Homocysteine must then either be reconverted into methionine or condensed with serine by CBS into cystathionine and excreted. These two paths are catalyzed by several different enzymes. The cystathionine synthesis is catalyzed by CBS, whereas the remethylation through the use of methyltetrahydrofolate is catalyzed by 5-methyltetrahydrofolate-homocysteine S-methyltransferase (methionine synthetase) or through other enzymes from betaine if the latter compound is used as a therapeutic agent. When CBS is deficient, homocysteine is elevated and thus hypermethioninemia and homocystinuria ensue; urine contains no cystathionine. Hypermethioninemia is due to increased methylation of homocysteine in liver by folate-dependent methylating enzymes. Numerous physiological disturbances account for the symptoms of CBS deficiency.

High homocysteine may cause undesirable disulfide cross-linkages, disrupting fibrillin. Among other vasoactive properties, homocysteine impairs the protein C-activating cofactor activity of thrombomodulin, and this feature may be involved in thrombotic events. In addition, both L-homocysteic acid and homocysteine-sulfinic acids derived from homocysteine are present in the urine of CBS-deficient patients. These two compounds are potent agonists

for N-methyl-D-aspartate (NMDA) receptors and might cause neuronal damage as a result of excessive stimulation of NMDA receptors. Two primary groups of patients are identified, based on their response to pyridoxine. In pyridoxine-responsive patients, a small residual activity of CBS is present that is enhanced by large doses of pyridoxine. Although the control activity does not attain control levels, it becomes sufficient to maintain a low level of the homocysteine pool. The CBS gene is mapped (see Table 31-2).

In 1967, it was shown that the biochemical abnormalities in some patients with CBS deficiency could be corrected by administering large doses of pyridoxine.^[42] Large international surveys indicate that approximately half of the patients are pyridoxine responsive. These patients are clinically heterogeneous, with some showing a clear-cut response and others a less dramatic response. Even the most responsive patient will have elevated plasma methionine and homocystinuria when loaded with methionine; therefore they should be kept under continuous treatment.

Because of interactions between folate and vitamin B₁₂ with homocysteine metabolism, homocystinuria occurs in acquired or inherited disorders of folate or vitamin B₁₂.

Epidemiology and Risk Factors. The cumulative frequency of CBS deficiency for countries with screening programs is 1 in 344,000. In parts of New South Wales in Australia this might be as high as 1 in 65,000 to 75,000. The disease is common in the Middle East, possibly occurring in 1 in 1,000 to 2,000 births. Approximately 75 patients with cblC and 30 with methylenetetrahydrofolate reductase deficiency are known.

Clinical Features and Associated Disorders. The phenotype of few diseases is as impressive as that of CBS deficiency, because numerous organs are involved. The main systems affected are the eye, the vascular system, the CNS, and the skeletal system.

Eye. Dislocation of the lens, ectopia lentis, is a constant feature but occurs usually after 2 years. The rate of lens dislocation is higher among patients who do not respond to pyridoxine. Marked myopia is associated with the loosened or subluxated lens. Cataracts, acute pupillary block glaucoma, and retinal degeneration may be additional complications.

Vascular System. Thromboembolic phenomena are dreaded complications of the disease, accounting for morbidity and mortality (see Fig. 31-1). They can occur at any age and in any vessel. Thrombosis in CNS causes neurological signs, such as hemiplegia, dystonia, or seizures; in the eye, optic atrophy; and in the kidney, severe hypertension. The risk of thrombosis is less in pyridoxine-responsive patients.

Central Nervous System. Mental retardation and neurological abnormalities are the main features. The developmental delay is usually apparent by the second year of life. Patients with pyridoxine-responsive disease are less affected. The degree of mental retardation varies between severe to normal, and it is not unusual to encounter an occasional pyridoxine-unresponsive child with normal or high IQ. Besides the neurological findings related to thrombotic events in the CNS, approximately 20 percent of the patients will suffer from seizures, mainly generalized convulsions. It is common for these individuals later in life to suffer from episodic depression, behavior disorders, and other personality disorders.

Skeletal Findings. Osteoporosis is a common late complication, and half of the patients will show some evidence of it by 20 years of age. It is more severe and appears earlier in pyridoxine-nonresponsive patients. Biconcave vertebrae are seen. The maturation of the skeleton is abnormal and leads to lengthening of the long bones (dolichostenomelia), which accounts for the marfanoid appearance of patients.

Other Features. Females with CBS deficiency experience frequent fetal loss. The offspring of men with CBS deficiency are normal. The risk factors for early vascular disease among heterozygotes and those individuals with mild homocystinemia have been investigated in detail. Since the pioneering publication by Wilcken and Wilcken,^[43] numerous reports and reviews support that preceding homocystinemia in normal subjects with mild homocystinemia may be responsible for vascular disease. However, most obligate heterozygotes do not have overt clinical atherosclerotic disease, and more studies are needed to conclude the risk factor for carriers.

Differential Diagnosis. Several symptoms of CBS are shared by other disorders. Lens abnormalities are encountered in a number of ophthalmological diseases. Another abnormality of sulfur metabolism, sulfite oxidase deficiency, also causes ectopia lentis. Thromboembolic phenomena and mental retardation are encountered in a large number of clinical conditions and are not detailed. The neurological symptoms of folate or vitamin B₁₂ metabolic abnormalities are not specific. Their presence is first suspected either by macrocytic anemia or by a positive urine homocystine test.

All children with lens, vascular, and CNS signs of CBS deficiency should be evaluated for homocystinuria. Any child with macrocytic anemia or neurological symptoms associated with a positive urine homocystine test should be evaluated for a possible defect in folate or vitamin B₁₂ metabolism.

Evaluation. The most consistent laboratory feature is homocystinuria. An easy test is urinary sodium nitroprusside reaction. If positive, homocystine should be identified by other procedures because most sulfur amino acids will yield a positive test. Some patients with pyridoxine-responsive disease will show marked responses to low doses of pyridoxine and the urine in such patients might give false-negative results. In most patients, blood methionine levels will be significantly elevated, which is a clue to CBS deficiency, unless a liver pathological process exists. Whereas in CBS deficiency homocystinuria is accompanied by elevated blood levels of methionine, other diseases associated with homocystinuria have accompanied hypomethioninemia and cystathioninuria. Some of these disorders show other laboratory findings, such as methylmalonicaciduria and megaloblastic anemia.

Management. The medical management of CBS deficiency requires correction of biochemical abnormalities, with the goal of preventing or halting the disease or improving the reversible clinical manifestations. This is best achieved in a newborn before any complication of the disease becomes apparent. Patients who are pyridoxine responsive require the administration of large amounts of pyridoxine. A patient should not be considered unresponsive until a dose of 500 to 1000 mg/day is given for several

weeks. The dose of pyridoxine recommended varies from as little as 25 mg/day to as large as 1200 mg/day. The neuropathy and ataxia resulting from the toxic effect of pyridoxine is not encountered in doses of 500 mg/day for at least as long as 2 years. Although it is not uniformly agreed on, pyridoxine-responsive patients should be given a methionine-restricted, cystine-supplemented diet, since they have reduced tolerance for high doses of methionine. Folate repletion may be necessary for

pyridoxine responsiveness and folate, 5 to 10 mg/day, should be provided. The preventive use of anticoagulants such as aspirin is also controversial; and if used they should be given in small quantities, such as 325 mg/day or less to an adolescent.

Patients who are not pyridoxine responsive and who are diagnosed later during childhood should be treated with large doses of betaine, 50 to 100 mg/kg/day. The compound increases the rate of homocysteine methylation by the action of a liver enzyme, betaine homocysteine methyltransferase. It reduces plasma homocysteine and increases methionine. In conjunction with diet therapy, it usually improves the clinical condition and retards the progression of disease. The best results are obtained in newborns detected to have the disease by providing a diet restricted in methionine and supplemented with cystine. At least four such formulas are commercially available and, when used together with betaine, ensure normal growth and psychological development. Experience is limited for the outlook of pyridoxine-responsive infants identified neonatally.

Prognosis and Prevention. Untreated patients with CBS deficiency die as a result of thromboembolic phenomena; mortality is much less in pyridoxine-responsive patients. The outcome is excellent in early-diagnosed and treated pyridoxine-responsive children. The mental development is normal, and thromboembolic phenomena are minimal or absent. The best one can hope for in a pyridoxine-unresponsive patient diagnosed late is to arrest the progression of the disease by treatment. By strict adherence to the therapy outlined, it is possible to normalize mental development in neonatally diagnosed pyridoxine-unresponsive patients.

In other syndromes associated with homocystinuria, the prognosis depends on early detection, early treatment, and the degree of the responsiveness of the disease to treatment. The neurological prognosis for the cblG and methylenetetrahydrofolate reductase deficient group is not as good as the others. Approximately 50 million newborns in the world, mainly in Japan and the United States, have been screened for CBS deficiency. The disease may be screened through blood methionine or urine homocysteine tests. The drawback of methionine-based screening is that only a few patients with the pyridoxine-responsive variant have so far been identified, whereas these are the patients that will benefit most from early detection. Screening based on homocysteine detection in urine has also been disappointing. The efficiency and false-positive and false-negative results of screening tests for CBS deficiency have not yet been settled.

DISORDERS OF LYSINE AND TRYPTOPHAN METABOLISM: GLUTARICACIDURIA TYPE 1 (see [Fig. 31-3](#))

Pathogenesis and Pathophysiology. Glutaricaciduria type 1 (GAT1) was first described in 1975^[44] and is caused by the deficiency of glutaryl-CoA dehydrogenase (GCDH), which is on the catabolic pathways of L-lysine and L-tryptophan. The presence of glutaric, 3-hydroxyglutaric, and glutaconic acids in urine is pathognomonic for the disease. Excess glutaryl-CoA leads to the formation of glutarylcarnitine, which can be detected both in blood and urine. The concentration of acids in the blood is not high enough to disturb the acid-base balance; and because there is no inhibition of ketone body and lactate utilization, or of urea formation, the disease does not usually cause acidosis or hyperammonemia. Its significant metabolic sequel is solely in the CNS. Chromosome location of GCDH is shown in [Table 31-2](#).

The mechanism of toxicity of glutaric acid in the CNS, particularly to the striatal system, is not well understood. Neither the degree of GCDH deficiency nor the amount of glutaric aciduria correlates with the severity of the disease. Glutaric acid is toxic toward striatal cells in culture. Glutaric, glutaconic, and 3-hydroxyglutaric acids are competitive inhibitors of glutamate decarboxylase (GAD), the enzyme responsible for gamma-aminobutyric acid (GABA) formation. Whether inhibition of GAD by itself accounts for neuronal death is uncertain. The block in GCDH might shift tryptophan metabolism to quinolinic acid which is a potent neurotoxin.^[45] Autopsy of brain in advanced cases shows severe neuronal loss and fibrous gliosis in basal ganglia, with some spongy degeneration of cortical white matter, indicating these as the target areas.

Epidemiology and Risk Factors. The disease is not rare but might be underdiagnosed. Over 100 patients have been described, 20 of whom are from the Middle East. It is estimated to affect 1 in 30,000 persons in Sweden. It is especially common in consanguineous communities, such as in Saudi Arabia, among the Saulteaux/Ojibway Indians in Canada, and in the United States among the Amish community in Pennsylvania.

Clinical Features and Associated Disorders. The infant is normal at birth, and the only detectable symptom might be macrocephaly. A typical history is rapid neurological deterioration and loss of developmental milestones after an infectious episode, which is usually mistaken for meningitis or encephalitis because a slight increased CSF protein level is usual. Seizures, dystonia (see [Fig. 31-3](#)), and choreoathetosis appear soon after and worsen, leading to a diagnosis of choreoathetoid cerebral palsy or postencephalitic cerebral palsy. Repeated viral infections each cause further deterioration, and the patient will eventually be severely crippled. Almost all patients show absolute or relative macrocephaly. In some patients, the clinical picture will be mild and no further deterioration will occur, particularly if no intercurrent viral infection takes place. An occasional infant identified through screening will show no or minimal neurological signs and will have macrocephaly and neuroradiological findings of GAT1, suggesting prenatal onset of the disease.

Evaluation. All infants with acute or chronic extrapyramidal signs should be investigated for GAT1. Results of routine blood cell counts, blood chemistries, and amino acid determinations are normal even in the most advanced patient; and unless the neurologist suspects and orders special tests, the disease remains undiagnosed. The characteristic biochemical findings are the presence of glutaric,

3-hydroxyglutaric, and glutaconic acids in the urine and of glutarylcarnitine in blood and urine. Use of tandem mass spectrometry to detect glutarylcarnitine in blood and urine has proved to be an unfailingly rewarding means of diagnosis.

The neuroradiological studies reveal a widened sylvian fissure or the "open opercular" sign (see [Fig. 31-3](#)), dense basal ganglia, total atrophy of the caudate heads in advanced disease, and evidence of mild white matter disease in the centrum ovale.^[46] These occur before the emergence of neurological deterioration. Findings on MRI or CT of the brain are characteristic of GAT1, and an experienced neuroradiologist will report the presence of the disease before the results of biochemical tests become available.

Differential Diagnosis. Among infants and young children with striatal necrosis, some have other definable causes, such as 3-methylglutaconicaciduria, propionicacidemia, or oxidative phosphorylation disease. Their clinical and laboratory presentations are different, and macrocephaly and the wide opercular signs are absent. Other causes of macrocephaly in infancy include Canavan's disease, Alexander's disease, and L-2 hydroxyglutaricaciduria. These conditions are progressive pyramidal tract diseases and should not be confused with GAT1.

Management. Treatment may be rewarding if initiated before the clinical manifestations of the disease. The treatment of choice is reducing lysine and tryptophan intake. Such formulas are available. The medications used are L-carnitine orally, 100 to 200 mg/kg/day; riboflavin, 50 mg/kg/day; and baclofen, 5 to 10 mg three times daily. The exact mechanism of action of baclofen is not known, but it has been effective in some instances. In one patient, vigabatrin caused significant clinical improvement. All intercurrent infections, particularly those with viral etiology, demand immediate intervention by administering L-carnitine intravenously (50 to 100 mg/kg repeated every 6 hours) and providing adequate calories through glucose and insulin drip. These treatments will be of little value in patients who have already suffered significant damage to striatum.

Prognosis and Prevention. Prognosis is poor for patients who have been diagnosed late, although the treatment might slow the progression of the disease. Limited information is available for patients diagnosed early. Prenatal diagnosis of the disease is made through study of organic acids in amniotic fluid or by measuring GCDH in cultured amniotic cells. Tandem mass spectrometry-based neonatal screening identifies GAT1.

BIOTINIDASE DEFICIENCY

Biotinidase deficiency was first recognized in 1983, among patients with late-onset multiple carboxylase deficiency.^[47] The worldwide frequency among 8 million newborns is 1 in 112,000.^[48] Biotin is the cofactor for such carboxylases as propionyl-CoA, 3-methylcrotonyl-CoA, acetyl-CoA, and pyruvate carboxylase. The most important source of biotin is through biotinidase; hence, when biotinidase is absent, a state of biotin deficiency gradually emerges. Biotinidase activity in brain is very low,^[49] and the brain totally depends on the transfer of biotin across the blood-brain barrier. When biotin is deficient, pyruvate carboxylase in the CNS might decrease, leading to localized lactic acidosis. Biotinidase-deficient patients suffer from central deafness before treatment, and hearing usually does not improve after treatment. The reason for selective targeting of the auditory center is unknown. Alopecia (see [Fig. 31-3](#)) and dermatitis in these patients are possible owing to depletion of fatty acids as a result of deficient acetyl-CoA carboxylase activity. Approximately 55 percent of patients develop clonic or myoclonic seizures, hypotonia, and developmental delay between 3 and 6 months of age. Hearing abnormality coincides with the emergence of seizures. Dermatitis, visual problems, and ataxia are the final events. The changes in acylcarnitines and organic acids appear only during acute decompensation, and the disease cannot be identified through these compounds. Individuals with partial deficiency might be at risk only for cutaneous symptoms. Immunological dysfunction manifests as candidal dermatitis as described

for propionicacidemia and methylmalonicacidemia.

Colorimetric and fluorometric procedures are available for measurement in serum. Prenatal diagnosis has not yet been reported. During acute decompensation the blood acylcarnitine and urine organic acid profiles are the same as seen in holocarboxylase synthetase (HCS) deficiency.

Biotin-responsive mild forms of HCS deficiency and milder forms of propionicacidemia must be ruled out by clinical and laboratory observations. Alopecia and rash can be encountered in deficiency of zinc or essential fatty acids. Biotinidase deficiency might be confused with severe combined immune deficiency.

Deafness persists even in a well-treated patient, but alopecia and other symptoms disappear with treatment. As little as 5 to 30 mg of biotin will be curative.

MITOCHONDRIAL ENZYME DEFECTS

Mitochondrial DNA (mtDNA) was first discovered in 1963, and in the following 20 years the basic principles of mitochondrial genetics were established. [50] These are maternal inheritance, replicative segregation, threshold expression, high mtDNA mutation rate (compared with nuclear DNA genes), and accumulation of somatic mutations with aging.

The mtDNA of the mother is transmitted to all of her children through the egg cytoplasm, containing 200,000 to 300,000 mtDNAs. The number of mitochondria increases hundred-fold, whereas the mtDNA copy number per mitochondrion decreases from 2 to 10 to 1 to 2 mtDNAs during oogenesis. After fertilization the early embryo goes through nuclear DNA replication and cell cleavage without significant increase in number of mitochondria or mtDNAs. The mtDNA copy number per mitochondrion varies according to cell type, with an inverse relationship between mitochondrial density and copy number. The highest mtDNA copy number is in brain mitochondria. Mutations in cellular mtDNAs result in mixed intracellular populations of mutant and normal genomes, a situation called heteroplasmy. When heteroplasmic cells divide, different mtDNAs partition randomly into daughter cells (replicative segregation), resulting in variation of cell genotypes.

What clinical phenotype a mitochondrial disease expresses depends on the severity of the mtDNA mutation, the percentage of mutant mtDNAs, and the differing energy

requirements and reserve of tissues. Each tissue requires a different minimum level of mitochondrial adenosine triphosphate (ATP) production (a threshold) to sustain normal cell function. In a family with heteroplasmic mtDNA mutations, different family members can inherit different percentages of mutant mtDNAs and therefore present with different clinical symptoms. The phenotypical effect of the mutations depends on the severity of the damage to the protein the gene encodes. Cells with the lowest potential to replicate, like neurons, appear to be the ones most susceptible to degenerative changes in proteins, lipids, nuclear DNA, and mtDNA. Which neurons accumulate mtDNA mutations is proportional to the metabolic rate. Thus, cerebral cortex, which in positron emission tomography (PET) shows a high glucose utilization rate, and basal ganglia, which also have dopaminergic neurons that generate hydrogen peroxide and oxygen radicals, are the brain areas most susceptible to accumulation of mtDNA damage.

Among the many disorders of oxidative phosphorylation, clinical classifications that focus on the most severe organ system presentations are misleading. [50] Because the expression of mtDNA defects of oxidative phosphorylation depends on the quantitative principles stated earlier, complete phenotypes are rarely exhibited. Biochemical classifications have the same shortcomings because the type and severity of the enzyme defect varies with the percentage of mutant mtDNA in heteroplasmic families. A molecular genetic classification is therefore the most useful. It includes four categories: class I, nuclear DNA mutations; class II, mtDNA point mutations; class III, mtDNA deletions and duplications; and class IV, genetics not yet defined. In keeping with the previous section of aminoacidopathies and organic acidopathies, these diseases are listed in [Table 31-5](#) by order of most likely age presentation. Only the major diseases are discussed here.

Subacute Necrotizing Encephalomyelopathy (Leigh's Disease)

Pathogenesis and Pathophysiology. At the molecular level, Leigh's disease can be caused by both mendelian (autosomal recessive nuclear coded DNA) and mtDNA defects. [51], [52] Areas affected are primarily the basal ganglia, brain stem, and cerebellum. The cerebral cortex and retinal pigment are less involved. Pathologically, there is spongy degeneration, demyelination, gliosis, necrosis, relative sparing of neurons, and capillary proliferation. Several enzyme complexes involved in mitochondrial respiratory metabolism show defects, singly or in combination. These are in cytochrome C oxidase (COX; complex IV), NADH dehydrogenase (complex I), pyruvate dehydrogenase complex (PDHC), and pyruvate carboxylase. The most commonly reported defect is within the ATPase 6 gene at mtDNA position mt8993, a T to G or T to C mutation, resulting in severe defects of ATP production. [53] This is the same gene defect that causes the NARP syndrome (neuropathy, ataxia, and retinitis pigmentosa) in adults.

Epidemiology and Risk Factors. Leigh's disease is a relatively common neurometabolic disease. About one half of patients are diagnosed in the first year of life, usually

TABLE 31-5 -- MITOCHONDRIAL ENZYME DEFECTS*

INFANTILE

- Subacute necrotizing encephalopathy or Leigh's disease (I, II)
- Progressive infantile poliodystrophy or Alpers' disease (IV)
- Lethal infantile mitochondrial disease (I)
- Others
- Hypertrophic cardiomyopathy and myopathy (II)
- Infantile bilateral striatal necrosis and Leber's hereditary optic neuropathy (II)
- Mitochondrial myopathies (I)
- Benign infantile mitochondrial myopathy and cardiomyopathy (I)
- Lethal infantile cardiomyopathy, X-linked or Barth's syndrome (I)
- Benign infantile mitochondrial myopathy (I)

CHILDHOOD

- Myoclonic epilepsy and ragged red fiber disease (II)
- Mitochondrial encephalomyopathy, lactic acidosis, and strokelike episodes (II)
- Chronic progressive external ophthalmoplegia, autosomal dominant (I)
- Kearns-Sayre syndrome, autosomal dominant (I)
- Others
- Mitochondrial myopathy (II, IV)
- Idiopathic dystonia (IV)
- Myoneurogastrointestinal disorder and encephalopathy (IV)
- Lufts disease (nonthyroid hypermetabolism) with generalized myopathy (IV)

ADOLESCENCE

- Leber's hereditary optic neuropathy (II)
- Kearns-Sayre syndrome (III)
- Chronic progressive external ophthalmoplegia (III)
- Others
- Leber's hereditary optic neuropathy plus multiple system degeneration (II)
- Inherited exertional myoglobinuria (I)

ADULTHOOD

- Malignant migraine (III)
- Neuropathy, ataxia, retinitis pigmentosa syndrome (II)

Others

Hypertrophic cardiomyopathy and myopathy (II)

Mitochondrial myopathy (II, IV)

*Diseases are listed by order of most likely age presentation The molecular genetics class is given in parentheses.

before age 6 months; in a fourth, the onset is early in the second year of life. Males are predominantly affected. There is a juvenile and an adult form.

Clinical Features and Associated Disorders. The usual age at onset is before the age of 1 year, with death usually before 5 years. A previously healthy, normal infant exhibits a progressive encephalopathy, with an early characteristic central hypoventilation syndrome. Central hypotonia is prominent early and may later be followed by spasticity. Brain stem findings are shown as poor feeding, sucking, and swallowing and as nuclear or supranuclear ophthalmoplegia. There may be optic atrophy but also pigmentary degeneration of the retina. If the onset occurs after the infant has obtained some upright posture, ataxia becomes evident. Seizures occur in the early-onset form, particularly when due to PDHC deficiency or the NARP mt8993 mutation. Movement disorders may occur later in the course and consist often of multifocal myoclonus. Serial CSF lactate and pyruvate levels are elevated. The diagnosis can usually be made by the combination of a typical course, elevated CSF lactate and pyruvate, and typical lesions on MRI.

Figure 31-4 (Figure Not Available) Algorithm for general approach to the investigation of diseases of oxidative phosphoryl. Reproduced with permission from The McGraw-Hill Companies, from Scriver C, ed: *The Metabolic and Molecular Bases of Inherited Disease*, 7th ed., New York, McGraw-Hill, 1995, p 1579.

Differential Diagnosis. Included is any infantile onset chronic or subacute progressive encephalopathy, but particularly the organic acidurias that present as progressive encephalopathy: glutaricaciduria type 1, biotinidase deficiency, and biotin-dependent phenylketonuria. Other mitochondrial disorders--lethal infantile mitochondrial disease, atypical peroxisomal disorder, and infantile neuroaxonal dystrophy--should be considered.

Evaluation (Fig. 31-4 (Figure Not Available)). In Leigh's disease blood amino acid screening may show nonspecific aminoaciduria. Blood and, more definitively, CSF lactate and pyruvate levels are elevated, with lactate:pyruvate ratios not always at 25:1. Blood ammonia and glucose values are usually normal, as are those of urine organic acids. Other useful tests include serum biotinidase determination, blood sampling for very long chain fatty acids and red blood cell catalase, and pipercolic acid determination for excluding peroxisomal disorders. On T2-weighted sequences of brain MR images, areas of increased intensity are seen in brain stem, cerebellum, and basal ganglia symmetrically. An electroencephalogram may show only background slowing consistent with a nonfocal encephalopathy. Nuclear MR spectrometry, if available, may show a decreased phosphocreatine-to-phosphate ratio in affected brain areas. Specific cause is investigated by enzyme analysis for COX and PDHC activity in cultured skin fibroblasts and/or muscle biopsy, and muscle biopsy is performed for mtDNA analysis (see Fig. 31-4 (Figure Not Available)).

Management. Supportive and symptomatic management includes nasogastric tube or gastrostomy for feeding problems to prevent aspiration, tracheostomy and ventilatory support for respiratory failure, prompt treatment of infections, frequent changes of position in bedridden patients to prevent skin ulceration, and the use of antiepileptic and antispastic drugs when appropriate. Metabolic treatment can be attempted, even while waiting for a definitive diagnosis, by starting with broad-spectrum cofactor supplementation therapy. This assumes that if the patient has a treatable mitochondrial disease, it will respond to factors that increase mitochondrial ATP production. Biotin (50 mg/day or more) and thiamine (300 mg/day or more) can be given in megadoses, in combination with the multivitamins. At least a 2-month trial should be given to determine therapeutic efficacy, although this approach is difficult to assess because of the phenotypical and genetic heterogeneity of these diseases. Dichloroacetate is available for lowering of lactic acid levels in research protocols, and it is hoped that it will soon be approved by the Food and Drug Administration. Doses of 15 to 200 mg/kg/day have been used in infants and children, with about a 20 percent fall in lactic acid levels. Coenzyme Q10, vitamin K, and vitamin C may also be tried.

Prognosis and Future Perspectives. The prognosis for Leigh's disease is grave: death is inevitable. The course at times may spontaneously remit, and therapies may seem to arrest the disease for periods of time. Death usually occurs by respiratory failure or complications such as sepsis.

Progressive Infantile Poliodystrophy (Alpers' Disease)

Pathogenesis and Pathophysiology. CNS locations affected by Alpers' disease are the same as those of Leigh's

disease, but in reverse order: most severe in cerebral cortex, then cerebellum, basal ganglia, and brain stem. Lesions show diffuse neuronal degeneration, characteristic spongiform or microcystic degeneration, and, in common with Leigh's disease, gliosis, necrosis, and capillary proliferation. [54] Biochemical abnormalities have not been specific and have included decreased pyruvate dehydrogenase activity, decreased utilization of pyruvate and NADH, and citric acid cycle dysfunction. The genetic abnormality and mechanism of transmission is unknown. It is even disputed whether Alpers' disease is a mitochondrial disease at all. The cortical spongy degeneration appears similar to that of adult Creutzfeldt-Jakob disease, now recognized as a prion disease.

Epidemiology and Risk Factors. The epidemiology is unclear, because the recognition of the syndrome has been unclear, and there is no known gene defect despite the familial occurrence.

Clinical Features and Associated Disorders. Age at onset and duration are similar to those of Leigh's disease. However, there is usually psychomotor delay before the abrupt onset of seizures. [55] The seizures may be focal status epilepticus and epilepsy partialis continua, but they evolve into multifocal myoclonus. Areflexia and hypotonia are initially present, with some signs of spasticity later. Ataxia and nystagmus may worsen, with all other neurological signs and symptoms, during infections. Approximately 40 percent of patients have associated hepatic dysfunction. The course is rapidly progressive after onset of seizures. Blindness and optic atrophy occur late.

Differential Diagnosis. This includes any of the infantile or late infantile progressive encephalopathies with primary involvement of cortical gray matter and presentation with refractory epilepsy. Probably the most common of these diseases is neuronal ceroid lipofuscinosis (Jansky-Bielschowsky or Batten-Spielmeier-Vogt presentations), which can be ruled out by looking for appropriate inclusion bodies in skin, conjunctival, or full-thickness rectal (ganglion cell) biopsy specimens with electron microscopy. Another mitochondrial disease with severe epilepsy is the myoclonic epilepsy and ragged red fibers (MERRF) syndrome (see subsequent section). Other storage diseases at this age, such as atypical GM₂-gangliosidosis (Tay-Sachs disease, Sandhoff's disease), infantile sialidosis, and galactosialidosis, could be diagnosed by testing for lysosomal enzyme activity, preferably on cultured skin fibroblasts, rather than blood. Other rare causes of a progressive encephalopathy with refractory seizures at this age, but important because they are treatable and reversible, are later-onset pyridoxine dependency and nonketotic hyperglycinemia (both usually neonatal-onset diseases), biotinidase deficiency, and disorders of biogenic amine metabolism, such as folate-responsive seizures. Sulfite oxidase deficiency and Menkes' disease usually present earlier in infancy. The former can be screened for by a commercially available sulfite oxidase urine dipstick test; the latter, by measuring serum copper and ceruloplasmin. Extremely rare at this age are slow virus (subacute sclerosing panencephalitis) diseases. Within the differential diagnosis are epileptic syndromes that appear to be progressive at the onset but that usually plateau into developmental arrest and retardation. These include the syndrome of severe myoclonic epilepsy and the Lennox-Gastaut syndrome.

Evaluation. Because there is no one pathognomonic clinical sign or laboratory study, Alpers' disease is a diagnosis of exclusion. Therefore, all rapidly progressive infantile encephalopathies need to be excluded by clinical story and/or laboratory tests. Measurement of amino acids, organic acids, lactate, and pyruvate should be done in CSF as well as in blood. Mitochondrial biochemical and DNA studies should be performed, looking specifically for the MERRF mutation, as well as functional neuroimaging studies (i.e., MR spectrometry, single photon emission computed tomography [SPECT], and PET if available), to garner evidence for defective energy metabolism and oxidative phosphorylation and to determine the biochemical geography. In Alpers' disease electroencephalograms (EEGs) are markedly abnormal, showing a diffuse encephalopathy. A characteristic electroencephalographic pattern consists of high-voltage, very slow delta waves mixed with low-voltage polyspikes. Serial visual evoked potentials extinguish over time. Structural neuroimaging studies (CT, MRI) show progressive marked cortical atrophy. Results of liver function tests are abnormal at the onset of seizures, before clinical features of hepatic degeneration.

Management. There is no specific treatment. The broad-spectrum approach described earlier for Leigh's disease should be applied in order not to miss a treatable

progressive encephalopathy. A trial of pyridoxine, 50 mg twice a day orally can be done to rule out pyridoxine- dependent/deficient seizures. If the serum and CSF glycine levels are elevated, the glycine cleavage enzyme activity should be assessed by liver biopsy in a laboratory qualified to do this test; and treatment should be started with dextromethorphan, leucovorin, and sodium benzoate for nonketotic hyperglycinemia. In symptomatic treatment of the seizures, valproic acid should be avoided, because the risk of accelerating the course and a resultant fatal toxic hepatitis is very high. Other treatments of refractory, non- surgically treatable epilepsy at this age, such as adrenocorticotrophic hormone or prednisone, ketogenic diet, and intravenous IgG, are unproven and may be harmful.

Prognosis and Future Perspectives. This is a fatal disease. Future treatment approaches depend on the elucidation of the underlying biochemical and molecular pathogenesis.

Lethal Infantile Mitochondrial Disease or Congenital Lactic Acidosis

The oxidative phosphorylation defects associated with extreme neonatal lactic acidosis involve defects in multiple complexes (mostly complex I and IV but also III) and various cytochromes. There are probably several genetic mechanisms of lethal infantile mitochondrial disease (LIMD): tissue-specific depletions of mtDNA, mtDNA mutations, and abnormal expression of specific complex I or IV subunits. The genetics of the mtDNA depletion syndromes could be autosomal recessive or dominant with variable expressivity. Three hypotheses could explain these: (1) there is a defect in a nuclear gene that controls mtDNA

replication and copy number; (2) there is abnormal timing of mtDNA replication (delayed) in embryogenesis; (3) an mtDNA point mutation interacts with specific nuclear alleles and replication is impaired.

These are rare diseases, and the epidemiology is unknown. Because the respiratory chain is influenced by mitochondrial and nuclear genomes, inheritance is either mendelian or maternal.

Presentation is usually in or shortly after the neonatal period, with marked hypotonia and weakness, failure to thrive, respiratory difficulty, and severe lactic acidosis. The hypotonia/weakness is due to a myopathy with lipid and glycogen accumulation and abnormally shaped mitochondria without inclusions but only rare, ragged red fibers. Death occurs ordinarily by 5 months, usually because of the uncorrectable lactic acidosis. Hepatic dysfunction is highly associated, with lesser involvement of kidneys (proximal tubule abnormalities and generalized aminoaciduria) and a cardiomyopathy. The brain itself is rarely involved, but when it is, bilateral basal ganglial abnormalities are shown on neuroimaging.

The differential diagnosis includes other infantile causes of lactic acidosis: primary defects of pyruvate metabolism, such as pyruvate dehydrogenase deficiency, or secondary disturbances, such as in various organic acidurias and fatty acid oxidation defects; Krebs' cycle defects; and defects of gluconeogenesis. [56] Before the serum lactic acid levels are known, the clinical picture resembles the hyperammonemia syndromes due to urea cycle defects.

Important tests to order include blood levels of amino acids; urine levels of organic acids; serum and CSF levels of lactate, pyruvate, and ammonia; liver and renal function tests, blood creatine kinase (skeletal and cardiac fractions); ultrasound evaluation of the heart; neuroimaging of the brain; and electroencephalography to document a toxic/ metabolic encephalopathy.

Supportive treatment of liver, renal, and cardiac failure is important, along with consultation with a center using experimental protocols. For respiratory chain defects, megadoses of vitamins K and C, coenzyme Q10, L-carnitine, and folic acid have all been tried with controversial benefit. If PDH deficiency is the cause, thiamine and lipoic acid may be therapeutic, because PDH requires these as cofactors. If biotinidase deficiency or multiple carboxylase deficiency is the cause, 50 mg of biotin daily can be given. Fructose-1,6-biphosphatase deficiency and glucose-6-phosphatase deficiency, both gluconeogenic defects, respond to frequent daily and continuous nocturnal feedings to prevent hypoglycemia. There is no effective treatment for pyruvate carboxylase deficiency or partial defects of the Krebs cycle. Correction of the metabolic acidosis and lowering of serum lactic acid is most effective with sodium dichloroacetate (DCA), 15 to 200 mg/kg/day administered intravenously or orally. DCA crosses the blood-brain barrier and inhibits the pyruvate dehydrogenase specific kinase, activating the PDHC and lowering brain and blood lactate levels.

LIMD is lethal. If definite nuclear gene mutations are identified in the future, prenatal diagnosis using chorionic villus sampling or amniocentesis should be feasible. The prognosis of the other congenital lactic acidoses depends on the underlying biochemical defects--best with biotinidase deficiency and the gluconeogenic defects, less with PDH, pyruvate carboxylase (PC), and Krebs' cycle defects.

Myoclonic Epilepsy and Ragged Red Fibers Syndrome

The majority of cases of MERRF syndrome have a heteroplasmic G to A point mutation at bp8344 in the tRNA^{Lys} gene.[57] This results in protein synthesis defects involving primarily complexes I and IV, which have the greatest number of mtDNA coded subunits. Any quantitative measure of energy metabolism-- [31] P-NMR, anerobic threshold determination, or biochemical analysis of skeletal muscle--shows decreased ATP-generating capacity. When mutant mtDNAs exceed 85 percent in a tissue, the patient becomes symptomatic. Neuropathology shows degeneration of cerebellar cortex, substantia nigra, dentatorubral and pallidolusian systems, locus ceruleus, inferior olivary nucleus, and pontine tegmentum.

The exact incidence is not known. Familial occurrence with maternal inheritance, usually before age 20, is the rule. Commonly, symptoms and signs overlap among MERRF, mitochondrial encephalopathy, lactic acidosis, and strokelike episodes (MELAS), and Kearns-Sayre syndrome (KSS).

The classic presentation is usually in late childhood, although it may begin in early adulthood, with progressive myoclonic epilepsy, ataxia, and action-induced polymyoclonus. Weakness and hypotonia due to a mitochondrial myopathy and a progressive dementia follow. Hearing loss may be associated. This presentation resembles the historical Ramsay Hunt syndrome of dysergia cerebellaris myoclonica.

MERRF is differentiated clinically from MELAS (see next section) by the lack of strokelike episodes in MERRF. Benign essential familial myoclonus is nonprogressive. The principal differential is with other causes of progressive myoclonic epilepsy in late childhood/early adolescence. These are storage diseases--neuronal ceroid lipofuscinosis (Kufs' type) and neuraminidase deficiency (sialidosis type 1); diseases of unknown etiology--Lafora's disease, Baltic myoclonus; and slow virus and prion diseases--subacute sclerosing panencephalitis and early-onset spongiform encephalopathy.

Tests to be ordered include serum and CSF lactate, pyruvate, and alanine levels; EEG and visual evoked potentials; MRI of the brain, which often shows areas of increased intensity in T2-weighted sequences; [31] P-NMR of muscle; muscle biopsy for biochemical tests of oxidative phosphorylation and for visualizing ragged red fibers, by light microscopy using the Gomori's trichrome stain, and by electron microscopy; and mtDNA analysis, looking for the MERRF and MELAS point mutations.

Seizures can be symptomatically treated with valproate (watching for carnitine deficiency) and clonazepam. There is a dearth of data as to whether measures for refractory myoclonic epilepsy--ketogenic diet, adrenocorticotrophic hormone or corticosteroids, or L-5-hydroxytryptophan plus carbidopa--have been effective. Corticosteroids have been used for the myopathy and improvement has been noted,

but this is not generally recommended at present. Because coenzyme Q10 improves electron transfer from complex I and riboflavin serves as a cofactor for electron transport in complex I (and II), these agents are reasonable to try (see Fig. 31-4 (Figure Not Available)). Use of vitamin K (menadione and phytonadione) has less rationale.

The course is chronic and slowly progressive. Different family members may become symptomatic, with different phenotypes, at different ages, depending on the percentage of the mutant DNA in muscle and brain. It would be important for all maternal relatives to have blood analyses for the mutant DNA and, if negative on muscle, to determine the risk of becoming symptomatic with age. Prenatal diagnosis by amniocentesis or chorionic villus sampling for mtDNA point mutations is unreliable presently because the genotype of that tissue may not reflect that of the embryo's muscle and brain.

Mitochondrial Encephalopathy, Lactic Acidosis, and Strokelike Episodes

About 80 percent of MELAS patients exhibit a heteroplasmic A to G point mutation in the dihydrouridine loop of the tRNA^{Leu(UUR)} gene at mt3243.^[58] Two other mutations in the same gene, at mt3250 and mt3271, have been identified in the remaining cases. The MELAS3243 mutation alters the dihydrouridine loop of the tRNA^{Leu(UUR)} gene and changes a nucleotide at the binding site for a nuclear DNA encoded transcription termination factor. It is hypothesized that the mutation reduces the binding affinity of the transcription termination factor. Another possibility is that this mutation impairs protein synthesis by interfering with polypeptide chain elongation. The cerebral infarcts are nonvascular, owing to transient dysfunction of oxidative phosphorylation within parenchyma. Areas of neuronal loss, demyelination, and astrocytic proliferation are found in the infarct-like brain areas. PET studies show reduced cerebral metabolic rates for oxygen but normal glucose utilization. Mitochondrial abnormalities of endothelial cells and smooth muscle cells produce a mitochondrial angiopathy. The vascular metabolic dysfunction may cause increased production of free radicals, which could damage vasodilators such as nitrous oxide, causing vasoconstriction.

The exact incidence is unknown. Most cases occur before age 20, and about a fourth of patients have a positive family history consistent with maternal inheritance.

Patients may present sporadically or in maternal pedigrees, in infancy, childhood, or adulthood. The overall course is of a progressive degenerative disease with strokelike episodes and a mitochondrial myopathy. Various symptoms appear singly or in combination and include hemiplegia, sudden cortical blindness, hemianopia, episodes of confusion and hallucination with fever, aphasia, migraine headaches in a maternal lineage preceding strokelike episodes, and maternally inherited diabetes mellitus type II and deafness. Multisystem complaints and signs include myalgia, fatigability, weakness, ophthalmoplegia, pigmentary retinal degeneration, cardiomyopathy, cardiac conduction defects and block, dementia, deafness, ataxia, myoclonus, seizures, lactic acidosis, and proximal renal tubule dysfunction.

Conditions to exclude include any other causes of stroke in childhood, infancy, or adulthood; other mitochondrial multisystem disorders, such as MERRF or KSS/chronic progressive external ophthalmoplegia (CPEO), or other uncharacterized disorders; and any neurological disease in adulthood with an overall progressive course but relapses that leave residuals, such as multiple sclerosis or other demyelinating diseases.

In the general diagnostic approach (see Fig. 31-4 (Figure Not Available)), the best diagnostic clues are found on CT and MRI, which show cortical infarcts that are not wedge shaped but cut across several vascular territories, usually located in the posterior quadrants initially. Basal ganglia calcifications, in particular, occur and are seen better by CT than MRI. Ventricular dilation and cortical atrophy are also seen. With a history of strokelike episodes, these neuroimaging findings, associated with lactic acidosis and a myopathy, should strongly suggest the diagnosis. Functional neuroimaging studies, such as SPECT using N-isopropyl- p -[¹²³I]-iodoamphetamine (IMP) tracer can detect regional hypoperfusion when structural studies (CT, MRI) are unrevealing. SPECT is useful not only in delineating the lesion but also in following the course. Analysis of mtDNA for the known point mutations on blood and muscle confirms the diagnosis.

Coenzyme Q10 in doses up to 300 mg/day may be needed for optimal benefit, starting at 4.3 mg/kg/day. Corticosteroids and a novel quinone not available in the United States, idebenone, have shown some benefit. MELAS is a progressive neurodegenerative disease with a guarded prognosis.

Chronic Progressive External Ophthalmoplegia and Kearns-Sayre Syndrome

These conditions are discussed together because of a common overlap.^[59] Most cases are spontaneous and have mtDNA deletions. Over 100 different deletions have been identified; 90 percent occur between the large arc between the two points of replication. Deleted mtDNAs localize to distinct regions along muscle fiber, whereas normal mtDNAs are evenly distributed, resulting in a periodic respiratory deficiency along the muscle fiber. The loss of tRNAs is rate limiting in these areas, causing deficits in protein synthesis and oxidative phosphorylation. Duplications may occur spontaneously or be maternally inherited and are detected in quiescent (muscle) and actively dividing tissue (lymphocytes). The mechanism of their generation is unclear. The exact incidence of these conditions is unknown. Most all cases are sporadic.

If ophthalmoplegia before the age of 20 years is accompanied by atypical retinitis pigmentosa, mitochondrial myopathy, along with cardiac conduction defects, a cerebellar syndrome, or elevated CSF protein (above 100 mg/dl), this constellation is termed KSS. Chronic progressive ophthalmoplegia with onset after age 20 is termed CPEO and, if coupled with a variety of other manifestations, CPEO-plus. These manifestations are many: lactic acidemia; eye and ear findings, including pigmentary retinopathy, optic atrophy,

and hearing loss; cardiac conduction defects, arrhythmias, and dilated or hypertrophic cardiomyopathies; CNS dysfunction, including dementia, seizures, and ataxias; peripheral nervous system damage, including motor/sensory neuropathies; mitochondrial myopathy; and multisystemic organ involvement in the form of diabetes mellitus, hypoparathyroidism, glomerulosclerosis, proximal renal tubule dysfunction, gastrointestinal motility problems, and respiratory failure.

Conditions to exclude include other mitochondrial diseases, primarily MERRF and MELAS; any disease causing ophthalmoplegia when that is the sole presenting symptom, especially myasthenia gravis; other diseases that cause multisystem involvement, such as collagen vascular diseases, particularly systemic lupus erythematosus; and in the appropriate setting, Lyme disease (caused by infection with *Borrelia burgdorferi*) or Whipple's disease. The ultimate diagnosis is made by muscle biopsy and mtDNA analysis. There is no proven specific treatment, although coenzyme Q10 and carnitine have been used. Implanted cardiac pacemakers can be used for conduction defects. Associated endocrine abnormalities--growth hormone deficiency, diabetes mellitus, or hypoparathyroidism--can be treated medically. Although these conditions are considered chronic, complete heart block may result in sudden death.

Leber's Hereditary Optic Neuropathy

Leber's hereditary optic neuropathy (LHON) was the first human disease proven to be due to an mtDNA point mutation.^[60] Pedigrees may be heteroplasmic or homoplasmic. Eleven different missense mutations have been identified. Approximately 80 percent are accounted for by mutations at bp11,778 and bp3460. There is much genetic heterogeneity, because the remaining cases reveal novel, complex mtDNA mutations that are primary or synergistic. Multifactorial etiopathogenesis probably exists.

The exact incidence of LHON is unknown. It is maternally inherited, has variable penetrance, and has male predominance. An X-chromosome locus has not been proven, with the sex differences being explained more by sex-related physiological differences.

LHON presents as loss of central visual acuity in adolescence or early adulthood, acutely or subacutely, although it rarely can occur in children. Fundoscopic examination shows telangiectatic microangiopathy and swelling of the nerve fiber layer around the optic disc in acute presentations and optic atrophy in subacute to chronic presentations. Up to almost one fourth of patients regain vision. In addition to blindness, complex neurological features include signs suggestive of multiple sclerosis, multisystem atrophy, or MELAS. Extrapyraxidal features like dystonia may develop with bilateral striatal necrosis.

The differential diagnosis includes other causes of optic neuritis, multiple sclerosis, MELAS, Leigh's disease, subacute combined degeneration due to vitamin B₁₂ deficiency, Friedreich's-like ataxia, other causes of multisystem degeneration. The general paradigm should be followed, but in leukocyte/platelet analysis, for major manifestations, MTND1*LHON4160 and MTND4*LHON11778 should be assessed. For minor manifestations, MTND4* LHON11778 and MKTND1*LHON3460 and MTND6* LHON14484 are assessed. If any of these are positive, then haplotype analysis is indicated. Laboratory evaluations necessary to rule out disorders in the differential diagnosis should be done simultaneously. Recovery from blindness depends on the mutation involved--5 percent in the most common and 22 percent in the second most common mutation.

Malignant Migraine

Various oxidative phosphorylation defects occur in the brain, although how they relate to the production of migraine is speculative. Migraine affects as much as 25 percent of the population and is frequently seen in maternal relatives of patients with diseases of oxidative phosphorylation. Malignant migraine refers to three situations: migraine patients who turn out to have MELAS; migraine patients who are maternal relatives of patients with oxidative phosphorylation diseases and who are unresponsive to the usual prophylactic medications; and migraine patients who develop strokes. Blood should be tested for biochemical and mtDNA defects of oxidative phosphorylation. If the blood tests are negative, muscle biopsy should be done for routine pathology, histochemistry and electron microscopy, oxidative

phosphorylation biochemistry, and mtDNA analysis to include Southern blot analysis for mtDNA rearrangements. Management is nonspecific. The prognosis is unknown and may depend on whether more specific mutations are found to be associated.

Neuropathy, Ataxia, Retinitis Pigmentosa Syndrome

The neuropathy, ataxia, retinitis pigmentosa (NARP) syndrome is due to a point mutation at bp8993 in the ATPase 6 gene (MTATP6*NARP8993), which changes a highly conserved leucine at position 156 to an arginine. The exact incidence is unknown, but this is a rare, functionally recessive, with variable systemic expression, adult-onset progressive disease. Presentation is with neuropathy or neurogenic weakness, ataxia, and pigmentary retinopathy. It can also be associated with dementia, generalized seizures, cerebellar and brain stem atrophy, and corticospinal degeneration. The first presentation is usually nyctalopia, followed by loss of peripheral vision. The differential diagnosis includes multisystem atrophy, familial ataxias in mid to late life, any other causes of retinitis pigmentosa, such as adult-onset neuronal ceroid lipofuscinosis, and peroxisomal disorders such as Refsum's disease. The evaluation includes specific analysis for MTATP6*NARP8993 and MTTL1* MELAS3243. Results of metabolic and muscle investigations are usually normal or slightly abnormal, with lactic acidemia only in the more severe cases.

Mitochondrial Myopathies

Mitochondrial myopathies are a ubiquitous accompaniment of most diseases of oxidative phosphorylation in all

classes (I to IV) but can occur as the sole symptom, owing to disorders of class I, II, and IV.^[61] In class I there may be autosomal dominant or recessive presentations with tissue-specific presentations; in class II these may or may not have ragged red fibers; and in class IV the distribution of the myopathy is variable: fascioscapulohumeral, limb-girdle, generalized, with childhood, adolescent, and adult-onset forms. Class IV present usually as singleton cases; familial cases suggest class I and II disorders.

Reye's Syndrome

Reye's syndrome is defined by the Centers for Disease Control and Prevention as an acute, noninflammatory encephalopathy with altered levels of consciousness and liver dysfunction.^[62] The liver disease must include either fatty metamorphosis of the liver or at least a threefold increase in alanine aminotransferase, aspartate aminotransferase, or serum ammonia.

Pathogenesis and Pathophysiology. A growing body of evidence suggests that Reye's syndrome may be a multiorgan disease due to diffuse mitochondrial injury of unknown origin.^[63] Mitochondria in hepatocytes, brain capillary endothelial cells, neurons, cardiac and skeletal muscle fibers, and pancreatic cells show histological damage. Liver mitochondrial enzyme activity is low.^[64] In one study, several depressed electron transport enzymes and lowered ATP/adenosine diphosphate (ADP) ratios were documented.^[62] Epidemiological studies strongly associate three virus infections (influenza B, influenza A, and varicella-zoster (see [Chapter 41](#))) with Reye's syndrome, although the mechanism of their involvement with the pathogenesis of the condition is unclear. There is no evidence of full viral replication in the two primary organs of damage: liver and brain. It has been suggested that viral proteins are toxic, that the infection causes release of toxins, or that the viral infection plus endogenous or exogenous cofactors, such as salicylates, aflatoxins, insecticides, or certain oils, combine to damage liver and brain.

Epidemiology and Risk Factors. Reye's syndrome occurs worldwide. In the United States, from 1982 to 1985, the incidence was approximately 0.3 in 100,000 persons, and the rate has been relatively stable since then.^[62] There is no solid evidence to establish a genetic basis for Reye's syndrome, and only a few cases occur within families.^[65] There may be two epidemiological patterns: (1) an epidemic form, not noted since the 1980s, that occurred mainly in winter and early spring, clustering in time and geographical region, and associated with outbreaks of influenza B and A, and (2) endemic Reye's syndrome with sporadic occurrence and associated with other viral infections, specifically varicella. Most Reye's syndrome cases associated with varicella occur in children between 5 and 9, whereas influenza type B-associated disease occurred in children aged 10 to 14. Salicylate usage has been associated with Reye's syndrome and the reduction in cases seen in the past years has been specifically linked to reduced salicylate ingestion in children.^[67]

Clinical Features and Associated Disorders. The clinical manifestations can be divided into a prodromal phase and the syndrome itself. During the prodrome, there is an upper respiratory tract infection in 60 to 80 percent of cases, and most documented cases have demonstrated influenza B, A, or varicella-zoster virus. During stage I of Reye's syndrome, vomiting is the primary feature. It is not known whether this effect is due to brain stem dysfunction or a systemic cause, but it is usually abrupt in onset and unremitting. The child becomes irritable and gradually lethargic. Most patients recover from this stage and never develop severe agitation and coma. With stage 2, restlessness and disorientation predominate, along with signs of dysautonomia, tachycardia, sweating, and dilated pupils. Seizures may develop, but status epilepticus is rare. With stage 3, coma ensues, with papilledema developing over 2 to 3 days but without lateralizing signs of focal neurological damage. Seizures develop in approximately half of these patients. In stage 4, there is cerebrate posturing and respiratory dysfunction. The coma of stage 5 is associated with flaccid tone and no response to painful stimuli. Brain stem reflexes, like cold caloric testing (see [Chapter 1](#)) are minimal or absent.

Evaluation and Differential Diagnosis. Laboratory studies during the prodromal phase are not diagnostic. Once vomiting develops, alanine aminotransferase and aspartate aminotransferase levels are often very high, often 20 to 30 times normal, but ammonia levels are in the normal range. As coma develops, ammonia levels increase threefold or more over the normal range. Other abnormalities of laboratory tests occur with increases in lactic acid and organic acids, suggesting a blend of respiratory alkalosis and metabolic acidosis, sometimes with hypoglycemia, especially in children younger than 3 years of age. Prolonged prothrombin times develop, but hemorrhaging is rare. The EEG is abnormal with diffuse slowing, and sometimes, burst suppression activity (see [Chapter 24](#)), but there is no specific pattern of diagnostic value. Liver biopsy shows highly characteristic fatty metamorphosis without inflammation. Neuroimaging with CT or MRI shows a normal brain or diffuse cerebral edema with ventricular compression. Diseases that should be excluded in the diagnosis are encephalitis and meningitis, UCDs, BCAA disorders, and other enzyme deficiency states, including propionicacidemia, glutaricaciduria, and disorders of ketogenesis. Finally, inadvertent intoxication with insecticides, salicylates, methyl bromide, margosa oil, and lead can give a combined picture of encephalopathy and hepatic damage in a young child.

Treatment and Prognosis. There is no specific therapy, and management is aimed at monitoring vital functions, correcting liver abnormalities, and controlling increased intracranial pressure until the disease runs its natural course. Hospitalization in an intensive care unit is recommended, because mental status and respiratory function can change abruptly. Salicylates must not be used, and serum glucose levels must be monitored. Vitamin K is often administered, and anticonvulsants are used to treat clinical seizures and sometimes subclinical epileptic activity that is evident on the EEG. Treatment of the hyperammonemia is particularly problematic because dialysis and exchange transfusions do not markedly reduce ammonia levels or improve outcome. Increased intracranial pressure is a major danger, and some centers use monitoring technology

(see [Chapter 26](#)) to provide a constant assessment of shifts in pressure gradients. The goal is usually to keep intracranial pressure below 20 mm Hg with a mean cerebral perfusion pressure (mean blood pressure minus mean intracranial pressure) maintained at 60 to 90 mm Hg.

Overall, mortality currently is 30 to 35 percent. Predictors of poor outcome appear to be young age, especially infants younger than 2 years old; high clinical stage at the time of hospital admission; rapid progression from vomiting to coma; maximal clinical stage; high creatine kinase levels; and ammonia levels above 300 µg/dl at the time of hospital admission. In those surviving, hepatic recovery is full but nervous system residua are many. Behavioral problems include attention difficulties, retardation, and aggressive impulsivity. Neurological problems include hemiparesis and quadriplegia, dysarthria, cortical blindness, and seizures. Even among children believed to have full recovery, 34 percent had measurable deficits in school achievement, visuomotor integration, sequencing, and problem solving.^[68]

FATTY ACID OXIDATION DISORDERS

Besides the mitochondrial enzyme defects characterized by disordered oxidative phosphorylation, 12 disorders of fatty acid oxidation and ketogenesis are known (Table 31-6).^[68] Medium-, long-, and short-chain acyl-CoA dehydrogenase deficiencies (MCAD, LCAD, SCAD) are caused by defects of the beta-oxidation spiral; the rest, except long-chain L-3 hydroxyacyl-CoA dehydrogenase (LCHAD) deficiency, are due to defects in the carnitine cycle.

In these disorders there are three main presentations: (1) acute toxic encephalopathy with episodes of nonketotic hypoglycemia in the first 2 years of life provoked by fasting (MCAD), (2) skeletal and/or cardiac myopathies with weakness (carnitine palmitoyl transferase [CPT] I and II deficiencies, LCAD, LCHAD, SCAD) and low plasma carnitine, and (3) the syndrome of nonketotic hypoglycemia plus very low plasma carnitine levels (<10 μM) and absent dicarboxylicaciduria (carnitine transport defect). The general

TABLE 31-6 -- FATTY ACID OXIDATION DISORDERS

INFANTILE
Medium-chain acyl-CoA dehydrogenase deficiency (MCAD)* (newborn to 14 years)
Long-chain acyl-CoA dehydrogenase deficiency (LCAD, VLCAD)
Short-chain acyl-CoA dehydrogenase deficiency (SCAD)
CPT II deficiency (severe infantile form)
CHILDHOOD
Carnitine transport defect* (3 months to 7 years)
CPT I deficiency
Long-chain L-3 hydroxyacyl-CoA dehydrogenase (LCHAD, trifunctional enzyme)
ADULTHOOD
CPT II deficiency (classical exercise-induced myoglobinuria)* (adult)

*Discussed in text.

approach includes history; physical/neurological examination; routine laboratory studies, particularly including liver and urine function tests and determination of electrolytes, pH, lactate, pyruvate, ammonia, blood glucose, and urine ketones; blood free carnitine and acylcarnitines; and urine gas chromatography/mass spectrometry for organic acids. This is followed by specialized techniques, including specific biochemical enzymatic analysis and molecular analysis. Because the enzymes in the beta-oxidation spiral exist in different forms with chain specificities that overlap and because oxidation of unsaturated fatty acids requires different enzymes, it is expected that other diseases of fatty acid oxidation involving enzymes in these steps will be described in the future.

Medium-Chain Acyl-CoA Dehydrogenase Deficiency

The optimal chain length specificity of MCAD is 8 carbons. The ability to oxidize fatty acids beyond medium-chain length is impaired 20 percent or less of control rates in cultured fibroblasts. Light microscopy of liver in acute cases shows steatosis, which disappears on recovery. The hepatic mitochondria show increased matrix density and intracrystal widening, giving a condensed appearance. There may be crystalloids in the matrix. These are in contrast to the findings of Reye's syndrome, in which electron microscopy shows matrix swelling and rarefaction. MCAD is the most common mitochondrial beta-oxidation disorder, with an estimated frequency being 1 in 10,000 to 20,000. Previous unexplained sibling deaths should raise MCAD as a possible diagnosis.

Most patients present between ages 3 and 15 months, rarely after 4 years. Phenotypical heterogeneity prevails, ranging from sudden infant death syndrome, to recurrent Reye's-like syndrome, to episodic nonketotic hypoglycemic coma. A common presentation is vomiting and lethargy, followed by fasting, associated with a prior viral respiratory or gastrointestinal infection. Presentation is usually to an emergency department as an acute toxic encephalopathy or coma, with hypoketotic hypoglycemia, hyperammonemia, and abnormal liver function tests. The serum carnitine value is low, and urine acylcarnitines are increased, with a specific profile. Enzyme assay for MCAD activity can be done on cultured skin fibroblasts, muscle, liver, or blood lymphocytes. The differential diagnosis includes other fatty acid oxidation disorders, exogenous toxic encephalopathies, and true Reye's syndrome. Specific management involves intravenous dextrose 10 percent, avoidance of fasting with frequent short feeds, L-carnitine 100 mg/kg/day in divided doses orally, and preventive management by neonatal screening of subsequent siblings and screening with acylcarnitine profiles of present siblings. The risk of death with the first episode (sudden infant death syndrome presentation) is about 20 percent. In delayed treatment there is a risk for developmental retardation, speech and language delay, behavioral problems and attention deficit disorder, muscle weakness, seizures, and failure to thrive.

Carnitine Transport Defect: Primary Generalized Carnitine Deficiency

Carnitine fails to be taken up in muscle, heart, and kidney but not liver, leading to insufficient carnitine to support fatty acid oxidation.^[70] The kidney fails to conserve carnitine by reabsorption, resulting in very low plasma carnitine levels, which then causes decreased passive diffusion into liver, impairing ketogenesis. Accumulating acyl-CoA compounds become substrates for peroxisomal beta-oxidation, which produces medium-chain fatty acids and dicarboxylic acids, which do not require carnitine for mitochondrial entry. They are then completely oxidized in mitochondria, which is the reason for lack of dicarboxylicaciduria in disorders of the high-affinity carnitine transporter. Treatment with L-carnitine restores plasma levels to normal (40 to 60 μM) but not skeletal muscle. Muscle function can be restored, however, with less than 10 percent normal muscle carnitine levels. This is a rare disorder, and the exact incidence is unknown. There are two major types of presentation, an early one (3 months to 2½ years) with nonketotic hypoglycemia, and a later one (1 to 7 years) with cardiomyopathy. The nonketotic hypoglycemia in the early presentation is accompanied by hyperammonemia and elevated alanine and aspartate aminotransferase levels, which may present after a short fast, particularly if the patient is being fed a carnitine-free formula. The cardiomyopathy in the later presentation is progressive, with cardiac decompensation and respiratory distress, and is often accompanied by skeletal muscle weakness. Mild to moderate anemia, nonresponsive to iron, may be present. Very low plasma carnitine levels (<10 μM) and absent dicarboxylicaciduria are practically pathognomonic of a carnitine transporter defect. The differential diagnosis includes carnitine deficiencies secondary to other disorders of the carnitine cycle, in which medium and long-chain acylcarnitines that accumulate from the metabolic block may induce a defect in tissue uptake of free carnitine. In this primary disorder the diagnosis is established by measuring carnitine uptake by fibroblasts and leukocytes (<10 percent of control rates). In the nonketotic hypoglycemia presentation, management involves the intravenous use of glucose and the long-term oral administration of L-carnitine at 100 to 120 mg/kg/day in two to three divided doses. Oral L-carnitine doses can be higher in the cardiomyopathy presentation, up to 175 mg/kg/day.

Carnitine Palmitoyl Transferase II Deficiency

In CPT II deficiency, long-chain acylcarnitines are transported across the inner mitochondrial membrane but cannot be converted to their corresponding long-chain acyl-CoAs. They accumulate in the mitochondrial matrix and are transported out into plasma. These elevated levels may produce cardiac arrhythmias. Dicarboxylicaciduria is absent, because of the same explanation given for carnitine transport defect. The exact incidence is unknown, but the adult form is more common than the infantile form. Risk factors are fasting and prolonged exercise.

There are two presentations: the adult muscular form, in which prolonged exercise induces weakness and myoglobinuria, and a severe infantile form, in which nonketotic hypoglycemic coma without dicarboxylicaciduria, seizures, hepatomegaly, cardiomegaly, and cardiac arrhythmia are accompanied by low plasma and tissue levels of carnitine with increase in long-chain acylcarnitines. The classic adult form is autosomal recessive and usually affects males between 15 and 30 years of age. The serum creatine kinase value is normal between episodes, carnitine levels are usually normal in plasma and tissues, and long-term muscle weakness is rare, although lipid storage may be seen on muscle biopsy. The differential diagnosis includes other carnitine cycle disorders. Management involves supportive treatment of the renal failure and measures to remove the myoglobin from kidney and avoidance of triggering factors--prolonged exercise, exposure to cold, infections, and fasting. Presentation in the neonatal period usually ends in death. In the adult form, about a fourth of patients develop renal failure secondary to the episodic

myoglobinuria.

[PreviousNext](#)

OTHER METABOLIC DISORDERS

Various Transporter Defects

HARTNUP'S DISEASE

Hartnup's disease is an autosomal recessive transport disorder of neutral amino acids, affecting the kidney and small intestine and leading to excessive neutral aminoaciduria 5 to 20 times normal.^[71] These monoamino/monocarboxylic amino acids include alanine, glutamine, histidine, serine, phenylalanine, tyrosine, tryptophan, asparagine, leucine, isoleucine, and valine but not proline. Plasma levels are normal. These same amino acids, particularly tryptophan, are retained in the gut and broken down by bacteria; and their breakdown products, indolic compounds, are excreted in the urine. Because tryptophan is excessively excreted in urine and not reabsorbed in the gut, it is not available for synthesis of niacin. Many subjects are discovered to have the aminoaciduria but have no clinical manifestations (Hartnup's disorder). When the disorder is symptomatic, it is called Hartnup's disease; and the main clinical manifestations are probably due to niacin deficiency, although the excessive indolic compounds may contribute to a metabolic encephalopathy. The actual carrier in the transport system or the gene responsible has not been identified. The biochemical phenotype is common, occurring in 1 in 30,000 newborns screened. However, only 10 percent or less actually develop the classical clinical phenotype. To develop the disease, multiple factors are probably involved--environmental, such as poor nutrition or intestinal diarrhea; and polygenic, such as low plasma amino acid levels that interact with the primary monogenic defect. Males and females are equally affected. Consanguinity in parents and affected siblings occurs not uncommonly. The disorder is worldwide and not associated with other genetic disorders.

The earliest clinical findings are photosensitive skin,

leading to the pellagra-like rash in late infancy or early childhood. Later, episodic neuropsychiatric symptoms appear--intermittent cerebellar ataxia and emotional lability to psychoses--together or separately and often triggered by poor nutrition and diarrhea, fever, or sun exposure. EEGs are nonspecific, and CSF studies are normal. Partial expressions, such as intestinal or renal tubular defects alone, may be seen. The differential diagnosis includes any cause of acute cerebellar ataxia in childhood: postinfectious cerebellitis, brain stem encephalitis, posterior fossa tumor, and vestibular neuronitis. When attacks are intermittent, particularly with the mental symptoms, episodic disturbances such as nonconvulsive status epilepticus, acute confusional migraine, other toxic-metabolic encephalopathies, or demyelinating disease should be considered. The rash with neurological signs should bring to mind other vitamin deficiency diseases, such as thiamine or biotinidase deficiency.

The evaluation involves simple urine amino acid chromatography, which will detect the neutral aminoaciduria, and oral loading tests with L-tryptophan, which will detect the indoluria. No consistent picture of abnormalities has arisen from brain CT, MRI, and PET studies. To treat symptomatic subjects, nicotinamide, rather than nicotinic acid, is given orally at 50 to 300 mg/day. Both the rash and ataxia respond. A high protein diet may help prevent attacks in those with low plasma amino acid resting levels. Although mental retardation may occur, dementia does not. There may be learning difficulties, but most patients have normal mentation. Further specific therapy awaits elucidation of the specific membrane transport carrier system and whether the defect is of transport activation, regulation, or direct transporting, as well as mapping and cloning of the gene. As yet there are no animal models.

MENKES' DISEASE

Menkes' disease, an X-linked disorder in which insufficient intestinal absorption of copper leads to deficiency of copper-requiring enzymes, is now known to be due to a gene located at Xq13.3.^[72] The gene product belongs to a highly conserved family of cation-transporting ATPases, which function in the transport of ions across cellular and intracellular membranes. The low serum copper levels, the high tissue levels (particularly intestinal mucosa, except liver), and studies from patients' cultured cells strongly suggest that the basic pathogenetic defect is the failure of a plasma membrane pump that usually extrudes copper from cells or the failure of a pump that ordinarily transports copper into an intracellular organelle-like endoplasmic reticulum. Deficient activity of copper-requiring enzymes explains the symptoms and signs. Deficiency of dopamine beta-hydroxylase, critical to the catecholamine synthesis pathway, may be related to autonomic abnormalities due to decreased sympathetic adrenergic function. Cytochrome-c oxidase deficiency probably can be related to hypotonia, weakness, and the lesions similar to those seen in Leigh's disease, without severe lactic acidosis associated with complex IV respiratory chain defects. Reduced lysyl oxidase activity relates to the arterial tortuosity and other connective tissue disorders. Reduced tyrosine hydroxylase leads to lack of pigmentation. Partial loss of copper-zinc superoxide dismutase (Cu-Zn SOD) could lead to oxidant stress and cytotoxicity because of lack of defense against oxygen free radicals. The incidence is estimated to be 1 in 100,000 to 250,000 live births, a rare condition. One third of the estimated 15 to 30 infants born annually in the United States are predicted to be nonfamilial new mutations.

Male infants usually present at 2 to 3 months with developmental arrest and regression, hypotonia, seizures, and failure to thrive. Seizures are an early presentation, are frequent, and are multifocal myoclonic jerks that are often stimulus-precipitated. Recurrent hypothermia and infections occur. The near-pathognomonic clinical sign is scarce, colorless, wiry, friable hair on scalp and eyebrows and, under the microscope, the characteristic appearance of pili torti (twisted hair shaft). Secondary microcephaly occurs later. A mild Menkes' disease variant occurs, with later onset and milder neurological findings. The occipital horn syndrome, another variant, has few mental or neurological signs but calcified occipital horns, changes in clavicles and long bones, and sometimes chronic diarrhea and arterial changes. The differential diagnosis includes any early infantile progressive encephalopathy presenting with seizures, such as storage disease (Tay-Sachs disease, Sandhoff's disease, infantile neuronal ceroid lipofuscinosis), aminoacidurias (nonketotic hyperglycinemia), disorders of biogenic amine metabolism (folinic acid-responsive seizures), mitochondrial diseases (Alpers' disease), sulfite oxidase deficiency, glucose transporter deficiency, or the nonprogressive infantile myoclonic epilepsies. To make the diagnosis, the clinical picture, along with typical radiological features (osteoporosis, scalloping of vertebral bodies, excessive wormian bone formation), microscopic examination of the hair, and very low levels of serum copper and ceruloplasmin after the neonatal period, is sufficient. Cultured skin fibroblasts show increased copper content. In families at risk, prenatal diagnosis and heterozygote carrier detection can be done by biochemical and mutational analysis of cultured amniocytes or chorionic villi. The therapeutic strategies must (1) bypass the block in intestinal copper absorption; (2) supply copper to intracellular enzymes that require it for a cofactor; and (3) identify and treat patients early, preferably presymptomatically. Intravenous copper histidine bypasses the intestinal block but produces no substantive neurological improvement nor increases life span. Therapy with vitamins C and E has been ineffective. Supportive care includes maximizing caloric intake, physical and occupational therapy, psychosocial support of families, and, most importantly, genetic counseling. Children usually die by the age of 3. Future treatments might explore the principle that lipid-soluble complexes can increase copper transport through cellular membranes. Gene therapy would be difficult because of the widespread, multisystem involvement and awaits functional characterization of the transport protein and progress in developing gene delivery systems to the brain.

GLUCOSE TRANSPORTER DEFICIENCY (DEVIVO DISEASE)

The erythrocyte glucose transporter is homologous to that in the brain, with both facilitating the diffusion of glucose across lipophilic plasma membranes.^[73] This condition is due to defective functioning of the type 1 glucose

transporter (GLUT1) in brain microvessels at the blood-brain barrier, causing low CSF glucose (hypoglycorrachia) and therefore decreased cerebral energy metabolism and brain function. GLUT1 is coded by a gene localized to chromosome 1 and is developmentally regulated, with the messenger RNA in brain increasing with increasing cerebral metabolic rate for glucose in infancy and childhood. Symptoms occur when this rate increases in early infancy, doubling or tripling that in the neonatal and fetal periods. This is a very rare condition, probably a spontaneous mutation, with patients being symptomatic heterozygotes.

At about age 3 months, a perfectly normal infant develops seizures--myoclonic, atypical absences, or unclassifiable--that are refractory to antiepileptic drugs. Developmental delay occurs the longer seizures are uncontrolled and the diagnosis is undiscovered, which can culminate in mental retardation and secondary microcephaly. The differential diagnosis includes any disease or condition causing refractory seizures in early infancy (see section on Menkes' disease). In this disorder, CSF glucose is 30 mg/dl or lower, with a reduced CSF/blood glucose ratio (about 0.33). CSF lactate is also low (0.97 mM/L or less). EEGs and neuroimaging studies are normal. Treatment involves seizure control with a ketogenic diet, because the diet provides ketone bodies as an alternative source of fuel for brain metabolism. The prognosis for seizure control and normal development is excellent, with early diagnosis and treatment. It is likely that the defect becomes less consequential with age as the cerebral metabolic rate for glucose slows down to adult levels.

Lesch-Nyhan Disease (Hypoxanthine- Guanine Phosphoribosyltransferase Deficiency)

Lesch-Nyhan disease is an X-linked recessive disease involving abnormal purine metabolism. The disorder is due to complete deficiency of hypoxanthine-guanine phosphoribosyltransferase (HPRT), an enzyme necessary for the recycling of free purine bases and reversion into their nucleotide forms, after nucleotides are metabolized during DNA or RNA synthesis or after serving as coenzymes.^[74] Specifically, if HPRT is deficient, hypoxanthine, a free purine base, cannot be reconverted back to inosine 5

- monophosphate (IMP), from which adenosine 5

-monophosphate (AMP) and guanosine 5

-monophosphate (GMP) are synthesized by separate pathways. There is an acceleration of the de novo purine biosynthesis pathway, so hypoxanthine is converted, by xanthine oxidase, to uric acid, resulting in hyperuricemia. However, the hyperuricemia does not explain the neurological symptoms, the pathophysiology of which is essentially unknown. Based on animal models, speculation is that self-injurious behavior may be related to supersensitivity of the D₁ subclass of dopamine receptors. Autopsies have revealed no specific cerebral gross anatomical or histopathological findings.

Incidence is rare, perhaps 1 in 380,000 births. The disorder occurs in many racial groups equally and is not more frequent in consanguineous populations. Patients are normal at birth, but by 6 months, developmental delay is evident. Axial hypotonia but appendicular spasticity and choreoathetoid movements appear in late infancy, and "cerebral palsy" is usually diagnosed at this time. The diagnosis is usually suspected in the toddler and early childhood years, when various kinds of compulsive self-mutilation, usually biting of lips, cheeks, or fingers, occur. Dysarthria makes communication difficult, and excitation may stimulate opisthotonus or torsion dystonia. Compulsive aggression can be directed toward anyone near the patient, including family members, and includes hitting as well as abusive language. Associated disorders are various hematological disorders, growth retardation, renal stones, and gouty arthritis if patients survive to adulthood.

Before the self-mutilating symptoms, other causes of nonprogressive or progressive extrapyramidal "cerebral palsy" should be considered, such as kernicterus, glutaricaciduria type 1, bipterin-dependent phenylketonuria, or biotinidase deficiency. Although some severely mentally retarded children of any etiology have self-abusive behaviors, such as head-banging, the relentlessness and compulsiveness of the self-injurious behavior in Lesch-Nyhan disease is extreme and unique.

The main clinical sign is self-injurious behavior resulting in tissue loss. Enzyme activity of HPRT can be assayed by radiochemical methods from dried blood spots, cultured skin fibroblasts, and hair follicle cells in probands and suspected female carriers. Biochemical analysis must be confirmed by molecular genetic analysis, particularly for female carriers. The entire HPRT locus has been sequenced, and the mutations in Lesch-Nyhan disease are extremely heterogeneous. The majority are detected by polymerase chain reaction-based techniques, usually amplification of genomic DNA and direct sequencing. In a small percentage, Southern blot analysis using HPRT complementary DNA as a probe is necessary to detect translocations or duplications.

Allopurinol, a xanthine oxidase inhibitor, decreases blood uric acid effectively but has no effect on the neurological symptoms. The following have been ineffective: folate, glutamine, magnesium, chlorpromazine, L-tryptophan, and clomipramine. Treatment with L-5-hydroxytryptophan plus carbidopa has been temporarily beneficial, but self-injurious behaviors re-emerge after discontinuing treatment or tolerance develops. Behavior modification--extinction, reinforcement of alternative behavior, or aversion therapy--shows inconsistent results. Physical restraints to prevent tissue injury are the most effective and include upper extremity splints to keep the arms straight, tying legs to wheelchairs so they cannot be brought up to the mouth, and dental guards to avoid teeth extraction as an extreme preventive measure.

Most patients are mentally retarded and do not stand or walk. Death frequently occurs during childhood. A patient with Lesch-Nyhan disease should be an ideal candidate for gene replacement therapy. The problem is to transfect an appropriate vector that would target brain cells, because neurological signs would not likely be affected by simple transplantation of infected cultured bone marrow cells into receptive hosts. Prenatal diagnosis using mutation detection and linkage analysis can detect 100 percent of affected males and excludes women who are suspected carriers if that family's HPRT mutation is known.

Porphyrrias

Porphyrrias are caused by enzymatic defects in the heme pathway. There are several forms, each with similar neurological findings, highlighted by abdominal pains and peripheral neuropathy. Those with autosomal dominant inheritance include acute intermittent porphyria (AIP), due to porphobilinogen deaminase deficiency, hereditary coproporphyrin (HCP) due to coproporphyrin oxidase deficiency, and variegate porphyria (VP), due to protoporphyrin oxidase deficiency. An autosomal recessive condition characterized by deficiency in delta-aminolevulinic acid dehydratase has been described.

In AIP, although the enzymatic defect is constant throughout life, neuropathic crises are interspersed between long periods of near-normal function. Abdominal pain usually is the initial symptom of a neuropathic attack, followed by a subacute motor neuropathy that may ascend from the feet, resembling Guillain-Barre syndrome. Facial, bulbar, and extremity weakness develops in most cases. Electromyographic studies help in distinguishing AIP from demyelinating neuropathy, since in the former, denervation and evidence of axonal neuropathy is more pronounced than slowed conduction velocities. In addition to these typical neuropathic signs, dysautonomia may be pronounced and lead to cardiac arrhythmias, blood pressure instability, and urinary retention. Neurobehavioral signs indicative of CNS involvement include psychotic behavior, delirium, and seizures, although the seizures are usually due to hyponatremia and inappropriate release of antidiuretic hormone.^[75]

Although the crises of AIP may be spontaneous in onset, certain risk factors are identified, including infection, ingestion of alcohol, and use of a large variety of drugs, including anticonvulsant medications. The diagnosis of AIP depends on the clinical presentation of intermittent painful crises, behavioral alterations, and neuropathy with excessive urinary excretion rates of delta-aminolevulinic acid and porphobilinogen. Treatment involves special dietary changes at the earliest sign of an attack. Patients must immediately increase their carbohydrate intake; and if this maneuver does not abort the crisis, intravenous dextrose and hematin should be given to prevent activation of hepatic delta-aminolevulinic acid synthetase. In light of the large number of drugs associated with exacerbation of AIP crises, the control of the painful abdominal cramps is problematic, although low-dose narcotics may be used in many patients, sometimes supplemented with very low doses of benzodiazepine derivatives.^[76]

HCP is much rarer than AIP. The neuropathic and systemic clinical manifestations of the two conditions are the same, except that a distinctive cutaneous photosensitivity occurs in one third of the HCP patients. Like AIP, HCP is punctuated with crises of neurological dysfunction that are precipitated by drugs, infections, and alcohol. HCP has a characteristic metabolic profile with elevated urinary and fecal coproporphyrins. Similar to AIP, delta-aminolevulinic acid and porphobilinogen are found in the urine but also found is coproporphyrin, a product not found in AIP. Enzyme assays for coproporphyrin oxidase will demonstrate the deficiency, but this test is not readily available.^[77]

VP is particularly found in southern Africa. It mimics AIP and CHP clinically, and photosensitivity is common.^[78] In addition, a variety of skin lesions, including hyperpigmentation, hypertrichosis, vesicles, and bullae, are seen in patients with VP. Excretion patterns are similar to those of HCP, except the excreted amount of porphobilinogen exceeds coproporphyrin in VP whereas they are approximately equal in HCP. Treatment is the same as for AIP and HCP.

Finally, delta-aminolevulinic acid dehydratase deficiency is unique in being an autosomal recessive disorder. Neurological findings, as well as systemic and dermatological signs, mimic those of the other porphyrias, and the differentiation is made exclusively on the biochemical findings of enzyme deficiency and the high urinary excretion of delta-aminolevulinic acid without porphobilinogen.^[79]

HISTORY AND DEFINITIONS

During the last several decades, information about chromosomal abnormalities has increased rapidly. Until recently, however, identified aberrations were limited to quantitative abnormalities of increased or decreased chromosomal material. Newer techniques have enabled us to identify numerous deletions and highly specific duplications, or translocations, which ultimately result in qualitative abnormalities of genes. Recombinant DNA techniques provide powerful tools for the definition of inherited neurological diseases and allow us to identify and define regulatory events that are the basis of cellular differentiation and embryogenesis.

Cognitive impairment is the primary neurological ramification of chromosomal abnormalities; however, most early reports of this finding were based on the study of individuals who were severely retarded. These individuals may have had multiple congenital anomalies with or without associated chromosomal disorders. Furthermore, various chromosomal anomalies may occur in seemingly normal adults with no obvious intellectual deficits.

This chapter focuses first on a number of clinical syndromes in which there are conspicuous neurological sequelae of chromosomal abnormalities and then on the most common neurocutaneous syndromes.

CHROMOSOMAL ANOMALIES

Autosomal Abnormalities

TRISOMY 21 (DOWN'S SYNDROME)

Pathogenesis and Pathophysiology. Several cytogenetic variants can produce Down's syndrome, and trisomy 21 is the most frequent. In this variant, Down's syndrome is due to an extra chromosome 21 or parts of it.^{1,2} Trisomy of subbands 21q22.1 to 22.3 of the distal part of the long arm of chromosome 21 is the smallest component sufficient to cause Down's syndrome. In patients with trisomy 21, the genes on the extra segment of the chromosome are not found in a double dose as is normal but are tripled. In approximately 1 to 2 percent of cases, Down's syndrome occurs in the setting of mosaicism, in which there are two or more cell populations. Each cell population has a different karyotype, and one has a trisomy 21. The fusion of chromosome 21 with another acrocentric chromosome, most commonly chromosome 14, 21, or 22, may also result in a clinical syndrome that does not differ from that produced by the triplication of the subband 21q22. Finally, a rare familial form of Down's syndrome has been reported that may result from familial mosaicism, maternal trisomy 21, or other cytogenetic causes. The exact method by which these chromosomal anomalies cause the clinical sequelae of Down's syndrome has yet to be determined.

Epidemiology and Risk Factors. Down's syndrome is the most common autosomal chromosomal abnormality in human live births that results in structural malformations associated with developmental retardation. This disorder occurs in about 1 of 1000 neonates, and the frequency of trisomy 21 increases with maternal age. While familial forms of Down's syndrome are rare, the risk of a mother having a second affected infant is approximately 0.5 percent. In a child with a translocation, chromosomal karyotyping should be performed in both parents, since if one parent has the translocation, the risk of having a similarly affected child is much higher.

Clinical Characteristics and Associated Disorders. The physical characteristics of patients with Down's syndrome are commonly recognized in the first month of life, if not in the newborn nursery. Common features include

brachycephaly with a round face, Brushfield's spots, a small mouth and a large protruding tongue, small ears, epicanthal folds with upslanting palpebral fissures, and a flattened or depressed nasal bridge. Although epicanthal folds and a transverse simian palmar crease are considered characteristic of Down's syndrome, they are found in only 50 percent of these patients. Brachydactyly and clinodactyly of the fifth finger are observed more commonly than the simian palmar crease. There is a widened space between the first and second toes.

In addition to the typical phenotypic features of the syndrome, associated congenital cardiac and gastrointestinal abnormalities may be present. A third to a half of patients with Down's syndrome have congenital cardiac defects, of which one third are endocardial cushion defects, and the remainder are ventricular septal defects. Tetralogy of Fallot and atrial septal defects also occur, and there is an increased incidence of moyamoya disease. More than half of patients have bilateral hearing loss, of which many cases are attributable to anomalies of the inner and middle ear. Malformations of the gastrointestinal tract, including intestinal atresia and imperforate anus, occur in about 5 to 7 percent of patients, and there is a reported increased incidence of Hirschsprung's disease. Although abnormalities of T-lymphocyte function have been reported, no specific relationship of these to the infection rate has been established. Other associated abnormalities include gastroesophageal reflux, pulmonary hypertension, upper airway obstruction, obstructive sleep apnea, and an increased incidence of thyroid dysfunction, diabetes mellitus, cataracts, and leukemia.

The major neurological features of Down's syndrome are developmental delay and severe, diffuse muscular hypotonia, which affects most patients. Convulsive disorders are also more commonly present in these patients. The pathogenesis of the convulsive activity in this population is probably multifactorial and may result from a combination of medical risk factors and inherent neurological abnormalities. As individuals with Down's syndrome age, however, other neurological signs may appear. About 20 percent of patients complain of neck pain or discomfort, and they may demonstrate torticollis, gait impairment, or corticospinal tract dysfunction. These features are believed to be related to atlantoaxial subluxation and instability and result in compression of the medulla and spinal cord.

By about the fourth decade of life, additional deterioration of cognitive function may become apparent. This deterioration has been attributed to dementia, which results from a degenerative process that has neuropathological similarities to Alzheimer's disease.^{1,2} Olfactory abnormalities may also appear, and these can pre-date the onset of dementia by 10 to 15 years.^{1,2}

Differential Diagnosis. It is impossible to distinguish the clinical features of Down's syndrome resulting from the "typical" trisomy 21 from those resulting from translocation. Other chromosomal abnormalities should be considered, but the phenotypic features and neurological signs generally make the diagnosis clear.

Evaluation. The diagnosis of Down's syndrome is made by the presence of the typical physical abnormalities and can be confirmed by chromosomal karyotype. Radiological studies such as plain skull films may demonstrate a brachycephalic skull in which the anterior fontanelle and metopic suture close late. Computed tomography (CT) may show calcifications in the basal ganglia and a large opercula, while magnetic resonance imaging (MRI) reveals evidence of delayed myelination in some cases.^{1,2} Other MRI studies have demonstrated smaller hippocampal and neocortical structures in patients with Down's syndrome compared to controls.^{1,2} Additionally, these investigations suggest that patients with Down's syndrome develop signs associated with brain aging at an earlier age than normal; these signs include increased rates of ventricular dilatation, peripheral atrophy, and deep white matter lesions. The electroencephalogram (EEG) may be abnormal and can become progressively disorganized with the evolution of Alzheimer's type dementia. Reports of postmortem evaluation have noted the presence of a small, spherical brain and a cerebellum that is reduced in size. Microscopic abnormalities include reduced neuronal density in cortical regions, a loss of cortical interneurons, a reduction in the number of spines along pyramidal cells, and an accumulation of undifferentiated fetal cells in the cerebellum. Abnormalities in the basal nuclei of the brain include a reduced cell count that shows a continued steady decline with age. In nearly all subjects who die after reaching the age of 35, changes consistent with Alzheimer's disease are found.

Management and Prognosis. There is no specific treatment for Down's syndrome. Compared to the general population, these patients have increased morbidity and mortality, primarily from cardiac causes.

TRISOMY 18 (EDWARDS' SYNDROME)

Edwards' syndrome^{1,2} is the second most common autosomal chromosomal abnormality associated with an extra autosome. The incidence of trisomy 18 is 0.3 per 1000 live births, and females are affected more often than males (3:1). In the majority of patients the entire chromosome 18 is trisomic, whereas other affected patients may have a mosaic state of partial trisomy. This anomaly is more frequent in the offspring of older mothers. A history of decreased in utero activity is typical, and there is an even distribution of premature, normal term, and postmature neonates with this disorder. Affected infants have a feeble cry, decreased adipose and subcutaneous tissue, and a paucity of muscle bulk. The face is generally small with a high nasal bridge, short palpebral fissures, ptosis, small mouth, narrow palate, and micrognathia. The hands are clenched, with the second finger overriding the third and the fifth overriding the fourth. The nails are hypoplastic, especially those on the fifth fingers and toes. Other commonly associated findings include rocker-bottom feet, a short sternum, small pelvis, umbilical and inguinal hernias, and diastasis recti. The skin can be redundant, and hirsutism of the head and back is notable. Cardiac malformations include ventricular and atrial septal defects and patent ductus arteriosus.

No consistent central nervous system (CNS) abnormalities are found in this disorder, but agenesis of the corpus callosum is the most common anomaly and may be associated with cerebellar or cerebral white matter heterotopias.

In those individuals who survive early infancy, severe mental retardation may occur. No specific therapy is available for patients with this syndrome. About half of patients expire before the age of 6 months, and only 10 percent survive 1 year.

TRISOMY 13 (PATAU'S SYNDROME)

The incidence of this trisomic syndrome, which occurs primarily in the offspring of older mothers, is approximately 1 in 7000, and it affects mainly females.^[1] It should be noted that translocation can also result in this syndrome, but mothers of these children are usually younger. The clinical characteristics of this syndrome include multiple congenital anomalies with varying degrees of mid-facial anomalies. Infants may have ophthalmic abnormalities including anophthalmia, cyclopia, microphthalmia, and colobomas. Facial defects, such as cleft palate and lip and micrognathia, can also occur. A variety of congenital cardiac abnormalities such as ventricular or atrial septal defects and patent ductus arteriosus may be present. Intestinal malrotation, Meckel's diverticulum, and a spectrum of urogenital structural abnormalities are commonly seen. Polydactyly, with the third and fifth fingers overlapping the fourth, occurs in most affected infants. Neurologically, patients have developmental retardation as well as an increased frequency of neural tube defects and microcephaly. Pathologically, the most common abnormality is arrhinencephaly, and this may be associated with the absence of the interhemispheric fissure and the olfactory bulbs and tracts as well as with a single ventricle. Sample case reports have also noted the presence of corpus callosum lipomas and frontal cranial defects. As in infants with trisomy 18, heterotopias in the cerebellum and cerebral white matter may be observed. As is true of other trisomic conditions, no specific therapy is available. The average length of survival is about 9 months, and about 90 percent of affected patients die before the age of 12 months.

PRADER-WILLI SYNDROME

The Prader-Willi syndrome is a sporadic disorder that occurs in about 1 in 20,000 live births and has a risk of recurrence in the same family of about 1 in 1000. The responsible abnormality on chromosome 15 can be documented by cytogenetic studies, and in about 50 percent of patients there is a deletion at 15q11-q13. The disorder that produces Angelman's syndrome has the same gene locus. The use of cytogenetic techniques and DNA polymorphisms has made it possible to discern the origin of the parental deletion. Patients with Prader-Willi syndrome inherit the chromosomal disorder from their father, whereas patients with the Angelman syndrome inherit the chromosomal abnormality from their mother.^[2]

Mothers of infants with the Prader-Willi syndrome note decreased in utero fetal activity, and often these neonates are born in breech presentation. The affected individuals are of short stature and have small hands and feet and a narrowed cranial bifrontal diameter.^[3] Their eyes are almond-shaped, and they often have strabismus. The face is long, and nearly 50 percent of patients have hypopigmentation of the skin. Other common features include a small phallus, cryptorchidism, and hypogonadism with a small flat scrotum. Affected infants have a feeble suck and severe hypotonia, which commonly requires the use of a feeding tube. Near the end of the first year of life, however, the hypotonia may become less severe. The degree of mental retardation may seem more prominent in early life and may be correlated with the severity of the hypotonia. At 1 to 3 years of age the patients gain considerable weight and become obese because of hyperphagia. As the hypotonia becomes less severe, they also seem to be more mentally alert, yet the intelligence level usually ranges from an IQ of 40 to 60. Although the primary explanation for the short stature, hyperphagia, and hypogonadism has not been specifically defined, there is evidence that suggests the presence of primary hypothalamic dysfunction. Recent improvements in MRI scanning techniques have demonstrated anomalous cortical growth on the banks of the Sylvian fissure in some children with Prader-Willi syndrome.^[4] These "growths" are seen even more frequently in children with Angelman's syndrome and are thought to represent misrouting of long projection axons. Electrophysiological studies and muscle biopsies have failed to reveal any clues to the cause of the severe hypotonia seen in these patients. At the present time, no direct therapy is available for the neurological aspects of this disorder.

Sex Chromosomal Abnormalities

KLINEFELTER'S SYNDROME

This syndrome, characterized by a 47XXY chromosomal karyotype, is the most common human sex chromosomal aberration and is associated with the sex chromatin-positive form of seminiferous tubular dysgenesis. The frequency of the 47XXY karyotype is reported to be 0.9 in 1000; 0.15 in 1000 have a mosaic form. About half of patients with a 47XXY disorder die in utero.

Affected children have small, firm testes, and adult patients have azoospermia.^[5] This disorder is a common cause of primary hypogonadism and male infertility. Although a male phenotype is typical, delayed or poorly developed secondary sex characteristics are present, and about half the patients have varying degrees of gynecomastia, androgen deficiency, and eunuchoid features. These patients tend to be tall and have long legs, and adults have an increased incidence of pulmonary disease, varicose veins, diabetes mellitus, and breast cancer.^[6] Serum levels of follicle-stimulating hormone and luteinizing hormone are increased early in the second decade, whereas testosterone concentrations are normal to low. Plasma levels of estradiol are normal or high. Affected individuals have cognitive abnormalities including impaired auditory sequential memory with delayed language development and associated learning disorders.^[7] There is a slight lowering of the mean IQ and an increased incidence of behavioral and personality abnormalities. A higher than normal prevalence of postural tremor has been reported, but the findings have not been replicated.

If androgen deficiency is present, administration of testosterone may produce an improvement in the secondary

sexual characteristics and increase the general well-being of the patient. Testosterone therapy may also lessen the degree of gynecomastia, but in those patients with notable breast enlargement, surgical reduction of the breast tissue may be important for cosmetic reasons.

XYY SYNDROME

The incidence of this abnormal sex chromosomal karyotype is about 1 in 1000 live male births. These patients have a normal male phenotype, although cryptorchidism and hypogonadism have been known to occur. Tall stature and acneiform eruptions are common characteristics. Although earlier studies suggested that affected patients had inordinately aggressive, impulsive behavior, this finding has not been reliably substantiated. Most patients have normal behavior, and their intelligence tends to be low normal. Delayed acquisition of speech and language skills may also be present. Other minor neurological findings include postural tremor and motor incoordination.

TURNER'S SYNDROME

Turner's syndrome, a form of gonadal dysgenesis resulting from a 45,X karyotype (X-chromosomal monosomy), is characterized by female phenotype, short stature, a shieldlike chest, a short and sometimes webbed neck, low-set ears, high-arched palate, small mandible, and sexual infantilism.^[8] The frequency of 45,X in female live births is 0.1 to 0.6 per 1000. A variety of other malformations can be associated, including congenital lymphedema, particularly of the hands and feet, cardiac and renal defects, skeletal anomalies, and abnormalities of the nails. An increased number of pigmented nevi has also been reported. Other disorders have been associated with this disorder, including Hashimoto's thyroiditis, obesity, inflammatory bowel disease, and rheumatoid arthritis. Nerve deafness occurs in approximately half the patients, and olfactory as well as taste deficits have been described. Eighteen percent of patients studied in one series were mentally retarded, although this high prevalence may be due to selection bias. The absence of the X chromosome does not cause intellectual impairment per se, but the majority of these patients have right-left disorientation and defects in perceptual orientation.^[9]

Psychological tests demonstrate that girls with Turner's syndrome perform poorly on visuospatial and intellectual measures and have difficulty with attention and social behaviors compared with age-matched controls.^[10] Others have reported that Turner's syndrome patients have significantly lower scores on all the Wechsler adult intelligence scale tests except verbal comprehension and reading level.^[11] The most significant difference is found in the visuospatial construction. Volumetric brain measures derived from MRI reveal no differences in overall cerebral or subcortical volume, yet the regional distribution of gray and white matter varies in the two groups. In general, girls with Turner's syndrome have a smaller proportion of tissue in the right and left parietal regions and a larger amount in the right inferior parietal-occipital region. Additional MRI studies have shown that measured volumes of the hippocampus; the caudate, lenticular, and thalamic nuclei; and the parieto-occipital brain matter bilaterally are smaller.^[12]

Treatment of patients with Turner's syndrome is directed at facilitating growth by administering recombinant growth hormone,^[13] correcting associated congenital anomalies, and carefully managing hormonal replacement therapy for sexual infantilism.

FRAGILE-X SYNDROME

Second only to Down's syndrome, the fragile-X syndrome is the most common cause of mental retardation in males and has a frequency of about 1 in 1500 males. It

is found in all ethnic groups and has been identified in patients with other chromosomal abnormalities. The higher incidence of mental retardation in males and reports of families in which only males are affected suggest a nonspecific X-linked inheritance, termed the Martin-Bell or Renpenning's syndrome. ^[20], ^[21] No cytogenetic abnormality had been found in this heterogeneous subgroup of the mentally retarded population until a fragile site in the terminal region of the long arm of the X chromosome (Xq27.3) was demonstrated when the cells were cultured without folic acid.

The hereditary transmission of the fragile-X syndrome has been described by Tarleton and Saul, and the fragile- X gene has been isolated, cloned, and characterized.^[22] It contains a trinucleotide sequence (CGG) that repeats in the normal genome 6 to 45 times, whereas the repeat is expanded to several hundred copies in patients with fragile- X syndrome. Carriers of the fragile-X syndrome, who are asymptomatic, have about 50 to 230 copies of this sequence. The expansion of the CGG repeat sequence is associated with methylation-induced inactivation of a sequence (CpG island) that is contiguous but separate from the *FMR-1* gene.^[23] This region is thought to initiate gene transcription. The degree of methylation correlates with the number of repeats, suggesting that the fragility of the site of the fragile-X (FRAXA) is related to the triplet repeats.

The characteristic physical features of affected males with fragile-X syndrome include a long face, prominent mandible, large ears, and macro-orchidism with no evidence of endocrine dysfunction. All signs may not be present in prepubertal males and are not always prominent in adults. Although affected children may be unusually tall, the adult male with fragile-X tends to be shorter than average. Other associated features include joint hyperextensibility, flat feet, scoliosis, mitral valve prolapse, and dilatation of the aortic root. Although no specific abnormality of connective tissue metabolism has been identified in patients with this syndrome, abnormal elastin fibrils have been observed in skin biopsies of some patients. Some heterozygote females may also have a long face, prominent ears, and joint hyperextensibility. These features are more commonly observed in mentally subnormal females than in those with normal intelligence.

The majority of adult males with fragile-X have mental abilities that are moderately retarded, but about 30 percent have severe mental impairment. A small number of males have low normal or mildly retarded intelligence, albeit with a variety of specific learning disabilities. There may be a

..

delay in acquisition of speech and language skills, and older patients often have a low-pitched, somewhat hoarse voice with features of perseveration, cluttering, and staccato speech. The degree of mental impairment in females is somewhat less than in males, with about a third of patients having mental abilities in the retarded range and about a half demonstrating specific learning disabilities. Attentional deficits, hyperactivity, and impulsive and aggressive behaviors are known to occur. Patients may additionally have macrocephaly, hypotonia, oculomotor dysfunction, and inordinate clumsiness with impairment of fine and gross motor movements. ^[24] An increased incidence of convulsive disorders may occur in nearly 25 percent of patients. These seizures are generally simple or partial complex seizures and tend to occur more frequently during the first 10 to 15 years of life. The seizures are usually well controlled by the administration of standard antiepileptic medications and appear to have no relationship to the degree of mental retardation. Tic disorders have also been reported in patients with fragile-X syndrome and their families.

There is no specific treatment for fragile-X syndrome other than providing special educational programs tailored to the specific disabilities of each patient. For patients with attentional deficit disorder and hyperactivity, these behaviors are sometimes improved by the administration of CNS stimulants.

NEUROCUTANEOUS DISORDERS

The neurocutaneous syndromes comprise a group of heterogeneous disorders characterized by dysplasia and a tendency to form tumors.^{[25], [26]} The CNS and skin are primarily involved, but other organ systems can be affected. Since the skin and nervous tissue originate from the same germ layer, the ectoderm, these disorders have been variously called congenital ectodermoses and congenital neuroectodermal dysplasias. Van der Hoeve believed that the ocular findings of neurofibromatosis and tuberous sclerosis were similar and suggested that they be classified together under the inappropriate term phakomatosis (Greek *phakos*: lentil, mole, or birthmark).^[27] He later added von Hippel-Lindau disease and Sturge-Weber syndrome to this category,

TABLE 32-1 -- SELECTED NEUROCUTANEOUS SYNDROMES

Disease	Clinical Features
AUTOSOMAL DOMINANT INHERITANCE	
Incontinentia pigmenti achromians (hypomelanosis of Ito)	Bilateral asymmetrical areas of hypopigmented whorls ("marbling"); central nervous system, eye, tooth, skin, nail, and bone anomalies
Rendu-Osler-Weber disease	Multiple angiomas of skin and mucous membranes that are dilations of capillaries and venules; bleeding from any site: nose, gastrointestinal, pulmonary, and urinary systems
Waardenburg's syndrome (I)	Frontal patch of white hair, heterochromia iridis, lateral displacement of inner canthus, and at times, cochlear deafness
Waardenburg's syndrome (II)	Clinical findings are similar to type I without the lateral displacement of inner canthus; deafness is more common
AUTOSOMAL RECESSIVE INHERITANCE	
Ataxia-telangiectasia	Ataxia and telangiectasias of the bulbar conjunctivae, malar eminences, ear lobes, and upper neck; increased increased of respiratory infections, lymphomas, Hodgkins disease, acute leukemia, and a variety of cancers; thymus gland is hypoplastic or absent; there is decreased IgA and IgG; increased chromosomal breakage and increased sensitivity to ionizing radiation of fibroblasts and lymphocytes
Chediak-Higashi syndrome	Rare, partial oculocutaneous albinism, photophobia, neuropathy, and recurring infection; giant cytoplasmic organelles are observed
Refsum's syndrome	Retinal pigmentary degeneration, polyneuropathy, and ataxia; sensorineural deafness, anosmia, and cardiomyopathy are usually present; abnormalities of the eyes, skin (ichthyosis), and bone are often present
Rothmond-Thomson syndrome	Erythematous skin lesions in early life followed by telangiectasias, atrophy, hypo- and/or hyperpigmentation, ectodermal dysplasia; body hair is sparse or absent; cataracts, short stature, hypogonadism, and skeletal abnormalities are common; intelligence is normal
Rud's syndrome	Ichthyosis and hypogonadism are major features; microcephaly, sensorineural deafness, polyneuropathy, and hypoplastic teeth and nails are less frequent
Sjogren-Larsson syndrome	Congenital ichthyosis associated with mental subnormality and corticospinal tract dysfunction
Xeroderma pigmentosum	Defect in DNA repair results in premature aging of tissues exposed to sunlight; microcephaly, mental subnormality, ocular changes, corticospinal tract dysfunction, ataxia, and movement disorders may be present
X-LINKED INHERITANCE	
Fabry-Anderson disease	A glycolipid lysosomal storage disease with a wide spectrum of clinical findings: angiokeratosis is a characteristic feature; lancinating limb pain is often the first symptom; joint pain may resemble that of juvenile rheumatoid arthritis; ocular, cardiac, and gastrointestinal symptoms may be present; cerebral vascular accidents can occur in young adults; neuropathy; renal disease manifests as inability to concentrate urine, urinary frequency, polyuria, and nocturia
Incontinentia pigmenti (Bloch-Sulzberger syndrome)	Seen almost entirely in females; characterized by skin lesions present during the first few weeks of life that are erythematous, macular, papular, vesicular, or bullous; second stage, skin lesions are variably verrucous, lichenoid, or keratotic; third stage, lesions are notable for hyperpigmentation; abnormalities of the eyes, central nervous system, hair, teeth, and bone are commonly associated

TABLE 32-2 -- DIAGNOSTIC CRITERIA FOR NEUROFIBROMATOSIS

Diagnostic Criteria for Neurofibromatosis 1
Six or more cafe au lait macules over 5 mm in greatest diameter in prepubertal individuals and over 15 mm in greatest diameter in postpubertal individuals
Two or more neurofibromas of any type or one plexiform neuroma
Freckling in the axillary or inguinal region
Optic glioma
Two or more Lisch nodules (iris hamartomas)
Distinctive osseous lesion such as sphenoidal dysplasia or thinning of long bone cortex with or without pseudoarthrosis
First-degree relative (parent, sibling, or offspring) with neurofibromatosis 1 by these criteria
Diagnostic Criteria for Neurofibromatosis 2
Bilateral eighth nerve masses seen with appropriate imaging techniques
First-degree relative with neurofibromatosis 2 and either unilateral eighth nerve mass or two of the following: neurofibroma, meningioma, glioma, schwannoma, and juvenile posterior subcapsular lenticular opacity

^{[28], [29]} and in 1941, Louis-Bar proposed that ataxia-telangiectasia should also be considered as one of the phakomatoses. During the last 50 years a wide variety of disorders, all of which are unusual and many of which lack dysplastic or neoplastic characteristics, have been considered to belong to this heterogeneous group of disorders. The major neurocutaneous syndromes are considered herein, and others are noted in [Table 32-1](#).

Autosomal Dominant Diseases

NEUROFIBROMATOSIS (VON RECKLINGHAUSEN'S DISEASE)

Pathogenesis and Pathophysiology. Neurofibromatosis^[30] is no longer considered a single clinical entity and has been divided into at least two distinct forms.^[31] The common form, once known as peripheral neurofibromatosis (NF), is called NF-1, and the rare form, once termed central NF, is NF-2. Both are inherited as autosomal dominant traits, and the gene locus responsible for NF-1 is on chromosome 17 (17q11.2), whereas that for NF-2 is on chromosome 22 (22q11.1 to 22q13.1). These disorders are due to abnormalities in the development of neural crest cells that produce hyperplasia, neoplasia, and dysplasias of the neuroectodermal elements and their supporting structures. Recently, the gene for NF-1 was found to code for a large, ubiquitously expressed protein (neurofibromin).^[32] This protein has structural and functional similarity to a family of proteins that has guanosine triphosphatase-activation properties. This family of proteins is involved in the regulation of the proto-oncogene *ras*. It has been speculated that the functions of the NF-1 gene product may be related to its ability to regulate *ras*-mediated cell proliferation.

Epidemiology and Risk Factors. NF-1 occurs in approximately 1 in 4000 to 5000 individuals. About half the cases appear to be sporadic, and the mutation rate has been estimated at 1 in 10,000 gametes per generation, one of the highest mutation rates in humans. Approximately 50 percent of patients have affected relatives, and in nearly all instances the distribution of cases is consistent with an autosomal dominant mode of inheritance. NF-1 is observed in all regions of the world and affects

men and women equally. The frequency of NF-2 is not known, and its natural history has been derived from studies of a large Pennsylvania family.

Clinical Features and Associated Disorders. NF-1 is characterized by cutaneous pigmentation, multiple tumors within the central and peripheral nervous systems, and lesions of the vascular and other organ systems^{[33], [34]} ([Table 32-2](#)). Focal hyperpigmented areas and cafe au lait spots, ranging in size from a few millimeters to centimeters, are more commonly found on the trunk than on the limbs, and they are not found on the scalp, soles, or palms ([Fig. 32-1](#)). These spots are light brown and result from an aggregation of neural crest-derived pigmented melanoblasts in the basal layer of the epidermis. Cafe au lait spots are present at birth and become more apparent with time. The number of cafe au lait spots probably does not significantly increase after the first several years of life, although the degree of hyperpigmentation usually does. The presence of six or more cafe au lait spots larger than 15 mm in greatest diameter is required for a diagnosis of NF, a criterion that is most useful when applied to the postpubertal patient. It should be recognized, however, that about 10 percent of the general population have cafe au lait spots without other stigmata of the disease. Less frequent cutaneous changes in NF-1 include diffuse axillary or inguinal freckling and

Figure 32-1 A 9-year-old patient with multiple cafe au lait spots of varying sizes, which are more common on the trunk than on the limbs.

Figure 32-2 Axillary and inguinal region freckling, as observed in this patient, is common in patients with neurofibromatosis.

large areas of faintly increased pigmentation (melanoderma) ([Fig. 32-2](#)).

Fibroma molluscum, soft or firm papules found in or just below the dermis that vary in size from a few millimeters to one or more centimeters, may also occur ([Fig. 32-3](#)). They are violaceous in color and vary in configuration from flat or sessile forms to pedunculated or lobulated forms. When compressed, these skin lesions tend to invaginate into the subcutaneous tissue. Hypopigmented spots similar to those observed in patients with tuberous sclerosis, discrete areas of skin hypoplasia, and angiomas may also be present in NF-1. All dermatological abnormalities may appear well before any neurological signs or symptoms occur.

Lisch nodules are iridic melanocytic hamartomas that are age-dependent and are found in 10 percent of patients less than 6 years of age, 50 percent of patients less than 30 years old, and in virtually all affected patients by the age of 50 years ([Fig. 32-4](#)). Optic gliomas, reported in 15 to 20 percent of patients, can present with decreased visual

Figure 32-3 An example of fibroma molluscum, which is a soft or firm papular or polypoid lesion found in or just below the dermis and which ranges in size from a few millimeters to 1 cm or (Courtesy of Dr. Mary Williams, Department of Dermatology, University of California Medical Center, San Francisco.)

Figure 32-4 Lisch's nodules are age-dependent iridic melanocytic hamartomas that are commonly observed in patients with neurofibromatosis (Courtesy of Dr. Creig Hoyt, Department of Ophthalmology, University of California Medical Center, San Francisco.)

acuity or visual field defects.^[35] These tumors can involve the optic chiasm and hypothalamus and rarely become manifest as the diencephalic syndrome of infancy. There is some controversy about the nature of the tumor, but optic gliomas of childhood are probably congenital, indolent, and slowly growing hamartomas. Congenital glaucoma may also be a complication of NF-1 and is sometimes associated with neurofibromas of the superior eyelid.

Neural tumors, or neurofibromas, can involve any nerve from the dorsal root ganglia to the terminal twigs of the peripheral nerves, and any organ can be involved ([Fig. 32-5](#)). Peripheral neurofibromas vary in size and occur more frequently on the trunk than on the limbs. Plexiform neuromas are composed of an overgrowth of neural elements of tumor and connective tissue that infiltrates normal tissue. These larger tumors can be superficial, affecting the skin and subcutaneous tissue, or deep, affecting visceral and adjacent tissues. Intracranial tumors occurring in NF-1 are primarily meningiomas and gliomas. There is an increased incidence of optic gliomas and neurofibromas in these patients, and schwannomas may also occur and may involve other cranial nerves. Intraspinal tumors can be present and are sometimes accompanied by spinal cord anomalies. While most tumors in this disorder are benign, some neurofibromas may undergo malignant transformation.

The diagnostic criteria for NF-2 require one or more of the following: bilateral eighth nerve masses; a parent, sibling, or child with NF-2; and either a unilateral eighth nerve mass or any two of the following: neurofibroma, meningioma, glioma, schwannoma, or juvenile posterior subcapsular lenticular opacity. Bilateral acoustic neuromas become manifest in over 95 percent of affected individuals. Symptoms of acoustic neuromas are usually referable to pressure on the vestibulocochlear and facial nerves, and patients may complain of tinnitus, buzzing, or background noise in the head. Alternatively, the initial symptom may be unilateral loss of hearing, which is noticed when the patient uses the telephone. Typically, symptoms begin in

Figure 32-5 An older teen-age patient with numerous neurofibromas (short arrow) as well as multiple lesions typical of fibroma molluscum (long arrow).

the second or third decade, but patients may become symptomatic in the first decade or as late as the ninth. Other features of NF-2 include cafe au lait spots and neurofibromas, although these are less commonly observed than in patients with NF-1. Presenile lens opacities or subcapsular cataracts have been found in nearly 50 percent of patients and may precede the symptoms of acoustic neuromas. Patients with NF-2 may have Schwann cell tumors of other cranial nerves or spinal roots, and meningiomas, astrocytomas, and ependymomas may present in the same patient. Optic gliomas, astrocytomas, and hamartomas are usually not found in this form of NF.

Associated features of NF include mental retardation or seizures, which occur in about 10 percent of NF patients, and about 40 percent have specific learning disabilities and hyperactivity. Occlusive cerebrovascular disease, although rare, can sometimes be demonstrated by angiography, which shows occlusive changes of the supraclinoid segment of the internal carotid artery associated with the telangiectasia characteristic of moyamoya disease.

Macrocephaly and short stature are reported in 10 to 40 percent of NF patients, and a variety of bony changes may also be present (including "ballooning" of the middle fossa, an enlarged or J-shaped sella, and dysplastic changes of the sphenoid). Patients with optic gliomas may have enlarged optic foramina, and bony defects of the orbit and other cranial bones are not uncommon. Scoliosis has been reported in 10 to 40 percent of patients and usually becomes manifest after the age of 6 years. Anterior meningocele, kyphosis, enlarged intervertebral foramina, bowing of the tibia and fibula, and bony overgrowth occur. Precocious puberty may occur in NF-1 patients with gliomas or hamartomas of the hypothalamus.

NF may be associated with a number of other neoplastic processes with a more than random frequency. These include leukemia, Wilms' tumor, neuroblastoma, multiple endocrine neoplasias, and pheochromocytoma. Of patients with pheochromocytomas, 4 to 23 percent are reported to have neurofibromatosis, whereas fewer than 1 percent of patients with neurofibromatosis have pheochromocytomas. Hypertension may also result from intimal proliferation and fibromuscular changes of the media of the small renal arteries, or from a pheochromocytoma.

Differential Diagnosis. The differential diagnosis of NF-1 is limited to the presence of a family history of the disease and the typical neurological and dermatological findings. NF-2 should be distinguished from sporadic, unilateral acoustic neuroma (SUAN). NF-2 usually presents prior to 40 years of age and is distinguished by the presence of brain and spinal tumors, cafe au lait spots, fibromas, and posterior capsular lens opacities. In contrast, SUAN presents after 40 years and has no associated findings.

Evaluation. The diagnostic tests used in patients with NF should be determined by the findings in the clinical examination because most studies will not be valuable in the asymptomatic NF patient. MRI can be useful in the evaluation of patients with possible intracranial, extracranial, and nerve root neoplasms. This neuroimaging study may also demonstrate incidental "bright areas" in patients with NF-1 that are consistent with "hamartomas" that may represent focal areas of heterotopic or dysplastic tissue. These focal areas of increased signal intensity on T2 images are not associated with vasogenic edema and are primarily seen in the basal ganglia, internal capsule, midbrain, cerebellum, and subcortical white matter. They are not visualized on contrast-enhanced CT. MRI findings suggestive of gliomas include the presence of vasogenic edema, mass effect, cavitation, enhancement with gadolinium, and decreased signal intensity on T1 images. When optic nerve gliomas are suspected, MRI with fat suppression techniques is a useful adjunctive study. The spine of a patient with NF-1 should also be imaged with MRI if there are symptoms or signs of intraspinal or nerve root compression. Isolated neurofibromas may involve the neural foramina and spinal canal, forming the so-called dumbbell tumor. Neoplasms involving the spinal canal and cord are best demonstrated with the use of gadolinium.

Patients who are at high risk for NF-2 should undergo MRI with gadolinium of the head, paying special attention to the cerebellopontine angle and internal acoustic meatus. Careful ophthalmic assessment should be performed to document the presence or absence of posterior capsular lenticular opacities and papilledema. Tests of vestibular and auditory function as well as brain stem auditory evoked potentials should be considered in the evaluation of these patients.

If symptoms suggest the presence of a pheochromocytoma, abdominal and mediastinal imaging should be performed, and neurotransmitter metabolites should be measured. Patients who are having problems with academic achievement should undergo neuropsychological studies to detect the presence and nature of any specific learning disabilities.

Management. Treatment of patients with NF is supportive and symptomatic. Patients with specific learning

disabilities should receive the benefit of special education programs. Patients with seizures should be treated with standard antiepileptic agents. Peripheral neurofibromas are generally indolent and do not require surgical removal unless they are subjected to repeated trauma and abrasion or show rapid growth. Plexiform neuromas may be removed for strictly cosmetic reasons. Intracranial and intraspinal tumors should be treated with neurosurgical intervention, irradiation, or chemotherapy when appropriate. Most investigators suggest managing optic gliomas conservatively, with serial MRI scans and visual field and acuity examinations, rather than by immediate surgery or chemotherapy.^{[36], [37]} The clinical course of patients with NF-2 may be relatively benign, and indications for acoustic neuroma surgery must be made on an individual basis. The presence of an acoustic neuroma does not inevitably lead to deafness and facial disfigurement; moreover, surgery in the region of the cerebellopontine angle is not without risk. Partial removal may be appropriate to preserve useful hearing in some cases. Counseling should address the issues of prognosis, genetics, and psychological and social adjustment.

Prognosis. Neurofibromatosis is a progressive disorder that requires continuous surveillance. The overall prognosis is determined by the location, number, and severity of the tumors that are present. It is important to note that most patients with the disease retain good function.

TUBEROUS SCLEROSIS

Pathogenesis and Pathophysiology. Tuberous sclerosis, or tuberous sclerosis complex (TSC), is an autosomal dominant disorder, and linkage analyses have indicated that the gene is located on the distal long arm of chromosome 9 (9q34). Though not substantiated, other studies have suggested that genetic heterogeneity exists within TSC, the gene in some families being mapped to 11q and in others to 16q. Other cases have been attributed to a gene mutation. Although the genetic basis of the disease has been established, the pathogenesis remains unknown. The lesions involve cells derived from the ectoderm and mesoderm, and the cellular elements demonstrate abnormalities in number and size.

Epidemiology and Risk Factors. Tuberous sclerosis has been identified in all races in all parts of the world. Both sexes are equally affected, and heredity is evident in 50 percent of cases. Prevalence is estimated at 1 in 50,000 to 1 in 300,000 people. This disorder accounts for nearly 1 percent of the institutionalized population in the United States and for 0.3 percent of patients with epilepsy.

Clinical Features and Associated Disorders. Though Bourneville^{[38], [39]} is credited with the first description of the disease, probably von Recklinghausen described it initially. Bourneville believed that the cerebral "scleroses" and renal tumors were associated findings, but he failed to recognize the importance of the typical facial skin lesions. Vogt believed that a triad of clinical findings including seizures, mental retardation, and adenoma sebaceum were characteristic of the disease,^[40] but the criteria for diagnosis have recently been revised ([Table 32-3](#)). TSC is characterized by a variety of clinical findings including seizures, varying degrees of mental subnormality, and dysplastic or neoplastic

TABLE 32-3 -- DIAGNOSTIC CRITERIA FOR TUBEROUS SCLEROSIS COMPLEX (TSC)

PRIMARY FEATURES

- Facial angiofibromas
- Multiple ungual fibromas
- Cortical tuber (histologically confirmed)
- Subependymal nodule or giant cell astrocytoma (histologically confirmed)
- Multiple calcified subependymal nodules protruding into the ventricle (radiographical evidence)
- Multiple retinal astrocytomas

SECONDARY FEATURES

- Affected first-degree relative
- Cardiac rhabdomyoma (histologic or radiographic evidence)
- Other retinal hamartomas or achromic patch
- Cerebral tubers (radiographical confirmation)
- Noncalcified subependymal nodules (radiographical confirmation)
- Shagreen patch
- Forehead plaque
- Pulmonary lymphangiomyomatosis (histological confirmation)
- Renal angiomyolipoma (radiographical or histological confirmation)
- Renal cysts (histological confirmation)

TERTIARY FEATURES

- Hypomelanotic macules
- "Confetti" skin lesions
- Renal cysts (radiographical evidence)
- Randomly distributed enamel pits in deciduous or permanent teeth
- Hamartomatous rectal polyps (histological confirmation)
- Bone cysts (radiographical evidence)
- Pulmonary lymphangiomyomatosis (radiographical evidence)

Cerebral white matter "migration tracts" or heterotopias (radiographical evidence)

Gingival fibromas

Hamartoma of other organs (histological confirmation)

Infantile spasms

DEFINITE TSC

One primary feature, two secondary features, or one secondary plus two tertiary features

PROBABLE TSC

Either one secondary plus one tertiary feature or three tertiary features

SUSPECT TSC

Either one secondary feature or two tertiary features

From Roach ES, Smith M, Hottenlocher P, et al: Report of the diagnostic criteria committee of the National Tuberous Sclerosis Association. *J Child Neurol* 1992;7:221.

changes of the skin, nervous system, and other organ systems.

The clinical expression of the disease is dependent on which organs are affected and the extent of their involvement. Seizures, either partial or generalized, are the most common symptom of the disease, and infantile spasms are particularly frequent during the first several years of life. The early onset and severity of the seizure disorder are correlated with the degree of mental abnormality. Mental function is notably variable, however, and about a third of patients have normal intelligence. Some patients develop normally during their early years only to experience a deterioration in mental function in the latter part of the first decade.

The most common skin lesion is the hypopigmented macule, which is found in about 90 percent of patients (Fig. 32-6). According to Fitzpatrick, the most frequent

Figure 32-6 A typical ash leaf-shaped area of hypopigmentation (arrows) found in most patients with tuberous sclerosis.

shape is the polygonal or "thumb-print" lesion, followed by the "ash leaf" spot, and finally by a "confetti-like" structure, characterized by myriads of tiny white macules.^[42] Adenoma sebaceum, which is an angiofibromatous lesion, had been generally considered the most common skin change in tuberous sclerosis, but the lesions occur in only 50 percent of patients (Fig. 32-7). The lesions appear in patches or in a butterfly distribution about the nose, cheeks, and chin. They are rarely apparent at birth, are usually first observed between the ages of 1 and 4 years, and tend to enlarge over time. Other skin changes include the "shagreen" patch (a "leathery" plaque), which is usually found over the lumbosacral or gluteal region, cafe au lait spots, fibromas, and angiomas. Subungual or periungual fibromas (Koenen's tumors) are found in about 20 percent of patients and affect the toes more commonly than the fingers. These lesions are usually first noted during adolescence. Gingival fibromas also can occur as well as pitting of the dental enamel.

Retinal tumors, which seldom affect vision, can occur and are thought to be astrocytic hamartomas. They are nodular or mulberry-like in configuration and may be solitary or multiple; they tend to calcify. Other associated ocular findings include gray-yellow glial patches, and iridic hypomelanotic spots, cataracts, and colobomas of the iris, lens, and choroid. Renal tumors occur in about half of patients with TSC and are primarily renal cysts or renal angiomyolipomas. These tumors can occur separately or in combination, and they are typically multiple, involving both kidneys. Although they can be symptomatic because of renal enlargement, they are usually indolent. Angiomyolipomas are also thought to be benign, yet they may result in hemorrhage and can cause serious morbidity or mortality. Early onset and severe hypertension can occur in patients with numerous renal cysts, and it has been suggested that patients with TSC have an increased risk of renal cell carcinoma. Cardiac rhabdomyomas are present in about half of patients and can be solitary, multiple, or infiltrative, diffusely affecting the myocardium. Newer techniques of echocardiography have facilitated early recognition of this tumor.

The lungs can also be affected in patients with TSC; they demonstrate multicystic lesions that have been shown to be similar pathologically to lymphangiomyomatosis.^[43] Pulmonary abnormalities occur almost entirely in females, presenting as dyspnea, spontaneous pneumothorax, and pulmonary hypertension. Endocrine abnormalities have also been reported.

Differential Diagnosis. The clinical features of TSC just described are characteristic, and although other neurocutaneous syndromes may have some similar features, it is rarely difficult to make the correct diagnosis. Infants who show developmental delay and intracranial calcifications and seizures should be evaluated for the possible presence of intrauterine infections such as toxoplasmosis and cytomegalovirus, among others.

Evaluation. Visualization of these hypomelanotic macules is enhanced by using a Wood light because melanin absorbs light of that frequency (360 nm), and areas deficient in melanin are visually accentuated. Imaging studies of affected patients can be effectively used to assist in diagnosis. Intracranial calcifications, commonly found in the region of the foramen of Monro or the periventricular region, are present in about 60 percent of skull radiographs in these patients. CT may demonstrate cerebral hamartomas, subependymal nodules, ventriculomegaly, and areas of demyelination. The calcified subependymal nodule (the tuber) is the most reliable finding on CT head scans, but periventricular calcifications can also be observed in patients with toxoplasmosis, cytomegalic inclusion disease, and Fahr's syndrome.^[44] MRI demonstrates with greater specificity not only the uncalcified subependymal nodules but also the distortion of the normal cerebral cytoarchitecture.^[45]

Other characteristic radiographic abnormalities include

Figure 32-7 Adenoma sebaceum are angiofibromatous lesions found about the nose, the nasolabial folds, or chin, and are present in about 50 percent of patients with tuberous sclerosis.

cystic changes of the phalanges and metacarpals, sclerotic areas in the long bones, and areas of increased or decreased bone density in the skull. Renal changes can be demonstrated by CT, MRI, or renal angiography, and the presence of a cardiac tumor is readily demonstrated by echocardiography. Patients with rare pulmonary involvement show a fine reticular infiltrate or multicystic changes on chest radiographs. Electroencephalography and examination of the cerebrospinal fluid are of little help in establishing the diagnosis.

The tubers can be located anywhere in the cerebral hemisphere but are commonly found in the cortical gyri. Smaller nodules can be located in the region of the sulcus terminalis or the basal ganglia, protruding into the ventricle. Those tubers situated in the region of the foramen of Monro or the aqueduct of Sylvius may become large enough to obstruct the normal flow of cerebrospinal fluid, resulting in hydrocephalus. The tuber is characterized pathologically by a decreased number of neurons with large, bizarre, and sometimes vacuolated "monster" neurons. A proliferation of fibrillary astrocytes, areas of demyelination, and abnormalities of cortical cytoarchitectonics are seen. Some vessel walls may show hyaline degeneration. The subependymal nodules are fibrocellular with round or oval cells and whorls of fibrillary glial tissue. Calcium and amyloid deposits may be present within the tuber or the subependymal nodule; cerebellar calcification rarely occurs.

Management. Convulsive disorders are treated by the administration of standard anticonvulsant medications; control, however, cannot be ensured. The individual TSC patient with recurrent partial seizures may experience some improvement with the excision of carefully identified epileptogenic foci. No specific treatment is available for the angiofibromatous lesions of adenoma sebaceum. They may be surgically removed if subject to repeated irritation or trauma, as is true, for example, of lesions obstructing the nares. Patients with TSC must not only receive careful medical management but should also be evaluated and followed by social workers and

psychologists. Genetic counseling for the family is mandatory.

VON HIPPEL-LINDAU DISEASE

Von Hippel-Lindau disease, which is inherited as an autosomal dominant trait, is characterized by hemangioblastomas of the retina and cerebellum. Von Hippel thought the retinal lesion was a hemangioblastoma, but he labeled it *angiomatosis retinae*.^[46] Lindau first recognized the association between the retinal and cerebellar hemangioblastomas; moreover, he was aware that patients could have other lesions, including spinal cord angiomas and cystic tumors of the pancreas, liver, and epididymis.^[47] Linkage analysis has localized the gene defect to chromosome 3p25-26.^[48],^[49] Additional findings include cysts of the pancreas, liver, and spleen as well as renal tumors. Compared with other neurocutaneous disorders, skin lesions are not associated with the disease.^[50]

The retinal hemangioblastoma is one of the earliest manifestations of the disease, and although it is reported to occur in childhood, it is usually found during or after the third decade. Aneurysmal dilation of the peripheral retinal vessels appears to be the earliest characteristic feature of the lesion, but, later, tortuous vessels marked by an afferent arteriole and venule leading to a raised retinal lesion appear. Some retinal lesions are small and easily overlooked. The retinal abnormalities have been divided into three stages: first, a pinkish red vascular lesion found in the midperipheral retina with visible "feeder" vessels and variable exudate; second, a pale gray lesion in which the feeder vessels can be observed on fluorescein retinal angiography; and third, retinal vascular lesions that are similar to diabetic microaneurysms but have no retinal vascular connections. These peripheral retinal lesions may not result in any visual impairment; however, if the lesion involves the macula or optic disc, progressive visual loss can occur.

The diagnosis of a cerebellar hemangioblastoma is usually made during the third or fourth decade, but there are reports of its occurrence before puberty. The presenting signs and symptoms are those of cerebellar dysfunction and increased intracranial pressure. These tumors may also involve the medulla and spinal cord, and about 80 percent of patients have an associated syringomyelia. Supratentorial hemangioblastomas, while uncommon, have been reported in the region of the pituitary gland and the third ventricle as well as the cerebral hemispheres.

Associated renal lesions are found in von Hippel-Lindau disease and include benign cysts, angiomas, and hypernephromas, which are common and are a significant cause of morbidity and mortality in the disease. Benign cysts may also be found in the pancreas, adrenal gland, and epididymis; they are usually asymptomatic. There is an increased frequency of pheochromocytomas in patients with von Hippel-Lindau disease.^[51] Retinal hemangioblastomas are recognized by careful ophthalmoscopy, and fluorescein angiography can show the vascular characteristics of the lesion. CT and MRI demonstrate the lesions of the cerebellum and spinal cord. The intra-abdominal lesions are shown by abdominal CT and ultrasonography.

Some retinal lesions are recognized because of visual impairment and retinal detachment.^[52] Obliteration of these lesions has been accomplished with cryocoagulation or photocoagulation. Cerebellar hemangioblastomas are removed surgically in about 90 percent of patients, who have a risk of recurrence of about 15 percent. Small renal tumors should be judiciously removed because the presence of multiple tumors is a possibility. In patients with cystic renal disease, nephrectomy should be considered, followed by dialysis.

Autosomal Recessive Disease

ATAXIA-TELANGIECTASIA

Syllaba and Henner^[53] first reported three adolescent patients with progressive choreoathetosis and ocular telangiectasia in 1926, but it was not until 1964 that Martin recognized their clinical description as ataxia-telangiectasia (AT).^[54] A second report in 1941 by Louis-Bar described a young boy with progressive cerebellar ataxia and extensive cutaneous telangiectasias; she identified the syndrome as one of the phakomatoses.^[55] After the 1958 descriptions by Bean,^[56] Boder and Sedgwick,^[57] ^[58] and Centerwall and

Miller,^[59] AT became recognized as a distinct disease, and multiple reports appeared in the literature.

AT is an autosomal recessive disorder characterized by a constellation of signs and symptoms associated with progressive cerebellar dysfunction, conjunctival and cutaneous telangiectasias, severe immune deficiencies, premature aging, and a predisposition to cancer.^[60] AT is inherited as a single mendelian locus on chromosome 11q22-23. Recent studies have identified the mutated gene in AT and its identification provides answers to the link between the mutated gene product in AT and the signaling pathways that regulate the cell cycle.^[61] In the normal cell cycle, surveillance checkpoints are used to arrest cells during the cell cycle, allowing either completion of certain events that are required at that point or repair of damage. During these delay periods, damaged DNA can be repaired so that subsequent cycles can occur normally. Clinical and laboratory work has suggested that the AT gene product is involved in maintaining the integrity of chromosomal DNA and in signal transduction mechanisms that operate to regulate the cell cycle or DNA repair. The exact biochemical roles of the gene product in these processes, however, remain unknown.

AT occurs equally among the sexes and is reported in all races and in all parts of the world. The prevalence of this disorder ranges from 1 in 40,000 to 100,000 births. Although AT is a multisystem disorder, progressive neurological deterioration is the hallmark of the syndrome.^[60] The early neurological features of AT are characterized by signs indicative of a progressive cerebellar degeneration, including ataxia and dysarthric speech. Ataxia is manifested by a swaying of the head and trunk and becomes apparent shortly after affected children begin to walk. It progresses and becomes severe enough to warrant the use of a wheelchair by 10 to 15 years of age. By this time, dyssynergia and intention tremor of the extremities interfere with normal activity. Speech is initiated slowly and slurred, and words are articulated poorly. Choreoathetosis can be present in older children and can even mask the ataxia. Myoclonic jerks, rigidity, dystonic posturing, muscular hypotonia, drooling, and arrest of cognitive development are also typical. These patients also have characteristic facies, described as relaxed, dull, sad, and inattentive when unstimulated. The examination also reveals oculomotor abnormalities, including slowly initiated voluntary horizontal movements of conjugate gaze with nystagmus-like jerks with fixation and refixation. The deep tendon reflexes are diminished, the plantar response is flexor, Romberg's sign is absent, and deep and superficial sensation is normal. Later neurological features may be dominated by spinal cord dysfunction, including abnormalities of position and vibratory sensation. Other patients demonstrate neuromuscular deficits with diffuse weakness, muscle atrophy, fasciculations, and absent tendon reflexes with intact sensory findings. Finally, in some patients there is a more mixed clinical picture including abnormalities of both sensory and motor function.

Non-neurological features vary and include vasculocutaneous, immunological, and neoplastic manifestations. The characteristic telangiectasias usually appear later than ataxia, typically at around 3 to 6 years of age in the region of the conjunctival angles of the eye. Once present, they steadily progress and spread in a symmetrical pattern across the exposed portion of the bulbar conjunctivae. These telangiectasias are bright red horizontal streaks that cause the eyes to look "bloodshot" and eventually involve the rest of the conjunctivae, eyelids, adjoining facial regions, external ears, neck, and antecubital and popliteal spaces. Rarely, the telangiectasias may be present on the dorsum of the hands and feet and on the mucosal surfaces of the palate. These abnormal vessels are not symptomatic and appear to be of venous origin, branching from subpapillary venous plexuses in the skin and dilated connecting venules in the conjunctivae.

Patients with AT also demonstrate progeric changes of the hair and skin, including early graying of the hair and atrophic, hidebound facial skin. Pigmentary changes are also frequent and consist of hyperpigmentation and hypopigmentation with cutaneous atrophy. A few patients may demonstrate partial albinism, vitiligo, and cafe au lait spots. Seborrheic dermatitis occurs in nearly all patients, and senile keratoses, atopic dermatitis, and eczema are also reported. Another prominent feature of AT is frequent sinopulmonary infections. These may range from infection of the ears, nose, and sinuses to chronic bronchitis and recurrent pneumonia. The latter two may result in bronchiectasis and pulmonary fibrosis. Chronic infections are typically due to common bacteria; however, they are sometimes poorly responsive to antibiotic therapy. The predisposition to infection is associated with the presence of an abnormal thymus and a marked deficiency of IgA, which is the predominant immunoglobulin in respiratory secretions. Neoplasms occur in an estimated 10 to 15 percent of patients with AT and are second only to pulmonary disorders as a cause of death. The most common neoplasms include Hodgkin's disease, malignant lymphomas, reticulum cell sarcoma, and histiocytosarcomas. Various other tumors have been associated with AT, including medulloblastoma, basal cell carcinoma, acute lymphocytic leukemia, and gliomas, as well as others. These patients also have retarded somatic growth with dwarfing and various skeletal disorders. Endocrine abnormalities are also prominent, and female hypogonadism with sexual infantilism is found consistently. Male hypogonadism also occurs but is less prominent and is characterized by a delay in puberty, incomplete spermatogenesis, and decreased Leydig cells. Other studies report an unusual type of diabetes mellitus that appears in late adolescence as well as anterior lobe pituitary abnormalities.

The laboratory evaluation of patients with AT reveals normal results on routine studies of the urine, blood (except for lymphopenia), and spinal fluid. Although glucose studies may reveal evidence of an insulin-resistant diabetes mellitus, thyroid function studies are normal. Elevations in serum alpha-fetoprotein and plasma

carcinoembryonic antigen are typically, but not invariably, present and are not required diagnostic criteria. Humoral or cellular immunological defects are also helpful in the diagnosis of AT, including low or absent levels of IgA, IgG2, and IgE, yet these are not invariable. Plain films of the skull may show decreased or absent nasopharyngeal adenoidal tissue, and CT and MRI studies of the head show cerebellar atrophy. Muscle and nerve biopsies may reveal evidence of denervation atrophy and axonal degeneration, respectively.

Treatment of patients with AT is supportive and includes

628

treatment of infections and the use of sunscreens to retard the cutaneous progeric changes. Early institution of pulmonary physiotherapy and physical therapy is important. Prenatal diagnosis is possible through the measurement of alpha-fetoprotein levels in amniotic fluid and the documentation of increased spontaneous chromosomal breakage of amniotic cell DNA.

Unknown Inheritance Patterns

STURGE-WEBER SYNDROME

Sturge is credited with the first report of this syndrome, which appeared in a 6-year-old girl who had a facial angioma, buphthalmos, and contralateral partial seizures.^[62] Sturge surmised that she had an underlying cerebral angioma, but it was not until 18 years later that a cerebral angioma affecting the leptomeninges of these patients was first described. Weber reported the presence of intracranial calcifications in skull radiographs of these patients, Dimitri noted double serpentine calcifications, and Krabbe correctly pointed out that the calcifications were located primarily in the cerebral substance rather than in the vessel walls. Van der Hoeve believed that this syndrome was the "fourth phakomatosis."

Sturge-Weber syndrome (SWS) is characterized by a congenital facial angioma (nevus flammeus, port-wine stain) that is associated with signs and symptoms of an ipsilateral leptomeningeal angioma. The facial angioma is usually unilateral, although it can be bilateral, and involves at least the upper face, superior eyelid, or periorbital region. Angiomas can also occur in other areas of the head including the nasopharynx, palate, lips, gingiva, and tongue, as well as the neck, trunk, and extremities. The facial angioma conforms to the sensory divisions of the trigeminal nerve, but its configuration may be determined by the embryological facial development. Leptomeningeal angiomas can also occur in the absence of any facial angioma. In this case, although the signs are similar to those of SWS, the patients should be considered to have a different disorder referred to as leptomeningeal angiomatosis. SWS has no known recognized pattern of inheritance, but there is one report of a father and son who had facial angiomas and glaucoma.

Most patients with SWS have seizures, often beginning in infancy, that are primarily partial motor seizures, but some patients have secondary generalization. Other seizure types, such as myoclonic, tonic, and atonic seizures as well as infantile spasms, can occur less frequently. Earlier studies noted a seizure frequency of 70 to 90 percent. In a retrospective study of 102 patients, 88 patients had a leptomeningeal angioma affecting one cerebral hemisphere, and 14 patients had bilateral hemispheric involvement.^[63] Seizures occurred in 75 percent of these patients. Among the patients with unilateral involvement, 63 had seizures, the mean age of seizure onset being 24 months. Thirteen of the 14 patients with bilateral involvement had seizures, the mean age of onset being 6 months.

At least half of patients with SWS are mentally subnormal, and behavioral problems are common. As seizures of early onset increase in frequency and severity, mental function and behavior often regress. In the retrospective study noted previously, 25 of 88 patients with unihemispheric leptomeningeal involvement who did not have seizures were of average intelligence; 1 of 14 patients with bilateral hemispheric involvement was unaffected by seizures, and that patient was of average intelligence. Others have documented that SWS patients with seizures have a notably higher incidence of developmental delay and emotional and behavioral problems, and these patients need special education. These observations are important considerations in patient management. Hemisensory deficits can occur but are sometimes difficult to document reliably in very young and mentally subnormal patients. Homonymous hemianopia has been noted in about one third of patients, and glaucoma secondary to choroidal angioma is found in one fourth. Other ocular abnormalities include iridic heterochromia in which the hyperpigmented iris is ipsilateral to the facial angioma, optic atrophy, and strabismus.

Electroencephalographic studies often show decreased amplitude and frequency of electrocerebral activity overlying the affected hemisphere. Other commonly noted abnormal electroencephalographic features include multiple and independent spike foci. Intracranial calcifications on skull radiographs are present in about 90 percent of patients, are usually found in the occipital or parieto-occipital region, and have a serpentine linear, parallel configuration ("tram sign"). They are rarely observed on plain skull radiographs during infancy but are present in most patients by the end of the second decade. CT of the head demonstrates intracerebral calcifications and cerebral atrophy more readily than do plain skull radiographs and has documented calcific deposits during the first few months of life. MRI, however, is the neuroimaging study of choice to show the extent of structural abnormalities of SWS.

Cerebral angiography demonstrates decreased cerebral venous drainage and dilation of the deep cerebral veins.^[64],^[65] A variety of vascular abnormalities, including thrombotic lesions, dural venous sinus abnormalities, and arteriovenous malformations, has been observed in about a third of patients. Positron emission tomography (PET) can provide some measure of cerebral metabolic impairment, and serial PET scans can demonstrate the progression of the disease process.^[66] Moreover, PET scans can provide important information that can be used to guide careful selection of patients for focal cortical resection or hemispherectomy. Single-photon emission computed tomography can also reveal useful information about cerebral perfusion.

Characteristic pathological features of SWS include thickened hypervascularized leptomeninges, which primarily affect the occipital, parietal, or temporo-occipital lobes. Meningeal vessels are small and tortuous, producing a dark, purplish blue color. These abnormal vessels rarely enter the underlying atrophic cerebral hemisphere. Calcific deposits are primarily located in the molecular and outer pyramidal cortical layers, but small calcific spicules can be found in some small cerebral vessels. The pathogenesis of calcium deposition in the brain substance is not well understood.

Management of patients with SWS requires careful attention not only to the patient's neurological deficits but also to the associated behavioral and emotional problems.^[67] Convulsive disorders are treated by administration of standard

629

antiepileptic drugs, but seizures in some patients may be refractory to medical management. These patients should be considered for focal cerebral resection of the affected lobes or hemispherectomy.^[68] Management of the associated problems of mentally subnormal patients or those with behavioral or emotional disturbances requires the skills not only of the physician but of competent psychologists and social workers as well.

The term dementia has an intellectually constricting effect on differential diagnostic considerations and should be applied with care. A confused elderly person seen for the first time might be described as demented but may in fact be confused because of toxicity from a narcotic analgesic received postoperatively. A more generic term that is less diagnostically constricting is encephalopathy. Encephalopathy can be acute, subacute, or chronic, and there are reversible and irreversible etiologies. Dementia is a type (or types) of chronic encephalopathy that can have many causes, including irreversible degenerative and potentially reversible nondegenerative causes.

The most important diagnostic step in evaluating dementias is to determine whether a chronic encephalopathy results from a degenerative or other potentially reversible cause. Clues may exist at any level of the diagnostic ladder, although typically only a subset of clues is found in any one patient. Historical clues suggesting a reversible process include fluctuating severity, altered level of consciousness or hypersomnolence, and visual hallucinations. Clues on mental status testing include finding the patient to be inattentive, disoriented, and somnolent but not particularly amnesic. Clues on physical examination include a variety of findings that may be common in elderly patients but are not part of the typical picture of Alzheimer's disease (AD) such as ataxia, hyperreflexia, and tremulousness.

Laboratory evaluation should be directed toward common medical ailments, and a reasonably recent complete physical evaluation should be available or obtained in all patients suspected of having a significant brain-related disease. Typical evaluations include thyroid function studies, vitamin B₁₂ or related tests, and serological tests for syphilis, even though the latter two have become relatively uncommon in the present day as causes of chronic progressive encephalopathy. When a nondegenerative-based chronic progressive encephalopathy is suspected, electroencephalography (EEG) may be helpful in demonstrating severe dysrhythmic slowing. Cerebrospinal fluid (CSF) examination may show an elevated IgG index and synthesis rate, and occasionally oligoclonal bands, suggesting an intrathecal inflammatory reaction. Autoimmune and paraneoplastic serologies may be helpful in such patients as well. Ultimately, if suspicion remains high based on noninvasive tests for a nondegenerative cause, cerebral angiography and meningeal and brain biopsy should be considered. In the absence of such invasive testing, an empirical therapeutic trial of prednisone could be considered in order to be certain that the steroid-responsive type of chronic inflammatory meningoencephalitis (CIME) does not exist.

If a degenerative disease is ultimately diagnosed, then it must be realized that an incurable, invariably progressive, and ultimately fatal condition has been diagnosed.

Chronic progressive encephalopathies can be divided into potentially reversible and irreversible diseases. More important than remembering a few specific diseases is to keep pathophysiological categories in mind. Some reversible causes of subacute and chronic widespread progressive encephalopathy include

1. inflammatory: CIME, sarcoidosis, primary and secondary central nervous system (CNS) vasculitides, CNS complications of systemic lupus erythematosus, and paraneoplastic limbic encephalitis
2. infectious: chronic meningitis due to fungi, tuberculosis, *Listeria monocytogenes*, Lyme disease, syphilis, CNS Whipple's disease.
3. nutritional: vitamin B₁₂ deficiency.
4. toxic: drugs (particularly prescription medications)
5. mass lesion: subdural hematoma, communicating (normal pressure) hydrocephalus, meningioma and other tumors

-
6. complex partial status epilepticus

Some irreversible causes of chronic widespread progressive encephalopathy include

1. degenerative: AD, Pick's disease, asymmetrical cortical degeneration syndromes (ACDS), diffuse Lewy body dementia (DLBD), progressive supranuclear palsy (PSP), Huntington's disease (HD), Parkinson's disease (PD).
2. vascular: multi-infarct dementia, disseminated intravascular coagulation
3. metabolic: storage diseases, leukodystrophies
4. neoplastic: meningeal metastases, gliomatosis cerebri

With this perspective in mind, this chapter considers the subset of irreversible causes of chronic progressive encephalopathies referred to as neurodegenerative dementing diseases, which affect adults. They fall into three broad categories: cortical, subcortical, and mixed. Essentially all neurodegenerative dementias have both cortical and subcortical pathology, but those that primarily target the cerebral cortex are clinically distinguishable from those that primarily target subcortical structures, so the distinction has both heuristic and practical value. Finally, there are some diseases that have a more balanced cortical- subcortical mix pathologically

and clinically.

CORTICAL DEMENTIA

Alzheimer's Disease and Alzheimer's Dementia

The two terms are related but not synonymous. AD is the disease process that ultimately results in Alzheimer's dementia. Alzheimer's dementia has a characteristic cognitive pattern. Early in a patient's course, AD may cause memory loss of insufficient severity to warrant the designation of dementia. Other patients with AD may follow an atypical course with progressive aphasia or progressive apraxia rather than a typical Alzheimer's dementia. Most of the time, however, AD causes Alzheimer's dementia.

Pathogenesis and Pathophysiology. AD is characterized by generalized cerebral cortical atrophy (Fig. 33-1) with widespread cortical neuritic (or senile) plaques (NP) and neurofibrillary tangles (NFT) (Fig. 33-2). Other typical pathological findings include neuropil threads, granulo- vacuolar degeneration, lipochrome accumulation, and Hirano bodies. NPs are composed of an amyloid core surrounded by dystrophic neurites, whereas paired helical filaments are the major constituent in NFTs, neuropil threads, and dystrophic neurites. None of these histological findings individually are entirely specific for AD, because NPs can be seen in clinically nondemented patients,^[1] and NFTs can occur in other neurodegenerative and prion disorders. Although recently debated, current neuropathological criteria for the diagnosis of AD requires that an adequate number of NPs be present within a specified age range in a clinically demented patient.^[2]

Synapse loss appears to be the most important correlate of dementia severity,^[3] but the number of NPs and NFTs and the density of beta-amyloid load have each been associated

Figure 12-1 Alzheimer's disease. Note the generalized cerebral cortical atrophy (Courtesy J. E. Parisi, Mayo Clinic, Rochester, Minnesota.)

with dementia severity. Mesial temporal structures, particularly the hippocampal formation, are involved early in AD, and this accounts for the amnesic syndrome in these patients. AD produces a lamina-specific pattern of damage to the entorhinal cortex that disrupts cortical input to the hippocampal formation from association and limbic cortices, and disrupts hippocampal outflow from the cornu Ammonis (CA) sectors and subiculum to the association cortices, diencephalon, basal forebrain, and amygdala. Hence, AD effectively disconnects the hippocampus from its major input and output pathways.^[4]

The plaque core in AD in isolation or occurring with Down's syndrome is composed of insoluble beta amyloid,^[5] and the gene for amyloid beta precursor protein (betaAPP) has been mapped to chromosome 21. The betaAPP is normally expressed in multiple cells of neural and non-neural origin and has several putative cellular functions. The betaAPP can be processed by nonamyloidogenic and amyloidogenic pathways. The fragment of betaAPP formed by the latter pathway, termed B-amyloid or Abeta, is a soluble secretory product composed of 39 to 43 residues. This pathway may generate Abeta at the cell surface, in the lysosomes, or in the Golgi apparatus, and the precise mechanism of Abeta processing may be cell-type specific.^[6] The form secreted in highest quantity is Abeta1-40, with lesser amounts being in the Abeta1-42 form. Each form is secreted in varying amounts in cognitively normal and abnormal individuals, and levels of each can be measured in both plasma and CSF. The insoluble Abeta1-42 form is contained in plaques. Additional amyloid-associated proteins are believed to interact with Abeta, which can also promote amyloid fibril formation and deposition as plaques.

Plaques, in which amyloid deposition is diffuse and distended neurites are absent, have been termed diffuse non- NPs. These plaques are present in nondemented aged and Down's syndrome patients. With the appearance of distended neurites, the plaques are then classified as diffuse NPs. Insoluble amyloid fibrils surrounded by distended neurites constitute a dense-core NP, which is equivalent

Figure 12-2 Photomicrograph of entorhinal cortex in Alzheimer's disease. The neuritic plaque is composed of an amyloid core surrounded by dystrophic neurites. The dark flame-shaped fibrillar structures are neurofibrillary tangles, which are chiefly made up of paired helical filaments (Bielschowsky silver stain; 200x; courtesy J. E. Parisi, Mayo Clinic, Rochester, Minnesota.)

to the classic NP. A "burnt-out" plaque is a dense core of amyloid without the surrounding distended neurites. The amyloid cascade hypothesis states that the initial abnormality in AD pathogenesis is amyloid deposition in the neuropil (forming plaques) and cerebral vessels (forming amyloid angiopathy).^[7] This deposition is neurotoxic, leading to cytoskeletal derangement with neurofibrillary tangle formation, leading, in turn, to neuronal degeneration. Studies from several laboratories suggest that Abeta1-42 is the crucial form of Abeta involved in this cascade. Abeta1-42 has been shown to form insoluble amyloid fibrils faster than Abeta1-40 in vitro. This form is deposited in the diffuse plaques of Down's syndrome patients far in advance of Abeta1-40, and this peptide is the primary form of Abeta deposition in the NPs of sporadic AD. Plasma Abeta1-42 is elevated in approximately 12 percent of patients, and CSF Abeta1-42 is reduced in patients with clinically diagnosed AD.^[8] The reduction of Abeta1-42 presumably reflects diminished clearance and subsequent deposition. It is hoped that interfering with Abeta1-42 formation or deposition may impact AD pathogenesis.

The six human isoforms of the microtubule-associated protein tau are derived from a single gene on chromosome 17. Tau normally binds to microtubules when dephosphorylated or only partially phosphorylated. Hyperphosphorylated tau is the major component of paired helical filaments, which are the major constituents of neurofibrillary tangles, neuropil threads, and dystrophic neurites. Accumulated paired helical filaments or microtubule destabilization, or both, may disrupt axonal transport and lead to NFT formation and neuronal death. In AD, tau concentration is elevated in the CSF.^[9]

The association between the type 4 allele of apolipoprotein E (ApoE epsilon-4) and late-onset familial^[10],^[11] and sporadic AD^[11] was recognized in 1993. An increased risk of developing sporadic AD and a decreased age of onset has been associated with the ApoE epsilon-4 allele, whereas risk decreases and age of onset increases with the ApoE epsilon-2 allele.^[12] However, ApoE epsilon-4 does not directly cause AD because it can occur in the absence of even one copy of the ApoE epsilon-4 allele, and two copies of this allele have been documented in cognitively and neuropathologically normal individuals. Disease progression does not appear to be associated with ApoE status.

ApoE is found in the NPs, vascular amyloid, and NFTs of AD. Amyloid deposition in NPs and blood vessels has correlated with ApoE epsilon-4 dosage (that is, whether there is one or two copies of the ApoE epsilon-4 allele), whereas the frequency of NFTs has not.^[13] ApoE promotes amyloid filament formation in vitro.^[14] ApoE epsilon-3, but not ApoE epsilon-4, binds to microtubule-associated protein tau, which may slow the rate of tau phosphorylation and self-assembly into parhelical filaments (PHF).

There are four types of ApoE receptors in the brain. One type, the low-density lipoprotein receptor-related protein (LRP) is found in hippocampal pyramidal cells and dentate granule cells. It is a highly conserved protein found also in nematodes, and it functions in membrane maintenance. LRP binds and internalizes not only ApoE but also several other ligands, all of which have been associated with NP. LRP internalization of its associated ligands may be impaired in AD, thus resulting in Abeta-ApoE complex aggregation and NP formation.^[15] The specific interactions between the various ligands and ApoE isoforms remain to be determined, but the potential may exist for developing therapeutic interventions that manipulate these interactions.

Limited pathological, clinical, and epidemiological studies have supported a role for immunological activation as an intrinsic component of the neurodegenerative process.^[16] The number of activated microglia is high in diffuse plaques and higher in diffuse NPs, but there are fewer microglia in more mature plaques with amyloid cores, suggesting that the inflammatory response may have a primary role in the early steps of plaque formation.

Chronic aluminum exposure was once thought to play a role in AD mainly due to encephalopathy occurring in dialysis patients who were exposed to toxic levels of aluminum. The possible mechanisms by which aluminum could lead to AD histopathology include promoting hyperphosphorylation of tau and subsequent formation of NFTs, altering processing of the betaAPP, which would lead to the formation of NPs, and initiating the inflammatory response.^[17]

However, at present, aluminum exposure is not thought to be a major risk factor for AD.

The oxidative stress hypothesis of neurodegeneration holds that free radical generation from metabolism is neurotoxic, and there is some evidence that Abeta may promote free radical formation.^[18] This has led some to propose the use of antioxidants clinically and in experimental trials in patients with clinically diagnosed AD.^[16]

Levels of acetylcholine, noradrenaline, serotonin, gamma-aminobutyric acid (GABA), glutamate, somatostatin, neuropeptide Y, and substance P have all been documented to be reduced in the brains of AD patients. However, reductions in acetylcholine and choline acetyltransferase are the most profound, and therefore they have been thought to be the most important. Such reductions are due to neuronal loss in the basal forebrain, which is the major region from which cholinergic projections originate.^[19] Only modest improvement in cognitive functions have been achieved with cholinergic agonists, presumably due to neuronal loss in the cortical targets that receive cholinergic input.

Pathological variants of AD include limbic AD, plaque- only AD (usually the Lewy body variant of AD^[20]), and the Lewy body variant (LBV) of AD. The pathophysiological relationship between LBV and AD and the appropriate nomenclature are still under debate (see diffuse Lewy body disease section).

There are four genetic variants of AD. AD1 results from a mutation in the APP gene on chromosome 21, resulting in increased amyloid formation and deposition in the brain, resulting, in turn, in late onset familial AD, as well as cerebral vasculature with consequent amyloid angiopathy. AD2 is another genetic subtype of late-onset familial AD reflecting the type 4 allele of apolipoprotein E located on chromosome 19.^[10] AD3 is a form of early-onset familial AD resulting from mutation of an integral membrane protein (presenilin-1) gene located on chromosome 14. Mutations in this gene may be responsible for more than 75 percent of cases of early onset familial AD with a mean onset before age 50.^[21] Finally, AD4 is another early-onset familial form of AD related to a mutation of another transmembrane protein (presenilin-2) located on chromosome 1 in seven related families of Volga German ancestry (and one Italian kindred) with autosomal dominant AD.^[22]

Alzheimer's pathology has also been found in some patients with non-Alzheimer-type patterns of dementia, including frontotemporal, aphasic, and perceptual-motor syndromes (see ACDS, later).

Epidemiology and Risk Factors. AD is the most common cause of dementia overall, accounting for more than half of all cases, and it increases in frequency with advancing age. Epidemiological age-specific estimates of incidence and prevalence vary by region and study due to differences in diagnostic criteria and population demographics. [Figure 33-3](#) and [Figure 33-4](#) show the incidence and prevalence rates for dementia (all causes) and AD in particular in Olmsted County, Minnesota.^[23] There is an exponential increase in both with advancing age at least through the ninth decade. Whether this trend continues into the tenth decade is presently unknown. The prevalence of severe dementia over the age of 60 is estimated at 5 percent, and over the age of 85, between 20 and 50 percent.

Figure 12-3 Incidence rates of dementia (all causes) and Alzheimer's disease in Olmsted County, Minnesota, by age for five quinquennial periods (1960 to 1984). pyrs = person (From Kokmen E, Beard CM, O'Brien PC, Kurland LT: Epidemiology of dementia in Rochester, Minnesota. Mayo Clin Proc 1996;71:275-282.)

Figure 12-4 Prevalence rates of dementia (all causes) and Alzheimer's disease in Olmsted County, Minnesota, by age for two prevalence dates: January 1, 1975, and January 1, 1980. pyrs = person (From Kokmen E, Beard CM, O'Brien PC, Kurland LT: Epidemiology of dementia in Rochester, Minnesota. Mayo Clin Proc 1996;71:275-282.)

The lifetime risk of developing AD is estimated to be between 12 and 17 percent.^{[23], [24]}

Following age, apolipoprotein E (ApoE) status is the second most important risk factor. In both familial late- onset^[10] and sporadic^[11] cases, the ApoE epsilon-4 allele increases risk and the epsilon-2 allele decreases risk.^[12] The lifetime risk of AD in people without a family history increases from 9 percent without an ApoE epsilon-4 allele to 29 percent with one copy of the ApoE epsilon-4 allele.^[25] ApoE epsilon-4 homozygotes make up roughly 2 percent of the population, but approximately 83 percent are estimated to develop AD in their lifetime,^[26] similar to the 91 percent reported in familial late-onset cases.^{[10], [11]} In limited populations, other genetic factors play a determining role including Down's syndrome (trisomy 21),^[27] familial early-onset Alzheimer's kindreds (chromosome 14),^[21] and the Volga German kindreds of familial early onset AD (chromosome 1).^[22]

Other purported risk factors are weaker and some are more controversial in that not all well-controlled epidemiological studies have found them to be significant. These risk factors include limited education, depression, gender, estrogen replacement therapy, use of vitamin E, head trauma, use of anti-inflammatory drugs, and a history of thyroid disease.

Clinical Features and Associated Disorders. AD has been considered the paradigm of a cortical dementia syndrome. The hallmarks of cortical dementia include not only memory loss, which is common to many dementia syndromes, but also elements of aphasia, apraxia, and agnosia. Further, in general, there is an absence of subcortical features such as parkinsonism. Some patients with pathologically proven AD, however, also exhibit features of mild parkinsonism, emphasizing that diagnostic boundaries are relative, not absolute. [Table 33-1](#) shows the National Institute of Neurological and Communicative Disorders and Stroke and the Alzheimer's Disease and Related Disorders Association (NINCDS-ADRDA) Work Group's diagnostic criteria for AD.^[28] Definite AD is defined by tissue confirmation. Probable AD is defined by the clinical picture of dementia in the absence of certain atypical features such as focal neurological abnormalities and for which another cause cannot be found. Possible AD is defined by the clinical picture of dementia, but with either atypical features in the course of the illness or with a second potentially contributory disease not believed to be the primary cause. In the absence of histological confirmation, therefore, the clinical picture of dementia is the most important diagnostic feature.

Dementia is not a homogeneous clinical syndrome. It is defined as disabling impairment of multiple cognitive domains. Hence, memory loss alone does not equal dementia, even though it may be the heralding symptom of a dementing illness and is the most commonly impaired cognitive domain among all dementia syndromes (cortical and subcortical). Degenerative dementia further implies disease progression over time. The pattern and evolution of cognitive deficits defines the syndrome of Alzheimer's dementia, even though pathologically defined AD may rarely not present in this way. Nonetheless, the overall clinical-pathological correlation of Alzheimer's dementia with AD is now approximately 87 percent.^[29]

Most clinical studies agree that the earliest clinical sign

TABLE 12-1 -- NINCDS-ADRDA CRITERIA FOR THE DIAGNOSIS OF ALZHEIMER'S DISEASE*

- I. Clinical Diagnosis of Probable Alzheimer's Disease
 1. Dementia established by clinical examination and mental status testing and confirmed by neuropsychological testing
 2. Deficits in at least two cognitive domains
 3. Progressive cognitive decline, including memory
 4. Normal level of consciousness
 5. Onset between ages 40 and 90 (most common after 65) years
 6. No other possible medical or neurological explanation
- II. Probable Alzheimer's Disease Diagnosis Supported by
 1. Progressive aphasia, apraxia, and agnosia
 2. Impaired activities of daily living

3. Family history of similar disorder

4. Brain atrophy on CT/MRI, especially if progressive

5. Normal CSF, EEG (or nonspecifically abnormal)

III. Other Clinical Features Consistent with Probable Alzheimer's Disease

1. Plateau in course

2. Associated symptoms: depression; insomnia; incontinence; illusions; hallucinations, catastrophic verbal, emotional, or physical outbursts; sexual disorders; weight loss; during more advanced stages increased muscle tone, myoclonus, and abnormal gait

3. Seizures in advanced disease

4. CT normal for age

IV. Features that Make Alzheimer's Disease Uncertain or Unlikely

1. Acute onset

2. Focal sensorimotor signs

3. Seizures or gait disorder early in course

V. Clinical Diagnosis of Possible Alzheimer's Disease

1. Dementia with atypical onset or course in the absence of another medical/neuropsychiatric explanation

2. Dementia with another disease not felt otherwise to be the cause of dementia

3. For research purposes, a progressive focal cognitive deficit

VI. Definite Alzheimer's Disease

1. Meets clinical criteria for probable Alzheimer's disease

2. Tissue confirmation (autopsy or brain biopsy)

VII. Research Classification of Alzheimer's Disease Should Specify

1. Familial?

2. Early onset (before age 65)?

3. Down's syndrome (trisomy 21)?

4. Coexistent other neurodegenerative disease (e.g., Parkinson's disease) ?

*National Institute of Neurological and Communicative Disorders and Stroke and the Alzheimer's Disease and Related Disorders Association Work Group's report summarizing the criteria for a diagnosis of Alzheimer's disease.

CSF, Cerebrospinal fluid; CT, computed tomography; EEG, electroencephalogram; MRI, magnetic resonance imaging study.

Reprinted from Mckhann G, Drachman D, Folstein M, et al; Clinical diagnosis of Alzheimer's disease: Report of the NINCDS-ADRDA Work Group under the auspices of Department of Health and Human Services Task Force of Alzheimer's Disease Neurology 1984;34:939-944. By permission of Little, Brown and Company (Inc.).

of AD is memory loss, which precedes the actual dementia. Abnormal cerebral metabolism, demonstrated by positron emission tomography (PET), may precede even mild memory loss.³² A few studies have correlated other relative cognitive inefficiencies occurring much earlier in life with the subsequent development of dementia, although interpretation of these findings has been a source of controversy.

Recent memory is easier to assess reliably than remote memory and is thought to be disproportionately severely involved. Nonetheless, remote memory is also abnormal, and there is a gradient effect regarding recall over a retrograde time interval: The oldest memories appear to be the best preserved, with proportionately greater forgetting as the retrograde interval shortens.³¹ In contrast, procedural memory appears to be relatively spared. Alzheimer's patients are able to learn simple skills as easily as normal controls and better than patients with subcortical patterns of dementia or patients with various types of sensorimotor deficits.³² Although apraxia is one of the defining features of cortical dementia, it is rarely severe in mild to moderate stages of AD and can be very difficult to distinguish from impaired comprehension in these patients. One very important skill that needs to be addressed clinically is driving. Despite the relative preservation of procedural memory, patients with mild Alzheimer's dementia have a higher rate of collisions and moving violations than age-matched controls,³³ although estimates of risk vary, especially during the first 2 years of the disease. Whether this actually results from impaired procedural memory, attentional factors, other cognitive aspects, or a combination is unclear, although visual tracking, memory, and Mini-Mental State score all correlate with a laboratory-based driving score.³³

Memory loss is a cardinal feature of Alzheimer's dementia but it is not the only abnormality in most patients. However, a subset of patients present with a circumscribed, slowly progressive amnesic syndrome, which is sometimes referred to as "age-associated memory impairment" (AAMI).³⁴ Despite the disarming terminology, memory loss in these patients should be distinguished from the milder memory problems of normal aging. AAMI has the same profile of risk factors as AD, including advanced age and ApoE,³⁵ and patients who have come to autopsy often prove to have AD. Such patients also have radiologically demonstrable hippocampal atrophy. Roughly half of patients who present with AAMI develop features of dementia over a 4- to 5-year period.³⁵

Aphasia, apraxia, and agnosia are the other categories of cognitive impairment that typically occur in cortical dementia syndromes and particularly in AD. In Alzheimer's dementia, these aspects do not dominate the clinical picture. A patient with a predominant aphasic syndrome (progressive aphasia) should not be assumed to have AD, though some do (see Asymmetrical Cortical Degeneration Syndromes). Rather, these aspects of cognitive pathology occur in discrete apportionments that define the dementia syndrome as typical Alzheimer's dementia. In patients with such an apportionment, clinicopathological correlation rates are high.³² In mild to moderate stages of dementia, anomia is prominent and readily detectable with neuropsychological testing using a variety of naming tests (see [Chapter 27](#)). Patients are, however, fluent and may have relatively good comprehension, so clinical detection is not always easy. As the disease progresses, the predominantly anomic aphasia gives way to a more fluent, or Wernicke's, type of aphasia with impaired comprehension. Nonfluent aphasia does not generally occur in AD, although preterminally patients become mute (see [Chapter 6](#)). This should not be the case in a patient who is still ambulatory, however.

Apraxia can be confused with impaired comprehension in mild to moderate stages of Alzheimer's dementia. Patients have difficulty performing tasks at which they were previously adept, such as repairing a household appliance or doing carpentry work. They also have difficulty learning

45

new procedures such as operating a new car, new appliance, or remote control device. They have some difficulty pantomiming gestures in the office setting but also have constructional apraxia. In moderately advanced stages, patients have trouble dressing and performing other activities of daily living. Patients with clinically evident apraxia typically also have significant perceptual difficulties (see later) and definitely should not be driving a motor vehicle.

Anosognosia, the failure to recognize illness, is a cardinal feature of Alzheimer's dementia and is typically present, even in mild stages of the disease. It is a useful sign to distinguish progressive amnesic syndromes from Alzheimer's dementia. A typical patient with AD is brought or sent for evaluation rather than coming of his or her own accord. He or she may deny significant memory problems and will actively try to explain away the observations of concerned family members and friends, even to the point of becoming hostile and accusative. This is one of the most difficult aspects of the disease because such patients often should not be driving or managing their own finances but will do so anyway, sometimes to their detriment.

In moderate to advanced stages, patients exhibit other so-called agnosic types of disturbances. Arguably, the difficulty such patients have in recognizing familiar people reflects prosopagnosia, save that they are not reliably benefited by voice recognition either. Difficulty finding their way could be compared with topographagnosia, another visual agnosic syndrome, but again this is not occurring in the pure form given the wealth of other cognitive problems accompanying it. Rarely, patients with histologically documented AD present with a disabling, primarily visual syndrome termed asimultanagnosia, in which there is an inability to view all parts of a complex visual scene in a single coherent time-space frame. Such patients fail to see a target object that is right in front of them, especially if it is surrounded by potentially distracting stray objects.³⁶ Strictly speaking, this is not an agnosic disorder, but another type of complex visual disturbance that resembles

agnosia and can occur in this setting. It is rarely the presenting feature. More commonly, it is a mild accompanying feature.

Psychiatric symptoms include both affective and psychotic disturbances. Depression interferes with a person's functional status and an accurate cognitive assessment, erroneously leading to the diagnosis of dementia; such is the nature of pseudodementia, which has been estimated to account for 4 to 5 percent of dementia cases.^[37] More commonly, depression may complicate the course of AD and other dementing illnesses. Antidepressant therapy should be strongly considered in such patients. Psychotic symptoms most commonly involve paranoid delusions and, less commonly, hallucinations. AD should be in the differential diagnosis of an elderly patient presenting de novo with an organic delusional syndrome or hallucinosis. Common paranoid themes involve infidelity and stealing. Hallucinations are generally complex, involving people (familiar or unfamiliar), animals, or both. The combination of anosognosia, paranoid delusions, and mild cognitive decline is potentially dangerous and very difficult to manage, especially if such individuals live alone, yet a significant minority of Alzheimer's patients have exactly that combination.

Two common vegetative groups of symptoms regard sleep disturbances and incontinence. Sleep-wake cycle disturbances are common and may be present even during relatively mild stages of the illness. They become more common and more severe during moderately severe stages. There are two aspects to the sleep-wake cycle disturbance. The first is the so-called sundowning effect, which means that the patient becomes more confused, agitated, and difficult to manage during the evening hours. The second regards either not sleeping at night, waking up during very early hours, or going to sleep very early in the evening. Sleep becomes fractionated into shorter segments throughout the 24-hour period. As the disease progresses to more advanced stages, patients may become generally less active, sleep more, and eventually, in terminal stages, are bedbound with little apparent conscious activity. Weight loss is common during the latter stages, as well. Incontinence (both urinary and fecal) is uncommon in mild stages but becomes increasingly frequent as the disease progresses and is universal in late stages. Early on, it may inadvertently result from voiding in the "wrong place" rather than actual sphincter control problems, but in later stages, sphincter control is lost.

Late and preterminal stage AD ensues after roughly a 5- to 10-year course but is highly variable and can be shorter or longer. In very advanced stages, patients are no longer ambulatory, become mute and incontinent, and are totally dependent on their caregiver or nursing attendant. Eventually dysphagia signals the terminal phase, and unless a feeding tube is placed, patients eventually die from inanition or aspiration, or both. Few patients live to these stages, with death resulting from intercurrent illnesses in most.

Down's syndrome has a strong association with AD. If a patient with Down's syndrome (trisomy 21) lives beyond the age of 40 years, it is a near certainty that there will be neuropathological evidence of AD at autopsy.^[27] Clinical dementia increases with age and peaks at roughly 40-75% over the age of 60.^[27] Analysis of the amyloid plaques has shown that trisomy 21 predisposes to larger plaques, presumably reflecting increased production of Abeta, in contrast to ApoE epsilon-4, which leads to greater numbers of plaques presumably reflecting increased probability of senile plaque initiation.^[38]

Not all neuropathologically defined cases of AD present with Alzheimer's dementia, as is elaborated in the discussion of ACDS. Patients with the syndromes of progressive aphasia, progressive apraxia (and other motor syndromes), and progressive asimultanagnosia have all been reported, on occasion, to have Alzheimer-type pathology. Such cases raise questions regarding the nosology of degenerative cortical syndromes.

Differential Diagnosis. AD is one disease among many, both degenerative and nondegenerative, that can produce the categorical syndrome of a chronic progressive encephalopathy. All-encompassing, indiscriminant differential diagnostic inclusion of a hundred conditions encompassed by this broad category is inefficient and impractical. So, too, is the reflex assumption that memory loss in an elderly individual equals dementia equals AD. Simply determining that a disease is degenerative already accomplishes the most important goal of excluding any possible or more effectively treated etiology. Reversible forms of dementia are truly chronic encephalopathies and often cause one or several of the following: hypersomnolence, acute or subacute deterioration, fluctuating

severity, severe electroencephalographic abnormalities, visual hallucinations, tremulousness, or unsteadiness, or it may be accompanied by non-neurological symptoms as well. Such symptoms may occur within the context of another disease process known to cause neurological problems sometimes, such as hypothyroidism, or may occur under specific circumstances such as immunosuppression. Irreversible forms of dementia are generally more slowly progressive (more than a year or two), fluctuate much less, do not occur within the context of another potentially causative disease, have recognizable clinical and cognitive profiles, and are not accompanied by many of the aforementioned clues of a reversible chronic encephalopathy. When analyzed in this way, a more realistic differential diagnosis of AD includes (1) other degenerative diseases, such as Pick's disease, nonspecific degeneration (progressive subcortical gliosis), and diffuse Lewy body disease; and (2) vascular dementia resulting from small vessel disease due either to atherosclerotic small vessel disease or amyloid angiopathy. In mild to moderate stages, clinical cognitive patterns can be very helpful in distinguishing various dementing illnesses. In late stages, however, patients are more diffusely impaired both cognitively and somatically, making it difficult to tell one degenerative brain disease from another.

Evaluation. Because the recognition of distinctive clinical cognitive patterns can be difficult, a practical approach must take into account some of the chronic encephalopathic causes as well as degenerative and related causes. Neuroimaging is essential. Magnetic resonance imaging (MRI) is preferred, if possible, but computed tomography (CT) is generally adequate. Structural processes such as chronic (or subacute) subdural hematomas, tumors (frontal lobe meningiomas and temporal lobe gliomas in particular), cerebrovascular lesions, prior traumatic encephalomalacia, relevant focal atrophy (see ACDS section), and meningeal enhancement are among the many important diagnostic clues that mitigate against a diagnosis of AD. Bilateral medial temporal or more generalized atrophy may be discernible, but this is nonspecific and in the absence of quantitation, it is difficult to use for diagnostic purposes. Physiological neuroimaging is not recommended for routine evaluation of patients suspected of having AD but may be helpful in ACDS (see later). Nonetheless, single photon emission computed tomography (SPECT) and PET have shown bilateral temporoparietal and posterior cingulate hypometabolism and hypoperfusion in AD.

Cognitive examination is essential, but whether formal neuropsychological assessment is required depends on the examining physician's skill in clinical cognitive assessment. In general, neuropsychological assessment is highly desirable in mild to moderate stages of dementia for both qualitative description of the dementia pattern (which has diagnostic significance) and quantitative estimation of cognitive disability. Although variable, a typical neuropsychological profile will show reduced performance IQ relative to verbal IQ, severe learning and memory impairment, and anomia. Frequently, there is also evidence of impaired aural comprehension, a generally reliable indicator of significant cognitive disability. Psychomotor speed is generally preserved, although with longitudinal assessment, it also declines.

Basic laboratory and general health measures are also essential. Cognitive decline has very different implications in a smoker with active lung cancer, severe anemia, or disseminated intravascular coagulation, for example, than in a previously healthy octogenarian. Recent chest x-ray study, electrocardiogram, urinalysis, complete blood counts, and a chemistry profile (which should include electrolytes, calcium, fasting blood glucose, and renal and liver function tests) are not specifically neurological but can be very relevant if they disclose a severe abnormality. Thyroid function tests and vitamin B₁₂ should be assessed. The actual frequency of B₁₂ deficiency-related dementia is questionable, however. In patients with severe vitamin B₁₂ deficiencies, anemia and combined systems disease with prominent myelopathic features seem to predominate. Cognitive decline in such a setting should certainly prompt consideration of B₁₂ deficiency, but in cases of mild B₁₂ deficiency without accompanying features, its significance is doubtful (see [Chapter 40](#)). CNS syphilis has become rare, but again should be screened with rapid plasma reagin or other syphilitic serological tests. The erythrocyte sedimentation rate is an arguably useful screening test for a variety of diseases that result in a systemic inflammatory response, and when the rate is highly elevated, it may be an important diagnostic clue.

The above-mentioned laboratory measures are the core tests to consider in essentially all patients. Additional tests that may not be necessary in every patient include EEG, spinal fluid examination, overnight oximetry, psychiatric evaluation, small bowel biopsy, Lyme disease serology, human immunodeficiency virus serology, various connective tissue disease serologies, and paraneoplastic serologies. Ultimately, invasive testing including cerebral angiography and meningeal or brain biopsy also have their place in the diagnostic armamentarium for chronic progressive encephalopathy but not when AD is the leading diagnostic consideration.

Degenerative diseases and depression are rarely accompanied by severe EEG disturbances. In contrast, EEG abnormalities are often severe (and usually nonspecific) in toxic, metabolic, inflammatory, infectious, and neoplastic encephalopathies. Complex partial status epilepticus and Creutzfeldt-Jakob disease may produce pathognomonic patterns. When in doubt, an EEG is a simple, noninvasive screening test for a wide variety of diseases, many of which are reversible. Patients suspected of having a chronic encephalopathy, perhaps reinforced by a severely abnormal EEG, should undergo spinal fluid examination, and tests should include immunological indices such as IgG index, IgG synthesis rate, and oligoclonal bands. Although these tests are nonspecific, they are markers of intrathecal inflammation, which does not generally occur in AD or any other degenerative neurological diseases. Other tests including cytology, cultures for fungi and mycobacteria, and routine tests such as total protein, glucose, cell count, and syphilis serology should also be obtained when a spinal tap is performed. Opening pressure should be recorded, especially in patients suspected of having communicating, normal pressure hydrocephalus.

Overnight oximetry is a useful screening test for obstructive sleep apnea, a common cause of hypersomnolence with secondary inattentiveness and mild memory impairment.

Psychiatric evaluation should be considered if depression is suspected, and if psychotic symptoms complicate the clinical picture. Small bowel biopsy should be considered if CNS Whipple's disease is suspected. Various serological tests should be considered for specific infectious diseases (such as Lyme disease, particularly if a patient is from an endemic area), autoimmune diseases (including Sjogren's syndrome), and paraneoplastic conditions in patients with prior or known provocative malignancies (especially oat cell lung cancer and ovarian cancer).

Management. There is no known way to entirely protect against AD, but some beneficial trends have been noted among people who take vitamin E supplements (and possibly other anti-oxidants), take anti-inflammatory drugs, and have a highly educated background, although many college graduates and accomplished professionals who take anti-inflammatory drugs for arthritis and vitamin E to stay young still develop AD. Some studies have suggested that among postmenopausal women, there is a slight protective effect with estrogen replacement. On the other hand, more women than men have AD and gender has itself been suggested as a risk factor.

There are few so-called memory tonics available to patients and physicians. At present, the only drug with possible cognitive enhancing effects in AD is tacrine, a centrally acting acetylcholinesterase inhibitor that is thought to partially reverse the decline in cortically projected acetylcholine that results from degeneration of the cholinergic basal forebrain.^[39] The effects of the drug are modest and side effects are significant, particularly when given at higher doses, which tend to be the more effective dosages (typically 30 or 40 ml, four times daily). Unfortunately, only about a fourth of patients tolerate those dosage levels, with nausea, diarrhea, and elevated liver enzymes often being the treatment-limiting side effects. Nonetheless, it can result in functionally important gains in some patients and should be considered in patients with mild to moderate stages of the disease. It should either not be used or be used with great caution in patients with cardiac conduction defects, liver disease, or seizures. A sudden decline in cognitive status or other neurological function, such as ambulation, in a patient with AD generally implies a secondary disease process, often one that is non-neurological such as a urinary tract infection, pneumonia, and fluid and electrolyte disturbances. Medication side effects (particularly those associated with tricyclic antidepressants, benzodiazepines, and narcotic analgesics) or complications from improper medication administration should be sought, especially if the patient has continued to administer his or her own medications without adequate supervision. Common neurological causes include subdural hematoma, stroke, and complex partial seizures. The differential diagnosis is extensive and is that of an acute encephalopathy.

Although it is disabling and characteristic of AD, cognitive loss is not the greatest obstacle posed by patients to their caregivers. Paranoid delusions and other psychotic symptoms are disruptive, pose extraordinary obstacles to effective caregiving, and are probably the most common reasons patients are sent to nursing homes. Small doses of neuroleptic medications may produce sufficient relief as to permit caregivers to continue to keep the patient at home, and these medications should be part of the therapeutic armamentarium. Haloperidol at doses ranging from 0.5 mg to 2 mg a day is often sufficient, but sometimes higher doses are required. Extrapyramidal side effects, however, can become dose-limiting problems. Risperidone is a newer neuroleptic agent with additional effects on serotonergic systems and may be associated with fewer extrapyramidal side effects at equivalent doses of haloperidol.

Antidepressants with anticholinergic side effects, including all the tricyclic antidepressants, often exacerbate the confusion in these patients and are generally not recommended. Rather, serotonin reuptake inhibitors (SRIs), such as fluoxetine, sertraline, and paroxetine, can enhance energy levels (and possibly attentiveness as a result in some patients) and have antidepressant effects without the risk of anticholinergic side effects. They should not be used, however, in agitated patients or in patients with psychotic symptoms because SRIs can exacerbate these behaviors. For anxiety, buspirone, although it is generally less effective than benzodiazepines, has much less risk of paradoxical agitation and should be tried first. Neuroleptic agents can also be considered for anxiety in some patients, especially if there are accompanying psychotic symptoms.

Sedative hypnotic agents can be used in patients in whom sleep-wake disturbances are disrupting their home care. Agents that have few side effects or risks of exacerbating confusion and agitation include diphenhydramine, chloral hydrate, and zolpidem. Many patients fall asleep without difficulty but awaken at an early hour. In such instances, it is important that the sleeping aid be given when they waken. These medications help patients fall asleep, but they will not reliably keep them asleep for prolonged periods, which is in part why they are more advisable than longer acting agents.

Treatment of the patient with AD ultimately means ensuring that their needs are met. Depending on what the patients cannot do for themselves, these things need to be done for them, or they need assistance with them. That includes dressing, cooking, bathing, eating, exercise (such as walking), and those problems listed earlier. The caregiver becomes an integral part of the patient's life and is vulnerable to depression, burn-out, and associated problems. Support groups are important for caregivers, as is respite care to give the caregiver time away from the patient. Adult day care should be considered for patients at mild to moderate stages as a way to provide not only respite care for the caregiver but a supervised social outlet for the patient, too.

Prognosis and Future Perspectives. AD, like all degenerative neurological diseases, is relentlessly progressive. Because the patients are elderly, and susceptible to a variety of other disease processes, AD itself is not the most common cause of death. However, if no other disease process supervenes, death usually ensues over roughly 6 to 10 years (there is great variability) after onset.

Increasing emphasis has been placed on early diagnosis in anticipation of preventive or retardant therapy. At the extreme of this approach is the fact that those individuals destined for AD have measurable differences throughout their lives,^[40] and one such study correlated certain aspects of verbal skills at the mean age of 22 years with the subsequent development of AD 50 to 60 years later.^[41] Other studies, however, still envision AD as a disease that begins in later life, but that various types of cognitive^[41] and

metabolic^[30] derangements can be measured at least several years in advance of clinically evident cognitive decline. Possible strategies for preventive and retardant therapy include

- interfering with a critical step in the amyloid/tau/ApoE pathway that results in plaque formation, or in the pathway that results in the hyperphosphorylation of tau leading to cytoskeletal disruption

- administration of ApoE epsilon-2 or analog to promote whatever salutary effect it appears to have in preventing AD

- use of a large family of growth factor compounds that normally function during embryogenesis, some of which promote neuronal growth and retard neuronal death

- use of antioxidants to interfere with the generation of free radicals that cause cellular damage.

Strategies for symptomatic therapy include

- the use of tacrine-like drugs that enhance cortical acetylcholine levels yet with less toxicity than tacrine.

- use of neurochemical cocktails that act on multiple neurochemical projection systems.

- the use of antipsychotic agents that provide greater antipsychotic effect with less extrapyramidal side effects.

Unless a very effective treatment or cure is found, the most important agenda item for the future lies not in the realm of science or medicine but in public policy. How to deal with the burgeoning elderly population and the growing number of Alzheimer's patients, many of whom require expensive chronic institutional care, will be issues of increasing societal and political focus.

Asymmetrical Cortical Degeneration Syndromes

This is a heterogeneous group of disorders that produce distinctive cortical syndromes including aphasia, apraxia, and agnosia but that have a more focal appearance than Alzheimer's dementia. They can be roughly localized by the more focal features, though only a small subset are truly focal. There are four primary categories, each with several subtypes, including progressive aphasia, progressive frontal lobe/frontotemporal syndromes, progressive perceptual-motor syndromes, and progressive bitemporal syndromes ([Table 33-2](#)).

Pathogenesis and Pathophysiology. Despite the semiological and pathological diversity of the ACDS group, there is a common clinicopathological theme among all members: clinical presentation is dictated by the topographical distribution of degeneration. Nonspecific degenerative changes, consisting of neuronal loss, gliosis, and vacuolation of neuropil predominantly affecting superficial cortical laminae ([Fig. 33-5](#)), are common to all clinical subtypes and probably account for the overall majority of pathological findings in ACDS.

Progressive Aphasia

NONFLUENT APHASIA. The degenerative focus centers on anterior perisylvian language cortices (Broca's area). Neuropathology of progressive aphasia has included (1) nonspecific degenerative changes, including increased neuronal lipofuscin, ^[42] neuronal loss, astrocytosis, and peri-neuronal microvacuolation in superficial laminae with or without occasional amyloid plaques ^[43]; (2) nonspecific degenerative changes with focal accumulations of achromatic

TABLE 12-2 -- ASYMMETRICAL CORTICAL DEGENERATION SYNDROMES CLASSIFICATION

Syndrome	Major Topography	Main Pathology	Cognitive Signs	Other Early Neurological Signs
PROGRESSIVE APHASIA				
Nonfluent	Dominant frontal operculum	Nonspecific	Nonfluent aphasia	Dysarthria, reflex asymmetry, memory loss
Fluent	Dominant temporal	Nonspecific	Fluent aphasia	
Anomic	Dominant anterior temporal	Picks	Anomia	Acalculia, apraxia, other parietal signs, memory loss
Mixed	Dominant perisylvian	Nonspecific	All aspects of speech disturbed	Abulia and other frontal lobe signs, memory loss Memory loss, dysarthria, acalculia, apraxia
PERCEPTUAL-MOTOR SYNDROMES				
Visual	Asymmetrical bilateral P-T-O	Alzheimer's	Asimultanagnosia	Alexia, memory loss
Motor	Asymmetrical parietofrontal	CBGD	Apraxia	Hemikineti-rigid syndrome, psychomotor slowing
Mixed	Asymmetrical P-F and P-O	CBGD	Asimultanagnosia and apraxia	Memory loss, aphasia, and any of the above
FRONTAL LOBE SYNDROMES				
Neuropsychiatric	Asymmetrical bilateral prefrontal	Pick's, nonspecific	Abulia, disinhibition	Memory loss, anomia, anosognosia
Spasticity	Orbitofrontal	Nonspecific (PLS)	Psychomotor slowing	Spasticity, dysarthria
Mixed	Asymmetrical bilateral precentral gyrus Asymmetrical bilateral frontal	Unknown	Spastic-dementia syndrome	Dysarthria
BITEMPORAL SYNDROMES				
Amnesia	Bilateral mesial temporal	Alzheimer's	Memory loss	
Prosopagnosia	Right inferior temporal (bilateral?)	Unknown	Prosopagnosia	Memory loss, alexia
Neuropsychiatric	Bilateral anterior temporal	Unknown	Anomia, amnesia, abulia	Psychomotor slowing, anosognosia

CBGD, Corticobasal ganglionic degeneration; PLS, primary lateral sclerosis; P, parietal; T, temporal; F, frontal; O, occipital. Adapted from Caselli RJ Focal and asymmetric cortical degeneration syndromes. *The Neurologist* 1995;1:1-19.

Figure 12-5 Photomicrograph of frontal cortex demonstrating nonspecific histology. Note the neuronal loss and gliosis, with spongiosis involving the superficial cortical I (Hematoxylin and eosin; 25x; courtesy J. E. Parisi, Mayo Clinic, Rochester, Minnesota.)

neurons^[44]; and (3) unusual combinations of Pick/Alzheimer ^[45] and Alzheimer/Pick/Lewy body disease type pathology in one family (without Pick bodies).^[45] The hippocampal formation is involved by the asymmetrical degeneration, but the nucleus basalis is spared.^[43] Additionally, pigmented brain stem nuclei may be affected.^[43]

FLUENT APHASIA. The degenerative focus is more posteriorly placed, including Wernicke's area, although usually the entire left temporal lobe appears atrophic. Neuropathology is similar to that of nonfluent aphasia, including nonspecific degenerative changes with moderate spongiosis of superficial cortical layers and involvement of the amygdala,^[43] but some patients have been found to have AD.^[46]

ANOMIC APHASIA. The responsible degenerative focus is in the left anterior temporal lobe. Neuropathologically, Pick's disease may cause generalized atrophy that is more severe in the left hemisphere, particularly the left anterior temporal lobe and insula, with sparing of the nucleus basalis of Meynert.^[47]

MIXED APHASIA. Again, the degenerative focus appears to involve the left perisylvian cortices, particularly the left temporal lobe diffusely. Neuropathological findings include nonspecific degenerative changes with focal spongiosis of superficial cortical layers ^[48] and AD.^[49]

Progressive Frontal Lobe Dementias (FLDs) and Frontotemporal Dementia (FTDs) Syndromes (Pick's Disease). Arnold Pick originally introduced the concept of a lobar atrophy with relevant progressive focal symptoms of a patient with progressive aphasic dementia, who at autopsy had, in addition to generalized cortical atrophy, focally accentuated atrophy of the left temporal lobe. The specific histological findings were later appreciated by Alzheimer in 1911, who observed distinctive intraneuronal inclusions, which were termed "Pick bodies." Swollen, ballooned, and poorly staining (chromatolytic) neurons were subsequently called "Pick cells."

Over the following decades, most investigators have included three pathological varieties of Pick's disease: lobar atrophy with swollen chromatolytic neurons (SCN) and Pick bodies (Pick's disease Type A), lobar atrophy with SCN but not Pick bodies (Pick's disease Type B), and lobar atrophy without SCN or Pick bodies (Pick's disease Type C, or nonspecific degeneration).^[50] Whether the findings in Pick's disease Types B and C are indeed variants of Pick's disease or different disease

processes is debated.

The cardinal pathological changes in Pick's disease Type A are lobar atrophy with corresponding neuronal loss that is most apparent in the first three cortical layers ([Fig. 33-6](#)). The maximally involved cortical gyri are very thin, and they are often described as walnut or knife-edge in appearance. When the temporal lobe atrophy is focally accentuated, the posterior one-third of the superior temporal gyrus appears relatively preserved. Marked caudate and hippocampal atrophy are also typical findings. Variable degrees of co-existing subcortical gliosis and degeneration of other subcortical nuclei can occur as well, although the basal forebrain tends to be spared. Pick bodies are argentophilic, eosinophilic, rounded cytoplasmic masses that appear densely black on silver stains ([Fig. 33-7](#)). They are

Figure 12-6 Pick's disease. Note the circumscribed frontotemporal cortical atrophy with relative sparing of the posterior one third of the superior temporal gyrus. The marked gyral thinning is often described as walnut or knife-edged in app(Courtesy J. E. Parisi, Mayo Clinic, Rochester, Minnesota.)

Figure 12-7 Photomicrograph of frontal cortex in classic Pick's disease (Pick's type A). The argentophilic, rounded cytoplasmic masses are Pick bodies, which are principally composed of 8 to 20 nm straight fila(Bielschowsky silver stain; 200x; courtesy J. E. Parisi, Mayo Clinic, Rochester, Minnesota.)

composed of 10- to 20-nm straight filaments that share antigenic properties with neurofilaments. Pick bodies tend to predominate in the most severely atrophic cortical regions and in the hippocampi. Pick cells also immunostain positively to neurofilaments, but they are not regarded diagnostic of Pick's disease because similar-appearing cells have been observed in several other disorders. The nucleus basalis is spared or only mildly affected in both Pick's disease and in FLD. ^[51]

Pick's disease usually involves the frontal and anterior temporal lobes, but rare cases with preferential parietal lobe atrophy have also been described. Therefore, patients with Pick's pathology have exhibited the FLD and FTD syndromes, progressive aphasia syndrome, ^[47] and progressive perceptual-motor syndrome (corticobasal ganglionic degeneration [CBGD]). ^[52] There are a few kindreds with autosomal dominant Pick's disease, but no chromosome has been identified by genetic analysis to date.

Progressive Spasticity (Primary Lateral Sclerosis). Neuropathologically, there is highly circumscribed atrophy of the precentral gyrus with loss of Betz cells, decreased numbers of pyramidal neurons, and laminar gliosis in the external and internal pyramidal cell cortical layers. ^[53] No lower motor neuron abnormalities are typically found in hypoglossal or spinal gray nuclei, and the substantia nigra is generally unaffected. ^[53]

Progressive Perceptual-Motor Syndromes VISUAL. To date, neuropathological studies of patients with dorsal visual syndromes have generally shown senile plaques and neurofibrillary tangles, which is typical of AD. The topographic distribution, however, differs from that seen in Alzheimer's dementia, with heaviest involvement of primary and association visual cortices in the occipital lobes and, to a slightly lesser degree, in the parietal lobes. ^[36] The nucleus basalis is involved in these cases. ^[36] Other pathologies include nonspecific degenerative changes (gliosis, neuronal loss, and vacuolation of superficial cortices), ^[54] and Creutzfeldt-Jakob disease (Haidenhain variant). ^[54] To date, there are no published pathological studies of patients with progressive ventral visual cortical disorders.

MOTOR. To date, most patients reported with this syndrome have had CBGD with neuronal achromasia or nonspecific degenerative changes (see section on CBGD). Other histological patterns have included Pick's disease, ^[52] AD with involvement of the nucleus basalis, ^[55] and PSP. ^[56] There is generalized but asymmetrical atrophy with the most severe focal degeneration generally occurring in superomedial frontoparietal regions, primary motor cortex, and parietal convexity cortex, but other cortical regions, including Wernicke's area, sometimes can be severely involved as well. The substantia nigra is also involved, but the nucleus basalis is spared in the absence of AD. ^[57]

MIXED. Pathological findings include CBGD and AD.

Progressive Bitemporal Syndromes

PROGRESSIVE AMNESIA. See Alzheimer's Disease.

PROGRESSIVE PROSOPAGNOSIA. See Progressive Visual Syndromes.

PROGRESSIVE BITEMPORAL NEUROPSYCHIATRIC SYNDROMES. On a clinical basis, patients with progressive bitemporal neuropsychiatric syndromes probably have either Pick's disease or AD, but neuropathological study is lacking.

Epidemiology and Risk Factors. There are no incidence and prevalence studies of this group of disorders, but clinical experience (at a tertiary care referral center) suggests that they are, as a group, perhaps a tenth as common as AD. Genetic factors may play a role, but the data are scant.

Clinical Features and Associated Disorders. There are four broad categories of ACDS, each of which can be further subdivided, and topographical and pathological correlations could be made for each (see [Table 33-2](#)).

In most cases, there are three properties of the atrophy topography that are radiologically discernible: (1) there is a lateralized major atrophic focus; (2) there is a contralateral area of focal atrophy that is less severe than the primary focus, the homologous cortices; and (3) there is milder generalized atrophy. Metabolic abnormalities reflect this pattern as well. ^[58]

Several types of ACDS are associated with amyotrophic lateral sclerosis (ALS), including progressive aphasia, ^[59] frontal lobe syndromes including Pick's disease ^[60] and nonspecific frontal lobe degeneration, ^[61] and bitemporal syndromes. ^[62] In such cases, longevity is determined by the ALS component, and in the case of progressive aphasia with ALS, the disease course appears particularly rapid. ^[59] Occasional patients with apparent primary lateral sclerosis (PLS) may have mild lower motor neuron abnormalities, and they appear to have a slower course than typical ALS. Patients with a bitemporal or frontotemporal syndrome and ALS may have a more severe neuropsychiatric syndrome with features of Kluver-Bucy syndrome ^[62] compared with those without ALS. Finally, subtypes of ACDS may overlap in the same patient, such as progressive aphasia and a progressive perceptual-motor syndrome.

Progressive Aphasia. Although original credit should probably go to Arnold Pick for correlating lobar atrophy with aphasic dementia, ^[63] Mesulam's 1982 report of progressive aphasia ^[42] essentially refocused modern neurology on the relationship of focal cortical degeneration to a progressive cortical syndrome. Because most patients are left-hemisphere dominant for language, most patients have left-sided asymmetrical atrophy. However, occasional patients are found who are left handed and who have right-hemisphere asymmetrical atrophy accompanying progressive aphasia. Cognitive deficits other than those directly attributable to language may also occur, especially memory impairment and constructional apraxia.

Nonfluent progressive aphasia generally reflects anterior perisylvian cortical degeneration (Fig. 33-8 (Figure Not Available)). It should be readily distinguished from typical AD. Speech is effortful, halting, and sometimes dysarthric. Naming ability is marked by phonemic paraphasic errors (for example, "calicopter" for helicopter), repetition is generally severely impaired, and although writing sometimes is easier than speaking, it is also usually abnormal. Aural and reading comprehension are less impaired in mild to moderate stages but deteriorate in most patients with disease progression. Some patients have orofacial apraxia but not gestural or limb apraxia. Verbal memory tests are difficult to administer, but verbal memory is typically impaired.

Fluent aphasia involves degeneration of temporal and posterior perisylvian cortices. Contiguous involvement of neighboring cortices may complicate the clinical picture, making it difficult to distinguish a focal left temporoparietal syndrome (with aphasia, amnesia, apraxia, and acalculia) from a so-called diffuse cognitive disorder, or Alzheimer's dementia. The nonlanguage impairments, however, are much less disabling than the language impairment in progressive fluent aphasia.

Fluency, articulation, and prosody are normal, but comprehension and naming are impaired. Sentence repetition appears to be impaired less consistently. The characteristic naming errors are semantic paraphasias, but phonemic paraphasias occur as well. Typically, a patient may recognize and describe the object or action they cannot name (e.g., "something that flies" for a helicopter), or give a generic descriptor. Spelling errors are frequent.

Anomic aphasia involves degeneration of anterior temporal cortices. Patients are fluent, comprehend well, and can repeat, read, and write with minimal difficulty. However, their speech lacks semantic precision. They substitute generic terms for specific words (e.g., "machine" for computer), and make semantic paraphasias (e.g., "staple" for paper clip). Anomia is a common feature of both AD and Pick's disease, but verbal memory is usually impaired even in the absence of dementia.

Mixed progressive aphasia is a more nonspecific pattern

Figure 12-8 (Figure Not Available) Progressive nonfluent aphasia. Ml(top) and SPECT (bottom) showing left frontal opercular atrophy(Reprinted from Caselli RJ, Jack CR Jr: Asymmetric cortical degenerative syndromes: A proposed clinical classification. Arch Neurol 1992;49:770-780. By permission of Little, Brown and Company [Inc.])

involving degeneration of left temporal and perisylvian cortices. Patients with this condition have impairment of all aspects of language, making classification into a single taxonomic category impossible. They are nonfluent, with impaired comprehension, naming, repetition, writing, and reading.

Progressive Perceptual-Motor Syndromes. Although most patients have a mixed sensory-motor syndrome (including visual or somatosensory systems, or both), there are a few patients who have a pure sensory (typically visual) or pure motor syndrome (typically a hemiakinetic rigid syndrome). Progressive spasticity is considered under Asymmetrical Cortical Degeneration Syndromes.

Progressive visual syndromes involve degeneration of parieto-occipital or parieto-temporal visual association cortices, or both. Visual association cortices can be broadly divided into dorsal (occipitoparietal) and ventral (occipitotemporal) pathways, and disorders of visual association cortices reflect this dichotomy. The occipitoparietal pathway is more concerned with localizing an object in space (where), and the occipitotemporal pathway is more concerned with object identification (what). Two broad types of complex visual disturbance have been described with ACDS. The more commonly reported is progressive asimultanagnosia, reflecting dysfunction of the dorsal cortical visual pathway. Patients cannot integrate the numerous components of an ordinarily complex scene into a coherent whole. When viewing a street scene, for example, they might describe a car or a person or a lamppost, but overlook the fact that it is an inner city rush hour. Occasional associated problems that also reflect posterior parietal and temporal involvement include alexia, acalculia, right-left disorientation, and mild deficits of memory and language (fluent aphasia). Eventually, patients may be found to have inferior quadrantanopia, although typically visual field testing produces inconsistent responses.

The second type of complex visual disorder resulting from ACD is visual agnosia, of which there are fewer reported examples. [64], [65] Visual agnosia results from dysfunction of the ventral cortical visual pathway. Some patients have been described with progressive prosopagnosia, which is a failure to recognize familiar faces. [65] Rarely, patients may describe progressive atopographagnosia, the inability to recognize familiar places. In later stages, both ventral and dorsal visual pathways become involved, and a more globally encompassing visual agnosia results, as illustrated best by Oliver Sacks' Professor P. [64]

Progressive Motor Syndromes (see also CBGD). Two major clinical characteristics, both slowly progressive in onset, make this disorder distinctive and easily recognized. The first are lateralized somatic deficits, including hemi-spasticity, hemiparesis, hemisensory impairment (usually in the form of astereognosis or tactile agnosia with less consistent impairment of more basic somatosensory modalities), and myoclonic jerks. Some patients may have a hemirigid or hemidystonic syndrome with tremor. The second is severe and disabling apraxia, including limb apraxia (inability to use the limb in a meaningful way, such as to use a comb), gestural apraxia (inability to pantomime or imitate symbolic movements), dressing apraxia, constructional apraxia, and apraxic agraphia. If the lateralized limb defects reflect dominant hemispheric dysfunction, then a mild fluent aphasia may be present that is milder than that seen in progressive fluent aphasia. When the lateralized limb defects reflect nondominant hemisphere dysfunction, it is uncommon (but possible) for a hemineglect syndrome to result.

Additional clinical abnormalities may include acalculia, psychomotor slowing, aphasia, and supranuclear oculomotor disturbances. Although patients with severe apraxia, psychomotor slowing, and mild aphasia may appear demented according to neuropsychological testing, they are usually rational, insightful, and upset by their condition. In late stages, patients can barely move or speak despite preserved consciousness.

Many patients have both a sensorimotor and a visuospatial disorder, combining features of both of the above- mentioned groups (Fig. 33-9 (Figure Not Available)).

Progressive Frontal Lobe and Frontotemporal Syndromes.

The three main frontal lobe syndromes are a progressive neuropsychiatric syndrome (frontal and frontotemporal dementia), a progressive spastic syndrome, and a mixture of these two.

The progressive neuropsychiatric syndrome is the best-known

Figure 12-9 (Figure Not Available) Progressive perceptual-motor syndrome. Ml(top) and SPECT (bottom) showing right greater than left parietal atrophy(Reprinted from Caselli RJ, Jack CR Jr: Asymmetric cortical degenerative syndromes: A proposed clinical classification. Arch Neurol 1992;49:770-780. By permission of Little, Brown and Company [Inc.])

example of this group and has been referred to as frontal lobe or frontotemporal dementia (Fig. 33-10 (Figure Not Available)). Pick's disease is prominently represented in this group. More recently, Brun [66] and Gustafson [67] described a similar clinical syndrome in the absence of Pick bodies. Although the clinical picture is characteristic, many clinicians have difficulty distinguishing these patients from those with Alzheimer-type dementia. Another common misdiagnosis is depression. The errors made by these patients tend to be omissions rather than commissions, and the term that describes this condition is abulia. They fail to change their clothes, to brush their teeth, to pursue their former interests, and to initiate many activities that constitute a normal day. Just as they fail to start something new, they may fail to stop what they are doing and perseveratively fixate, in a seemingly idiosyncratic fashion, on some particular activity, such as going to the bathroom, sorting through their wallet, or watching television. Some patients have greater disinhibition and emotional lability, crying at the least provocation, or laughing loud and long. They may complain that they are hungry yet be unmoved to fix themselves a snack. Some may perseveratively want to eat over and over. Memory and language (especially naming) are typically impaired. Despite their sometimes reduced temporal latency in responding to the examiner (they may start answering a question before the physician has finished asking it), their answers are brief, and often consist of "I don't know." Patients with FLD may stick close to their caregiver and generally cause fewer disruptions than patients with AD, particularly in mild to moderate stages (although there are notable exceptions).

Associated clinical abnormalities reflect dysfunction of other frontal lobe functions including spasticity and nonfluent aphasia. Because Pick's disease has a predilection for the temporal as well as the frontal lobe, some patients also develop signs referable to the temporal lobe, particularly anomia.

The syndrome of progressive spasticity has been termed PLS, and historically, the nosological focus has been on its relationship to ALS (see [Chapter 36](#)) rather than other frontal lobe degenerations. PLS reflects degeneration of the precentral gyrus and primary motor cortex. [53] Cognitive impairment is minimal but can include emotional lability, mild frontal lobe-related cognitive deficits, and mild memory impairment. [68]

Some patients present early in their course with a combination of both spasticity and FLD/FTD. [69] Conceivably, these patients have Pick's disease because Pick's disease produces spasticity late in the course of the illness, but patients with AD have also been reported to present (rarely) with progressive spasticity.

Progressive Bitemporal Syndromes. The three syndromes in this category are progressive amnesia, progressive prosopagnosia, and progressive neuropsychiatric syndrome. Progressive amnesia is discussed in the section on AD, and progressive prosopagnosia is discussed in the section on progressive visual syndromes because this entity overlaps both categories of ACDS. Patients with a progressive neuropsychiatric syndrome due to bitemporal degeneration (Fig. 33-11 (Figure Not Available)) have severe anomia and amnesia, relative indifference to their condition, and mild perseverative behaviors that are shared with patients in the frontal lobe group. Psychomotor speed is normal or only mildly impaired. Neuroimaging shows bilateral severe anterior temporal atrophy and hypoperfusion with relative sparing

of the frontal lobes.

Differential Diagnosis. The two broad categories to consider are nondegenerative structural focal brain lesions, such as a slowly growing tumor and other degenerative conditions. Regarding the first, a slowly progressive neurological syndrome that can be reasonably localized could be neoplastic, whether malignant or benign. Rarely, high-grade arterial stenoses cause stuttering infarction mimicking a slowly progressive degenerative cortical syndrome,

Figure 12-10 (Figure Not Available) Progressive frontotemporal dementia. M(*top*) and SPECT (*bottom*) showing right greater than left frontal and anterior temporal atrophy in a patient with autopsy-documented Pick's disease (Reprinted from Caselli RJ, Jack CR Jr: Asymmetric cortical degenerative syndromes: a proposed clinical classification. *Arch Neurol* 1992;49:770-780. By permission of Little, Brown and Company [Inc.]

Figure 12-11 (Figure Not Available) Progressive bitemporal neuropsychiatric syndrome: M(*top*) and SPECT (*bottom*), showing right greater than left anterior temporal atrophy (From Caselli RJ: Focal and asymmetric cortical degeneration syndromes. *The Neurologist* 1995;1:1-19.)

but this is very uncommon. Other pathological processes that could occur focally, including infection or abscess and demyelinating or vasculitic conditions, should also be considered. Other degenerative illnesses include Creutzfeldt-Jakob disease in rapidly progressive cases and the wide variety of degenerative pathologies discussed earlier. For example, a patient suspected of CBGD may have AD at autopsy. Among the frontal lobe, aphasic, and bitemporal varieties of ACDS, an association with ALS must also be considered.

Evaluation. The most important diagnostic test is adequate structural neuroimaging. MRI is preferable to CT, but either will generally suffice to evaluate the possibility of a tumor. In addition to excluding nondegenerative structural abnormalities, a magnetic resonance angiographic (MRA) study could be included, if available, to search for a potentially relevant high-grade arterial stenosis. Patients with ACDS usually, but not invariably, have radiologically discernible focal atrophy in the symptomatic region. It is often subtle and of insufficient severity to permit blinded diagnosis of ACDS. However, in a patient with progressive anomic aphasia for example, focal left anterior temporal atrophy should be considered important not only because of the absence of a tumor but because it shows the responsible lesion to be an atrophic one, presumably degenerative. Formal neuropsychological assessment can be helpful to assess quality and severity of cognitive impairment to a greater extent and usually demonstrates a pattern that is not typical for Alzheimer's dementia. It is also useful for monitoring disease progression. Other laboratory studies are less helpful because of the apparent focal nature of the ACDS. Metabolic encephalopathies do not usually cause the syndrome of slowly progressive aphasia, which is difficult to confuse with a diffuse encephalopathy. Nonetheless, it is still reasonable to make certain that basic laboratory data is normal, as was discussed for AD.

Management. Considerations similar to those discussed for AD are applicable here with minor additions. First, patients with ACDS are usually aware of their limitations and are not likely to get themselves in trouble unwittingly by wandering, refusing medications, and so forth. They require nursing home placement less often if a caregiver exists. Physical therapy is important for patients with CBGD and PLS, especially because of the complications resulting from altered muscle tone and gait unsteadiness. Occupational therapy is particularly important for ACDS patients with apraxia and spatial disorders to assist with dressing, eating, and other activities of daily living. Speech therapy is appropriate to consider for progressive aphasia not only because of the aphasia but in later stages of nonfluent aphasia in particular, because of dysphagia as well. Late-stage complications are similar for AD but perhaps are most severe for CBGD. In this condition, because all avenues of communication are lost, including speech and praxis, and because muscle tone contorts them into painful dystonic postures with contracture formation, there remains relative preservation of insight, perhaps compounding their suffering further. Trials of carbidopa and levodopa (Sinemet) in CBGD should be considered, even though it is usually of minimal efficacy at best. In patients with CBGD with severe myoclonus, small doses of clonazepam can also be considered. Finally, in cases with severe dystonic posturing, especially hand closure, selective botulinum toxin injection can be considered to accomplish limited goals, such as allowing the hand to be opened for maintenance of skin hygiene and to retard contracture formation.

Prognosis and Future Perspectives. All of the ACDSs are progressive and follow a similar time course to AD. Most patients have a more generalized cortical degenerative process that becomes more significant in later stages, but occasionally patients have a highly focal process with minimal evidence of generalized decline, even at the time of their death. Prognosis is better in the group with the

highly focal process. Otherwise, ACDS of all types, like AD and other degenerative brain diseases, results in death after relentless progression.

ALS-Dementia Complex

Pathogenesis and Pathophysiology. The nosological distinction among frontotemporal lobe dementia (FTD), FTD with motor neuron disease (MND), and classic MND has been debated, with some arguing that FTD with MND is a distinct disorder and others suggesting each represents a phenotype along a continuum of the same disease.^[70] The histological findings do not clarify nosology because in the majority of cases, they are nonspecific: neuronal loss, gliosis, and microvacuolation or spongiform changes predominantly affecting the superficial cortical layers and subcortical white matter. Degeneration is usually greatest in frontotemporal regions and, less commonly, in perisylvian language cortices. The nucleus basalis of Meynert appears normal, as do cortical levels of choline acetyltransferase and somatostatin.^[71] Variable degrees of degeneration also occur in the amygdala, hippocampus, thalamus, caudate nucleus, and substantia nigra.

Epidemiology and Risk Factors. Dementia rarely occurs in patients with ALS, although known associations include the Parkinson-ALS-dementia complex of Guam, which occurs in the indigenous Chamorro population^[72]; familial ALS^[73]; and sporadic cases from both Eastern^[74] and Western^[59],^[61],^[62],^[70] populations. Pathogenesis in most patients is uncertain, and histopathological features are generally nonspecific.

Clinical Features and Associated Disorders. Frontal lobe or frontotemporal dementia is the most common dementia pattern, followed by aphasic dementia. Clinical descriptions in the literature, however, have varied and include unqualified dementia,^[74] dementia of the Alzheimer type, Pick's disease,^[60] and dementia with Kluver-Bucy syndrome,^[62] in addition to frontotemporal^[61] and aphasic dementia.^[59] Bulbar symptoms have been consistently prominent.

For some years, an association with Creutzfeldt-Jakob disease was suspected, but this is no longer thought to be the case.^[75]

Differential Diagnosis. Certain types of the ALS-dementia complex may be rapidly progressive, with anarthria within 1 year and death within 2 years. Given the severity, rapid progression, and sometimes paucity of limb abnormalities, Creutzfeldt-Jakob disease should be considered. In rapidly progressive cases, carcinomatous meningitis can also cause encephalopathy and polyradiculopathy, which might be mistaken for ALS-dementia complex, so CSF evaluation can be useful. Head and neck tumors, particularly carcinoma of the posterior tongue with CNS metastases can cause severe dysarthria and mental status changes, and they should not be overlooked particularly when dysarthria is the main finding. Finally, neuromuscular weakness due to ALS, myasthenia gravis, acid maltase deficiency, myotonic dystrophy, and any other disease of sufficient severity to compromise ventilatory capacity may lead to a hypoxic encephalopathy that, in the absence of a corroborating history, might be mistaken for ALS-dementia complex, so arterial blood gases should be considered in some cases.

Evaluation. Both the nature of the neuromuscular disorder and the cognitive disorder must be established. EMG is important for the neuromuscular disorder and an essential diagnostic step but may not be conclusive, especially in bulbar cases. Further evaluation of the ALS aspect of this disorder is considered in the section on ALS but may include acetylcholine receptor antibody and creatine phosphokinase among other tests. Regarding the cognitive disturbance, formal mental status assessment is the first step, and if there is any doubt, formal neuropsychological assessment focusing particularly on frontal lobe and language function should be performed. Evaluation of the dementia should then proceed with similar considerations, as discussed for AD, with particular attention to neuroimaging. In this context, MRI is preferable to CT because imaging of lower brain stem structures in particular is better accomplished by MRI. In selected circumstances, as discussed earlier, additional consideration should be given to EEG, CSF examination, consultation with an otolaryngologist, and arterial blood gas evaluation.

Management. Treatment considerations overlap those for ALS (see the section on ALS). Caregiving for the demented patient is discussed under AD. This is a particularly difficult condition because of the combination of neuromuscular and cognitive problems that confront the patient.

Prognosis and Future Perspectives. As with other neurodegenerative diseases, progression is inevitable and generally more rapid than in AD, with death occurring within 3 to 5 years in typical cases. Unlike uncomplicated ALS, in which the mind is preserved, causing some individuals to opt for feeding tubes, external ventilatory

support, and other life-sustaining measures, ALS-dementia complex also produces severe intellectual decline, making justification of such measures difficult.

[PreviousNext](#)

SUBCORTICAL DEMENTIA

Parkinson's Disease with Dementia

There are several forms of primary degenerative parkinsonism, including idiopathic (or sporadic) PD, sporadic PD with superimposed pathological features of AD, familial PD (or parkinsonian syndromes), and Parkinson's-ALS- dementia complex of Guam. Pathological substrates differ among these conditions, as do the frequency of cognitive disturbances. In patients with pathological evidence of AD, dementia is usually (but not invariably) present. In familial cases, genetic defects and pathological changes differ between kindreds, so it is difficult to generalize to sporadic PD. In each case of PD, however, when dementia is described, it is most consistent with a "subcortical pattern" to distinguish it from typical Alzheimer-type dementia.

Pathogenesis and Pathophysiology. Memory performance in nondemented and demented patients with PD is qualitatively different,^[76] ^[77] suggesting that cognitive impairment in nondemented and demented PD patients reflects

different anatomical or neurochemical systems,^[76] or separate pathogenetic processes.^[77] Histological components of the Parkinson's dementia picture include both Parkinson's and Alzheimer-type pathology. Therefore, one must consider the roles of cortical Lewy bodies, concomitant AD pathology, and cholinergic deficiency in the pathogenesis of dementia in PD (see the section on diffuse Lewy body disease). Recent studies using ubiquitin staining in previously pathologically diagnosed PD demonstrate that 76 percent of cases have neocortical Lewy bodies compared with only 32 percent of cases studied only with routine hematoxylineosin stains.^[78] Concomitant AD changes meeting diagnostic criteria for AD diagnosis have been found in up to 50 percent of patients with PD dementia.

PD is characterized by nigral degeneration with Lewy bodies in the pigmented brain stem nuclei, but the contribution of medial substantia nigra neuronal loss, the most consistent pathological finding in PD, to dementia is unclear. The basal ganglia interfaces with the limbic system through a subset of structures collectively referred to as the ventral striatum and ventral pallidum. Cortical input to the ventral striatum is from the hippocampal formation through the precommissural fornix, and dopaminergic input comes from the ventral tegmental area (part of the mesocorticolimbic dopaminergic system). Analogous to the concept that the dorsal or neostriatum and its neocortical targets are part of a so-called motor loop, so, too, have the ventral striatum and its allocortical or paralimbic targets been termed a cognitive loop.^[79] However, the role of the cognitive loop remains speculative, and it is unknown whether any cognitive alterations in PD or dementia reflect this loop.

Epidemiology and Risk Factors. Considering the heterogeneity of parkinsonian syndromes, potential co-occurrence of AD, and the cognitive side effects of antiparkinsonian treatment, estimates of dementia prevalence in PD vary considerably. Most range between 20 and 30 percent.^[80] Based upon autopsy studies, about half of demented parkinsonian patients have coincident AD pathology.^[81]

Clinical Features and Associated Disorders. Although PSP was the original model for subcortical dementia, this model is applicable to PD, which is much more common than PSP. The concept was intended to distinguish subcortical dementia from the cortical dementia of AD. Subcortical dementia-related memory impairment is benefited more by cuing than the memory disturbance of cortical dementia. Patients have equal or greater difficulty learning new material but have relatively less difficulty retrieving it, possibly due to disturbed frontal or frontostriatal function involved in attending to and organizing the memory task. Subcortical dementia is not usually accompanied by aphasia, apraxia, and agnosia. However, it is accompanied by psychomotor slowing, an early feature of Parkinson's dementia.^[76] ^[77] Patients perform disproportionately poorly on timed tests whether the tests use motor responses (such as the digit symbol substitution subtest of the Wechsler Adult Intelligence Scale-Revised [WAIS-R]), or whether they are purely cognitive (such as the controlled oral word association test). PD results in disproportionately poor performances on visuospatial tasks, although this aspect does not seem to be a major source of clinical disability, and the cause is debated. Depression is more common in PD with or without dementia than in AD. Finally, the noncognitive (motor) parkinsonian features make distinction from AD and related cortical degenerative syndromes generally possible. The distinction has clinical value, despite overlap with cortical dementia on both clinical and pathological grounds that blur nosological boundaries. For example, a subset of patients with Alzheimer's disease have mild extrapyramidal features,^[76] and there is important subcortical pathology in the basal forebrain of AD. The coincidence of Alzheimer's pathology in patients with Parkinson's disease with so-called subcortical dementia has already been alluded to earlier. There are certain kindreds in which a parkinsonian syndrome is invariably accompanied by severe dementia. Nondegenerative quasiparkinsonian syndromes in which cognitive impairment is present can have many etiologies including multi-infarct dementia, normal pressure hydrocephalus, and post-encephalitic parkinsonism, and are discussed elsewhere.

Differential Diagnosis. The main question in patients presenting with parkinsonism and dementia is whether the entire picture is explained by PD and whether it will respond to levodopa therapy. The differential diagnosis of PD is extensive, and dementia can occur in many of the conditions discussed in the section on PD. Some of the differential diagnoses that are of particular note that are also degenerative include PSP, multiple systems atrophy (MSA), DLBD, and CBD. Occasionally, frontal lobe disorders may be mistaken for parkinsonian syndromes with dementia, including both degenerative etiologies, such as Pick's disease, and nondegenerative etiologies, such as frontal lobe meningiomas. Other progressive, nondegenerative diseases that have loosely fitting parkinsonian features include multi-infarct dementia and normal pressure hydrocephalus. Occasionally, parkinsonian features occur in patients with AD (see AD and DLBD sections).

Evaluation. MRI is generally preferable to CT, in part because of the multifocal areas of increased T2 signal (often missed or poorly defined by CT) in periventricular, basal ganglia, and other locations that may signify a small vessel multi-infarct state. Evaluation is similar to that described for AD save that response to therapy offers additional diagnostic information (see later).

Management. Dopaminergic therapy is discussed in the section on PD, but certain special considerations apply here. First, dopaminergic therapy is more likely to cause hallucinations and delusions in parkinsonian patients with dementia, as well as in patients with related parkinsonian syndromes, than in those with uncomplicated PD. Second, neuroleptic therapy is more likely to cause an exacerbation of parkinsonian symptoms. Third, so-called on-off motor fluctuations may be accompanied by mild fluctuations in cognitive status as well. There are no perfect solutions, and antipsychotic therapy with atypical agents such as risperidone and clozapine, which produce fewer parkinsonian side effects than standard agents, will need to be tried cautiously if absolutely required. Tacrine, although not generally recommended, could be considered given the frequency of Alzheimer-type pathology, including cholinergic deficiency, although again there is at least the theoretical risk that increasing central cholinergic tone could mildly exacerbate the parkinsonian syndrome.

Prognosis and Future Perspectives. Prognostic con

siderations are similar to those discussed for AD except that the combination of parkinsonism and dementia is a more difficult management problem, and because dementia is usually a late complication of PD, it may signify a shorter lifespan than for patients with either uncomplicated PD or AD.

There is ongoing development of more highly selective neuroleptic agents with less toxicity than clozapine. One recent report suggested that selective serotonin receptor blockade may offer one such strategy. See the section on Movement Disorders.

Multiple System Atrophy

This is an uncommon and heterogeneous group of disorders generally characterized by atypical, relative dopamine-unresponsive parkinsonism with variable degrees of cognitive impairment. MSA includes olivopontocerebellar atrophy (OPCA), striatonigral degeneration, and parkinsonism with orthostatic hypotension and dysautonomia (Shy- Drager syndrome).

Pathogenesis and Pathophysiology. Neuropsychological studies in both sporadic and familial cases of OPCA have demonstrated frontostriatal dysfunction.^[82] A similar profile of frontostriatal impairment occurs in MSA with predominantly striatonigral degeneration features, which is qualitatively different from PD and PSP.^[83] Therefore, it would appear the cognitive impairment in the various forms of MSA results, at least in part, from frontostriatal dysfunction. Cerebellar dysfunction may play an additional role in OPCA.

Epidemiology and Risk Factors. Of five clinical subtypes of OPCA that have been described on both genetic and sporadic bases, mild to moderate decline has been described in types III, IV, and V.^[82] Approximately 60 percent of familial and 35 percent of sporadic cases have accompanying cognitive impairment.^[84] (Also see

Shy- Drager syndrome and striatonigral degeneration.)

Clinical Features and Associated Disorders. Patients with dominantly inherited OPCA (type IV) have frontal lobe-related cognitive impairments,^[82] but the apparent mild intellectual decline in most OPCA may be related more importantly to motor impairment and depression without actual dementia and without evidence of aphasia, agnosia, or apraxia.^[85] Multiple systems atrophy of the Shy- Drager variety has been less studied. Given the clinical similarities to other parkinsonian syndromes, as well as its clinical heterogeneity, mild "subcortical" patterns of cognitive impairment are possible, but it should not presently be regarded as a cause of severe dementia.

Management. Considerations are similar to those discussed for Parkinson's dementia, but successful treatment of psychotic symptoms in OPCA has been reported.

Progressive Supranuclear Palsy

Pathogenesis and Pathophysiology. Although the anatomical substrates underlying the parkinsonian and oculomotor disorder are relatively well understood (see [Chapter 34](#)), those underlying the cognitive symptoms are not. In addition to mesocorticolimbic dopaminergic alterations (see the section on Parkinson's disease dementia), there is evidence of more pronounced frontal lobe dysfunction than in other subcortical dementias on the basis of neuropsychological tests^[86],^[87] and PET.^[88] These findings have been attributed to primary striatal damage, which disrupts normal processing in the frontostriatal "cognitive" circuit such that frontal deafferentation occurs.^[86] Striatal damage could also explain disruption in the anterior cingulate attention and lateral-orbitofrontal social affect circuits.^[86]

Rarely, patients with PSP have variable degrees of aphasia, anomia, alexia, apraxia, or hemineglect, and some have had a frank progressive perceptual-motor syndrome similar to CBD.^[86] Anatomical distribution of degeneration is atypical in such cases and may be maximally present in the parietal cortex. All 10 cases in another report had neocortical tangles and neuropil threads; the density of tangles was highest in Brodmann's area 4.^[89] Pronounced transentorhinal and entorhinal cortical degeneration resulting in hippocampal-isocortex disconnection similar to that occurring in AD has rarely been observed in PSP with severe dementia.

In summary, the typical subcortical pattern of dementia probably reflects substrates that are similar to those found in Parkinson's dementia with greater physiological disruption of frontal lobe function, but atypical cases have presented as definite cortical patterns of dementia due to predominantly cortical patterns of pathology.

Epidemiology and Risk Factors. The incidence of PSP is roughly three new cases per million per year, and the prevalence is 1.5 cases per million, making it about 1 percent as common as PD.^[90] Median survival after symptom onset is approximately 6 to 7 years.^[90] No clear predisposing or genetic factors have been identified to date.

Clinical Features and Associated Disorders. In addition to the extrapyramidal and oculomotor abnormalities that characterize PSP (see [Chapter 34](#)), certain cognitive features occur that led to the characterization of subcortical dementia are discussed in the section on Parkinson's dementia. In addition, there are frontal lobe features that appear to be more prominent than in other types of subcortical dementia.^[87]

Differential Diagnosis. PSP is part of the differential diagnosis of the patient with atypical parkinsonism with dementia (discussed in the Parkinson's disease dementia section) and is usually distinguished clinically on the basis of the oculomotor disturbance and levodopa unresponsiveness.

Evaluation. In addition to the evaluation outline for PD and AD, SPECT and PET may show frontal and basal ganglia hypometabolism.

Management. Severe dementia and psychosis is less common in PSP than in Parkinson's disease dementia, although treatment considerations are otherwise similar for Parkinson's dementia.

Prognosis and Future Perspectives. Disease progression is similar (relentless) to that of other neurodegenerative conditions. Median survival after symptom onset is 6 to 7 years, and patients are typically wheelchair bound at least a year before that.

Huntington's Disease

Pathogenesis and Pathophysiology. The cognitive impairment in HD, like other subcortical dementias, primarily

reflects frontostriatal dysfunction, and there is pathological evidence of both subcortical and cortical pathology. Grossly, the cortical gyri appear normal to slightly atrophic. Coronal sections reveal striking caudate greater than putamen and pallidum atrophy. Neuronal loss and gliosis follow the same regional distribution. The medium-sized spiny type I striatal neurons are preferentially affected, whereas the aspiny type I neurons that contain somatostatin and neuropeptide Y are unaffected. Several neurotransmitters are decreased in the striatum, most notably GABA and acetylcholine. Glutamic acid decarboxylase and choline acetyltransferase are also diminished.

Milder degenerative changes occur in the neocortex and thalamus. Cross-sectional areas within the frontal, temporal, and parietal lobes were decreased compared with controls, with atrophy in HD being greater than in PSP.^[91] Quantitative analysis in HD patients compared with that of controls has revealed moderate to severe neuronal loss in the cortex and striatum, which was differentially distributed in the cortical laminae in primary sensory and association cortices.^[92] Ubiquitin-reactive dystrophic neurites were identified in all cortical but no subcortical areas,^[93] and these neurites have been hypothesized by some to correlate with dementia. Evidence exists for excitotoxic damage and mitochondrial DNA mutations and oxidative stress^[94] in the pathogenesis of cortical pathology in HD.

Clinical Features and Associated Disorders. Lieberman and associates found that 90 percent of patients were demented by a mean age of 48.3 years, and that dementia preceded the onset of chorea in 24 percent.^[90] There are discrepant studies with regard to the existence of preclinical cognitive abnormalities, although preclinical metabolic abnormalities are detectable with PET.^[95] Whether or not it is the critical determinant of cognitive decline, cognitive decline correlates pathologically and radiologically with degree of caudate atrophy^[96] and hypometabolism.^[97] Three areas of particular interest in the dementia of HD are frontal lobe-related or frontostriatal-related neuropsychiatric deficits, declarative memory impairment, and motor learning difficulties. Visuospatial disturbances have been demonstrated in some studies. With regard to frontostriatal neuropsychiatric deficits, patients may present initially with either primarily psychiatric or cognitive disturbances, although both may occur together. Regarding cognitive disturbances, prospective study of cognitive decline in early cases has shown that psychomotor slowing is a characteristic early feature,^[98] and memory impairment, although present early on, does not deteriorate as rapidly, or correlate as well with caudate atrophy, as does psychomotor speed.^[98] Patients with HD have greater perseveration and less initiation than AD patients, and they have greater problems with concentration and sustained attention. The overall pattern of frontal lobe-related deficits nonetheless appears qualitatively distinct from purely frontal cortical damage and has instead been attributed to frontostriatal dysfunction.

Regarding declarative memory impairment, much work has focused on the qualitative differences between HD and amnesic patients, including both AD and Korsakoff's patients. HD causes memory loss, but it appears to be less severe compared with that of AD at matched stages of dementia severity, although this factor has been more consistent at milder stages of dementia. Most studies have found that patients with HD have greater difficulty learning a task (such as a list of words), but they benefit more greatly by cued recall or recognition compared with free or unassisted recall. This has been thought to reflect greater impairment of retrieval than storage mechanisms, and it affects remote memory retrieval as well as more recently learned material.^[31] There are many similarities in the memory disturbance between HD and PD, suggesting similarities between the subcortical dementia illnesses, but overlap is imperfect. For example, patients with HD have greater impairment of learning and free recall, better recognition memory, and more perseveration than PD patients.^[99]

In contrast to the mild impairments of verbal learning, motor learning is severely impaired. There is a "double dissociation" between the performance of AD and HD patients on tests of these two memory systems: AD patients do poorly on verbal and well on motor learning, and HD patients do well on verbal and poor on motor learning.^[32] Demented PD patients perform poorly on both,^[32] which is interesting to consider in light of known overlap with AD pathology in a large subset of these patients. The most likely anatomical substrates, supported by the overlap with PD, are the basal ganglia, their frontal lobe connections, and related motor structures.

Differential Diagnosis. see [Chapter 34](#). In the absence of chorea, the family history is critical in reaching a diagnosis. In the absence of both chorea and a family

history, the differential diagnosis is that of other subcortical dementias and chronic progressive encephalopathies.

Evaluation. The clinical examination may provide compelling evidence for HD, which can be confirmed genetically. Ancillary tests include MRI or CT to ascertain caudate atrophy, and (optionally) SPECT or PET to ascertain caudate hypometabolism. Neuropsychological assessment is useful to document the nature and severity of cognitive decline, particularly in mild to moderate stages of the illness. Other causes of chorea should be sought, as discussed in the Movement Disorders section.

Management. see [Chapter 34](#) . Pharmacological management of dementia and chorea often involves dopaminergic antagonists including neuroleptic drugs but is far from adequate.

Prognosis and Future Perspectives. Death occurs within 10 to 20 years after onset, although suicide is more prevalent in at-risk and early-onset HD patients. Aspiration and inanition result from severe dysphagia, as well as from an apparent increased metabolic demand in patients with HD. See also Movement Disorders section.

MIXED CORTICAL-SUBCORTICAL DEMENTIAS

Corticobasal Ganglionic Degeneration

Pathogenesis and Pathophysiology. The characteristic pathological changes in CBGD include asymmetrical frontoparietal cortical atrophy with corresponding neuronal loss and gliosis, substantia nigra degeneration, and swollen achromatic neurons.^[100] Variable degrees of degeneration in

other subcortical nuclei also occur. The achromatic neurons immunostain positively to neurofilaments (Fig. 33-12). Some have regarded these neurons to be related to Pick cells, although immunohistochemical and ultrastructural analyses suggest that CBGD can be differentiated from Pick's disease, PSP, and AD.^[101] CBGD is a diffuse cytoskeletal process characterized by the accumulation of pathologic tau proteins.^[101] Impaired neurofilament phosphorylation, transportation, or degradation or distal axonal damage may be involved in the pathophysiology of neuronal achromasia. Neuronal achromasia may, therefore, represent the end result of one or more pathophysiological processes.

The profile of cognitive impairment reflects dysfunction predominantly of frontal and parietal cortices, including apraxia, psychomotor slowing, and visuoperceptual disturbances. Memory is also impaired. However, CBGD pathology has also been observed in occasional patients with FTD and progressive aphasia.

Epidemiology and Risk Factors. CBGD was originally described in 1967 by Rebeiz and colleagues^[102] There are few data regarding epidemiology or risk factors, although clinical experience suggests that the prevalence may be similar to that of PSP or about 1 percent that of PD. There has been little evidence to date of a familial tendency.

Clinical Features and Associated Disorders. The vast majority of cases have exhibited a progressive perceptual-motor syndrome (see the section on ACDS, presented earlier), and the term progressive asymmetrical rigidity and apraxia syndrome has been proposed.^[103] Less common presentations with a similar histology include frontotemporal dementia and progressive aphasia. Asymmetrical hyperreflexia, postural instability, frontal release signs, oculomotor impairment, and hypokinetic dysarthria commonly occur. Dysphagia begins insidiously in the latter stages of the disease, and eventually aspiration pneumonia and death ensue.

Characteristic CBGD histological findings have been reported to co-exist with Pick's disease and AD, and alternate presentations with the same histology have included FTD and progressive aphasia, as noted earlier.

Differential Diagnosis. See the section on ACDS. The most common misdiagnoses are stroke, PD, and perhaps AD. CBGD falls within the spectrum of ACDS, and clinicopathological correlations are far from perfect, as previously discussed. Other degenerative histologies underlying a progressive apraxic or perceptual-motor syndrome include nonspecific degeneration, AD, Pick's disease, and PSP.

Evaluation. Neuroimaging is the single most important aspect in evaluating any focal-appearing cerebral syndrome, as discussed in the section on ACDS. A fairly consistent finding on CT and MRI is asymmetrical cortical atrophy, which is predominantly parietal with variable involvement of contiguous regions in patients with a progressive perceptual-motor syndrome. The laterality of atrophy correlates with the laterality of clinical impairment.

Asymmetrical cortical (and subcortical) hypoperfusion on SPECT is usually more extensive than the MRI appearance of atrophy. Asymmetrical fluorodeoxyglucose cortical hypometabolism and asymmetrical striatal fluorodopa hypometabolism on PET are also found in this disorder, but these tests should be regarded as ancillary.

The neurological and neuropsychological pattern of deficits is distinctive and should not be mistaken for an Alzheimer- or Parkinson-type pattern of dementia.

Management. Pharmacotherapy generally provides minimal if any improvement in most symptoms, but an empirical trial of levodopa is nonetheless reasonable and will occasionally result in modest symptomatic amelioration of rigidity. Clonazepam may yield modest improvement in myoclonus, but it may cause sedation with worsening of balance and cognitive function. Botulinum toxin injection can permit a clenched dystonic hand to be opened for hygiene maintenance. Pharmacotherapy should be supplemented

Figure 12-12 Corticobasal ganglionic degeneration. A, Note the circumscribed perirolandic cortical atrophy. B, A ballooned achromatic neuron typical of corticobasal ganglionic degeneration is shown in the center of the photomicrograph (Hematoxylin and eosin; 50x; courtesy J. E. Parisi, Mayo Clinic, Rochester, Minnesota.)

with physical, occupational, and speech therapies. Passive range of motion exercises may retard the development of contractures. Ambulation becomes impaired in all individuals at some point, hence the need for gait assistance devices. Apraxia is often the most debilitating feature of the disorder. A home assessment by an occupational therapist can aid in determining which changes could be made to facilitate functional independence, although experience to date has been disappointing. Speech therapy and communication devices can optimize communication when dysarthria, apraxia of speech, or aphasia is present, although they are generally of minimal benefit. Therapists also counsel patients and families on swallowing maneuvers and food additives to minimize aspiration when dysphagia evolves. Decisions regarding placement of feeding gastrostomy tubes should be discussed before dysphagia becomes problematic.

Prognosis and Future Perspectives. Most patients succumb to the disease in 7 to 10 years. Death usually results from aspiration pneumonia or urosepsis.

The main focus of a recent symposium on CBGD and other ACDS^[103] regarded nosological status and terminology.

Diffuse Lewy Body Disease (Lewy Body Dementia)

Pathogenesis and Pathophysiology. Between 20 and 30 percent of brains of patients with a degenerative dementia have concomitant AD and PD changes, therefore making Lewy body-related pathology the second most common histopathology behind AD. A much smaller percentage have diffuse Lewy bodies without AD changes. Therefore, the dementing disorders associated with Lewy bodies can be categorized into three groups: PD without cortical Lewy bodies or AD changes, PD with cortical Lewy bodies but not concomitant AD changes (DLBD), and PD with cortical Lewy bodies and AD changes (the Lewy body variant of AD or LBV). Numerous data indicate that PD and AD have distinctly separate clinical, pathological, pathophysiological, and genetic correlates. However, there is a significant proportion of patients with combinations of the classic features of PD and AD, which suggests that there is a pathophysiological relationship between them. We will therefore take a middle stance and discuss LBV and DLBD separately when sufficient data indicates distinctions can be made, and we will discuss them together when these distinctions are not apparent.

Pathologically, the gross appearance of the brain is normal to slightly atrophic. The substantia nigra is pale. In the LBV of AD, there are sufficient numbers of NPs to apply the neuropathological diagnosis of AD. NFT counts are more variable. Lewy bodies, if present in the cortex, are invariably also present in the brain stem. The Lewy bodies in the brain stem are easily seen on sections stained with hematoxylin-eosin, where they tend to reside in the substantia nigra, locus caeruleus, and raphe nuclei. Cortical Lewy bodies often lack the surrounding halo that is typical of those in the brain stem, and are more difficult to visualize unless immunostains for ubiquitin are used (Fig. 33-13). The locations of maximal numbers of cortical Lewy bodies include the cingulate gyrus, insular cortex, and parahippocampal gyrus. Ubiquitin-positive neuritic changes are also present in the CA2/CA3 region of the hippocampus, whereas Lewy bodies are rarely found in the hippocampus. The degree of neuronal loss in the hippocampal CA subfields is variable in LBV and DLBD. These findings suggest that the type of ubiquitin-positive changes may be site specific. The cholinergic neurons in the nucleus basalis are markedly depleted.

As noted earlier, a subgroup of AD cases with primarily plaque-only changes were found to have numerous extranigral Lewy bodies.^[20] In those cases with more typical NPs

and NFTs, the number of NFTs tends to be less in AD- plus-PD brains than in AD-only brains. All of these cases had sufficient numbers of NPs to apply the neuropathological diagnosis of AD. However, because frequent NPs have also been observed in cognitively normal individuals, debate has surrounded the issue of whether these cases represent a variant of AD (thus the name LBV of AD) or a distinct entity (thus the name DLBD) with co-existing AD changes.

Katzman and colleagues^[104] have provided several lines of evidence supporting the LBV of AD concept: (1) the clinical features of AD and LBV are similar, (2) the LBV has been observed in several familial AD1 cases, (3) the LBV has also been observed in rare Down's cases, and (4) the LBV is frequently observed in ApoE epsilon-4/epsilon-3 cases. Other investigators have observed an association between ApoE epsilon-4 dosage and PD-related changes, but interestingly, the severity of ubiquitin-positive neuritic changes in the hippocampus correlated with ApoE epsilon-4 dosage, whereas the frequency of cortical Lewy bodies did not.^[105] It has been suggested that the LBV of AD may represent the result of a co-existent gene that promotes LB rather than NFT in degenerating neocortical neurons.^[104]

The cardinal features of LBV and DLBD involve dementia and mild to moderate parkinsonism. The extrapyramidal symptoms reflect basal ganglia and nigral degeneration. The nature of cognitive impairment in LBV and DLBD is likely multifactorial. In both conditions, the degree of neurofibrillary degeneration is less than in pure AD. Although supportive data are lacking, the presence and frequency of cortical LB may be a contributor, and the effects of LB and AD changes may be additive in LBV. Subcortical degenerative changes underlie the psychomotor slowing. Prominent hallucinations, delusions, illusions, and behavioral dyscontrol are also characteristic clinical features. It is unclear whether the neuropsychiatric features reflect unique qualities of cortical Lewy bodies themselves; the topographic distribution of LB or cortical degeneration, or both; or neurochemical abnormalities.

The nucleus basalis atrophy and marked cholinergic deficiency in brains affected by LBV mirror that noted in brains affected by AD only, although findings in pure DLBD are less clear. Choline acetyltransferase activity has been found to be lower in patients with LBV than in those with AD only.^[106] Reportedly, some patients with LBV with very low levels of this enzyme have improved while on tacrine therapy, but parkinsonism can worsen with tacrine. The brains of patients with AD plus PD changes have also been found to have reduced levels of dopamine and homovanillic acid compared with normal brains and those affected by AD only.

Epidemiology and Risk Factors. The relationship among DLBD, AD, and PD is debated because there is evidence to support all points of view, that is, that DLBD is related to AD and to PD and that can be a distinct entity unrelated to either. Hence, it is unclear whether epidemiological data that relate to AD and PD are relevant for DLBD. There are no large epidemiological studies, but autopsy series suggest that the mean age of onset of DLBD is 57 years, that it affects men more often than women (male to female ratio 1.7:1), and that death ensues after roughly 10 to 15 years.^[107] In this series, there were 20 patients who died with PD and 8 who died with DLBD, suggesting that the prevalence of DLBD is, very roughly, 30 percent that of PD^[107] (although personal clinical experience suggests that it is less common than that). Extrapyramidal findings occur with increasing frequency as AD progresses (in close to 30 percent of patients^[108]), but how often this reflects Lewy body-related pathology is uncertain. In an autopsy series of AD, 15 percent of patients had some type of Lewy body-related pathology.^[109] The relationship of ApoE to DLBD depends on how closely DLBD is related to AD, and although ApoE genotype appears relevant, the relationship is weaker than for AD.^[110]

Clinical Features and Associated Disorders. AD and PD are both part of the nosological spectrum of DLBD, which seems to bridge the cortical and subcortical degenerative dementias. The literature is divided on whether parkinsonian or cognitive symptoms present first, but all investigators agree that both are important components.^[107], ^[111] In general, the clinical picture of a mild parkinsonian syndrome with a more severe dementia and prominent visual hallucinations and paranoid delusions should prompt consideration of DLBD. Although the parkinsonism can be levodopa responsive, levodopa may exacerbate the psychosis, and in the early to middle stages, the neuropsychiatric disturbance is generally the more disabling feature. As the disease progresses, however, both components worsen, and the patient may eventually develop severe parkinsonian symptoms and become wheelchair bound. Rest tremor is less frequent (about 29 percent of patients^[107]) than in PD, but bradykinesia is a predictable feature. The quality of the dementia resembles the subcortical pattern with pronounced psychomotor slowing, absence of severe aphasia, agnosia, or apraxia, and concurrent parkinsonism. Atypical features, including impaired vertical gaze and progressive spasticity, have been described further, highlighting the clinicopathological overlap that occurs among many of the degenerative dementias.

Differential Diagnosis. The differential diagnosis of DLBD is particularly broad because of its overlap with cortical and subcortical degenerative dementias, as well as the clinical similarities with nondegenerative dementing illnesses. Dementia and mild parkinsonism is perhaps the most common presenting symptom complex of small vessel-type multi-infarct dementia (another, and perhaps the most common, cause of subcortical dementia). Prominent visual hallucinations can be an important clinical feature of certain reversible chronic progressive encephalopathies, including chronic inflammatory meningoencephalitis, chronic meningitides occurring on infectious or neoplastic bases, and many toxic-metabolic encephalopathies. Although they do occur in other degenerative dementias, including AD and PD, they are less frequent and should not be considered typical early features.

Evaluation. In addition to the usual tests for dementia evaluation (MRI, neuropsychological testing, and laboratory studies, as described in the section on AD), the EEG is particularly useful. Many reversible chronic progressive encephalopathies produce severe dysrhythmic slowing, whereas most degenerative diseases, at least in early stages, produce mild or no dysrhythmic slowing. A severely abnormal EEG should prompt strong consideration of more exhaustive laboratory studies looking for unusual autoimmune

causes and other systemic medical causes of encephalopathy, as well as a CSF examination. CSF tests should include microbiological, cytological, and immunological studies (including IgG index, IgG synthesis rate, and oligoclonal bands). These immunological studies may provide evidence of an intrathecal immunological response that, although nonspecific, may be more sensitive than fungal cultures or cytology and therefore may be the only sign of an autoimmune process. If the patient has a so-called psychotic delirium with minimal parkinsonian features, a severely dysrhythmic EEG, and a CSF profile that suggests an inflammatory mediated process, in the absence of another obvious cause, meningeal and brain biopsy should be considered, observing for CIME, CNS vasculitis, CNS infection, and meningeal carcinomatosis. Because CIME is very steroid responsive, an empirical trial of corticosteroid therapy could be considered, especially if there is reticence to perform a brain biopsy.

Management. As noted earlier, treatment of the parkinsonian syndrome may exacerbate the neuropsychiatric disorder, and treatment of the neuropsychiatric disorder may exacerbate the parkinsonian syndrome. A decision, therefore, must first be made regarding whether treatment is necessary at all, and if so, what symptoms warrant treatment. Generally, the neuropsychiatric syndrome is the most disabling aspect in mild to moderate stages, and selective neuroleptic therapy with risperidone should be considered as a first choice. Very low dose therapy should be tried initially because risperidone, despite its selectivity, can exacerbate parkinsonism. More selective, but more hazardous because of potential blood dyscrasias, is clozapine. Treatment of the parkinsonian syndrome is similar to that of PD, generally beginning with Sinemet at a very low dose and gradually titrating the dose to symptoms and side effects. Other nonpharmacological aspects of caregiving are similar to those described for AD except that physical and occupational therapies are of greater importance at an earlier stage due to the extrapyramidal syndrome. Benefits, however, are generally modest.

Prognosis and Future Perspectives. As noted earlier, the mean age of onset of DLBD is 57 years, and death ensues after roughly 10 to 15 years.^[107] Treatment is difficult, often inadequate, and caregiving is especially difficult usually because of the psychosis.

DLBD is an important nosological entity because it appears to occupy an intermediate position between AD and PD, two common degenerative diseases that are generally thought to have little in common. Therefore, understanding the genetics and disease mechanisms of DLBD may provide important insights into its more frequent cousins as well. Also, this group of patients will be an important testing ground for newer antipsychotic agents with greater selectivity.

HISTORY

Because they attract visual attention, movement disorders have been described in both medical and nonmedical historical material for hundreds of years. Early etiological explanations reflected the knowledge and prejudices of their times, with various life forces and demonic possession being cited as common causes. Early clinical descriptions of these disorders, however, extend far beyond historical interest and are important documents rich in details of phenomenology and natural history. Gilles de la Tourette syndrome, although not named until the nineteenth century, was vividly described in the *Malleus Maleficarum* (1489), and Paracelsus described various forms of chorea in careful detail. Parkinson's disease, the prototypical movement disorder, was first reported by James Parkinson in 1817, and his succinct and vibrant description of the disease in the context of the pollution of London in the Industrial Revolution covered not only the major clinical features of the disease but also suggested the possibility of a causative role of environmental toxins. Specifically, in the United States, the country practitioner George Huntington extensively described Huntington's chorea in the 1800s, basing his description on his and his father's experiences with a large New York kindred. Clear phenomenological descriptions occupied primary attention during the nineteenth century, largely steered by the supervision of Charcot and other European neurologists. In the first half of the twentieth century, a clearer focus was placed on the basal ganglia due to early histological and biochemical studies. The molecular, biological, and physiological bases of both hypokinetic and hyperkinetic disorders have received primary attention during the past "decade of the brain."

HYPOKINETIC MOVEMENT DISORDERS

Parkinson's Disease

Pathogenesis and Pathophysiology. Pathological findings of Parkinson's disease (PD) include depigmentation and neuronal loss in the substantia nigra (SN) and the presence of Lewy bodies and pale bodies ([Fig. 34-1](#)). Because the degenerating cells in the SN normally synthesize the neurochemical dopamine, the pathophysiological hallmark of PD is dopaminergic underactivity at the site of these cells' axonal projection--that is, the striatum (caudate nucleus and putamen). Lewy bodies are eosinophilic inclusions composed of neurofilament, tubulin components, α -synuclein and ubiquitin. Pale bodies are composed of neurofilament interspersed with vacuolar granules. Besides the substantia nigra, they are also present in the basal ganglia, cortex, brain stem, and spinal cord. Although characteristic of PD, Lewy bodies are also seen in Alzheimer's disease, Hallervorden-Spatz disease (HSD), ataxia-telangiectasia, and, rarely, in patients without clinical neurological disease. ^[1]

The mechanism of Lewy body formation and cell death in PD is not known, but the degenerative process is highly localized at the beginning of the illness. Anatomical studies have found that the area first affected in the disorder is the pars compacta in the ventrolateral SN (SNpc) with its fibers projecting to the putamen. ^[2] Neurochemical changes resulting from this selective neurodegeneration consist mainly of loss of dopamine (DA), and it is estimated that 60 to 85 percent of nigral neurons and striatal DA is lost prior to the development of PD symptoms.

The most actively studied hypothesis of the origin of PD has focused on selective oxidative stress. Metabolic pathways for DA generate numerous byproducts that include

Figure 34-1 A and B, An isolated Lewy body, a distinctive eosinophilic cytoplasmic inclusion body found in the substantia nigra of Parkinson's disease.

hydrogen peroxide, superoxide anions, and hydroxyl radicals. Interaction between these chemicals and membrane lipids leads to lipid peroxidation, membrane disruption, and, potentially, cell death. In support of this hypothesis, several observations are pertinent: (1) glutathione peroxidase, a tripeptide normally present in brain that is reduced with oxidative stress, is markedly reduced in the SN of patients with PD; (2) elemental iron, which can facilitate the formation of free radicals in the nervous system, is increased in the brains of PD patients; (3) the iron-chelating protein ferritin is decreased or of normal concentration in PD, so that compensatory increases to handle elemental iron do not occur; and (4) specific enzymatic activity defects in complex 1 of the mitochondrial respiratory chain appear to occur in the SN of the brains of patients with PD. Whereas all these events develop and probably reflect or provoke oxidative stress in the SN, the actual precipitant, whether genetic, environmental, dietary, or multifactorial, remains to be determined.

Whereas the primary lesion involves dopamine, other neurotransmitter systems are also affected. At the level of the striatum, muscarinic cholinergic function competes with dopaminergic activity, and hence in PD, there is a relative overactivity of acetylcholine. Also, other pigmented nuclei besides the substantia nigra degenerate, and changes in norepinephrine and serotonin result from changes in the locus ceruleus and dorsal raphe, respectively.

Epidemiology and Risk Factors. Population-based surveys in the United States, Portugal, and Italy have reported that the prevalence of PD ranges from 107 to 187 per 100,000 population. ^[3] A recent community study of the elderly in a suburb of Boston, however, found parkinsonian features in 159 of 467 (34 percent) individuals aged 65 years or older. ^[4] This study suggests that at least one third of the elderly exhibit some evidence of PD or other parkinsonian disorders.

Although both environmental and inherited factors have been implicated in the pathogenesis of PD, no specific cause has been found. Case-controlled studies have documented an increase in risk for PD associated with a family history of PD, insecticide exposure, herbicide exposure, rural residency at the time of diagnosis, well water exposure, and nut or seed eating 10 years prior to diagnosis. ^[5] Numerous reports suggest the possibility that the frequency of PD is decreased in patients with a history of cigarette smoking, but these data remain controversial. ^[6] The best studied model of parkinsonism is that produced by 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), a meperidine analog first developed during the production of an illicit drug. This compound, when injected intravenously, produces parkinsonism in humans and animals. ^[7]

Twin studies suggest that genetic predisposition may play a role in the development of PD, ^[8] and a number of parkinsonian pedigrees have been reported. ^[9] The gene locus in one autosomal dominant pedigree was isolated to chromosome 4q21.23 and was later found to involve Ala53Thr substitution in the α -synuclein gene. ^[10] Jankovic and colleagues ^[11] and others have found that PD and essential tremor (ET) coexist relatively frequently, and ET has been considered by some a risk factor for PD. Further studies, however, are needed to confirm this observation.

Clinical Findings and Associated Disorders. The cardinal features of PD include resting tremor, rigidity, bradykinesia, and postural instability. Many movement disorder specialists consider a good response to levodopa or dopamine agonists useful in clinically supporting the diagnosis. ^[12] The *rest tremor* usually consists of an oscillatory movement of 4- to 7-Hz frequency that involves the limbs, jaw, face, and tongue but almost never involves the head itself. The tremor of the forearm is often pronating and supinating, while the hand tremor has been described as "pill-rolling." Early in the course of the disease, the tremors and other signs are usually asymmetrical but eventually become bilateral. In addition to the rest tremor that is so distinctive of PD, most patients also have a *postural tremor*, which is evident with the hands extended or in action. This postural tremor probably represents re-emergence of rest tremor or coexistent ET (see later discussion). Tremor in patients with ET, in contrast to PD, often involves not only the hands but also the head and voice, rarely affects the legs, and improves frequently with alcohol, propranolol, or primidone. Some PD patients or their relatives have an associated postural tremor that appears as ET and precedes the onset of PD symptoms by several years or decades, suggesting a possible link between the two conditions, at least in some families.

Bradykinesia (slowness of movement) or *hypokinesia* (poverty of movement) is manifested by slowing of activities of daily living such as dressing, feeding, brushing teeth, and bathing. Other features of bradykinesia or hypokinesia include masked facies (hypomimia), hypokinetic dysarthria, drooling, and slow and small handwriting (micrographia).

On examination, rapid alternating movements are performed slowly and with decreasing amplitude. In more advanced stages, frequent arrests of movement, called "freezing" or "motor blocks," may be seen. These are manifested by an interruption in finger tapping or hand clasping, start hesitation such as an inability to initiate gait or other movements, and freezing when turning or walking through narrow passages.

Postural instability also often occurs in the more advanced stages of the disease. This gait and postural difficulty are frequently accompanied by small steps and festination, a tendency when standing or walking to propulse involuntarily or to retropulse and fall. In the distinctive "pull test" the examiner stands behind the patient and tugs briskly on the shoulders; the PD subject takes several small steps backward, possibly falling into the examiner's arms.

Most of the other signs of PD represent variations of these cardinal characteristics: sialorrhea, dysphagia, difficulty in turning in bed, and ambulatory problems that become progressively worse. Sleep disruption is common in PD patients, who demonstrate fragmented sleep and frequent awakenings. Recent studies suggest that a distinctive sleep aberration, REM behavioral disorder (see [Chapter 54](#)), may be a frequent early element of PD. Additionally, akathisia, an uncomfortable feeling that drives the patient to move, can be a prominent and poorly appreciated aspect of untreated PD, and this behavior may be related to dopaminergic dysfunction. Besides motor symptoms, PD patients may also exhibit several behavioral changes, including depression in at least one third of patients, and dementia in an equal proportion. Frontal release, or "cortical disinhibition" signs, may be seen, but they are not specific for PD. Pain, burning, coldness, numbness, and other sensory symptoms, often wrongly attributed to bursitis or arthritis, are reported by about half of patients. Seborrhea, particularly that involving the face, is an example of systemic involvement in PD.

The mean age of clinical onset of PD is the mid fifties, but the range is very wide, and some patients present in their twenties and thirties, while others show no signs until their eighties. Although there are many exceptions, young patients often present with tremor-predominant disease and elderly patients with gait dysfunction and

akinesia. Juvenile PD is a childhood and adolescent disease, presenting with parkinsonism and dystonia, and has a different histological appearance than PD.

Differential Diagnosis. Besides PD, there are many other causes of parkinsonism ([Table 34-1](#)). The second most common group is the parkinsonism-plus syndromes (12 percent), a conglomerate term for a large number of degenerative disorders in which parkinsonism is one of several neurological features. Drug-induced parkinsonism (8 percent), and hereditary degenerative conditions, such as juvenile Huntington's disease (HD), are less frequent. Cyanide intoxication and carbon monoxide poisoning associated with bilateral pallidal necrosis are examples of an acute cause of parkinsonism, ^[10] and other toxins like carbon disulfide and manganese can also produce parkinsonism, the latter often preceded by psychiatric difficulties ("manganese madness"). Reversible parkinsonism is caused by drugs, especially neuroleptics and metoclopramide, and lesser known agents such as alpha-methyldopa, reserpine, amiodarone, and certain calcium channel blockers must also be considered in the differential diagnosis. Finally, patients in whom PD is suspected should be screened for potential illicit narcotic exposure, a travel history, or an underlying medical illness such as the acquired immune deficiency syndrome (AIDS) that would predispose them to opportunistic infections including abscesses, and a family history of neurological disorders should be obtained as well. A past medical history of stroke or hypertension may suggest a subcortical vascular encephalopathy presenting with parkinsonian features, and old meningitis or head trauma could suggest normal pressure hydrocephalus presenting with freezing, festination, and a gait disorder sometimes confused with parkinsonism.

Evaluation. When all four cardinal characteristic signs are present, and the patient shows a brisk response to dopaminergic therapy, the diagnosis is straightforward. Part of the workup usually includes a magnetic resonance (MR) scan, looking for evidence of alternate diagnoses like stroke, intoxications, or other degenerative disorders.^[11] Although it is not yet firmly established, cerebrospinal fluid (CSF) homovanillic acid (HVA), the final metabolite of dopamine, especially when expressed as a ratio to CSF xanthine, may become a future marker of disease activity.

Management. The large array of drugs used in the treatment of PD is outlined in [Table 34-2](#) with standard doses and side effects. Treatment of symptomatic PD is based primarily on restoring a deficiency of dopamine (DA) due to a loss of dopamine-producing cells in the SN. ^[11] This neurotransmitter is synthesized from the amino acid tyrosine. The conversion of tyrosine to levodopa is facilitated by the rate-limiting enzyme tyrosine hydroxylase; levodopa is in turn converted into dopamine by the nonspecific enzyme dopa-decarboxylase. These dopaminergic neurons synapse with cholinergic interneurons and gamma-aminobutyric acid (GABA)-ergic outflow neurons in the striatum.

Five subtypes of DA receptors have been identified; the D₁ and D₂ receptors are most prominent in the striatum, and the D₃, D₄, and D₅ receptors are present in the limbic system and other dopaminergic pathways. The D₁ receptor is linked to adenylate cyclase. In contrast, the D₂ receptor is activated by DA and DA agonists. The different roles of D₁ and D₂ receptors in regulation of striatal function have not been fully defined, but the D₂ receptor appears to be more important in mediating the parkinsonian symptoms. In the brain in PD, the D₁ receptors in the striatum appear to be reduced (downregulated), whereas the D₂ receptors are increased (upregulated).^[12] As a result of nigrostriatal deficiency, activation of the indirect D₂-mediated, inhibitory (GABA) striatopallidal pathway is increased, resulting in disinhibition of the subthalamic nucleus and the globus pallidus internum (GPi), the main output nucleus from the basal ganglia. The increased activation of the GPi is further enhanced by disinhibition of the decreased activity of the direct D₁-mediated, inhibitory (GABA) striatopallidal pathway ([Fig. 34-2](#)).

The most effective treatment for the symptoms of PD is levodopa, but the chronic use of levodopa is complicated by the development of two motor problems, namely, fluctuations and dyskinesias in about half the patients after 5 years of therapy. Fluctuations are irregular and clinically

TABLE 34-1 -- CLASSIFICATION OF PARKINSONISM

I. Primary Parkinsonism
Parkinson's disease
Juvenile parkinsonism
II. Multiple System Degenerations (Parkinsonism-Plus Syndromes)
Progressive supranuclear palsy (PSP)
Multiple system atrophy (MSA)
Striatonigral degeneration (SND)
Olivopontocerebellar atrophy (OPCA)
Shy-Drager syndrome (SDS)
Lytico-Bodig or parkinsonism-dementia-ALS complex of Guam (PDACG)
Cortical-basal ganglionic degeneration (CBGD)
Progressive pallidal atrophy
III. Hereditary Parkinsonism
Hereditary juvenile dystonia-parkinsonism
Autosomal dominant Lewy body disease
Huntington's disease (HD)
Wilson's disease (WD)
Hereditary ceruloplasmin deficiency
Hallervorden-Spatz disease (HSD)
Olivopontocerebellar and spinocerebellar degenerations (OPCA and SCA)
Familial amyotrophy-dementia-parkinsonism
Disinhibition-dementia-parkinsonism-amyotrophy complex
Gerstmann-Strausler-Scheinker disease
Familial progressive subcortical gliosis
Lubag (X-linked dystonia-parkinsonism)
Familial basal ganglia calcification
Mitochondrial cytopathies with striatal necrosis
Ceroid lipofuscinosis
Familial parkinsonism with peripheral neuropathy
Parkinsonian-pyramidal syndrome
Neuroacanthocytosis (NA)
Hereditary hemochromatosis
IV. Secondary (Acquired, Symptomatic) Parkinsonism
Infectious: postencephalitic, AIDS, SSPE, Creutzfeldt-Jakob disease, prior diseases
Drugs: dopamine receptor-blocking drugs (antipsychotic, antiemetic drugs), reserpine, tetrabenazine, alpha-methyldopa, lithium, flunarizine, cinnarizine
Toxins: MPTP, CO, Mn, Hg, CS ₂ , cyanide, methanol, ethanol

Vascular: multi-infarct, Binswanger's disease

Trauma: pugilistic encephalopathy

Other: parathyroid abnormalities, hypothyroidism, hepatocerebral degeneration, brain tumor, paraneoplastic diseases, normal pressure hydrocephalus, noncommunicating hydrocephalus, syringomyelia, hemiatrophy-hemiparkinsonism, peripherally induced tremor and Parkinsonism, and psychogenic disorders

Modified from Fahn S, Marsden CD, Jankovic J: Principles and Practice of Movements Disorders. New York, Churchill Livingstone, 1996.

unpredictable responses to medications, and dyskinesias are involuntary, usually choreic, but sometimes dystonic movements that are drug induced. Levodopa is absorbed in the small intestine via a large neutral amino acid (LNAA) transporter system and is then converted to DA by the ubiquitous enzyme dopa-decarboxylase. Conversion to DA outside the blood-brain barrier activates the area postrema and is largely responsible for some of the early side effects of levodopa, particularly nausea and vomiting. The addition of dopa-decarboxylase inhibitors that do not cross the blood-brain barrier (e.g., carbidopa or benserazide) minimizes DA formation in the periphery and greatly improves patient tolerance to therapy. This is the concept behind the use of the carbidopa-levodopa combination (e.g., Sinemet), which is prescribed as a ratio of carbidopa to levodopa (25/100, 25/250, or 10/100) and more recently has become available in a controlled-release formulation (CR 50/200 or CR 25/100). Approximately 100 mg of carbidopa per day is needed for effective peripheral blockade. Although carbidopa is useful in preventing the "peripheral" side effects of levodopa, the motor side effects of fluctuations and dyskinesia as well as psychiatric reactions such as confusion, delusions, and visual hallucinations are not prevented or ameliorated by its addition to levodopa.

In the early stages of levodopa therapy, motor fluctuations correlate well with plasma levodopa levels. Initially, patients may report a "wearing-off" or end-of-dose deterioration in mobility, which is thought to result from a reduced duration of therapeutic plasma and brain levels of levodopa. A typical patient may also notice dyskinesias or involuntary movements related to peak plasma levodopa levels ("peak dose dyskinesia"). Most patients have this pattern of response characterized by improvement-dyskinesia-improvement (IDI). About 15 percent of patients who are treated chronically with levodopa experience initial dyskinesia within a few minutes after ingestion of levodopa; this is followed by an improvement in parkinsonian symptoms for 2 to 4 hours and then by subsequent recurrence of dyskinesia, usually in the form of dystonia. This biphasic dyskinesia pattern of dyskinesia-improvement-dyskinesia is referred to as the DID response. Treatment of these motor fluctuations is based on "smoothing out" the plasma concentration curves either by giving more frequent smaller doses of levodopa, converting to the controlled-release

TABLE 34-2 -- MEDICATIONS FOR PARKINSON'S DISEASE

Medications	Dosage	Side Effects
Dopaminergic Drugs		
Precursor amino acid: Levodopa		Nausea, hypotension, confusion, hallucinations, dyskinesia
Carbidopa/levodopa	10/100, 25/100, 25/250, 100-1000 mg/24 hr	
Controlled release	25/100, 50/200, 200-1400 mg/24 hr	
Dopamine agonists		Somnolence, confusion, hallucinations, hypotension
Bromocriptine	2.5-60 mg/24 hr	
Pergolide	0.25-6 mg/24 hr	
Pramipexole	0.125-4.5 mg/24 hr	
Ropinirole	0.25-24 mg 24 hr	
Monoamine oxidase B inhibitor		Sleep disturbance, lightheadedness, hallucinations
Selegiline (Deprenyl)	5--10 mg/24 hr	
Indirect agonist		Hallucinations, dry mouth, livedo reticularis, ankle swelling, myoclonic encephalopathy in setting of renal failure
Amantadine	100-300 mg/24 hr	
Catecholamine-O-methyl transferase inhibitor		Used in conjunction with levodopa: dyskinesia, lightheadedness
Tolcopone	300-600 mg/24 hr	
Entacopone		
Other Drug Classes		
Anticholinergics		Confusion, sleepiness, blurred vision, constipation
Trihexiphenidyl	2-15 mg/24 hr	
Biperiden	1-8 mg/24 hr	
Novel neuroleptics: used for psychosis and unusual tremors		Fatal neutropenia, somnolence
Clozapine	12.5-100 mg/24 hr	
Miscellaneous		
Amitriptyline: used for sleep fragmentation	10-50 mg 24 hr at bedtime	Dry mouth, forgetfulness, blurred vision, constipation
Baclofen: used for dystonic cramps	10-80 mg 24 hr	Sleepiness, dizziness

form of levodopa, or, in the patient with markedly advanced disease, titrating the medication by having the patient sip very small quantities of Sinemet dissolved in water or juice every 30 or 60 minutes throughout the waking day.^[13] In patients with advancing disease who have had prolonged levodopa therapy, more complex and less predictable ("on-off") motor fluctuations occur. For instance, patients may change from relatively normal function to a frozen akinetic state in as little as 15 seconds (sudden on-off), or they may develop severe dyskinesia at both the peak effect of the levodopa dose and at the end of the dose (biphasic dyskinesia). The mechanism of these motor fluctuations and dyskinesias is not well understood, but there is a growing body of evidence supporting the notion that some of these problems arise from the combination of loss of presynaptic DA storage capacity and postsynaptic receptor alterations.^[14]

Figure 34-2 Basal ganglia circuitry relevant to pathogenesis of PD. GABA, Gamma-aminobutyric acid; SMA, supplementary motor area.

In the 1980s, the monoamine oxidase-B inhibitor (MAO-B) deprenyl (selegiline) was reported to delay the clinical progression of PD. In a large multicentered trial, the Deprenyl and Tocopherol Antioxidative Trial of Parkinson's Disease (DATATOP), deprenyl but not tocopherol delayed the need for levodopa by approximately 9 months.^[15] Whether this is due to deprenyl's beneficial effect on the parkinsonian symptoms or to a putative neuroprotective action is a subject of continued debate. Other MAO-B inhibitors, such as lazabemide, have been evaluated in PD as well, but long-term protocols aimed at defining neuroprotective mechanisms have not been carried out.

In the early stages of PD, anticholinergic (e.g., trihexiphenidyl) therapy may provide moderate improvement. This strategy is based on the neurochemical competition between DA and acetylcholine in the striatum. Amantadine, an antiviral agent, has mild dopaminergic activity and possibly anticholinergic action as well. Amantadine and anticholinergic agents may produce dry mouth, nausea, vomiting, blurring of vision, visual hallucinations, and other mental changes. Because of the anticholinergic side effects, patients with glaucoma, prostatic hypertrophy, and dementia may experience exacerbations of these conditions with these agents.

Amantadine may also cause pitting edema and livedo reticularis, a purplish-reddish mottling of the skin, particularly the skin below the knees; it should be avoided in patients with impaired renal function.

Since the introduction of bromocriptine and pergolide, DA agonists, which are agents that stimulate dopamine receptors themselves, have played an increasingly important role in the treatment of PD. Because these medications have a relatively long half-life, they are used most frequently to prolong the effects of levodopa and thus smooth out motor fluctuations. While some movement disorder

specialists advocate the use of DA agonists in the early phases of pharmacological therapy, others introduce DA agonists after the dose of levodopa has reached 300 to 600 mg/day or when levodopa-related fluctuations emerge. Side effects associated with DA agonists include nausea, drowsiness, confusion, hallucinations, orthostatic hypotension, exacerbation of dyskinesias, erythromelalgia, and, rarely, pulmonary fibrosis. The latter two side effects have been attributed to the ergot structure of pergolide and bromocriptine, and they should not occur with the recently approved non-ergoline DA agonists pramipexol and ropinirole. ^[16], ^[17]

All agonists used in PD activate D₂ receptors, although the profiles for other dopamine receptor classes and other neurotransmitter systems differ. Pramipexole, ropinirole, and cabergoline are some of the newer promising DA agonists currently being evaluated in clinical trials in the United States and abroad. ^[16], ^[17] Among DA agonists, apomorphine is the only short-acting compound. As an injectable DA agonist, it can be useful in "rescuing" some PD patients from unpredictable off-periods. Because of the strong emetic response with this agent, however, coadministration of the peripheral DA receptor blocking drug domperidone is usually necessary.

Another new class of drugs is the catechol- O-methyltransferase (COMT) inhibitors such as entacapone and tolcapone. By limiting DA metabolism, they increase levodopa bioavailability, prolong the "on" response to levodopa, reduce motor fluctuations effectively, and allow a reduction in daily levodopa dosage. ^[18]

Of particular interest in PD during the last several years has been the use of various surgical procedures, which have capitalized on a growing knowledge of basal ganglia anatomy and physiology (see Fig. 34-2). Two basic models have been studied, constructive and destructive surgery. In the former, attempts are made to provide a new cell source of dopamine at the level of the denervated striatum. The most notable of these efforts is the use of human fetal mesencephalic transplantation, and early reports of success with this procedure have led to U.S. government-sponsored controlled trials of this therapy in patients with advanced PD.^[19] In addition, growth factors or neurotrophins may be infused into the ventricular CSF or brain tissue itself. In the area of destructive surgery, attempts to ablate overactive pallidal or thalamic function have led to pallidotomies and thalamotomies as well as deep brain stimulation procedures that reversibly inactivate function by the use of high-frequency overstimulation (depolarization blockade). These studies have shown that dyskinesia is improved with pallidal procedures, and severe tremor is reduced or even ablated with thalamic surgery.^[20], ^[21] Potential side effects of all surgical procedures involving the basal ganglia include hematomas, ischemic cerebrovascular accidents, and damage related to needle passage through the cortex.

Because of the remarkable array of options in the treatment of PD, it is reasonable to approach the treatment of each patient with a basic algorithm ^[22] (Table 34-3). For all patients, education, exercise, and good nutrition are considered useful. If patients have no significant functional impairment in terms of independent living, consideration of a mild dopaminergic drug with a putatively neuroprotective strategy in the form of deprenyl can be considered. If

TABLE 34-3 -- AN ALGORITHM FOR MANAGING PARKINSON'S DISEASE AT DIFFERENT PHASES

For all patients: Education, physical or exercise therapy, good nutrition

For patients with no clinically significant disability:

Consider selegiline

Consider referral to study centers for trials of new neuroprotective strategies

For patients with clinically significant disability:

Job security threatened or health endangered:

Levodopa, usually controlled-release formulation

Job security NOT threatened and health NOT endangered:

Young and tremor-predominant disease: Anticholinergic drugs or amantadine

Older patients: Amantadine, dopamine agonists

Very elderly patients (80 or older): Levodopa

Above patients with progressive disability:

Add levodopa either as controlled-release or standard formulation

Once on levodopa, if added prolongation of effect is needed, add selegiline if patient is not currently taking it or, in the future, catechol- c-methyl (COMT) transferase-inhibitors may become available

Patients with specific complications:

Patients on levodopa who develop motor fluctuations:

More frequent, small doses of levodopa or liquid Sinemet

Selegiline agonists (or COMT inhibitors)

Consider neurotransplantation or pallidal surgery

Patients with unremitting tremor:

Thalamic surgery (ablative or deep brain stimulation)

Patients with hallucinations:

Reduce medications. Stop all drugs except Sinemet

Consider Clozapine or other neuroleptic with few extrapyramidal side effects

Modified from Hughes AJ, Calasimo C, Kleedorfer B, et al: The dopaminergic response in multiple system atrophy. J Neurol Neurosurg Psychiatry 1992;55:1009-1013.

symptoms need urgent treatment to protect the patient's safety or job security, levodopa is introduced because it is the most effective drug with the most rapid onset of action. If symptoms can be treated more slowly, the use of anticholinergic drugs in young patients with tremor-predominant PD is often helpful, and amantadine or dopamine agonists can be used as dopamine drugs that may delay the need to start levodopa in other patients. In patients who are just starting Sinemet, the controlled-release form is often selected to minimize the number of doses needed each day. As the disease progresses, combinations of drugs are usually needed, and most patients will require both an agonist and Sinemet within the first 7 years of therapy. In elderly patients, especially those with hallucinations or dementia, however, Sinemet alone, usually in the regular formulation, is often the most practical regimen because of its relative simplicity. In terms of referral to a movement disorder specialist, if the patient develops complicated dyskinesia, a prominent behavioral problem, or additional neurological signs that suggest the presence of another parkinsonian disorder (Parkinson-plus syndromes), he or she should be evaluated in a center that has expertise in these unusual problems and has access to experimental drugs and surgical protocols.

One particularly difficult problem in managing PD patients is hallucinosis. Patients who are treated chronically with dopaminergic drugs develop visual hallucinations that can become frightening and severely disabling to the patient and caregiver. In this situation, the drug dosage

should be reduced, and most patients are best managed on Sinemet alone. In some instances, novel neuroleptics with few extrapyramidal side effects can be used.

Clozapine has been successful in abating hallucinations and psychotic behavior in PD patients, but it is an expensive drug and is associated with the potentially lethal side effect of agranulocytosis.^[23] Other antipsychotic drugs and alternate therapies are currently being evaluated for this area of serious disability.

Prognosis and Future Perspectives. Survival of patients with PD has greatly improved since the development of levodopa. Prior to the advent of levodopa, mortality among PD patients was three times the normally expected mortality. However, with the advent of levodopa and other medications, the life span of PD patients is almost the same as that of an age-matched control population without the disease.^[24] Some studies have suggested that PD patients are more likely to die from infection than from cancer compared to an age-matched group of controls. Early, even presymptomatic, detection of disease is paramount to early intervention, and major efforts are currently aimed at identifying biological markers for both the presence of disease (trait marker) and disease activity (state marker).

Parkinsonism-Plus Syndromes

In addition to Parkinson's disease, parkinsonism is one of the major clinical features in several other primary neurodegenerative conditions. However, because they all have additional features not typical of Parkinson's disease and share an overall worse prognosis and poorer response to antiparkinsonian therapy, they are often grouped together under the conglomerate term parkinsonism-plus syndromes. Within this group, each condition has distinctive characteristics that must be recognized and distinguished from one another and from PD.

PROGRESSIVE SUPRANUCLEAR PALSY

Pathogenesis and Pathophysiology. Progressive supranuclear palsy (PSP) is the most common and best recognized entity among the parkinsonism-plus syndromes. PSP is an idiopathic condition with no known precipitant or strong genetic component. Postmortem analysis of the brains of PSP patients show neuronal loss, gliosis, and neurofibrillary tangles composed of straight and paired helical filaments.^[25] The SN, subthalamic nucleus, globus pallidus, superior colliculus, pretectal area, and substantia innominata are the sites of maximum involvement. Dopaminergic, cholinergic, and adrenergic neurotransmitter systems are affected, provoking a far more diffuse degenerative process than that seen in Parkinson's disease.^[26]

Epidemiology and Risk Factors. A medically based survey in central New Jersey found that the age-adjusted prevalence of PSP was 1.38 per 100,000 population, and men appeared to be slightly more frequently affected than women.^[26] Most patients experience the initial symptoms during their sixth and seventh decades. No clear geographical, occupational, or temporal clusters of PSP have been found. Although PSP is not considered a genetic disorder, rare familial clusters have been reported and Conrad and colleagues have identified an association with a particular tau genetic factor.

Clinical Features and Associated Disorders. PSP shares some clinical features with PD, such as bradykinesia, rigidity, dysarthria, dysphagia, and dementia. However, PSP patients rarely exhibit tremor and usually have much more profound postural instability. In addition, axial rigidity is more prominent than limb rigidity. Some patients with PSP also develop severe palilalia, emotional incontinence, and other evidence of bilateral frontal lobe dysfunction.^[25]

The best known feature of PSP, vertical ocular gaze paresis, may be overcome by passive head movement, which activates the oculocephalic reflexes (hence the designation supranuclear). Riley and colleagues^[27] reported five patients who presented with "pure akinesia" of gait, speech, and handwriting without rigidity, tremor, dementia, or eye movement abnormalities on clinical examination. None of the patients responded to levodopa, and four demonstrated subtle changes in vertical saccades on eyelid movement recordings.^[27] The diagnostic criteria for PSP have been recently refined as a result of careful clinical-pathological correlative studies, and the greatest diagnostic confidence is placed in the combined clinical features of early frequent falls within the first year of clinical disease and vertical downward supranuclear paresis on examination.^[28]

Differential Diagnosis. Whereas PSP is idiopathic, the same clinical syndrome has been associated with Alzheimer's disease, multiple strokes, multiple system atrophy (MSA), posthypoxic encephalopathy, and Whipple's disease. Parkinson's disease itself and the other parkinsonism-plus syndromes, including corticobasal ganglionic degeneration, Lewy body dementia, normal pressure hydrocephalus, and "multi-infarct parkinsonism" must also be considered. Rarely, other conditions such as dentato-rubro-pallido-luysian atrophy (DRPLA), neuroacanthocytosis, progressive external ophthalmoplegia, and hydrocephalus may present with oculomotility disorders that are suggestive of PSP.

Evaluation. Magnetic resonance imaging (MRI) should be performed in patients in whom PSP is suspected to rule out a multi-infarct state or hydrocephalus. Single-photon emission computed tomography (SPECT) and positron emission tomography (PET) demonstrate prefrontal hypoactivity and show evidence of severe involvement of the dopaminergic terminals as well as the postsynaptic DA receptors in the striatum.^[29]

Management. Although PSP is associated with loss of multiple neurotransmitters, pharmacological therapies remain disappointing. Levodopa ameliorates the bradykinesia and rigidity in about a third of cases, but the benefit rarely persists beyond 1 or 2 years. DA agonists rarely provide additional benefit. If, however, the dopaminergic drugs improve the bradykinesia but have no impact on poor balance, the medicated patient may feel more agile and independent, only to fall more frequently, leading to consequently greater disability. Anticholinergic drugs and tricyclic antidepressants with anticholinergic effects (e.g., amitriptyline) may be helpful in treating emotional incontinence. Idazoxan, a noradrenergic drug, produced modest improvement in a small number of patients, but sympathomimetic and other side effects have limited further development of this drug.^[30] Blepharospasm, occasionally associated

with PSP, responds to botulinum toxin injection, and dry eyes may be treated with topical lubricants. Although physical, occupational, and speech therapy are of limited potential, these options may be beneficial in some patients and their families. Electroconvulsive therapy, adrenal implantation, and pallidotomy have been of no benefit.

Prognosis and Future Perspectives. The median interval from onset of the initial symptom, regardless of its nature, to onset of gait difficulty is estimated at 0.3 years; to the need for gait assistance, 3.1 years; to confinement to bed or wheelchair, 8.2 years; and to death, 9.7 years.^[26] The problems that most frequently cause complications or death are falls and aspiration.

MULTIPLE SYSTEM ATROPHY

Pathogenesis and Pathophysiology. The pathogenic mechanisms of MSA remain unknown, and in contrast to PD, there is no evidence that genetic factors play a role. Whereas the initial neurodegenerative events are unclear, in well-established cases, the staining characteristics and distribution of oligodendroglial fibrillary cytoplasmic inclusions are distinctively different from the neurofibrillary tangles of Alzheimer's disease, PSP, postencephalitic parkinsonism, and others.^[31] Highly variable neuronal loss and gliosis are seen in the substantia nigra, caudate, putamen, cerebellar cortex, pyramidal tract, Edinger-Westphal nucleus, locus ceruleus, inferior olives, dorsal motor nucleus of the vagus, Purkinje cells, intermediolateral cell column of the spinal cord, spinocerebellar tracts, and Onuf's nucleus. Reduced dopamine or norepinephrine levels occur in the nigra, nucleus accumbens, septum, hypothalamus, and locus ceruleus.^[31]

Epidemiology and Risk Factors. In a review of autopsies of parkinsonism, Quinn reported frequencies ranging from 3.6 to 22 percent, with a mean of 8.2 percent (68/833 cases).^[32] However, no study has been undertaken to determine the population prevalence of MSA. At one large referral center, 100 patients with MSA reported a median age at onset of 53 years (range, 33 to 76 years).^[33]

Clinical Features and Associated Disorders. MSA encompasses three neurodegenerative syndromes, which in the past were considered clinically distinct: *striatonigral degeneration* (SND), *olivopontocerebellar atrophy* (OPCA), and *Shy-Drager syndrome* (SDS). All these conditions share similarities with one another and with PD. The hallmark features of MSA are parkinsonism that is poorly responsive to levodopa therapy and varying degrees of autonomic, cerebellar, and pyramidal dysfunction. SDS is diagnosed clinically when dysautonomia far outweighs the other signs, SND is designated when anterocollis and pyramidal dysfunction are prominent, and OPCA is used to characterize the patient with prominent cerebellar features of ataxia, limb dyssynergia, and kinetic tremor. For all MSA patients, autonomic insufficiencies include orthostatic hypotension, postprandial hypotension, anhidrosis with thermoregulatory disturbances, poor lacrimation and salivation, constipation, and impotence. Disturbances in bladder emptying and incontinence may also occur. In addition, emotional lability, pyramidal signs, supranuclear ophthalmoplegia, anterocollis, myoclonus, sleep apnea and other ventilatory dysrhythmias, respiratory stridor, polyneuropathy, amyotrophy, and dementia may be present in any of the forms.^[28] The variety of clinical presentations is wide, and pure autonomic failure, sleep apnea syndromes, some forms of peripheral neuropathies, and conditions that clinically resemble amyotrophic lateral sclerosis all may represent forms of underlying MSA.

Differential Diagnosis. Parkinson's disease, particularly in patients with prominent postural instability and gait disturbance, may be difficult to distinguish from MSA.^[34] PSP and other parkinsonism-plus syndromes can be particularly difficult to separate, especially in the first 5 years of clinical illness. Vascular encephalopathies with multiple subcortical strokes may produce a similar constellation of signs, and the condition of pure autonomic failure can be difficult to differentiate from MSA in the early course of illness.

Evaluation. MRI may be useful to rule out a multi-infarct state, normal pressure hydrocephalus, or other causes of parkinsonism. An MRI scan demonstrating marked hypointensity of the striatum and linear hyperintensity lateral to the putamen on T2 weighted images suggests iron deposition and supports the diagnosis of MSA.^[32] PET scans of MSA are similar to those of PSP and usually confirm a decreased density of striatal D2 receptors.^[35] External urethral and rectal sphincter electromyography (EMG) is abnormal in almost all patients with MSA. Resting, supine, and standing norepinephrine levels are of questionable value, but supine and standing norepinephrine levels have been found to be slightly elevated in patients with MSA, whereas in those with pure autonomic failure they are usually decreased.^[36]

Management. Levodopa may provide some relief, usually short-term, for the rigidity, bradykinesia, and postural instability typical of MSA.^[37] Patients with MSA usually require larger doses of levodopa than patients with PD, but side effects, such as increased orthostatic hypotension and facial dystonia, often limit the usefulness of levodopa. Patients rarely derive any meaningful benefit from DA agonists, anticholinergics, amantadine, or other antiparkinsonian drugs. Symptomatic orthostatic hypotension can be treated with sodium and volume repletion unless the patient is at risk of congestive heart failure or renal insufficiency. Ancillary measures such as wearing elastic stockings to increase central venous volume and elevating the head of the bed 6 inches may also be attempted but often prove uncomfortable. Fludrocortisone, a mineralocorticoid, often improves orthostatic symptoms by increasing vascular volume. Some patients benefit from the inhibition of vasodilator prostaglandin synthesis brought about by indomethacin, and from the use of the alpha-adrenergic agonist clonidine and the peripheral vasoconstrictor ephedrine. Midodrine, an alpha-adrenergic agonist, has benefited some patients with moderate and severe orthostatic hypotension of various causes.^[38] Urinary frequency or incontinence, if due to detrusor hyperreflexia, may respond to peripherally acting anticholinergic agents such as oxybutinin or propantheline given at bedtime. Intranasal desmopressin at bedtime may offer relief from nocturnal urinary frequency. Impotence may respond to yohimbine, papaverine, or a penile implant. Constipation can be treated with cisapride, stool softeners, and bulk-forming agents. Hallucinations caused by dopaminergic therapeutic agents usually respond to a lower

dose of dopaminergic medications or to clozapine at bedtime.^[23] This latter therapy must be used cautiously, however, in patients with hypotension. All patients receiving this drug must be monitored for agranulocytosis with weekly white blood cell counts.

Prognosis and Future Perspectives. Based on autopsy-proven cases of MSA, the average survival time is expected to be less than a decade (mean survival 8.0 years,^[32] median survival 9.5 years.^[33] Future studies may focus on the role of iron and oxidative stress in this disorder and the pathological hallmark of glial cytoplasmic inclusion bodies.

OTHER PARKINSONISM-PLUS SYNDROMES

Corticobasal Ganglionic Degeneration. Corticobasal ganglionic degeneration (CBGD) is a distinctive parkinsonism-plus syndrome because specific cortical signs are associated with it and it has a particular pathological picture. Autopsy in patients with CBGD reveals asymmetrical, focal frontoparietal atrophy, "ballooned" and enlarged cells in the cortex, depigmentation of the substantia nigra without Lewy bodies, and diffuse neuronal loss.^[39] There is no familial predisposition, and no environmental factors increase the risk of disease. Clinically, patients usually develop symptoms after age 60, and neurological signs of CBGD include focal or asymmetrical rigidity, bradykinesia, postural and action tremor, and marked dystonia, usually predominantly in one upper extremity. The most characteristic symptom, however, is limb apraxia, and the involved extremity can become so dysfunctional that it moves completely by itself and can be considered an "alien limb."^[40] In most instances, the condition starts as an apparent case of PD, but the cortical sensory loss, dystonia, and apraxia are noticed quickly as distinctive. PSP and MSA can present with these signs and therefore must always be considered in the differential diagnosis. The parkinsonism can be treated with modest success in some cases by introducing levodopa or DA agonists, but the marked disability resulting from the limb dyspraxia is progressive, untreatable, and markedly disabling. Botulinum toxin can relieve elements of the dystonia. The condition usually progresses steadily, and death occurs within 10 years of diagnosis.^[40]

Parkinsonism-Dementia Amyotrophic Lateral Sclerosis Complex (PDALS). This distinctive condition occurs on the island of Guam (locally known as Lytico-Bodig disease) and has been the focus of significant research because of the possibility that genetic and environmental causes may be contributive.^[41] A study of over 2000 affected and nonaffected individuals in Guam showed that the incidence of this disorder peaked in the 1950s and has gradually declined since that time. Early studies focusing on possible environmental dietary toxins were encouraging, but recent work has failed to identify any agent consistently, and the once-held hypothesis that native flour contains a causative neurotoxin is no longer considered tenable.^[42] Pathologically, depigmentation, basophilic inclusion bodies, and cell loss in the substantia nigra are apparent in cases of PDALS. Neurofibrillary tangles without senile plaques are present in the substantia nigra, anterior horn cells, and pyramidal tracts.^[42] Clinical findings in PDALS range from motor neuron disease in younger patients to parkinsonism with severe dementia in the older population. The amyotrophic lateral sclerosis (ALS) form is seen predominantly in the Chamorros, while the parkinsonism-dementia presentation may be seen in both Chamorro and Filipino residents. The amyotrophic lateral sclerosis seen in Guam does not differ clinically from the motor neuron disease seen in the remainder of the world. Although no cause has been established, the coexistence of these neurodegenerative conditions in one population with overlapping signs supports the continuation of hypotheses based on a common cause. The differential diagnosis for PDALS includes Alzheimer's disease, diffuse Lewy body disease, postencephalitic parkinsonism, PD, the parkinsonism-plus syndromes, lower body parkinsonism and other causes of parkinsonism, as well as ALS and the various forms of motor neuron disease.^[43] Regardless of its form of clinical presentation, the disorder is relentlessly progressive, and death usually occurs within 10 years of diagnosis.

Hemiatrophy/Hemiparkinsonism. Hemiatrophy/ hemiparkinsonism (HA/HP) is an uncommon disorder that involves the onset of parkinsonism on one side of the body in association with a hemiatrophic face, arm, or leg in varying combinations. First described by Klawans,^[44] the disease presents with unilateral parkinsonism; the hemiatrophy is completely unnoticed by the patient. In a hemiparkinsonian patient, therefore, comparative examination of the size of the hands and feet may be necessary to diagnose the condition. Compared to PD, the parkinsonism of HA/ HP usually begins at a younger age and generally remains on the hemiatrophic side for several years before it sometimes becomes bilateral. Unilateral dystonic movements are a common early feature and may respond well to levodopa. The cause is unknown, but early birth injury from hypoxia or trauma has been suggested as a possibility, and there may be some relationship between this syndrome and a distinct form of dystonia termed dopa-responsive dystonia.^[44] Hemiatrophy of the contralateral cortex may be seen on MR in some patients.

Stiff-Person Syndrome

Pathogenesis and Pathophysiology. Stiff-person syndrome (SPS) is believed to be an idiopathic disorder in some patients and an autoimmune disorder with functional impairment of spinal neurons due to antibodies directed against the enzyme glutamic acid decarboxylase (GAD) in others.^[45] This enzyme is essential for the conversion of glutamic acid to GABA, an inhibitory neurotransmitter found throughout the central nervous system.^[46] In a paraneoplastic form of SPS, amphiphysin, a protein associated with synaptic vesicles, has been implicated, and this product's gene has been mapped to 7p13-14.^[47] Neurophysiological studies show continuous excessive firing of the motor unit, suggesting that the disorder is due to disinhibition of the descending pathways to the Renshaw cells or gamma motor system.^[48] Autopsy information, albeit limited, has failed to demonstrate any abnormalities in the brain stem, spinal cord, peripheral nerve, or muscle.

Epidemiology and Risk Factors. The disorder is more common in women and is frequently associated with other

autoimmune disorders (diabetes mellitus, thyroiditis, myasthenia gravis, pernicious anemia, and vitiligo).^[49]

Clinical Features and Associated Disorders. Typically, SPS patients present with painful muscle cramps and severe lordosis secondary to chronic spasm of the paraspinal muscles. Although predominantly a disease of the axial muscles, cranial involvement has been reported in 25 percent of patients, and spread to the proximal limbs occurs. Examination reveals marked lumbar and thoracic muscle spasms. Stress or exertional activity may provoke painful spasms that may last for hours. Because of hypertonicity, the gait may resemble that of a "tin soldier."

Differential Diagnosis. Among the primary differential diagnoses are dystonia and orthostatic tremor. In both instances, patients may complain of tight cramping

muscles and pain, especially when standing. Other rare conditions resembling SPS include tetanus, progressive encephalomyelitis with rigidity, and Isaac's syndrome. Tetanus secondary to infection with *Clostridium tetani* is usually associated with a laceration injury and progresses from focal muscle spasm at the site of inoculation to bulbar and generalized spasms. Progressive encephalomyelitis usually begins with pain and sensory changes, and in these patients, a paraneoplastic disorder is possible. Isaac's syndrome is often familial and is associated with peripheral neuropathy, but most important, it usually causes more symptoms in the appendicular muscles than in the axial ones.

Evaluation. Electromyographic demonstration of continuous motor unit activity is essential to confirm the diagnosis of SPS. The presence of reduced motor activity after benzodiazepine administration is also important. Diagnostically, spinal fluid analysis may reveal increased immunoglobulin or oligoclonal bands, and the presence of GAD antibodies is helpful in confirming the autoimmune form of this diagnosis.

Management. Treatment is based on controlling rigidity; currently, diazepam (20 to 300 mg/day) is the most effective medication for this purpose. Baclofen, clonazepam, valproic acid, and clonidine have been reported to improve symptoms. The role of treatment for autoimmune conditions, such as plasmapheresis, corticosteroids, or azathioprine, has yet to be defined.^[42] Intrathecal baclofen and botulinum toxin may also be beneficial, but because of the rarity of this syndrome, controlled clinical trials of these drugs for this purpose have not been undertaken. Although these patients may be in pain, extreme caution must be used in mixing narcotic medications with benzodiazepine derivatives, especially if the patient's spasms induce respiratory acidosis because of the rigidity of the diaphragmatic muscles.

Prognosis and Future Perspectives. Without treatment, SPS progresses to total disability related to generalized rigidity and secondary musculoskeletal deformities. The pathogenetic autoimmune mechanisms remain to be elucidated.

HYPERKINETIC MOVEMENT DISORDERS

Huntington's Disease

This primary neurodegenerative disorder usually begins during adult life, often after the affected individuals have already borne their children. It is inherited in an autosomally dominant pattern, and the disorder has clinical manifestations that often vary among involved family members, and patients may have predominantly behavioral, cognitive, or movement disorder signs.

Pathogenesis and Pathophysiology. Huntington's disease (HD) is caused by a mutation on chromosome 4 consisting of an unstable expansion of CAG repeats. Normal individuals have between 11 and 34 repeats, whereas those with HD have between 37 and 86. The trinucleotide CAG codes for glutamine, and the increase in polyglutamine is thought to cause an overexpression of the gene whose protein is termed huntingtin. This product tightly binds with ubiquitin to form intranuclear inclusions and may subsequently interfere with normal mitochondrial bio-energetic mechanisms.^[49] It is not known why the striatum is preferentially affected because the HD mRNA product has been found in all examined tissues.^[50] Neuronal loss in the caudate and putamen has been correlated with a longer CAG trinucleotide repeat length, and the preproenkephalin medium spiny neuron seems to be particularly vulnerable.^[51]

Pathological changes in the brain of patients with HD include generalized atrophy with neuronal degeneration in the cortex and severe loss of medium spiny projection neurons with preservation of cholinergic aspiny interneurons in the caudate and putamen. Marked caudate atrophy is the pathological hallmark of the disease, and this finding can be detected on MR scans. MR spectroscopy demonstrates changes that reflect increased levels of lactic acid, suggesting a bioenergetic defect. Additional evidence, particularly in experimental models of HD, suggests that mitochondrial dysfunction may be a possible pathogenetic mechanism of neuronal cell death.^[52]

Several important biochemical abnormalities have been noted in postmortem brain tissue, particularly in the striatum. These include decreases in choline acetyltransferase (CAT) activity and acetylcholine (ACh), a reduction in the total number of cholinergic muscarinic receptors, and depletion of GAD, substance P, angiotensin-converting enzyme, cholecystokinin, enkephalin, and other peptides. In contrast, the concentrations of DA, norepinephrine, serotonin, neurotensin, somatostatin, and thyrotropin-releasing hormone (TRH) are normal or increased.^[52] The result of these changes suggests a functional overactivity of the cerebral glutaminergic and striatal dopaminergic systems and an underactivity of the GABAergic systems.

Epidemiology and Risk Factors. The estimated prevalence of HD is 5 to 10 per 100,000 people in the United States.^[53] Because the CAG repeat length is unstable in sperm, affected fathers often transmit a very high repeat sequence, resulting in an early onset of disease in their offspring.

Clinical Features and Associated Disorders. Gradual onset of chorea, dementia, and behavioral abnormalities in a young or middle-aged adult should suggest the possibility of HD. Slowed saccadic eye movements are usually the first detectable clinical sign, and in 85 percent of patients chorea is the predominant movement disorder. Movements may start as fine, irregular body jerks that have no functional significance, but coordination, gait, and balance difficulties gradually supervene. In the juvenile form of HD, rigidity, bradykinesia, resting tremor, dystonic postures,

ataxia, seizures, myoclonus, and mental retardation are more prominent, and this presentation is termed the Westphal variant of HD. Even in patients with adult-onset and prominent chorea, bradykinesia and postural reflex compromise can occur and may be sources of significant functional disability. In the terminal phases of HD, dysarthria, dysphagia, and respiratory difficulties become the most disabling and life-threatening problems.^[52]

Cognitive impairment is a source of major disability in these patients. Memory difficulties, concentration problems, confusion, and forgetfulness can occur (see [Chapter 33](#)). In addition, depression and other emotional disturbances may be severe and can lead to erratic, impulsive behavior as well as suicidal ideation. Other psychiatric disturbances include delusional thoughts, paranoia, and hallucinations.^[52] Eventually, patients become demented, and most require assistance and supervision in daily living activities.

Differential Diagnosis. Besides HD, other less common hereditary choreas include hereditary benign chorea and neuroacanthocytosis (see later discussion in this chapter). If a family history of choreic or psychiatric disorders is lacking, numerous other disorders should be considered, including tardive dyskinesia, CNS vasculitis, Wilson's disease (WD), Sydenham's chorea, and toxin exposure. Drugs causing chorea include oral contraceptives, levodopa, CNS stimulants, neuroleptics, phenytoin, carbamazepine, and ethosuximide. If the diagnosis is approached from the perspective of genetic testing, other hereditary neurodegenerative conditions with expanded trinucleotide repeats of CAG include Kennedy's syndrome (X-linked spinal and bulbar muscular atrophy), myotonic dystrophy, spinocerebellar atrophy type 1, and dentato-rubro-pallido-luysian atrophy ([Table 34-4](#)).

Evaluation. In addition to taking a complete family history, blood should be drawn for DNA testing. Careful counseling about the implications of the diagnosis is essential when working with patients who are at risk for the disease. Issues of privacy are particularly important because giving subjects positive diagnostic information reveals information about the parents' genetic makeup. MR scans can detect the presence of caudate and cerebral atrophy. When the family history is in doubt, an assiduous search of autopsy reports on relatives can sometimes unearth the diagnosis in the genealogy.

Management. DA receptor-blocking agents (e.g., haloperidol or fluphenazine) and dopamine-depleting agents (e.g., tetrabenazine, reserpine) reduce the choreic movements but may not improve other symptoms of Huntington's disease. Because of their potentially serious side effects, including tardive dyskinesia (neuroleptics), depression (dopamine-depleting drugs), and parkinsonism (both drug classes), the antidopaminergic drugs should be reserved for patients with disabling chorea or serious psychosis. The tricyclic antidepressants and selective serotonin reuptake inhibitors (SSRI) are often helpful in ameliorating the affective disorders but may precipitate myoclonus. Antiglutamatergic drugs and facilitators of mitochondrial metabolism are currently being tested in clinical trials. Psychological support, genetic counseling, long-term planning, and access to social service agencies are important elements of patient management.

TABLE 34-4 -- ETIOLOGICAL CLASSIFICATION OF CHOREA

1. Developmental and aging choreas
 - a. Physiological chorea of infancy
 - b. Cerebral palsy--anoxic, kernicterus
 - c. Minimal cerebral dysfunction
 - d. Buccal-oral-lingual dyskinesia and edentulous orodyskinesia in elderly
 - e. Senile chorea (probably several causes)
2. Hereditary choreas
 - a. Huntington's disease
 - b. Benign hereditary chorea
 - c. Neuroacanthocytosis
 - d. Other CNS "degenerations": Olivopontocerebellar atrophy, Azorean disease, ataxia telangiectasia, tuberous sclerosis, Hallervorden-Spatz, dentato-rubral-pallido-luysian atrophy (DRPLA), familial calcification of basal ganglia, others
 - e. Neurometabolic disorders: Wilson's disease, Lesch-Nyhan disease, lysosomal storage disorders, amino acid disorders, Leigh's disease, porphyria
3. Drug-induced choreas: neuroleptics (tardive dyskinesia), antiparkinsonian drugs, amphetamines, tricyclics, oral contraceptives, anticonvulsants, anticholinergics, others
4. Toxin-induced choreas: alcohol intoxication and withdrawal, anoxia, carbon monoxide, Mn, Hg, thallium, toluene
5. Metabolic causes

- a. Hyperthyroidism
 - b. Hypoparathyroidism (various types)
 - c. Pregnancy (chorea gravidarum)
 - d. Hyper- and hyponatremia, hypomagnesemia, hypocalcemia
 - e. Hypo- and hyperglycemia (latter may cause hemichorea, hemiballism)
 - f. Acquired hepatocerebral degeneration
 - g. Nutritional--e.g., beriberi, pellagra, vitamin B₁₂ deficiency in infants
6. Infectious causes
 - a. Sydenham's chorea
 - b. Encephalitis lethargica
 - c. Various other infections and postinfectious encephalitides, including Creutzfeldt-Jakob disease
-

Prognosis and Future Perspectives. Despite recent advances in treatment, this disorder results in progressive functional decline and eventual death, usually within 12 to 15 years of onset. Neural transplantation with fetal striatal or other cell sources may become experimental options in the future.

Other Forms of Chorea

Senile chorea (essential chorea) begins after age 60 and is unaccompanied by any particular neurobehavioral symptoms or a family history of chorea. Whereas some patients have caudate atrophy similar to that seen in HD, others have predominant putaminal degeneration. In occasional cases, genetic detection studies in these patients reveal that the correct diagnosis is actually HD. Treatment of the chorea is similar to that used for HD.

Paroxysmal dyskinesia is a chronic condition that becomes manifest by a sudden onset of transient choreoathetosis, dystonia, or both. The familial paroxysmal dyskinesias are subdivided into kinesigenic and nonkinesigenic disorders depending on whether or not they are induced by sudden voluntary movements. In the familial (autosomal dominant or recessive) kinesigenic paroxysmal choreoathetosis,

the movements are brief, usually lasting less than 3 minutes, and occur many times daily, sometimes up to 100 times a day).^[54] Nonkinesigenic and exertional paroxysmal dyskinesias may also be transmitted as autosomal dominant disorders, and the movements in these forms tend to be more dystonic than choreic in nature. The episodes of dyskinesia are usually more prolonged (lasting 2 minutes to 4 hours) and less frequent (occurring three to five times a day). Attacks are precipitated by alcohol, coffee, fatigue, stress, or excitement. Kinesigenic dyskinesias respond well to anticonvulsant medications such as phenytoin, carbamazepine, or phenobarbital. In contrast, the nonkinesigenic dyskinesias respond poorly to most medical therapy, although some patients improve with clonazepam.^[54] Pathophysiologically, these conditions appear to be an interface between movement disorders and epilepsy, since in some conditions assiduous electrode placement over the frontal and frontocentral regions may reveal epileptic spikes and phase reversals.^[55] Secondary paroxysmal dyskinesias may be associated with structural lesions of the premotor cortex or basal ganglia, and specific causes include multiple sclerosis and hypocalcemia.^[54]

Neuroacanthocytosis (NA) is a rare disorder with autosomal dominant, recessive, or even X-linked inheritance and is manifested by chorea, tics, dystonia, parkinsonism, self-mutilatory behavior, amyotrophy, areflexia, elevated creatine phosphokinase (CK), and other symptoms.^[56] One of the most distinguishing features of NA is an eating dysfunction that is due to orolingual dystonia and is manifested by expulsion of food from the mouth by a protruding tongue. Involuntary vocalizations and parkinsonism also occur. Although the mechanism of acanthocyte formation in NA is unknown, abnormal protein to fatty acid ratios and in some cases abnormal erythrocyte surface antigens have been found. It is possible that, as in the periodic ataxias, some of the paroxysmal dyskinesias represent abnormalities of the calcium channel or other channelopathies. Acanthocytes in most patients can be seen in fresh blood smears, but erythrocytes may require incubation in normal saline for 3 to 5 minutes prior to wet mount preparation. CT or MRI of the head may demonstrate cerebral or caudate atrophy. PET scans reveal 42 and 54 percent reductions in putamenal and caudate fluorodopa uptake, respectively, and a 65 and 53 percent reduction in the D₂ receptor density in these areas.^[56] Treatment may involve the use of dopamine-blocking agents in the form of neuroleptics (haloperidol, fluphenazine) or dopamine-depleting drugs (reserpine, tetrabenazine). As the disease progresses, most care is supportive. Whereas the course of progression varies, death usually occurs within 15 years of diagnosis.

Sydenham's chorea (SC, also known as St. Vitus' dance) develops following exposure to the bacteria *Streptococcus pneumoniae* and, in the age of antibiotic therapy, is rare.^[57] Most typically, Sydenham's chorea is associated with infection and other sequelae of rheumatic fever. Autopsy studies of patients with Sydenham's chorea reveal edema, chromatolysis, and atrophy that affect primarily the striatum, but the cortex, thalamus, and other basal ganglial nuclei may be variably involved as well.^[58] The clinical picture involves a child with diffuse chorea, motor impersistence, and variable degrees of weakness. Unlike arthritis and carditis, chorea may not develop for weeks or even months after acute infection has occurred. Children are often very distressed in the midst of the chorea, rest poorly, and can develop a number of behavioral abnormalities. In addition to high titers of antistreptolysin, approximately 50 percent of patients have IgG antibodies that react against neurons in the caudate and subthalamic nuclei. The condition is usually self-limited, but during the period of marked chorea, dopamine-blocking or -depleting agents (see earlier discussion) can be used. Because prolonged drug usage is usually not necessary, major concerns about the induction of tardive dyskinesia from neuroleptic drugs do not exist.

In the evaluation of these forms of primary choreic disorders, other secondary choreas must be considered. *Chorea gravidarum* and endocrine-metabolic choreas, such as *birth control pill chorea*, should be considered in appropriate women with hyperkinetic movements. Prior Sydenham's chorea may be a risk factor for these conditions. Estrogens may serve as a facilitator of dopamine pharmacology, either directly at the receptor sites or through second messengers. In pregnancy, DA receptor-blocking drugs (neuroleptics) should be avoided, particularly during the limb-genesis period of the first trimester. Benzodiazepines may be appropriate in the second and third trimesters, but fetal respiratory depression must be avoided. *Hyperthyroidism*, either primary or pituitary in origin, can be associated with various movement disorders, including chorea.

Primary Dystonia

Pathogenesis and Pathophysiology. Dystonia consists of sustained, repetitive, patterned contractions of the muscles producing twisting (e.g., torticollis) or squeezing (e.g., blepharospasm) movements or abnormal postures that may be present at rest, when changing position, or when performing a specific motor activity.^[59] The most frequently encountered form of generalized dystonia is primary dystonia, formerly referred to as dystonia musculorum deformans or idiopathic torsion dystonia. It is an autosomal dominant disorder in which the genetic defect, consists of a three base pair deletion in a gene on chromosome 9q32-34 (DYT1), coding for an ATP-domain protein. Rarer forms of pure dystonia unrelated to this defect or due to enzyme deficiencies have been described ([Table 34-5](#)) but are not well delineated.

Although autopsy studies have produced no reproducible histological or biochemical abnormalities in patients with primary dystonia, the disorder is thought to be due to altered physiological control of descending pathways from the basal ganglia and brain stem. Subtle changes on MRI have been reported in patients with primary dystonia, but in most patients no discernible abnormalities can be identified on imaging tests. PET studies have also failed to reveal consistent abnormalities. Studies using blink, acoustic, and vestibulo-ocular reflex testing, however, have revealed abnormalities suggesting that the brain stem reflexes have enhanced excitability.^[59] Changes in norepinephrine, serotonin, and dopamine levels have been found in some patients.

Epidemiology and Risk Factors. Limited information is available about the epidemiology of primary dystonia,

Modified from Jankovic J, Fahn S: *In* Tolosa E (eds): Parkinson's Disease and Movement Disorders, 3rd ed. Baltimore, Williams & Wilkins, 1998, in press.

but data from Rochester, Minnesota reveal a prevalence of 34 per million population; specific cultural groups are more likely to develop primary dystonia than others,

however, and among Jews of eastern European ancestry the prevalence is at least double that seen in other groups.

Clinical Features and Associated Disorders. Primary dystonia may involve the entire body (generalized dystonia) or may be confined to one body part (focal dystonia), for example, the head (cranial dystonia) or neck (cervical dystonia); alternatively, it may involve contiguous body

parts (segmental dystonia), for example, the neck, shoulder, and arm. The most common form of limb dystonia is dystonic writer's cramp. Although primary dystonia is a highly variable condition, there are a number of important clinical patterns. First, primary dystonia, regardless of its eventual outcome (focal, segmental, or generalized), usually begins as a focal condition, and in children the legs and feet are the areas most commonly affected. Second, environmental conditions affect dystonia, and, importantly, in the early stages of primary dystonia, dystonia is usually seen only during activity, for example, when walking or running (action dystonia). In addition, and related to exacerbation of disease with action, dystonic signs usually become prominent in the middle and later part of the day. This feature is most pronounced in a particular form of dystonia, termed dopa-responsive dystonia (see subsequent discussion), in which diurnal fluctuation in the gait disturbance may be so marked that the patient is almost normal in the early morning but becomes virtually crippled by late afternoon or evening. Third, the younger the age at onset, the more likely the dystonia is to become severe and spread to many body regions. Likewise, adult-onset primary dystonia is almost always focal or segmental and does not become generalized. Fourth, patients with primary dystonia often report that certain postures or sensory "tricks" or "gestes antagonistes" improve their dystonia. For example, gentle counterpressure by a hand against the chin in a patient with torticollis may enable the patient to maintain the primary or normal position of the head. Finally, one of the features in many patients with dystonia is an associated tremor in addition to the contorted posture. This tremor, termed dystonic tremor, involves the patient's attempt, conscious or not, to overcome the dystonia. It is most pronounced when the patient works maximally to resist the pull of the dystonic muscles and is least apparent when the patient permits the involved body part to drift with the dystonic spasm.

Differential Diagnosis. In addition to primary dystonia, the differential diagnosis of the dystonic patient (see [Table 34-5](#)) must include, first, dystonia-plus syndromes, (see later discussion), a conglomerate term that includes other forms of primary dystonia associated with additional neurological deficits, and second, secondary forms of dystonia, in which the dystonia is related to underlying damage from a known pathological cause. In the latter category, causes of dystonia are numerous and include exposure to DA receptor-blocking drugs ("tardive dystonia"), hypoxic encephalopathy, head trauma, encephalitis, human immunodeficiency virus (HIV) and other infections, peripheral or segmental nerve injury, inherited disorders (e.g., Wilson's disease), metabolic disorders and other inborn errors of metabolism, mitochondrial disorders, and chromosomal abnormalities.^[56] Unilateral dystonia (hemidystonia) is usually not part of the clinical picture of primary dystonia but is associated with a structural lesion in the contralateral striatum, particularly the putamen.

Evaluation. The diagnosis of primary dystonia should be considered in any patient with an abnormal posture and a family history of variable problems with cramps, spasms, tremors, and crippling conditions. In the initial evaluation the clinician should gather information about age at onset, initial and subsequent areas of involvement, course and progression of disease, tremor or other movement disorders, possible birth injury, developmental milestones, and exposure to neuroleptic medications, as well as a family history of dystonia, parkinsonism, or other movement disorders. Consanguinity or Jewish ancestry should be noted as well. Since the clinical expression of primary dystonia is highly variable even within families, the history and family tree may be extremely difficult to establish with confidence. Some family members may have severe problems and require extensive assistance with activities of daily living, while others may show only mild symptoms (e.g., writer's cramp).^[57] Evidence of other conditions known to produce dystonia but associated with other neurological dysfunctions (e.g., cognitive, pyramidal, sensory, or cerebellar deficits) should be evaluated along with secondary causes of dystonia. The ceruloplasmin level should be obtained in all patients in whom onset of dystonia occurs before the age of 50, since Wilson's disease is highly treatable. Other blood tests, including genetic tests, depend on the clinical setting, and the various storage and metabolic disorders should be evaluated individually. An MR scan is important in the evaluation of structural abnormalities, and skull, neck, and spine evaluations may be needed if there is evidence of a secondary myelopathy or scoliosis due to axial dystonia.

Management. In treating primary dystonia, high-dose anticholinergic therapy (e.g., trihexyphenidyl in doses of up to 70 mg/day) may be effective in ameliorating dystonia, particularly in younger patients. However, many patients are unable to tolerate such high doses because loss of memory, hallucinations, blurring of vision, and other anticholinergic side effects may occur. In addition, all patients with childhood-onset dystonia deserve a trial of levodopa, using Sinemet in doses of up to 100/1000 mg/day.^[58] Other agents such as oral baclofen, carbamazepine, and tetrabenazine have been reported to be beneficial in some dystonic patients. Recent interest has focused on the use of intrathecal baclofen in patients with generalized and axial dystonia, but controlled trials of this usage have not been published.

Intramuscular injections of botulinum toxin type A are the most effective treatment for focal dystonia and may be used in a limited form in patients with segmental or generalized dystonia.^[59] Because it acts at the presynaptic membrane, this potent neurotoxin prevents release of acetylcholine at the nerve terminal, causing muscle weakness. Injection into dystonic muscles requires knowledge of the muscle anatomy and the site of muscle innervation, and some clinicians perform this procedure with the aid of EMG guidance. Treatment is necessary every 3 to 5 months in most patients, and this therapy has been used safely in some patients for more than 15 years. However, some patients develop resistance to the clinical response, and antibodies to the A toxin may develop. If the dose is limited to less than 300 units per procedure and the treatment is given no more frequently than every 3 months, the risk of immunoresistance is minimized. Other types of botulinum toxins, namely B and F, are currently being investigated for the treatment of focal dystonia.

Thalamotomy is occasionally performed in patients with otherwise medically intractable disease. It is more effective for distal than for proximal dystonia.^[60] Unfortunately, when these procedures are bilateral, patients may be left with

severe dysarthria, dysphagia, and memory deficit. In this regard, pallidotomy may have some advantages. Cervical cord stimulation, peripheral nerve section, rhizotomy, and myotomy are occasionally effective.

Prognosis and Future Perspectives. Prognosis in primary dystonia is highly dependent on age of onset; the younger the age at onset, the higher the likelihood of spread and progression to generalized disabling dystonia. The biological markers and pathophysiological mechanisms of dystonia remain to be elucidated. It is likely that the gene or genes for primary dystonia will be identified, and the study of the gene product may provide clues to the pathogenesis of primary dystonia.

Other Forms of Primary Dystonia

Several other forms of primary inherited degenerative syndromes are associated with dystonia.^[56] Like the parkinsonism-plus syndromes, the major hallmark in these dystonia-plus syndromes is dystonia, but this is accompanied by movement disorders. *Dopa-responsive dystonia* (DRD) is also an autosomal dominant disorder caused by a mutation in the GTP cyclohydrolase I gene on chromosome 14q, which causes a defect in dihydrobiopterin synthesis. These patients present with dystonia and parkinsonism that has a marked diurnal fluctuation. In the early morning they may be symptom-free or only mildly affected, but then a progressive gait disorder and cramping and rigidity develop during the day. These patients are markedly sensitive to low doses of levodopa, and often doses of Sinemet as low as 25/100 mg/day are effective in obliterating clinical signs. For this reason, it is particularly important to recognize DRD, and all children with dystonia and adults with leg or trunk dystonia deserve a trial of levodopa. Another syndrome, *X-linked dystonia-parkinsonism*, is much rarer and is confined largely to inhabitants of the Philippines.^[57] These patients, mostly men, develop severe axial dystonia and a hunched parkinsonian posture. Falls, dysphagia, and voice compromise follow, and these signs usually are preludes to death. In contrast, *myoclonic dystonia* (see later section on essential myoclonus) is a benign autosomal dominant disorder marked by a combination of dystonia and jerking myoclonic movements, usually starting in the first or second decade of life without other neurological deficits. These patients show a dramatic response to alcohol^[57] and are treated with this product combined with benzodiazepines with usually excellent results.^[56]

Hallervorden-Spatz Disease

Pathogenesis and Pathophysiology. Hallervorden-Spatz disease (HSD) is a rare autosomal recessive disorder associated with excessive iron deposition in the globus pallidus (GP).^[61] The most striking autopsy finding in HSD patients is the asymmetrical rust-brown pigmentation of the GP and zona reticulata of the substantia nigra (SN). The iron pigmentation occurs both extracellularly and intracellularly but is predominantly found in astrocytes, microglia, and neurons. "Mulberry" concretions are also typically present in the extracellular space. Numerous and large spheroid bodies, identified by myelin staining and surrounded by pigment granules, are typically present throughout the medial GP, SN zona reticulata, cortex, and subthalamic nucleus.^[62] The spheroid bodies apparently represent degenerating myelinated axons.

Clinical Features and Associated Disorders. HSD was initially described in a single family of 12 children, three of whom died at birth; eight of the remaining nine

developed athetosis, tremor, and visual difficulties. Dystonia and rigidity are the major hallmarks of this childhood illness, but other associated features include gait and posture disturbances, chorea, athetosis, tremor, dysarthria, blindness with retinitis pigmentosa, intellectual decline, spasticity, and seizures. Myoclonus is rare and usually is a preterminal sign. Although the onset usually occurs in the first decade of life, rare patients with adult-onset HSD starting in the fourth to sixth decade and presenting as parkinsonism have been described.^[62]

Differential Diagnosis. HSD has a wide spectrum of presentation and therefore a potentially large differential diagnosis. A disease of iron deposition in the basal ganglia, HSD shares some features with other disorders associated with deposition of metals, such as Wilson's disease and manganese toxicity. Other disorders with overlapping clinical features include juvenile Huntington's disease, neuroacanthocytosis, and neuronal ceroid lipofuscinosis.

Evaluation. CT scans reveal high signal intensity in the medial GP, and MRI demonstrates decreased signal intensity in the GP on T2- or proton density-weighted images; these abnormalities are produced by iron deposition bilaterally in the pallidum.^[62] In some cases, the center is hyperintense, giving rise to the term "eye of the tiger" sign. Ophthalmological examination may be particularly helpful because it may show optic degeneration and retinitis pigmentosa.

Management. There is no specific treatment for HSD. Chelation therapy to remove excess iron accumulation in the basal ganglia has not been useful. Parkinsonism in some patients has responded to levodopa and bromocriptine therapies, but anticholinergic agents have failed to improve symptoms of tremor, dystonia, or bradykinesia. The choreoathetosis may benefit from benzodiazepines, but dopamine antagonists are generally not used because of the risk of worsening parkinsonism. Antiepileptic drugs are useful for the control of seizures. Supportive care and physical, occupational, and speech therapy should also be instituted when appropriate.^[62]

Prognosis and Future Perspectives. The mean duration of the disease is 11 years, and 45 percent of patients die before reaching the age of 20 years.^[61] Putative gene markers have been found recently, but further studies are needed before the gene mutation is characterized and the gene product is identified.

Gilles de la Tourette Syndrome and Other Tic Disorders

Pathogenesis and Pathophysiology. Tics are repetitive movements that usually involve the eyes, face, shoulders,

neck, and vocal apparatus more than the rest of the body. When childhood-onset tics are multifocal, motor, and vocal, last longer than 1 year, and naturally wax and wane, the term Gilles de la Tourette syndrome (GTS) is applied.^[63] Once considered a rare psychiatric condition, GTS is now recognized as a relatively common neurological disorder with both motor and behavioral manifestations. In approximately 60 percent of cases of GTS, a family history of similar disorders can be found, which suggests that it is an autosomal dominant disorder. No genetic marker, however, has yet been identified. Because tics respond to dopamine-depleting drugs and DA receptor antagonists (neuroleptics), striatal DA receptor supersensitivity and developmental striatal DA terminal hyperinnervation have been proposed as possible causes of GTS symptoms.^[64] Some clinical data indicate that neurotransmitters other than DA may be involved in other aspects of GTS.^[65] Obsessive-compulsive disorder (OCD), a condition thought to be related to serotonergic neurochemistry, is present in at least half of patients with GTS, and this observation suggests that the serotonergic pathways in GTS may be altered. There is also some support for the idea that the opiate or second-messenger system may be involved in this disorder.^[64]

Epidemiology and Risk Factors. Because most children with GTS have mild and undiagnosed symptoms, past prevalence estimates may be low. One review of epidemiological prevalence data in children found that prevalence estimates ranged from 0.5 to 50 per 10,000 population.^[66] Kurlan reported that the frequency of tics in children ranged from 4 to 24 percent and that 26 percent of children in special education classes had tics compared to 6 percent of children in regular classes.^[67] These studies suggest that children requiring special education may represent a high-risk population for tics. Some worsening of tics during pregnancy has been observed. Although genetic factors are clearly the most important determinants, there is some evidence that perinatal complications increase the risk of GTS.

Recent studies have emphasized the familial nature of GTS, with approximately a third of probands having a positive family history of simple tics and another third having a positive family history of the full GTS.^[64] Transmission is often bilinear, meaning that both parents are affected. Typically, the father has a history of tics that may or may not persist through adulthood, and the mother has features of OCD. This pattern suggests that GTS represents one part of a spectrum, of which the mildest manifestation is a simple or transient tic of childhood and the most severe manifestation is the full syndrome that includes motor as well as behavioral features. This clinical heterogeneity makes specific definition of GTS problematic for genetic studies.

Clinical Manifestations and Associated Disorders. Tics are defined as simple or complex repetitive movements that occur out of background of normal motor activity. They are usually fast (myoclonic) but can be slow (dystonic). They increase with fatigue and after stress and decrease with concentration.^[68] GTS is characterized by chronic waxing and waning motor and vocal tics, usually beginning between the ages of 2 and 21 years. It affects boys more frequently than girls. About half the patients start with simple motor tics, such as frequent eye blinking, facial grimacing, head jerking, or shoulder shrugging, or with simple vocal tics such as throat clearing, sniffing, grunting, snorting, hissing, barking, or other noises. Complex motor tics include squatting, hopping, skipping, hand shaking, and ritualized movements such as compulsive touching of objects, people, or self. Complex vocal tics include semantically meaningful utterances, including shouting of obscenities and profanities (coprolalia). Although coprolalia and other disturbing or socially unacceptable phenomena (copropraxia, coprographia, and mental coprolalia) can occur, these features are not necessary to the diagnosis of GTS. Of great clinical importance, tics can be voluntarily suppressed for seconds to minutes, but this suppression may be followed by a rebound burst of exaggerated abnormal involuntary movements. For this reason, tics may not be seen in the doctor's office, even though they may be disabling at school or at home. Many patients also report a premonitory phenomenon prior to the onset of motor tic. This crescendo urge, tension, or abnormal sensation in the distribution of the tic is relieved with the performance of the involuntary movement. In addition to these motor and vocal tics, many patients develop behavioral disorders, especially OCD and attention deficit hyperactivity disorder (ADHD), impulsive and self-destructive behavior, sleep abnormalities, and alterations in mood and sexual behavior. Learning disability often overlaps with hyperactivity and ADHD.

Differential Diagnosis. GTS is considered one end of a continuum of primary tic disorders^[69] that includes transient tic disorder of childhood (tic or tics lasting less than 1 year) and chronic multiple tic disorder (motor or vocal tics, but not both). These semantic differences probably have no pathophysiological distinction, and therefore these primary tic disorders can be considered as clinical variants of one process. In contrast, several forms of secondary tics should be excluded, including hypoxic head injury, head trauma, encephalitis, carbon monoxide intoxication, Huntington's disease, neuroacanthocytosis, and startle disorders.^[69] In these cases, tics are usually combined with other abnormal movements, often chorea, cognitive impairment, or other neurological deficits. Tics must also be differentiated from other hyperkinetic movement disorders, including myoclonus, blepharospasm, stereotypies, and hyperekplexia.^[69] It may be difficult to differentiate complex motor tics and compulsions.

Evaluation. The diagnosis of GTS is usually made by the history and can be verified by neurological observation. However, given the voluntary suppressibility of tics and the characteristic waxing and waning quality of the disease, it is possible that tics may be absent at the time of an examination. Asking the patient or the parents to bring a videotape of the movements taken during a period of relaxation and fatigue is often of greater diagnostic yield than several minutes of scrutiny in the doctor's office. Neuroimaging or other diagnostic studies are generally not required. A careful family history is critical, specifically as it relates to a history of tics, unusual habits or rituals, obsessive-compulsive symptoms, and other manifestations of GTS. Attention should be paid to the possibility of neonatal or perinatal injury and whether the child met developmental milestones appropriately. Blood tests in selected

cases may include genetic testing for Huntington's disease and neuroacanthocytosis.

Management. Because most tic disorders are mild, the majority of patients require no pharmacological therapy. Education and identification of normal patterns of waxing and waning of symptoms are often the only interventions needed. Because of the fluctuating nature of GTS, however, at some point many patients require short-term drug therapy. In such cases, therapy should be targeted to the symptoms that are particularly troublesome for the patient, and distinctions should be made between tics, ADHD, and OCD. Tics most often respond to DA receptor blockers such as pimozide, fluphenazine, haloperidol, and risperidol. Many clinicians prefer pimozide (1 to 8 mg/day) and fluphenazine because they may be less sedating than other neuroleptic drugs. However, all neuroleptics carry a risk of tardive dyskinesia and require regular follow-up. Tetrabenazine, a monoamine depletor and DA receptor blocker, also improves tics, and, although it is not readily available in the United States, it does not carry a substantial risk of tardive dyskinesia. OCDs often respond to clomipramine, sertraline, fluoxetine, and paroxetine. Patients who have difficulty with OCD and also report problems in falling asleep or wetting the bed may be good candidates for the tricyclic antidepressant clomipramine. Clonidine,

guanfacine, and methylphenidate are helpful for patients with ADHD, and lithium carbonate and carbamazepine are sometimes used for patients who have severe mood changes and impulse control problems.^[69] Supportive individual or family counseling may help the patient and the family adapt to the many internal and external stresses associated with the GTS. In addition, neuropsychological testing to identify the patient's strengths and weaknesses usually allow the patient to reach his or her maximum academic potential. The local and national Tourette Syndrome Association can serve as an important resource for educational material and as a patient advocate in the school and work environment.

Prognosis and Future Perspectives. Most patients show a marked improvement after adolescence and have few or no clinically significant tics as adults. Ten to 30 percent continue to be symptomatic throughout early adulthood and middle age.^[64] The pathogenic mechanism for GTS remains unknown, but current research focuses on the identification of genetic and biochemical mechanisms of this complex neurobehavioral disorder.

Other Stereotypies

Stereotyped motor behavior can occur in normal children and in children with a variety of other primary neurodegenerative conditions. Repetitive head banging, an example of stereotypic activity, is seen in 15 percent of normal children.^[70] In addition, thumb sucking, rocking, and other ritualistic behaviors are common during childhood. Most stereotypies, however, represent evidence of underlying brain dysfunction and hence require recognition. Stereotypic movements occur in at least a third of mentally retarded patients and are a characteristic feature of various autistic disorders such as infantile autism and Rett's, Angelman's, and Asperger's syndromes.^[59] In all these conditions, stereotypies present as repetitive, coordinated, purposeless, involuntary movements such as chewing, lip smacking, body rocking, shoulder shrugging, marching in place, shifting of weight, and thrusting movements of the trunk and pelvis. Respiratory dyskinesia can produce grunting vocalizations, hyperventilation, and shortness of breath.

Rett's syndrome occurs only in girls and is believed to be linked to the X chromosome but is lethal in hemizygous males.^[56] Some authors have suggested that Rett's syndrome is a result of disordered lipid metabolism, whereas others believe that these children have a derangement of the neuronal mitochondria. Typically, these children develop normally through the first 6 to 12 months of life, but then motor abnormalities (stereotypies, dystonia, chorea) emerge, accompanied by cognitive regression. The stereotypies observed most frequently in girls with Rett's syndrome include clapping, wringing, clenching, washing, patting, and rubbing behaviors. Other hyperkinetic disorders of movement include oromandibular dystonia, other dystonias, scoliosis, myoclonus, and choreoathetosis. All patients also have gait disturbances, and parkinsonian findings are manifest chiefly as hypomimia, rigidity, and bradykinesia.^{[56], [70]}

Children with *Angelman's syndrome* have a jerky gait (puppet movements), a tendency to exhibit hand flapping stereotypies, and laughter with minimal stimulus. Patients with Angelman's syndrome and Prader-Willi syndrome both have a similar 15q11-13 chromosomal deletion, and parental origin of the chromosomal abnormality has been postulated to play a role. The children have psychomotor and cognitive delay and ataxia; speech is almost completely absent.^[71] Seizures are present in nearly all patients, and 72 percent have early feeding problems. Eventually, 70 percent of these children learn to walk, and many are able to help with household chores. The most characteristic movement in this disorder is hand flapping with elbow and wrist flexion, but athetosis and tremulousness may also be present.

Asperger's syndrome is an autistic disorder manifested by poor reciprocal interaction, inappropriate emotional expression, impaired nonverbal communication, circumscribed interests, and repetitive activities. These children generally function at a higher intellectual level than most patients with pervasive developmental disorders. Like other autistic patients, they have stereotyped motor behavior, clumsiness, and tics.^[56] Abnormalities in patients with Asperger's syndrome include cortical atrophy with widened Sylvian fissure anomalies (the opercular sign). Increased lipofuscin is present in the brain, conjunctiva, and muscle, and the substantia nigra has reduced pigmentation.

Because many children in the above categories receive treatment with chronic neuroleptic agents, their primary stereotypies must be distinguished from drug-induced tardive dyskinesia. Prominent lingual-facial buccal movements are typical of the latter condition and are less characteristic of the primary stereotypies.

In all these disorders routine laboratory data, spinal fluid analysis, and chromosomal studies are usually normal. No consistent neurochemical abnormalities have been found. Postmortem studies in patients with Rett's and Angelman's syndrome reveal microcephaly and mild neuronal loss with

diffuse gliosis.^[56] Evaluation for Asperger's syndrome by MRI may reveal abnormalities.^[71] In all instances, therapy for patients with stereotypies is empirical and involves primarily the use of neuroleptic agents or dopamine-depleting drugs such as reserpine and tetrabenazine.

Painful Legs-Moving Toes Syndrome

Painful legs-moving toes syndrome (PLMTS) is a movement disorder associated with significant sensory symptoms. The condition is idiopathic in origin but usually develops in association with back pain and often in the context of prior back injury or surgery. No specific pathophysiological mechanisms have been elucidated, and although a spinal cord or peripheral nervous system origin has been proposed, electrophysiological studies are often normal.^[72] Because the condition sometimes follows herpes zoster infection, primary involvement of the posterior roots and ganglia has been suggested to explain the syndrome. The movements are not a response to the pain because after local anesthesia or sympathetic blockade, the movements promptly recur. Clinically, the condition involves continuous writhing movements of the toes and pain in the legs. The pain may range from mildly irritating to excruciatingly severe.^[72] In most cases, it has a constant, boring quality, but it can be burning or crushing. It does not, however, have a shooting or electric quality like a radicular irritation. The toe movements are sinuous and crawling, usually continuous throughout the waking hours and incessantly repetitive. Unlike akathisia, the patient feels no relief in moving and instead tires from fruitless attempts to stop the movement. There is no effective treatment for painful legs-moving toe syndrome, but sympathetic blockade and anticonvulsants have been used.^[73]

Action or Non-Rest Tremors (Table 34-6)

Essential tremor (ET) is the most frequent hyperkinetic movement disorder. Its age-adjusted prevalence is 2 to 5 percent^[74] and, as a lifelong illness, ET may affect any age group. It has a bimodal distribution of age at onset, with two peaks, adolescence and the fourth to fifth decade of life. In many families, ET is inherited in an autosomally dominant pattern, and in these patients, the term *familial tremor* can be used interchangeably with ET. Although central mechanisms are thought to be causative, no specific structural abnormality has been noted in the brains of patients with ET. Because ET can be exacerbated by hyperthyroidism and by caffeine and noradrenergic drugs, alterations in the central norepinephrine chemistry have been suggested.

In contrast to the resting tremor characteristic of PD, ET is a *postural* tremor, which is characteristically present during maintenance of a position. This tremor is typically an alternating flexion-extension movement, whereas supination-pronation oscillation is more characteristic of Parkinson's tremor. ET is also faster (7 to 10 Hz) than the PD tremor (4 to 7 Hz), and when fully developed, it usually involves the head, neck, and voice. Tremor often interferes

TABLE 34-6 -- CLASSIFICATION AND DIFFERENTIAL DIAGNOSIS OF TREMORS

1. Rest tremors
 - a. Parkinson's disease
 - b. Other parkinsonian syndromes (less commonly)
 - c. Midbrain ("rubral") tremor: Rest < postural < kinetic
 - d. Wilson's disease (also acquired hepatocerebral degeneration)
 - e. Essential tremor--only if severe: Rest < < postural and action
2. Postural and action ("terminal") tremors
 - a. Physiological tremor
 - b. Exaggerated physiological tremor (these factors can also aggravate other forms of tremor)
 - i. Stress, fatigue, anxiety, emotion

- ii. Endocrine: hypoglycemia, thyrotoxicosis, pheochromocytoma, adrenocorticosteroids
 - iii. Drugs and toxins: Beta agonists, dopamine agonists, amphetamines, lithium, tricyclic antidepressants, neuroleptics, theophylline, caffeine, valproic acid, alcohol withdrawal, mercury ("Hatter's shakes"), lead, arsenic, others
 - c. Essential tremor (familial or sporadic) ?subtypes
 - d. Primary writing tremor
 - e. With other CNS disorders
 - i. Parkinson's disease
 - ii. Other akinetic-rigid syndromes
 - iii. Idiopathic dystonia, including focal dystonias
 - f With peripheral neuropathy
 - i. Charcot-Marie-Tooth syndrome (controversial whether to call this the Roussy-Levy syndrome)
 - ii. Variety of other peripheral neuropathies (especially dysgammaglobulinemia)
 - g. Cerebellar tremor
 - 3. Kinetic (intention) tremor
- Disease of cerebellar "outflow" (dentate nucleus and superior cerebellar peduncle): Multiple sclerosis, trauma, tumor, vascular disease, Wilson's acquired hepatocerebral degeneration, drugs, toxins (e.g., mercury), others
- 4. Miscellaneous rhythmical movement disorders
 - a. Psychogenic tremor
 - b. Orthostatic tremor
 - e. Rhythmical movements in dystonia (dystonic tremor)
 - d. Rhythmical myoclonus (segmental myoclonus--e.g., palatal or branchial myoclonus, spinal myoclonus, limb myorhythmia)
 - e. Oscillatory myoclonus
 - f. Asterixis
 - g. Clonus
 - h. Epilepsia partialis continua
 - i. Hereditary chin quivering
 - j. Spasmus nutans
 - k. Head bobbing with 3rd ventricular cysts
 - l. Nystagmus

Modified from Weiner WJ, Lang AE: Movement Disorders: A comprehensive survey. New York, Futura, 1989.

with handwriting, drawing, holding a spoon, using a drinking cup, and manipulating tools. ^[74] The vocal cords may be affected, resulting in a wavering voice. Although ET usually occurs in isolation, it can be associated with various other neurological conditions including dystonia, parkinsonism, and certain inherited peripheral neuropathies (e.g., Charcot-Marie-Tooth disease). The differential diagnosis includes normal physiological tremor and the tremors associated with anxiety, thyrotoxicosis, and alcohol withdrawal as well as drug-induced tremors resulting from bronchodilator use, corticosteroids, various CNS stimulants, lithium, and sodium valproate. ET diminishes with rest, ethanol, beta-noradrenergic blockers (usual dose, propranolol 80 to 240 mg/day), primidone (25 to 750 mg/day), and benzodiazepines. In addition, some patients may benefit from gabapentin

and injections of botulinum toxin directly into the contracting muscles. ^[59] Thalamotomy or high-frequency thalamic stimulation may be an option in patients with severe tremors that are refractory to other treatment. ^[75]

Orthostatic tremor and *primary writer's tremor* are two particular forms of tremor that are highly dependent on posture. In the former, patients can usually walk with only mild discomfort, but when asked to stand in place for several seconds, they develop hard and cramping calves and thighs that shake uncontrollably. Although considered by some to be a variant of ET, this tremor does not respond to the usual drugs described above, and clonazepam (1 to 10 mg/day) is usually far more effective. Baclofen can also be used. The differential diagnosis includes dystonia and stiff-person syndrome. Similarly, primary writer's tremor does not occur outside the very specific activity of writing. It is thought that the complicated posture and muscle activation of writing induces the contractions in the agonist and antagonist hand muscles that induce the tremor. Sometimes the hand cramps at the same time, suggesting the presence of an underlying dystonia. The handwriting becomes sloppy, shaky, and large. Patients may respond to the medications used for ET, but often they improve more with anticholinergic medicines, again suggesting that dystonia may underlie these tremorous movements. Importantly, changing to a large, fat pen that requires different muscles for holding and writing with it, or switching to typing is often the most helpful of all therapies.

Cerebellar kinetic tremor, sometimes referred to as an intention tremor, is most apparent during a goal-directed limb movement such as that used in the finger-to-nose or heel-to-shin test. In contrast to postural tremor, the patient's greatest disability occurs at the "end point," when a sudden destabilization occurs with severe shaking. This tremor is usually caused by a lesion in the cerebellar outflow (dentatorubral) tracts, ^[74] and therefore it is seen most typically in patients with multiple sclerosis, cerebrovascular accidents, or primary cerebellar disorders. Likewise, *rubral tremor*, a tremor that mixes rest, postural, and kinetic tremors, is generally not an idiopathic tremor and is induced by structural disease in the midbrain or fiber pathways connecting this region with the cerebellar and thalamic nuclei. Treatment of these tremors is frustrating, and no reliable pharmacological success has been reported. Because these patients are generally not weak and overshoot their targets as they move, stabilization of the involved limbs with wrist weights can reduce the amplitude and disability of the tremor.

Dystonic tremor is a prominent form of shaking that occurs as a compensation for dystonic spasms and must be recognized so that the underlying dystonia can be treated (see earlier discussion). Finally, *palatal tremor*, also termed palatal myoclonus, is characterized by continuous and synchronous contractions of the soft palate that occur at frequencies of 100 to 150 per minute (range, 20 to 600 per minute). Patients may not notice the jerking movements unless they are accompanied by persistent ear clicks caused by the repetitive opening and closing of the eustachian tubes. Concomitant contractions of other muscles, including the larynx, extraocular muscles, neck, diaphragm, tongue, and face, may be observed. These patients may have additional symptoms including postural tremor, oscillopsia, dysphagia, and dysarthria. The movements, which generally persist throughout life with infrequent remissions, may be idiopathic or due to brain stem or cerebellar disease. The anatomical and physiological bases underlying palatal tremor involve the hypertrophic degeneration of the olivary nucleus located within the medulla oblongata. The alteration of the inferior olive develops secondary to a lesion within the Guillain-Mollaret triangle, a pathway extending from the contralateral dentate nucleus via the superior cerebellar peduncle and ipsilateral central tegmental tract. Palatal tremor is usually resistant to therapy and is unnecessary in most patients. 5-Hydroxytryptophan, the serotonin precursor, and carbamazepine are variably effective. Others have reported success with clonazepam, tetrabenazine, and trihexyphenidyl. Surgical intervention, including perforation of the tympanic membrane and tamponade of the eustachian tubes, is unsuccessful.

Wilson's Disease

Pathogenesis and Pathophysiology. Wilson's disease (WD), or *hepatolenticular degeneration*, is an autosomal recessive disorder of copper metabolism. The specific genetic biochemical defect appears to be an abnormality of a copper-binding, membrane-associated adenosine-triphosphatase-associated protein, and the allele for this protein has been localized to the long arm of chromosome 13. ^[76] It is postulated that most of the symptoms result from excess deposition of copper in tissues, particularly in the brain and liver.

Epidemiology and Risk Factors. This rare neurodegenerative movement disorder occurs in approximately 1 in 40,000 people. Although the disorder may not become clinically evident until the fourth or fifth decade of life, the initial presentation most often appears in the early twenties. ^[77]

Clinical Features and Associated Disorders. Clinical features are age-dependent. Children with WD exhibit a typical facies (so-called sardonic smile), behavioral abnormalities, and various motor disorders. ^[77] These include tremor (particularly in a wing-beating position), dystonia, rigidity, postural instability, dysarthria, and ataxia. Some patients also exhibit mental and behavioral changes and seizures. Almost all patients show evidence of hepatic dysfunction. The adult patient usually presents with parkinsonian features, dystonia, athetosis, and slow (myorhythmic) or coarse postural (so-called wing-beating) tremor. In adults, the neurological symptoms predominate over the hepatic dysfunction, and the disorder appears to be less rapidly progressive. Approximately a third of patients present with psychiatric symptoms. These range from irritability and loss of impulse control to mania and depression, sometimes with catatonic symptoms.

The clinical hallmark of the disorder is the presence of a brownish-golden ring at the corneal rim (Kayser-Fleischer ring), which is due to the deposition of copper in the cornea. This sign is seen in almost all patients with neurological or psychiatric manifestations of WD, although slit-lamp examination is sometimes necessary to detect the copper deposition. ^[77] Other ocular abnormalities seen in

Wilson's disease include "sunflower" subcapsular cataracts, retinitis pigmentosa, optic nerve atrophy, and loss of smooth pursuit.

Differential Diagnosis. The differential diagnosis of WD depends on the phenotypical presentation. In children, evaluation usually centers around hepatic disorders, whereas in adults, diagnostic considerations center around the type of movement disorder seen (tremor, chorea, dystonia, or parkinsonism). Although Kayser-Fleischer rings are extremely helpful in confirming this diagnosis clinically, they are also seen in patients with silver intoxication, primary biliary cirrhosis, Addison's disease, carotinemia, and chalcosis as a result of unilateral trauma to the eye with copper-containing foreign bodies. ^[77]

Evaluation. All patients should be evaluated by an ophthalmologist for the presence of the Kayser-Fleischer ring. Decreased serum ceruloplasmin (less than 20 mg/dl) in 90 percent of patients, increased urinary copper excretion (more than 100 µg/ml), impaired hepatic and renal function, hemolytic anemia, and aminoaciduria may also be present. In most cases a 24-hour urinary copper screen will detect elevated urinary copper levels (more than 100 µg/24 hours). If these tests are not diagnostic, liver biopsy should be performed with copper measurements (copper greater than 200 µg/g dry weight). ^[77] T2-weighted MRI scans may show the "face of the panda" sign in the midbrain due to hypodensity of the superior colliculi and hyperdensity in the medial substantia nigra and tegmentum. Fluorodopa PET scans are abnormal in symptomatic patients, demonstrating evidence of nigrostriatal damage.

Management. Because good recovery of hepatic and neurological function is possible in most patients, treatment must be instituted quickly. The goal of therapy is to reduce copper intake by means of a low-copper diet and increase copper excretion. D-Penicillamine is the chelating agent most often used; its side effects are potentially serious but preventable. These include nephrotic syndrome, fever, thrombocytopenia, dermatitis, vitamin B₆ deficiency, seizures, and zinc deficiency, which causes impairment of taste and smell. Pyridoxine should be administered along with penicillamine. Some investigators suggest using tetrathiomolybdate, a drug that both blocks copper absorption and binds to bloodborne copper, as an initial therapy. In addition, zinc acetate may be used as a maintenance therapy because of its low potential for serious side effects other than gastrointestinal effects. Dietary education about foods containing high levels of copper should be undertaken, and specific restrictions should be placed on liver and shellfish. ^[77] In patients who have sustained severe liver damage at the time of treatment, liver transplantation may be considered but remains controversial.

Since the disorder is inherited as an autosomal recessive trait, it is important to screen other members of the family with a neurological examination, serum ceruloplasmin level, and slit-lamp examination of the cornea. The clinical manifestations of the disorder and progression of disease may be prevented by early institution of copper chelation therapy.

Prognosis and Future Perspectives. If WD is recognized early in the course of the illness and is treated aggressively with initial and maintenance chelation therapy, it is potentially a curable disorder. Without treatment, patients progress to disability and death. The gene for WD has been identified on chromosome 13, but several mutations within the gene have been found, and therefore, DNA testing is not yet practical. ^[77]

Hemifacial Spasm

Hemifacial spasm (HFS) is characterized by intermittent twitching of the muscles supplied by one facial nerve. It is thought to result from compression of the facial nerve at its junction with the brain stem by an aberrant or ectopic posterior fossa artery. Whereas many cases are idiopathic in origin, a review of 539 cases of HFS for which the cause was specified showed that compression by vascular structures was responsible in 94 percent of cases, tumor in 4 percent, and bony or other abnormalities in 2 percent. ^[78] The average age-adjusted annual incidence for patients of all ages is 0.78 per 100,000, and the prevalence has been estimated at 14.5 per 100,000 in women and 7.4 per 100,000 in men. ^[79] Onset generally occurs between the second and eighth decades of life, the average age at onset being 45 to 51. Onset during infancy is atypical and usually indicates an underlying tumor, anomaly, or other pathology. Women are more commonly affected than men, and Asians have a particularly high risk compared with other populations. Although familial cases have been reported, most are sporadic. Trigeminal neuralgia can be associated with the development of HFS, suggesting that ephaptic transmission may underlie the pathophysiology of these two syndromes.

Clinically, symptoms begin in the periorbital region and spread to the ipsilateral facial muscles during the next few months. Spasm occurs spontaneously, is almost always unilateral, and is exacerbated by voluntary facial movements such as lip pursing, stress, fatigue, anxiety, or a change in head position. The movements often persist during sleep. Stapedius muscle contraction frequently accompanies contraction of the muscles of facial expression and may produce ipsilateral tinnitus. ^[78]

HFS must be differentiated from other conditions that cause involuntary facial movements. Blepharospasm and other forms of facial dystonia are almost always bilateral. Postparalytic facial spasms generally reflect either fixed contraction of the facial muscles or synkinesis or both. There is always a history of preceding facial weakness (e.g., Bell's palsy), and spontaneous spasms are generally absent. Spastic parietic facial contracture may be confused with HFS. The involved side is weak and contracted, unlike the situation in HFS, in which the facial muscles are relaxed between twitches. Facial myokymia is characterized clinically by undulating movements of the facial muscles. Facial tics are rapid, stereotyped, and relatively well coordinated movements that may also occur in regions distant from the face. Hemimasticatory spasm involves muscles innervated by both the facial and trigeminal nerves.

In the patient with normal results on neurological examination, including careful attention to brain stem testing (e.g., blink reflex and extraocular motility), further work-up is usually not needed. If, however, neurological abnormalities, such as facial sensory deficits or an abnormal corneal blink reflex, are present, MRI and possibly MR

angiography are suggested. Specific attention to the cerebellopontine angle and brain stem is required to detect possible tumors or arteriovenous malformations.

Although some clinicians treat HFS first with clonazepam, botulinum toxin injection to the involved muscles is now the treatment of choice. ^[78] The role of surgical decompression has diminished with the advent of this therapy, but surgery is still performed in some clinical settings. Endoscopic surgical correction may offer a permanent treatment with less morbidity than posterior fossa exploration. Myectomies, nerve sectioning, and phenol injections have essentially been replaced by botulinum toxin injections.

Essential Myoclonus

As with other movement disorders, myoclonus may be classified in several ways including phenomenologically, anatomicophysiological (see [Chapter 16](#)), and etiologically. The etiological divisions are physiological, essential, epileptic, and symptomatic myoclonus. Physiological forms include benign hiccups and hypnic jerks, which are sudden movements experienced by many normal individuals when falling asleep. These two phenomena rarely require evaluation or treatment. ^[80] Because epileptic myoclonus and the vast array of symptomatic causes of myoclonus are described in the appropriate etiological chapters in this book, this section reviews

only the hereditodegenerative (essential) forms of myoclonus.

Pathogenesis and Pathophysiology. Using the term paramyoclonus multiplex, Friedreich presumably was first to describe a patient with essential myoclonus. Although myoclonus has been clinically well defined, there has been no biochemical investigation that has explained the pathophysiological mechanism underlying essential myoclonus. Cerebral blood flow studies utilizing SPECT and xenon-133 or [technetium-99m]-d,l-hexamethylpropylene-amineoxime have revealed focal asymmetries in cerebral blood flow patterns consisting of relative hypoperfusion of the left cerebral hemisphere combined with an associated crossed cerebellar diaschisis.^[81] This pattern could result from small lesions in the brain stem or basal ganglia, with secondary deafferentation of the ipsilateral frontal lobe and contralateral cerebellum, suggesting that essential myoclonus has a subcortical origin. Electrophysiological studies also suggest a subcortical origin for this form of myoclonus.

Epidemiology and Risk Factors. Essential myoclonus is a rare disorder; however, the overall prevalence in the population is unknown.

Clinical Features and Associated Disorders. Since its initial description, the diagnostic criteria for this form of myoclonus have evolved to the present state ([Table 34-7](#)). The jerks in essential myoclonus are brief (50 to 200 msec) and may be generalized, multifocal, segmental, or unilateral. Myoclonic jerks mainly involve the muscles of the neck or upper body and are exacerbated by action, particularly writing or outstretching of the arms. The jerks abate during sleep and are ameliorated by alcohol. The beneficial effects of the latter are at times dramatic and nearly diagnostic; however, following withdrawal of alcohol, the condition frequently becomes worse on the rebound.^[82]

TABLE 34-7 -- DIAGNOSTIC CRITERIA FOR ESSENTIAL MYOCLONUS

-
1. Onset of myoclonus in first or second decade
 2. Males and females equally affected
 3. Benign course
 4. Dominant mode of inheritance with variable severity
 5. Absence of seizures, dementia, gross ataxia, or other deficit
 6. Normal EEG
 7. Normal somatosensory evoked potentials
-

Some individuals with essential myoclonus have associated dystonic movements, including spasmodic torticollis and blepharospasm. The presence of dystonia is an exception to the diagnostic criteria, as noted above. Further complicating these diagnostic criteria is the occurrence of myoclonus in patients with hereditary dystonia, so-called myoclonic dystonia or dystonia with alcohol-responsive lightning-like jerks. Whether these entities represent different disorders remains to be elucidated by future genetic studies.^[83]

In contrast to the hereditary form, the characteristics of sporadic essential myoclonus are more heterogeneous. Patients with this disorder range in age from 2 to 64 years at onset, have normal neurological findings on examination, and normal EEG results. The myoclonic jerks may be oscillatory, rhythmical segmental, nonrhythmical segmental, or nonrhythmical multifocal; the trunk and proximal limb muscles, followed by the muscles of the neck and face, are most affected. Generally, patients do not demonstrate marked progression of symptoms or disability.

Differential Diagnosis. Because essential myoclonus has no known cause, its diagnosis is one of exclusion, and other causes must be evaluated. The coexistence of myoclonus and epilepsy suggests the presence of a form of epileptic myoclonus, which may present with either focal or generalized myoclonus. In these patients epilepsy is the dominant feature, the syndrome is generally age-related, and in most cases EEG abnormalities are associated (see [Chapter 52](#)). Myoclonic syndromes associated with underlying diseases that cause a predominant encephalopathy, ataxia, dementia, or pyramidal or extrapyramidal signs as major features of the illness are termed symptomatic myoclonias. Syndromes comprising symptomatic myoclonus with seizures are termed progressive myoclonic epilepsies (PME) (see [Chapter 52](#)), although the seizures are generally minor or late developments. Symptomatic causes of myoclonus include a variety of disorders ([Table 34-8](#)).

Evaluation. The evaluation of essential myoclonus relies on a detailed history and a thorough neurological examination. Neuroimaging studies (head MRI and CT) in patients with essential myoclonus are normal, but these studies are helpful in patients with alternative diagnoses such as stroke, degenerative disorders, and trauma. Electrophysiological tools, including EMG, electroencephalography (EEG), and somatosensory evoked potentials (SEPs), can be particularly valuable in distinguishing the levels of neural dysfunction in patients with myoclonic syndromes. In essential myoclonus, these studies are normal; however, EEG results are generally abnormal in patients with epileptic myoclonus and the PMEs, showing epileptiform discharges. Patients with metabolic or toxic causes of myoclonus may also show

TABLE 34-8 -- SYMPTOMATIC MYOCLONUS

Medications (amantadine, etomidate, penicillin, buspirone, diclofenac, lithium, metoclopramide, tricyclic antidepressants, levodopa, dopamine agonists)
 Procedures (water-soluble contrast media, post-thalamotomy)

diffuse slowing on EEG. SEPs are also normal in patients with essential myoclonus, as well as subcortical and spinal forms of myoclonus, but are abnormal in those syndromes originating in the cortex, including most PMEs. Blood, cerebrospinal fluid, and tissue biopsies, although normal in patients with essential myoclonus, should be used in the appropriate clinical settings.

Treatment. Despite its nonprogressive, benign nature, essential myoclonus can significantly impair the performance of routine daily activities, and symptomatic treatment of the myoclonic jerks can result in substantial improvement in the patient's quality of life. Although alcohol has been shown to alleviate the movements in a number of patients with essential myoclonus, the limitations of this pharmacological therapy are obvious. Manipulation of brain serotonin levels, although beneficial in some forms of myoclonus, has generally been unsuccessful in the treatment of essential myoclonus. A variety of medications may be used in this and other myoclonic disorders ([Table 34-9](#)). The benzodiazepines, particularly clonazepam, are the most consistently effective medications used for the treatment of essential myoclonus. In addition, favorable treatment results have been observed with certain anticholinergic medications including benztropine and trihexyphenidyl.

Startle Syndromes

The startle syndromes are characterized by an exaggerated motor response to unexpected auditory, and at times somesthetic or visual, stimuli. Confusion has overtaken the classification of these syndromes as various terms have been introduced. Hyperreflexia has often been used synonymously with any startle disorder; however, the word hyperexplexia (to jump excessively) was used to describe the autosomal dominantly inherited exaggerated startle reflexes in a large Dutch kindred. Matsumoto and Hallett have advocated the use of the proper Greek term hyperexplexia to denote any movement disorder in which there is a physiological demonstration of exaggerated startle reflexes and have incorporated this terminology in dividing the startle syndromes into five main types ([Table 34-10](#)).^[84]

The pathophysiology of hyperexplexia has been recently elucidated, and now there is general agreement that the motor response in patients with hereditary and symptomatic hyperexplexia is a pathological exaggeration of the normal startle reflex.^[85] To elicit a startle response in normal humans, an acoustic stimulus must have a volume of approximately 100 dB and a rise time of less than 5 msec. The response to such an unexpected stimulus varies in normals, and eye blinking may be the only visible reaction. Typically, however, facial grimacing, head flexion with shoulder abduction, elbow flexion, pronation of the forearms, and fist clenching occur. In normals, habituation (a decrease in magnitude of response with repetition of the stimulus) occurs with four to five repeated stimuli. Electrophysiologically, surface EMG recordings demonstrate a bilaterally symmetrical response composed of a blink response and activation of other craniocervical muscles with variable limb muscle recruitment. The overall pattern of muscle recruitment suggests that the normal human auditory startle reflex originates in the caudal brain stem. The audiogenic jumps seen in hyperexplexias are believed to be generated by the normal startle circuit under heightened excitability, perhaps of cerebral origin. Hereditary hyperexplexia is inherited as an autosomal dominant trait caused by

TABLE 34-9 -- MEDICATIONS FOR THE TREATMENT OF MYOCLONUS

Medication	Common Initial Dose	Usual Maximum Dose	Clinical Uses
Chlorpromazine	25-50 mg IV	50 mg po tid	Hiccups
Clonazepam	0.5-1.5 mg/day	20 mg po qd	Most forms of myoclonus
L-5-Hydroxytryptophan with carbidopa	25 mg po qid	500 mg po qid	Posthypoxic myoclonus
	25 mg po qid	50 mg po qid	
Metoclopramide	10 mg IV	10 mg po tid	Hiccups
Piracetam	7.2 g/day po	16 g/day po	Cortical myoclonus
Tetrabenazine	25-50 mg po qd	200 mg po qd	Segmental myoclonus
Valproic acid	15 mg/kg/day po	2000 mg/day	Most forms of myoclonus

IV, Intravenously; po, by mouth; qd, each day; qid, four times daily; tid, three times daily

TABLE 34-10 -- STARTLE SYNDROMES

- II. Symptomatic hyperreflexia
- III. Startle epilepsy
- IV. Jumping, latah, myriachit
- V. Psychogenic startle

mutations in the alpha-1 subunit of the inhibitory glycine receptor, which is localized to chromosome 5q.^[86]

The hallmark of hyperexplexia is an exaggerated startle response to a sudden, unexpected stimulus. Children with hyperexplexia are born with continuous stiffness and demonstrate a flexor posture, both of which disappear with sleep. Severely affected children startle excessively to sudden stimuli, and infants characteristically flex rather than extend their arms as seen with the normal Moro response. Apnea and cardiorespiratory arrest can occur, perhaps due to stiffness of the chest wall. The increased tone gradually disappears during the first several months of life, yet the startle response can interfere with walking and may result in trauma from falls. Severely affected patients have startle attacks throughout life; they often become worse during adolescence, and variable improvement occurs later in life. Other affected individuals may have infrequent attacks that may become worse with stress or illness. Violent bilateral flexion of the legs can occur during descent into slow-wave sleep or rarely during the daytime. Abdominal muscle involvement has been postulated to result at times in inguinal and abdominal hernias.

Other cerebral (perinatal anoxia), diencephalic (stroke), and brain stem (inflammatory, hemorrhage) lesions have also been associated with hyperexplexia, but most reports lack the physiological investigations necessary to prove that the startle reflex was involved. Certain psychiatric diseases including post-traumatic stress disorder may be associated with evidence of hyperarousal and an exaggerated startle reflex. Others have observed increased startle reactions in catatonic schizophrenics, patients with GTS, and newborns following in utero exposure to cocaine. The majority of acquired cases of exaggerated startle, however, are idiopathic and have no identifiable cause. An additional differential diagnostic consideration in the presence of exaggerated startle is startle epilepsy. Characterized by epileptic seizures triggered by sudden unexpected stimuli preceded by a startle, this disorder has been described in patients with severe brain damage, most commonly perinatal anoxic encephalopathy, but also in those with Down's syndrome, Sturge-Weber syndrome, and Tay-Sachs disease. Finally, a group of behaviors including "jumping," latah, and myriachit have been considered to represent startle phenomena, but others suggest that these entities are merely culturally based, conditioned behaviors. As a group, individuals with these behaviors demonstrate an initial violent start in response to a sudden stimulus that is variably followed by automatic speech (echolalia, echopraxia, or coprolalia) and the exhibition of aggressive gestures or defensive postures.

Clonazepam and other benzodiazepines are considered the drugs of choice for the treatment of hyperexplexia; when effective, they reduce the severity and frequency of the startle reactions. Valproic acid, 5-hydroxytryptophan, and piracetam have also been successful in certain patients.

HISTORY AND DEFINITIONS

The degenerative and congenital ataxias comprise a wide spectrum of disorders in which ataxia is the leading symptom. The neuropathological hallmark of these diseases is degeneration or malformation of the cerebellar cortex and the spinal pathways. In many cases, the brain stem and the basal ganglia are also involved.

Traditionally, classifications of ataxia were based on neuropathological criteria. Thus, Holmes (1907) distinguished between spinocerebellar degeneration, degeneration of the cerebellar cortex, and olivopontocerebellar atrophy (OPCA).^{1,2} More recently, a clinical classification introduced by Harding (1983) has gained wide acceptance ([Table 35-1](#)).³ This classification distinguishes between hereditary and nonhereditary ataxias. Hereditary ataxia is further subdivided into ataxias with autosomal recessive inheritance such as Friedreich's ataxia (FRDA), and ataxias with autosomal dominant inheritance. In recent years, a number of genes for hereditary ataxias have been localized, and their mutations have been identified ([Table 35-2](#)). The nonhereditary ataxias include both diseases with an unknown etiology (e.g., idiopathic cerebellar ataxia [IDCA]) and symptomatic ataxias with a known cause. Symptomatic ataxias, many of which are due to alcoholism or malignant disease, are covered in other chapters.

HEREDITARY ATAXIAS

Autosomal Recessive Disorders

FRIEDREICH'S ATAXIA

Pathogenesis and Pathophysiology. Friedreich's ataxia is an autosomal recessive disease. Recently, a gene, X25, was identified in the centromeric region of chromosome 9q, the critical region for FRDA. X25 encodes a 210-amino acid protein, frataxin, with mitochondrial localization. In normals, high levels of mRNA transcribed from X25 are found in tissues that undergo degeneration in FRDA. A few patients have point mutations in X25, but the majority are homozygous for an unstable intronic GAA repeat expansion. FRDA patients have undetectable or extremely low levels of the mRNA transcribed from X25, suggesting

TABLE 35-1 -- CLASSIFICATION OF ATAXIA

HEREDITARY ATAXIAS	
Autosomal recessive ataxias	
Friedreich's ataxia	
Congenital ataxias	
Early-onset cerebellar ataxia	
Ataxia-telangiectasia (see Chapter 32)	
Ataxia with isolated vitamin E deficiency (see Chapter 40)	
Autosomal dominant cerebellar ataxia (ADCA)	
Without retinal degeneration	
With additional noncerebellar symptoms (ADCA-I)	
Spinocerebellar ataxia type (SCA1)	
SCA2	
SCA3 (Machado-Joseph disease)	
SCA4	
With a pure cerebellar syndrome (ADCA-III)	
SCA5	
SCA6	
With retinal degeneration (ADCA-II)	
SCA7

Episodic ataxias (EA)	
EA-1	
EA-2	
NONHEREDITARY ATAXIAS	
Idiopathic cerebellar ataxia (IDCA)	
With pure cerebellar syndrome (IDCA-C)	
With additional noncerebellar symptoms or multiple system atrophy (IDCA-P/MSA)	
Symptomatic ataxias	
Alcoholism (alcoholic cerebellar degeneration)	
Toxins (antiepileptics, lithium, solvents)	
Malignancy (paraneoplastic cerebellar degeneration)	
Malabsorption (acquired vitamin E deficiency)	
Hypothyroidism	
Physical causes (heat stroke, hyperthermia)	

TABLE 35-2 -- INHERITED ATAXIAS AND ASSOCIATED CHROMOSOME AND GENETIC MUTATIONS

AUTOSOMAL RECESSIVE ATAXIAS		
Friedreich's ataxia	9q13-21	Intronic GAA repeat expansion
Ataxia-telangiectasia	11q22-23	Phosphatidylinositol kinase
Ataxia with isolated vitamin E deficiency	8q	Alpha-tocopherol transport protein
AUTOSOMAL DOMINANT CEREBELLAR ATAXIA		
Spinocerebellar ataxia type I (SCA1)	6p21.3	CAG repeat expansion
SCA2	12q23-24.1	CAG repeat expansion
SCA3 (Machado-Joseph disease)	14q32.1	CAG repeat expansion
SCA4	16q24	
SCA5	11cen	
SCA6	19p13.1	Calcium channel (CAG repeat expansion)
SCA7	3p14-21.1	CAG repeat expansion
Dentatorubral-pallidoluysian atrophy (DRPLA)	12p12.3-13.1	CAG repeat expansion
Episodic ataxias (EA)		
EA-1	12p	Human potassium channel
EA-2	19p13.1	

that reduced frataxin levels are the primary cause of the neurodegeneration and cardiomyopathy characteristic of FRDA. [3]

The first pathological changes in FRDA are thought to occur in the dorsal root ganglia with the loss of large sensory neurons. In advanced cases, the neuropathological abnormalities include axonal sensory and motor neuropathies, degeneration of spinal tracts (spinocerebellar tracts, posterior columns, pyramidal tract), and hypertrophic obstructive cardiomyopathy. There is only occasional involvement of the cerebellum with loss of Purkinje cells and moderate cerebellar atrophy.

Epidemiology and Risk Factors. Prevalence rates of FRDA range from 0.4 to 4.7 per 100,000.^[1] As in other recessive disorders, birth from a consanguineous marriage is a major risk factor for FRDA. In families with one affected child, each of the remaining children carries a risk of 25 percent for the development of FRDA. Children descended from an unaffected sibling of an FRDA patient and a nonconsanguineous spouse have an estimated risk of about 1 in 1000 of developing FRDA.

Clinical Features and Associated Disorders. FRDA usually appears before the age of 25 years, most often in children between 10 and 15 years old. In most patients, ataxia of gait and stance is the first manifestation of the disease. In others, skeletal deformities, in particular scoliosis, are present prior to the onset of ataxia. A number of clinical symptoms are present from the beginning of the disease in virtually all patients. These include progressive ataxia, areflexia of the lower limbs, and impaired vibration or position sense. About two thirds of the patients have extensor plantar responses. There is progressive weakness of the extremities, which is due to pyramidal tract dysfunction and distal muscle atrophy. Despite pyramidal involvement, muscle tone is usually normal or decreased. However, some patients may suffer from spontaneous flexor spasms. Less than 10 percent of patients with FRDA experience a reduced appreciation of pain and light touch sensation. Oculomotor disturbances are a frequent finding in FRDA. Typically, they include fixation instability with square wave jerks and reduced gain of vestibulo-ocular reflex. In contrast to cerebellar disease, gaze-evoked nystagmus is an unusual finding. In the course of the disease, all FRDA patients develop dysarthria characterized by slow, hesitating, and scanning speech. In the later stages of the disease, optic atrophy with reduced visual acuity and progressive sensorineural hearing loss can occur. Bladder function is usually unimpaired, although some patients complain of frequency and urgency in the late stages of the disease. There is no evidence that FRDA is associated with cognitive impairment. FRDA is associated with a number of non-neurological symptoms including skeletal deformities, such as scoliosis and pes cavus, and hypertrophic obstructive cardiomyopathy. Ten percent of patients have diabetes mellitus.^{[2][3][4]}

The advent of molecular diagnostic tests for FRDA has allowed identification of atypical variants of this disease. These include late-onset cases in which the disease begins after the age of 25 years and cases in which the tendon reflexes are retained or exaggerated.^{[5][6][7]} It is estimated that about 10 to 15 percent of all FRDA patients have late-onset disease.

Differential Diagnosis. A large number of disorders involving an early onset of progressive ataxia may cause confusion with FRDA. In most instances, however, FRDA can be clearly distinguished from other disorders by its highly characteristic clinical phenotype. To aid diagnosis, a number of typical diagnostic criteria have been proposed. These include (1) progressive ataxia with an onset before the age of 25 years, (2) lower limb areflexia, (3) decrease of position or vibration sense in the lower limbs, and (4) dysarthria within 5 years after onset of ataxia.^{[8][9]} In atypical cases of FRDA with retained tendon reflexes or late disease onset, a definite diagnosis can be made only by genetic testing.

Hereditary motor-sensory neuropathies (HMSN) may mimic the phenotype of FRDA, although these patients do not develop oculomotor abnormalities, dysarthria, or cardiomyopathy. HMSN has been subdivided on the basis of motor nerve conduction velocity (MNCV) into type I (MNCV of less than 37 m/sec [demyelinating form]) and type II (MNCV of more than 37 m/sec [axonal form]). Since motor nerve conduction velocity is usually normal in patients with FRDA, nerve conduction tests can be used to distinguish between HMSN type I and FRDA. However, nerve conduction findings in HMSN type II are essentially the same as those in FRDA. This may lead to considerable diagnostic confusion that requires genetic testing to resolve. The differential diagnosis of FRDA further includes Refsum's disease, ataxia with isolated vitamin E deficiency, and abetalipoproteinemia. To exclude these diseases, serum levels of phytanic acid and vitamin E should be measured, and a lipid electrophoresis should be performed.

Evaluation. Nerve conduction studies in patients with

FRDA show signs of sensory axonal neuropathy. Sensory nerve action potentials (SNAPs) are absent in more than 90 percent of these patients. In the remainder, SNAPs are reduced in amplitude. MNCV is either normal or moderately reduced.^[10] Motor evoked potentials (MEPs) to transcranial magnetic stimulation are abnormal in almost all FRDA patients, with loss of response or increased central motor conduction time (CMCT) indicating pyramidal tract involvement. Somatosensory evoked potentials (SEPs) are always abnormal in FRDA. Cortical N20 responses after median nerve stimulation are absent or delayed, and P40 responses after tibial nerve stimulation are usually missing, whereas positive waves with latencies of 60 to 80 msec may be recorded in some patients. Brain stem auditory evoked potentials (BAEPs) are often abnormal in FRDA. Abnormalities consist of an absence or delay of waves III and V, whereas wave I is usually preserved, suggesting pathological conduction along the central auditory pathways.^[11] Visual evoked potentials (VEPs) are abnormal in about two thirds of FRDA patients, who show an absence or increased latency of P100 responses.^[12] Magnetic resonance imaging (MRI) is the method of choice for studying the atrophic changes underlying FRDA. Typically, MRI shows severe atrophy of the cervical spinal cord but little evidence of cerebellar atrophy ([Fig. 35-1](#)).^[13]

Electrocardiography and echocardiography are useful for studying cardiac involvement in FRDA. The most common electrocardiographic abnormality seen in FRDA is the presence of T-wave inversion. Echocardiography may reveal interventricular septal hypertrophy, left ventricular wall hypertrophy, and a reduction in the dimensions of the left ventricle. A molecular diagnosis of FRDA can be made by the demonstration of homozygosity for the GAA repeat expansion by polymerase chain reaction (PCR).

Management. At present, since there is no specific treatment for FRDA, management of FRDA patients remains symptomatic and palliative. It has been claimed that a number of compounds including 5-hydroxytryptophan, amantadine, and buspirone have a beneficial action on ataxia. However, the efficacy of these drugs has not been proved in controlled trials. Physical therapy is recommended. All FRDA patients become dependent on canes or wheelchairs within years after the onset of disease.

Cardiomyopathy rarely requires medical treatment. If necessary, propranolol, verapamil, or digoxin is used. A minority of FRDA patients with diabetes mellitus require insulin or oral antidiabetic drugs. Surgical intervention to correct skeletal deformities is indicated only in exceptional cases.

Prognosis and Future Perspectives. FRDA is a progressive disorder. On average, FRDA patients become wheelchair-bound 10 to 12 years after disease onset. Median survival after disease onset is approximately 35 years.^[14] The recent discovery of the FRDA gene, X25, raises the hope that the pathogenesis of FRDA will be better understood in the future. It is assumed that reduced levels of frataxin, the protein encoded by X25, is the primary cause of neurodegeneration and cardiomyopathy in FRDA.^[15] Studies investigating the normal function of frataxin will be of critical importance in elucidating the pathogenetic mechanisms leading to FRDA.

Figure 35-1 T1-weighted MRIs of the brain and cervical spinal cord in Friedreich's ataxia. The images are the midsagittal plane of the *(upper panel)*, and an axial slice at the level of the dens ax(*lower panel*). There is severe shrinkage of the cervical spinal cord. In contrast, the cerebellum and brain stem are of normal size.

CONGENITAL ATAXIAS

Pathogenesis and Pathophysiology. Cerebellar malformations are often part of complex malformation syndromes that affect diverse structures in the central nervous system (CNS). In addition, some cerebellar malformations are more or less limited to the cerebellum. In these latter forms, congenital ataxia is often a prominent clinical feature, although it may be associated with other symptoms such as mental retardation, spasticity, and seizures. In some cases of severe cerebellar malformation, ataxia is surprisingly mild.

The etiology of congenital ataxia is poorly understood. The occasional appearance of congenital ataxia in siblings suggests that congenital ataxia may be inherited in an autosomal recessive manner. The molecular genetic basis of congenital ataxia, however, has been incompletely explored. Sporadic cases of congenital ataxia outnumber familial

cases by far. Whether sporadic cases are also due to recessive mutations or whether they have other causes is unknown. Animal experimental studies show that a variety of exogenous factors such as toxins, viral infection, hypoxia, and irradiation may lead to cerebellar malformations. ^[16]

Epidemiology and Risk Factors. Congenital ataxia due to cerebellar malformation is a rare condition. Precise information on the epidemiology of congenital ataxia is not available.

Clinical Features and Associated Disorders. *Cerebellar aplasia* seldom occurs alone. It is characterized by complete or near complete absence of the cerebellum. The clinical picture of patients with cerebellar aplasia is variable. The life expectancy of patients with this disorder ranges from a few weeks to a normal life span. In general, patients with cerebellar agenesis have profoundly impaired motor development and persistent motor deficits. However, there are reports of patients with subtotal cerebellar aplasia who learned to stand, walk, and run. Compensation appears to be best if intelligence is normal. ^[17]

Vermian aplasia is often associated with a reduction in the size of the cerebellar hemispheres and anomalies of the cerebellar and olivary nuclei. As in cerebellar aplasia, survival ranges from a few weeks to a normal life span. The clinical picture of patients with vermian aplasia is not uniform. It may be associated with a nonprogressive cerebellar syndrome but may also be completely asymptomatic. If vermian aplasia is associated with other malformations, a neurological syndrome with no features of cerebellar dysfunction may be present.

Joubert's syndrome is an autosomal recessive disorder with a distinctive clinical picture. It comprises episodes of hyperpnea alternating with apnea, abnormal eye movements, ataxia, and mental retardation. Most patients die before the age of 3 years. Neuropathologically, complete or partial vermian aplasia is found along with changes in the cerebellar cortex and dentate nucleus. ^[18]

Cerebellar hypoplasia is characterized by reduced size of the entire cerebellum or parts of it. Cerebellar hypoplasia may be detected by chance in neurologically healthy individuals. Often, however, it is associated with congenital ataxia. In affected children, motor milestones are delayed. When the child begins to walk, the gait is ataxic, and falls are frequent. Limb movements and speech may also be affected. ^[19]

The *Dandy-Walker malformation* is a complex malformation of the CNS characterized by partial or complete aplasia of the cerebellar vermis associated with a large posterior fossa cyst. Other abnormalities include enlargement of the posterior fossa, abnormally high placement of the tentorium, and elevation of the transverse sinuses. The Dandy-Walker malformation is almost always associated with hydrocephalus. The clinical syndrome accompanying this malformation is related to the extent of the hydrocephalus. Despite the presence of vermian aplasia, congenital ataxia is not a typical feature of the Dandy-Walker malformation (see [Chapter 28](#)).

Chiari malformations consist of caudal herniation of parts of the cerebellum and brain stem into the upper cervical canal. Although these malformations affect the cerebellum, they do not lead to congenital ataxia (see [Chapter 28](#)).

Differential Diagnosis and Evaluation. Congenital ataxia can be distinguished from other types of early-onset ataxias by the nonprogressive nature of the disorder. Clinical distinctions among the various cerebellar malformations underlying congenital ataxia are impossible. MRI is the method of choice for the evaluation of patients with congenital ataxia because it clearly shows the size of the cerebellum and the presence of any associated anomalies such as cysts and hydrocephalus. ^[20] Electrophysiological investigations do not reveal consistent abnormalities.

Management, Prognosis, and Future Perspectives. There is no specific treatment for congenital ataxia. If cerebellar malformations occur in combination with hydrocephalus, surgical shunting is required. Congenital ataxia itself is a nonprogressive and benign condition. Children with normal intelligence can compensate for cerebellar defects particularly well. However, the cerebellar malformations that underlie congenital ataxia are often associated with other malformations of the CNS. These may lead to mental retardation, epilepsy, disorders of breathing, and noncerebellar motor symptoms. The prognosis in children affected by complex malformation syndromes is poor, and many of them die in the first weeks of life.

EARLY-ONSET CEREBELLAR ATAXIA WITH RETAINED TENDON REFLEXES

Pathogenesis and Pathophysiology. Early-onset cerebellar ataxia with retained tendon reflexes (EOCA) denotes a type of degenerative ataxia with disease onset before age 25 that is distinguished from FRDA in that patients with EOCA retain tendon reflexes. ^[21] The occurrence of EOCA in siblings suggests an autosomal recessive disorder. Segregation analysis performed in EOCA patients, however, yielded segregation ratios that were lower than the expected value of 0.25 for autosomal recessive inheritance, suggesting that genetic heterogeneity exists among EOCA patients. ^[7] Other cases appear to be nonhereditary and idiopathic. The high proportion of male patients in most series of EOCA patients suggests the possibility that inheritance is based on the X chromosome in some cases. The molecular genetic basis of EOCA is unknown. The major neuropathological abnormality in EOCA is diffuse cerebellar atrophy. Occasionally, additional degeneration of brain stem nuclei and medial cerebellar peduncles occurs, suggesting the presence of OPCA.

Epidemiology and Risk Factors. The prevalence of EOCA has been reported to be 0.5 to 2.3 per 100,000. ^[4] As in other recessive hereditary disorders, birth from a consanguineous marriage is a risk factor for EOCA. In families in which one child is affected by EOCA, the remaining children have an increased risk of developing the disorder. However, this risk appears to be smaller than the estimated risk of 25 percent for an autosomal recessive disorder.

Clinical Features and Associated Disorders. By definition, EOCA starts before the age of 25 years. On average, disease onset occurs at the age of 17 years. All EOCA patients suffer from a progressive cerebellar syndrome marked by ataxia of gait and stance, ataxia of limb movements, dysarthria, and cerebellar oculomotor abnormalities (gaze-evoked nystagmus, saccade hypermetria,

broken smooth pursuit, reduced optokinetic nystagmus, and impaired suppression of vestibulo-ocular reflexes by fixation). About half of the patients have an impaired vibration or position sense. Other noncerebellar symptoms, such as pyramidal tract signs, skeletal muscle atrophy, pale optic discs, cardiomyopathy, diabetes mellitus, and skeletal deformities, are rare or absent. ^{[7], [21]}

Differential Diagnosis. There are a number of rare types of early-onset cerebellar ataxia of unknown etiology that resemble EOCA in many respects but have characteristic additional features. These disorders include *early-onset cerebellar ataxia with hypogonadism* (Holmes' syndrome), *with optic atrophy and spasticity* (Behr's syndrome), *with cataract and mental retardation* (Marinesco-Sjogren's syndrome), *with retinal degeneration and deafness* (Hallgren's syndrome), *with spasticity, amyotrophy, and bladder dysfunction* (autosomal recessive spastic ataxia Charlevoix-Saguenay), and *with myoclonus* in the absence of severe epilepsy and dementia (Ramsay Hunt syndrome).

Evaluation. EOCA can be distinguished clinically from FRDA by the presence of tendon reflexes. In addition, the oculomotor abnormalities in FRDA and EOCA patients are different, and EOCA patients usually do not have cardiomyopathy. On MRI, EOCA patients are found to have cerebellar atrophy, whereas FRDA patients have isolated cervical spinal cord atrophy. Nevertheless, the differentiation of FRDA and EOCA may be difficult in exceptional cases of FRDA with retained tendon reflexes. In these cases, a molecular genetic test for FRDA must be performed.

EOCA may be confused with other early-onset disorders associated with ataxia, such as ataxia telangiectasia, abetalipoproteinemia, Refsum's disease, ataxia with isolated vitamin E deficiency, juvenile and adult forms of GM₂-gangliosidosis, adrenoleukodystrophy, and mitochondrial encephalomyopathies. To exclude these disorders, the workup of an EOCA patient should include determination of the serum levels of alpha-fetoprotein, serum lipids, phytanic acid, vitamin E, hexosaminidase A, and very long chain fatty acids. In addition, cerebrospinal fluid (CSF) lactate levels should be measured. In some cases, a muscle and skin biopsy may be helpful to exclude mitochondrial encephalomyopathies and lipid storage diseases.

Nerve conduction studies show evidence of axonal neuropathy in the majority of EOCA patients. Nerve conduction velocity (NCV) is usually normal or mildly reduced. However, there are exceptional cases in which the NCV is as low as 20 m/sec. Cortical potentials of SEPs are absent or moderately delayed. Abnormal BAEPs are found in more than half of EOCA patients. The abnormalities include loss of waves I, III, and V and delay of waves III and V, suggesting pathology of the auditory nerve and the central auditory pathways. MRI usually shows cerebellar atrophy. In some cases, the brain stem is also atrophic, suggesting the presence of OPCA.

Spinal cord atrophy is not a typical feature of EOCA. ^[1]

Management, Prognosis, and Future Perspectives. At present, there is no specific treatment for EOCA. As in FRDA, 5-hydroxytryptophan, amantadine, or buspirone may be tried, although there are no controlled trials that clearly demonstrate the efficacy of these drugs in relieving ataxia. Physical therapy is recommended. Many EOCA patients become dependent on canes or wheelchairs within years after the onset of disease. EOCA is a progressive disorder; however, it progresses more slowly than FRDA. On average, EOCA patients become wheelchair-bound about 20 years after disease onset. Reliable data concerning survival in EOCA are not available.

Autosomal Dominant Disorders

AUTOSOMAL DOMINANT CEREBELLAR ATAXIA WITHOUT RETINAL DEGENERATION

Autosomal dominant cerebellar ataxias (ADCAs) without retinal degeneration comprise a heterogeneous group of dominantly inherited neurodegenerative diseases in which ataxia is the leading symptom. In most families, additional extracerebellar symptoms (saccade slowing, ophthalmoplegia, optic atrophy, pyramidal signs, amyotrophy, basal ganglia symptoms, dementia: ADCA-I) are present, whereas families with a pure cerebellar syndrome (ADCA-III) are less frequent. ^[22]

The genetic heterogeneity of ADCA has been established. In ADCA-I, the disease loci have been assigned to chromosome 6p (spinocerebellar ataxia type 1 [SCA1]), 12q (SCA2), 14q (SCA3), and 16q (SCA4). ^[23] ^[24] ^[25] ^[26] In an ADCA-III family with an almost pure cerebellar phenotype, a linkage with a marker on chromosome 11cen was demonstrated (SCA5). A novel locus, SCA6, has been identified on 19p (see [Table 35-2](#)). ^[27]

Machado-Joseph disease (MJD) is a dominantly inherited ataxic disorder in which there is great phenotypical variation. MJD was first described in patients of Azorean descent. Later, the MJD phenotype was also observed in families of non-Azorean origin. Although MJD patients may have some clinical features, such as prominent eyes, severe dystonia, and amyotrophy, which are less frequently seen in North American and European ADCA families, there is no convincing clinical evidence to separate MJD from ADCA-I. ^[22] The gene locus of Japanese MJD families has been mapped to chromosome 14q, coincident with the localization of SCA3. Subsequent work has shown that the same mutation causes MJD in Japanese families and ADCA in European and North American SCA3 families. ^[28]

Spinocerebellar Ataxia Type 1

Pathogenesis and Pathophysiology. The SCA1 locus in this autosomal dominant disorder was found on chromosome 6p in both Japanese and American families using serological markers of the human leukocyte antigen (HLA) system. In 1993, Orr and colleagues isolated the SCA1 gene and showed that the mutation was an unstable CAG trinucleotide repeat expansion within a translated region of the gene. ^[24] Although the repeat length in normals varies from 6 to 39 trinucleotides, SCA1 patients have one allele within a range of 40 to 81 repeat units. The mutated SCA1 genes contain uninterrupted CAG stretches. In contrast, normal alleles have a midstream CAT interruption. ^[29] Repeat length and the presence or absence of the interruption appear to be critical factors in the stability of trinucleotide repeats. Repeats in the normal size range containing a CAT interruption are stable in parent-to-offspring transmission.

Expanded uninterrupted repeats in SCA1 patients are unstable and have a tendency to expand further during meiosis, particularly during spermatogenesis. This mechanism leads to larger expansions in the offspring of affected males. Mitotic instability of the expanded repeats also occurs, leading to varying repeat lengths in different body tissues. ^[30]

In patients with SCA1 there is an inverse correlation between the length of the CAG repeat and the age of onset, the largest alleles occurring in patients with juvenile disease onset. Because of the instability of expanded repeats during gametogenesis, the age of onset varies with features of anticipation. Anticipation is most pronounced in the offspring of affected males. ^[24]

The wild-type SCA1 gene encodes ataxin-1, a protein that contains a polyglutamine stretch of variable length. Normal ataxin-1 and its mutated form are expressed ubiquitously within the body at comparable levels. The physiological function of ataxin-1 is unknown. It is also unknown how the trinucleotide repeat mutation causes the SCA1 phenotype. Like Huntington's disease, it is assumed that the pathogenetic mechanism is not loss of the physiological function of ataxin-1 but rather gain of a new toxic function.

Neuropathological findings in SCA1 vary. In most cases, OPCA is found as well as degeneration of the ascending spinal pathways with minor degeneration of the pyramidal tract. ^[31] In the cerebellar cortex, Purkinje cells are primarily affected.

Epidemiology and Risk Factors. The prevalence of ADCA has been reported to be 1.2 in 100,000 with large regional variations due to founder effects. ^[32] In a recent nationwide study a frequency of 3 percent of SCA1 among 149 ADCA families was reported. ^[33] SCA1 is a genetically determined disorder with no known environmental risk or precipitation factors. Children of an SCA1 patient have a 50 percent risk of developing the disease.

Clinical Features and Associated Disorders. The onset of SCA1 occurs at any time from adolescence to late adulthood with features of anticipation. On average, the disease starts at around the age of 35 years. All SCA1 patients suffer from a progressive cerebellar syndrome marked by ataxia of gait and stance, ataxia of limb movements, dysarthria, and cerebellar oculomotor abnormalities (gaze-evoked nystagmus, saccade hypermetria, broken-up smooth pursuit, reduced optokinetic nystagmus, and impaired suppression of vestibulo-ocular reflex by fixation). In the majority of patients additional noncerebellar symptoms are present. Pyramidal tract signs, skeletal muscle atrophy, and pale optic discs are found in more than 50 percent of SCA1 patients. Gaze palsy, slow saccades, decreased vibration sense, and bladder dysfunction occur less frequently, and basal ganglia symptoms and dementia are rare symptoms. Dysphagia is a typical feature of the late stages of disease. ^[31], ^[34], ^[35] A recent study performed in a large Siberian SCA1 kindred suggests that the severity of associated symptoms such as dysphagia and muscle atrophy increases with CAG repeat length. ^[36]

Differential Diagnosis and Evaluation. SCA1 should be differentiated from other hereditary cerebellar ataxias as well as from symptomatic ataxias. The diagnosis of SCA1 is made by the demonstration of CAG repeat expansion at the SCA1 locus. Clinically, SCA1 cannot be distinguished with certainty from other forms of ADCA-I. However, the presence of pyramidal tract signs, pale optic discs, and dysphagia is suggestive of SCA1 because these symptoms are less frequently found in other mutations leading to ADCA.

NCVs are in the normal range or moderately reduced. SNAPs are reduced in almost all patients, suggesting the presence of sensory axonal neuropathy. Patients with widespread atrophy of the skeletal muscles demonstrate chronic neurogenic electromyographic (EMG) features. MEPs in response to transcranial magnetic stimulation are abnormal in almost all SCA1 patients; the loss of responses or increased CMCT indicates pyramidal tract involvement. SEPs due to tibial nerve stimulation are usually delayed or absent. Similarly, visual evoked potentials (VEPs) are abnormal in almost all SCA1 patients, who show a loss or delay of P100. Abnormalities of BAEPs, with delays in peaks I, III, and V and increased interpeak latencies, are found in about half of SCA1 patients. MRI shows diffuse cerebellar atrophy, brain stem atrophy, and shrinkage of the cervical spinal cord. ^[35]

Management. At present, there is no specific treatment for SCA1. As in the other ataxias, a trial with 5-hydroxytryptophan, amantadine, or buspirone may be undertaken, although there are no controlled trials that clearly demonstrate the efficacy of these drugs in relieving ataxia. Physical therapy is recommended. Many SCA1 patients become dependent on canes or wheelchairs within years after disease onset. Patients with severe dysphagia should be fed by means of gastric tubing to avoid undernourishment and aspiration.

Prognosis and Future Perspectives. SCA1 is a progressive disorder. On average, SCA1 patients become wheelchair-bound about 13 years after the disease begins, and median survival after disease onset is 18 to 20 years. SCA1 is caused by an expansion of a CAG repeat within the translated region of a gene of unknown function. CAG repeat expansions have been also found in patients with SCA3, Huntington's disease, and dentatorubral-pallidoluysian atrophy (DRPLA), suggesting that these disorders share common pathogenetic mechanisms. It remains to be established in future molecular biological studies how expanded CAG repeats lead to regional specific neurodegeneration. Recently, transgenic mice have been generated that overexpress an expanded SCA1 allele in their Purkinje cells. ^[37] It is hoped that this animal model will be helpful in elucidating the pathogenesis of SCA1 and other CAG repeat disorders.

Spinocerebellar Ataxia Type 2

Pathogenesis and Pathophysiology. SCA2 is an autosomal dominant hereditary disorder. Genetic analysis of a large Cuban founder population led to the mapping of the SCA2 locus on chromosome 12q.^[23] Recently, a protein containing a polyglutamine expansion was detected in the brain of an SCA2 patient, suggesting that SCA2 is caused by a CAG repeat expansion.^[38] Subsequent molecular studies confirmed that SCA2 is caused by a CAG repeat mutation, with expanded alleles ranging from 35 to 39 repeats.

Neuropathological examinations of SCA2 patients have consistently revealed OPCA, characterized by a marked reduction in Purkinje cells and degeneration of the inferior olives, pontine nuclei, and pontocerebellar fibers. In most cases, additional degeneration of the posterior columns and

spinocerebellar pathways is evident, as well as cell loss in the substantia nigra.^[39]

Epidemiology and Risk Factors. The incidence and prevalence of SCA2 are unknown. There are large regional variations due to founder effects. Large SCA2 families have been found in Cuba, Tunisia, Martinique, Austria, Germany, and Italy. SCA2 is a genetically determined disorder with no known environmental risk or precipitation factors. Children from SCA2 patients have a 50 percent risk of developing the disease.

Clinical Features and Associated Disorders. SCA2 can begin at any time from early childhood to late adulthood with features of anticipation. On average, the disease starts around the age of 35 years. All SCA2 patients suffer from a progressive cerebellar syndrome marked by ataxia of gait and stance, ataxia of limb movements, and dysarthria. Saccade slowing is a highly characteristic feature that is observed in the majority of SCA2 patients. About half the patients have vertical or horizontal gaze palsy. Cerebellar oculomotor abnormalities are rarely found in SCA2 patients. Typically, tendon reflexes are absent or decreased. Pyramidal tract signs are present in less than 20 percent of the patients. Vibration sense is decreased in most patients, but sensation is otherwise normal. Dementia, basal ganglia symptoms, pale optic discs, and bladder dysfunction are usually absent.^{[35], [38], [40]}

Differential Diagnosis and Evaluation. Diagnosis of SCA2 is made by the demonstration of the CAG repeat expansion at the SCA2 locus. Clinically, SCA2 cannot be distinguished with certainty from other forms of ADCA-I. However, the presence of slow saccades, axonal neuropathy, and severe OPCA on MRI is suggestive of SCA2.

Evaluation. Nerve conduction findings are similar to those seen in SCA1 with low-amplitude SNAPs and normal or slightly reduced NCVs. In contrast to SCA1, MEPs in response to transcranial magnetic stimulation and VEPs are usually normal in SCA2. BAEPs are abnormal in less than half of SCA2 patients. SEPs after tibial nerve stimulation are usually abnormal. MRI shows diffuse cerebellar atrophy with marked brain stem atrophy, suggesting the presence of OPCA. In addition, the cervical spinal cord is atrophic in most patients ([Fig. 35-2](#)).^[35]

Management. At present, there is no specific treatment for SCA2. Principles of symptomatic and palliative therapy are identical to those described for SCA1.

Prognosis and Future Perspectives. SCA2 is a progressive disorder. On average, these patients become wheelchair-bound about 15 years after disease onset. Median survival after disease onset is approximately 25 years. Patients in whom the disease begins in childhood appear to have a worse prognosis. Future studies must explore the mechanisms by which the SCA2 mutation leads to the regional specific pattern.

Spinocerebellar Ataxia Type 3--Machado-Joseph Disease

Pathogenesis and Pathophysiology. SCA3, or Machado-Joseph disease (MJD), is an autosomal dominant disorder. The SCA3-MJD locus on chromosome 14q was found in Japanese families with the MJD phenotype and in European ADCA families. Subsequently, the gene was isolated, and the mutation was shown to be an unstable trinucleotide CAG repeat expansion present within the coding region of the gene.^[26] The repeat length in normals varies between 14 and 40 trinucleotides, but SCA3-MJD patients have one allele with 62 to 84 repeat units. Both the normal and mutated SCA3 genes contain uninterrupted CAG stretches. Expanded SCA3 alleles display intergenerational instability and show a tendency toward further expansion. Repeat lengths vary in different body tissues due to the mitotic instability of the expanded repeats.

In SCA3 there is an inverse correlation between the length of the CAG repeat and the age of onset, the largest alleles occurring in patients with juvenile disease onset. Because of the intergenerational instability of the expanded repeats, the age of onset varies from generation to generation with features of anticipation. In contrast to patients with SCA1, there is no paternal effect on age of onset.^{[26], [31]}

Neuropathologically, SCA3 is characterized by degeneration of the spinocerebellar tracts, vestibular nuclei, and dentate nucleus. The cerebellar cortex and the inferior olives are spared. In most cases, the pontine base is only moderately affected. The substantia nigra and the subthalamopallidal connections are frequently involved.^[31]

Epidemiology and Risk Factors. The prevalence of ADCA has been reported to be 1.2 in 100,000, with large regional variations due to founder effects.^[32] In a recent nationwide study SCA3 was found to occur in 21 percent of a population of 149 ADCA families.^[33] SCA3 is a genetically determined disorder with no known environmental risk or precipitation factors. Children of SCA3 patients have a 50 percent risk of developing the disease.

Clinical Features and Associated Disorders. SCA3 begins at any time between early childhood and late adulthood with features of anticipation. On average, the disease starts around the age of 40 years. The clinical picture of SCA3-MJD is characterized by a wide range of clinical manifestations, the precise nature of which depends partly on the CAG repeat length. All SCA3-MJD patients suffer from a progressive syndrome marked by ataxia of gait and stance, ataxia of limb movements, and dysarthria. Vertical or horizontal gaze palsy is a frequent additional finding that occurs independently of age of onset. Saccade velocity is usually normal. Dementia, basal ganglia symptoms, pale optic discs, and bladder dysfunction are absent in most cases. In patients with a repeat length of more than 74, the disease begins early, usually before the age of 30 years, and clinical features of pyramidal tract and basal ganglia involvement are evident. Most of these patients have increased tendon reflexes, extensor plantar responses, spasticity, and dystonia. In patients with an intermediate repeat length of 71 to 74 units, the disease begins in middle age; clinical signs include mainly ataxia and gaze palsy. In patients with a repeat length of less than 71, the disease begins later, and they show signs of peripheral neuropathy with loss of tendon reflexes, amyotrophy, and decreased vibration sense. However, the boundaries between these clinical syndromes are vague, and the clinical phenotype of an individual may change as the disease progresses. Therefore, we do not advocate dividing SCA3-MJD patients into clinical subtypes.^{[28], [31], [34], [35], [41]}

Differential Diagnosis and Evaluation. Diagnosis of SCA3 is made by demonstration of the CAG repeat expansion at the SCA3 locus. Clinically, SCA3 cannot be distinguished with certainty from other forms of ADCA-I. The

presence of dystonia is suggestive for SCA3. However, even in patients with SCA3, dystonia is infrequent and occurs mainly in those with an early disease onset. Absence of cerebellar atrophy on MRI is typical of SCA3 and may help to distinguish SCA3 from other mutations leading to ADCA.

Evaluation. The results of electrophysiological investigations resemble those in patients with SCA2, with evidence of peripheral axonal neuropathy and posterior column involvement; MEPs in response to transcranial magnetic stimulation and VEPs are normal in most patients. On MRI, the cerebellum and brain stem appear normal or only moderately shrunken. As in patients with SCA1 and SCA2, the cervical spinal cord is atrophic in most patients (see [Fig. 35-2](#)).

Management. At present, there is no specific treatment for SCA3. Principles of symptomatic and palliative therapy are identical to those described for patients with SCA1. Patients with generalized dystonia may respond to anticholinergics.

Prognosis and Future Perspectives. SCA3 is a progressive disorder. On average, these patients become wheelchair-bound about 15 years after disease onset.

Median survival is 25 to 30 years. Progression is faster in patients with long repeats and early disease onset. The SCA3 mutation is an expanded CAG repeat that is similar to the mutations found in Huntington's disease, SCA1, and dentatorubral-pallidoluysian atrophy (DRPLA). Future studies must explore the mechanisms by which the SCA3 mutation leads to the regional specific pattern of neurodegeneration in this disorder.

Spinocerebellar Ataxia Type 5

Pathogenesis and Pathophysiology. SCA5 is an autosomal dominant hereditary disorder that has been described in a large American ADCA-III family with an almost pure cerebellar phenotype. Using linkage analysis, the SCA5 locus has been mapped to chromosome 11cen. The SCA5 gene has not yet been cloned, and the mutation is unknown.

Epidemiology and Risk Factors. To date, SCA5 has been described in a single American ADCA-III family. Information on the incidence and prevalence of SCA5 is not available. In our experience, ADCA-III families account for less than 25 percent of all ADCA families. SCA5 is a genetically determined disorder with no known environmental risk or precipitation factors. Children from SCA5 patients have a 50 percent risk of developing the disease.

Clinical Features and Associated Disorders. SCA5 begins at any time between childhood and late adulthood with features of anticipation. The most dramatic examples of decreasing age at onset are observed with maternal transmission. On average, the disease starts at about the age of 30 years. The clinical syndrome is predominantly cerebellar and is marked by ataxia of gait and stance, ataxia of limb movements, dysarthria, and cerebellar oculomotor disturbances. Bulbar involvement has been noted in only two patients in whom the disease had an early onset.^[27]

Differential Diagnosis and Evaluation. Since the SCA5 gene has not yet been isolated, a test that allows a molecular diagnosis of SCA5 in individual patients is not available. In appropriate families, a diagnosis of SCA5 can be made by linkage analysis with markers closely linked to the SCA5 locus on chromosome 11cen. Clinically, SCA5 can be distinguished from other types of ADCA by its predominantly cerebellar syndrome and its slower rate of progression.

Information about the electrophysiological characteristics of SCA5 is lacking. In patients with ADCA-III, nerve conduction and evoked potential studies produce normal results. MRI of SCA5 patients shows cerebellar atrophy with no evidence of brain stem involvement.

Management, Prognosis, and Future Perspectives. At present, there is no specific treatment for patients with SCA5. Symptomatic and palliative therapy is similar to that described for SCA1. Although SCA5 is disabling, the disease progresses slowly, and life expectancy is not shortened. Quantitative data about the rate of progression in SCA5 are not available. At present, the chromosomal localization of the SCA5 gene is known. To further understand the pathogenesis of SCA5 and to develop diagnostic tests, the SCA5 gene must be cloned and the mutation identified.

Other Degenerative Ataxias The ADCAs without retinal degeneration and with additional extracerebellar symptoms (ADCA-I) are a heterogeneous group of autosomal dominant diseases, some of which are due to mutations at the SCA1, SCA2, or SCA3 locus. An additional locus, SCA4, has been mapped to chromosome 16q in an American family characterized clinically by cerebellar ataxia, pyramidal tract signs, and sensory neuropathy. Detailed information about SCA4, however, is lacking.^[25] The SCA6 locus maps to chromosome 19p. The mutation has been identified as a small CAG repeat expansion in a gene that codes for the alpha_{1A} voltage-dependent calcium channel subunit. Clinically, SCA6 families have an almost pure cerebellar phenotype.

AUTOSOMAL DOMINANT CEREBELLAR DISORDERS WITH RETINAL DEGENERATION

Pathogenesis and Pathophysiology. ADCA with retinal degeneration is an autosomal dominant disorder that is distinct from other types of ADCA in that it has the constant additional feature of retinal degeneration. ADCA with retinal degeneration has also been named ADCA-II.^[22] The gene locus of ADCA-II, SCA7, has been mapped to chromosome 3p.^{[50], [51]} All available data suggest that ADCA-II is a genetically homogeneous disorder. Recently, a protein containing a polyglutamine expansion was detected in the brains of patients with SCA7, suggesting that SCA7 is caused by a CAG repeat expansion.^[39] The clinical observation of marked anticipation in ADCA-II families also points toward an unstable mutation. Neuropathological examinations of ADCA-II patients have consistently revealed the presence of OPCA. All patients have primarily macular degeneration, which then spreads to involve the retina. There is often secondary atrophy of the optic nerve.

Epidemiology and Risk Factors. ADCA-II has been described in a small number of families. Information about the incidence and prevalence of ADCA-II is not available. ADCA-II is a genetically determined disorder with no known environmental risk or precipitation factors. Children

from ADCA-II patients have a 50 percent risk of developing the disease.

Clinical Features and Associated Disorders. ADCA-II begins at any time between childhood and late adulthood with features of anticipation. Anticipation is greater when the disease is transmitted by males. On average, ADCA-II begins around the age of 25 years. The clinical picture and the course of the disease depend on the age of onset. In patients with late disease onset (after the age of 40 years), cerebellar ataxia is always the first symptom. There are some exceptional patients who never develop visual problems. In most patients, however, ataxia is followed by progressive loss of vision. In about half the patients with late disease onset, there is no evidence of retinal degeneration

or optic atrophy, suggesting that retinopathy affects only the macula. All patients in whom the disease begins earlier (before the age of 40 years) have visual problems, starting either prior to or at the same time as the appearance of cerebellar ataxia. The majority of these patients have retinal degeneration, and some also have optic atrophy. Tendon reflexes are usually absent. A number of additional symptoms occur in less than half the patients and tend to be more frequent in patients with a long disease duration. These symptoms include gaze palsy, dysphagia, hearing loss, and muscle weakness. Dementia and basal ganglia symptoms are not typical features of ADCA-II.^{[52], [53]}

Differential Diagnosis and Evaluation. The diagnosis of ADCA-II is based on the clinical observation of ataxia

in combination with progressive visual loss and a positive family history suggesting autosomal dominant inheritance. In selected families, the diagnosis can be further substantiated by demonstration of linkage to the SCA7 locus. Autosomal dominant retinitis pigmentosa is clearly distinct from ADCA-II in that ataxia is not a feature of this disorder. Sporadic cases involving ataxia and retinal degeneration may pose considerable diagnostic problems, particularly if reliable information about the family history is lacking. The differential diagnosis of these cases includes early-onset cerebellar ataxia with retinal degeneration (Hallgren's syndrome), Refsum's disease, abetalipoproteinemia, and neuronal ceroid lipofuscinosis.

MRI shows cerebellar and brain stem atrophy, suggesting the presence of OPCA. The electrophysiological features of ADCA-II have not been systematically studied. Electroretinography may be used to detect retinal degeneration early. There is no specific treatment for SCA7.

Prognosis and Future Perspectives. ADCA-II is a progressive disorder, and it progresses more rapidly in patients with early disease onset. On average, patients in whom the disease begins in childhood die 5 years after disease onset, whereas adult patients survive for about 15 years after onset. At present, the chromosomal localization of SCA7 is known. Immunocytochemical studies suggest that the mutation is an expanded CAG repeat. To further clarify the pathogenesis of SCA2 and to

develop a diagnostic test for SCA7, the SCA7 gene must be cloned and the mutation identified.

DENTATORUBRAL-PALLIDOLUYSIAN ATROPHY

Pathogenesis and Pathophysiology. DRPLA is an autosomal dominant disease that occurs mainly in Japan. The DRPLA gene is localized on chromosome 12p. DRPLA patients show an unstable expanded CAG repeat within a coding region of the gene. Whereas the repeat length in normals varies between 7 and 23 trinucleotides, in DRPLA patients there is one allele within a range of 49 to 79 repeat units. As in other trinucleotide repeat disorders, DRPLA alleles display intergenerational instability and show a tendency toward further expansion. Larger expansions frequently occur with paternal transmission. There is an inverse correlation between the length of the CAG repeat and the age of onset, the largest alleles occurring in patients with juvenile disease onset. Because of the intergenerational instability of expanded repeats, the age of onset varies with features of anticipation. ^[42]

DRPLA is also observed as an apparently sporadic disease. Molecular analysis in such patients has revealed expanded alleles of the DRPLA gene, showing that the molecular basis of inherited and sporadic DRPLA is the same. ^[43] The gene product encoded by the DRPLA gene, atrophin, is a 190-kD protein of unknown function that has been detected in various body tissues. In the brain, the DRPLA gene product is localized in the cytoplasm of neurons. An additional 205-kD protein has been found in DRPLA patients that probably represents the mutated protein with an elongated polyglutamine stretch. ^[44]

The degenerative pathological changes seen in DRPLA mainly affect the dentate nucleus with its projection to the red nucleus and the external pallidum with its projection to the subthalamic nucleus. Usually the dentatorubral system is more severely affected. Atrophy may also be seen in other basal ganglia nuclei, the thalamus, and the inferior olives. In several cases, degeneration of the posterior columns and spinocerebellar tracts has been described. Involvement of the pontine tegmentum has been found also, and this appears to correlate with oculomotor abnormalities.

Epidemiology and Risk Factors. DRPLA has been predominantly reported in Japan, but diseases with similar features have been occasionally observed in non-Japanese families. It has recently been shown that the Haw River syndrome, a hereditary disease occurring in an African-American family, is genetically identical with DRPLA. ^[45] In Japan, the prevalence rate of DRPLA has been estimated to be 0.1 per 100,000. ^[46]

Clinical Features and Associated Disorders. Onset of DRPLA occurs at any time from infancy to late adulthood with features of anticipation. On average, clinical features begin to appear at about the age of 30 years. The clinical picture of DRPLA is characterized by a wide range of manifestations, the precise nature of which depends on the age of onset and the length of the CAG repeat. The most constant clinical findings in DRPLA are cerebellar ataxia, dysarthria, and progressive dementia. These features are present in almost all patients regardless of age of onset and repeat length. Patients in whom the disease begins before the age of 21 years and who have large expansions show the clinical syndrome of progressive myoclonus epilepsy. Some of them have opsoclonus. In patients with a later disease onset and shorter expansions, myoclonus and seizures are less prominent. Instead, many of these patients have involuntary choreic or dystonic movements and psychiatric abnormalities including personality changes, hallucinations, and delusional ideas. Various oculomotor disturbances have been described including gaze-evoked nystagmus, broken-up smooth pursuit, square-wave jerks, and vertical gaze palsy. ^[43]

Differential Diagnosis and Evaluation. The diagnosis of DRPLA is made by demonstration of an expanded CAG repeat at the DRPLA locus. The differential diagnosis of juvenile-onset disease presenting with progressive myoclonus epilepsy includes Unverricht-Lundborg disease, mitochondrial encephalomyopathy with ragged red fibers (MERRF), neuronal ceroid-lipofuscinosis, Lafora body disease, and sialidosis. Adult-onset disease may be confused with Huntington's disease. Clinically, the presence of ataxia and seizures makes Huntington's disease unlikely and points to a diagnosis of DRPLA. DRPLA is distinct from ADCAs in that it has the clinical feature of dementia. A syndrome of ataxia, myoclonus, and rapid cognitive decline similar to that seen in DRPLA may occur in patients with Creutzfeldt-Jakob disease. Compared to DRPLA, however, Creutzfeldt-Jakob disease usually progresses faster. In exceptional cases, DRPLA may be mistaken for schizophrenia.

Molecular studies have shown that DRPLA and the Haw River syndrome are identical. Electroencephalographic (EEG) background activity is slowed in almost 80 percent of DRPLA patients. More than half have epileptiform EEG patterns, and EEG reveals photosensitivity in about one

third. ^[47] MRI of DRPLA patients shows atrophy of the superior cerebellar peduncles. In addition, T2-weighted images show high-intensity signals in the pallidum. ^[48], ^[49]

Management. At present there is no specific treatment for DRPLA. DRPLA patients with epilepsy require standard antiepileptic treatment. Phenytoin should be avoided because it may worsen ataxia.

Prognosis and Future Perspectives. DRPLA is a progressive disorder. Quantitative data concerning the rate of progression in DRPLA are not available. As in Huntington's disease, SCA1, and SCA3, future research in DRPLA will focus on study of the mechanisms by which expanded CAG repeats lead to neurodegenerative cell death.

EPISODIC ATAXIAS

Episodic ataxia type 1 (EA-1) is an autosomal dominant disorder that is due to a missense mutation in the potassium channel gene, KCNA1, on chromosome 12p; the mutation leads to inefficient repolarization of the nerve cell membrane subsequent to an action potential. ^[54] EA-1 is a rare familial disorder. There is no information about the epidemiology of this disorder.

Onset of EA-1 occurs in early childhood. Clinically, EA-1 is characterized by brief attacks of ataxia and dysarthria. The attacks last for seconds to minutes and may occur several times per day. They are often provoked by movements and startle. Apart from ataxia, the attacks may have dystonic or choreic features. EA-1 is associated with interictal myokymia (i.e., twitching of the small muscles around the eyes or in the hands). Ataxia or gaze-evoked nystagmus is absent between attacks. ^[55]

A routine molecular genetic test for EA-1 is not available because different point mutations within the KCNA1 gene may lead to the disorder. Clinically, EA-1 can be differentiated from EA-2 by the shorter duration of the attacks, the presence of myokymia, and the absence of interictal ataxia and nystagmus. A number of rare metabolic defects of autosomal recessive inheritance may give rise to intermittent ataxia. These disorders include metabolic syndromes with hyperammonemia, aminoacidurias without hyperammonemia, and disorders of pyruvate and lactate metabolism. Interictal EMG of the muscles displaying myokymia shows spontaneous repetitive discharges that subside after nerve blockade. These abnormalities have also been termed neuromyotonia. ^[56] Neurographical and evoked potential studies do not reveal additional abnormalities. MRI of the head is normal.

Acetazolamide (250 mg 2 times a day) is beneficial in reducing attacks in some but not all kindreds. Anticonvulsants are used to reduce myokymia. EA-1 has a favorable prognosis in that the attacks tend to abate after early childhood. Electrophysiological studies of the abnormal potassium channels contribute to our understanding of the precise cellular mechanisms leading to intermittent ataxia and myokymia in EA-1, and improved understanding of the pathophysiology may lead to more effective therapies.

Episodic ataxia type 2 (EA-2) is an autosomal dominant disorder in which the responsible gene has been mapped to chromosome 19p. ^[56] The mutation causing EA-2 has been identified. The mutation affects the gene for the alpha_{1A} voltage-dependent calcium channel subunit and disrupts the reading frame. A CAG repeat expansion of the same gene is associated with a progressive form of ataxia, SCA6. The pathophysiology of EA-2 is poorly understood. A magnetic resonance spectroscopy study showed an abnormally elevated pH level in the cerebellum that was normalized by acetazolamide. ^[57]

EA-2 is a rare familial disorder, and information about its epidemiology is not available. Clinical onset of EA-2 usually occurs during childhood but may begin at any time from 6 weeks to 30 years of age. EA-2 is characterized clinically by recurrence of acute attacks of ataxia of gait and stance, limb ataxia, and dysarthria. The attacks last from several hours to a day or more. Emotional stress, exercise, and fatigue, but not movements or startle, may precipitate the attacks. The frequency of attacks varies widely, ranging from several times a day to less than once a month. Neurological examination between attacks discloses mild gait ataxia and

gaze-evoked nystagmus. Some patients develop progressive ataxia and dysarthria. ^[56], ^[59]

The differential diagnosis of EA-2 corresponds to that described for EA-1. In contrast to EA-1, however, EA-2 is often associated with MRI abnormalities. In particular, patients with progressive interictal ataxia show atrophy of the cerebellar vermis. ^[56] Electrophysiological investigations do not show consistent abnormalities.

Continued acetazolamide (250 mg 2 times a day) therapy completely abolishes episodes of ataxia in patients with EA-2. Cessation of acetazolamide usually prompts rapid recurrence of the attacks. ^[56] Experience with the first EA-2 family treated with acetazolamide suggests that acetazolamide remains effective in reducing attacks for up to 20 years. It is not clear whether acetazolamide is also effective in slowing the progressive ataxia that occurs in some family members. The clinical characteristics of EA-2 and its responsiveness to acetazolamide suggest that EA-2 is a channelopathy.

NONHEREDITARY, IDIOPATHIC CEREBELLAR ATAXIA

Pathogenesis and Pathophysiology. Idiopathic cerebellar ataxia (IDCA) refers to a heterogeneous group of nonhereditary degenerative ataxias that begin after the age of 25 years.^[60] The etiology of IDCA is unknown. Clinically and pathologically, there are two major types. The cerebellar type, IDCA-C, is characterized by a purely cerebellar syndrome and an almost exclusive degeneration of the cerebellar cortex. The plus type, IDCA-P, often has additional clinical features that suggest involvement of the basal ganglia, pyramidal tracts, and autonomic nervous system.^[61] Pathologically, there are various combinations of OPCA, striatonigral degeneration, degeneration of the intermediolateral spinal columns, and Onuf's nucleus that qualify this disorder as the cerebellar type of multiple system atrophy (MSA-C). The hypothesis that IDCA-P is part of the spectrum of MSA is supported by the observation that brains of patients with IDCA-P show MSA-typical oligodendroglial argyrophilic intracytoplasmic inclusion bodies.^[62] The etiology of both types of IDCA is unknown.

Epidemiology and Risk Factors. There are no studies on the epidemiology and risk factors of IDCA.

Clinical Features and Associated Disorders. On average, IDCA starts around the age of 55 years. Both types, IDCA-C and IDCA-P/MSA are characterized clinically by a progressive cerebellar syndrome marked by ataxia of gait and stance, ataxia of limb movements, dysarthria, and cerebellar oculomotor abnormalities (gaze-evoked nystagmus, saccade hypermetria, broken-up smooth pursuit, reduced optokinetic nystagmus, and impaired suppression of vestibulo-ocular reflex by fixation). Saccade slowing never occurs in IDCA. Although the syndrome remains purely cerebellar in IDCA-C, patients with IDCA-P/MSA have additional noncerebellar symptoms, the most frequent of which are akinetic-rigid parkinsonism, pyramidal tract signs, bladder dysfunction, orthostatic hypotension, and

Figure 35-3 T2-weighted MRIs of the basal ganglia, pons, and middle cerebellar peduncles in IDCA-P/MSA. Hypointensities of basal ganglia. Upper left: Normal. Upper right: Hypointensity at the dorsolateral margin of the putamen in beginning IDCA-P/MSA. Lower left: Strong hypointensity extending through part of the body of putamen in IDCA-P/MSA. Lower right: Hypointensity extending throughout the putamen, with intensity exceeding that in globus pallidus in late-stage IDCA-P/MSA. Note the hyperintensity at the lateral putaminal border. Hyperintensities in the upper pons (left side) and middle cerebellar peduncle (right side). Upper panel: Normal. Lower panel: Hyperintensities of the transverse pontine fibers between tegmentum and the base of (left) and in the middle cerebellar peduncles (right) in IDCA-P/MSA.

vocal cord palsy. These symptoms may be present years before any manifestation of ataxia, they may occur simultaneously with ataxia, or they may develop later. Male patients often have erectile dysfunction years before any neurological symptoms appear.^{[60] [61] [62] [63]}

Differential Diagnosis and Evaluation. The clinical phenotype of advanced IDCA-P/MSA, consisting of ataxia, parkinsonism, and autonomic failure, is highly characteristic and rarely causes confusion with other disorders. In contrast, IDCA-C and incomplete or beginning forms of IDCA-P/MSA must be carefully distinguished from symptomatic cerebellar ataxia. Degeneration of the cerebellar cortex in patients with chronic cerebellar ataxia may be due to alcoholism, various toxic causes (antiepileptics, cytostatic drugs, lithium, solvents, heavy metals), remote effects of malignancy (paraneoplastic cerebellar degeneration), malabsorption with vitamin E deficiency, increased body temperature (heat stroke, neuroleptic malignant syndrome, sepsis), and hypothyreosis.

Routine nerve conduction velocity and EMG studies in patients with IDCA give normal results in most cases. However, EMG of the external sphincter muscles is useful for distinguishing MSA from other disorders. Because of degeneration of Onuf's nucleus, external sphincter EMG reveals denervation activity and an increased number of polyphasic potentials.^[64] Whether evoked potentials are helpful to distinguish MSA from IDCA-C has not been systematically explored. MRI of IDCA-C patients consistently shows pure cerebellar atrophy without brain stem or spinal cord involvement. Atrophy is often pronounced in the cerebellar vermis. Some IDCA-C patients have additional supratentorial atrophy. Patients with IDCA-P/MSA develop OPCA with diffuse cerebellar atrophy and additional shrinkage of the base of the pons and the middle cerebellar peduncles. In contrast to ADCA, the size of the cervical spinal cord remains normal (see [Fig. 35-2](#)). T2-weighted images in patients with IDCA-P/MSA may show hypointense signals in the putamen, suggesting involvement of the basal ganglia. In addition, there are hyperintense areas in the pons and middle cerebellar peduncles, reflecting degeneration and gliosis of the pontocerebellar fibers ([Fig. 35-3](#)). However, these are not early signs, and their absence does not exclude a diagnosis of IDCA-P/MSA.^{[14] [63]}

Management. At present, there is no specific treatment for IDCA. As in other types of ataxias, a trial with 5-hydroxytryptophan, amantadine, or buspirone may be attempted, although there are no controlled trials that clearly demonstrate the efficacy of these drugs in relieving ataxia. Physical therapy is recommended. Many IDCA patients become dependent on canes or wheelchairs within years after the onset of disease. Additional noncerebellar symptoms in IDCA-P/MSA patients require adequate symptomatic treatment. Parkinsonian symptoms in these patients respond to dopaminergic medications, although the response is less robust than it is in patients with idiopathic Parkinson's syndrome. Many patients develop urinary retention and have to be supplied with suprapubic catheters. For management of orthostatic hypotension, elastic stockings and oral treatment with mineralocorticoids are recommended.

Prognosis and Future Perspectives. While IDCA-C patients have an almost normal life expectancy, the prognosis for those with IDCA-P/MSA is poor. Patients become wheelchair-bound approximately 5 years after the onset of disease. Median survival after disease onset is 8 to 10 years.^{[61] [62]} The cause of IDCA is unknown. Unlike the situation with the hereditary ataxias, major progress in understanding the pathogenesis of IDCA is not to be expected in the near future.

HISTORY

The disorders discussed in this chapter have been characterized by several generations of clinicians and scientists according to clinical presentation and muscle and nerve histochemistry and electrophysiology. With the application of molecular biology techniques starting in the mid-1980s, the door has opened to understanding these diseases at the molecular level. Several of them are clearly monogenic in origin, such as Duchenne and Becker muscular dystrophy, whereas others, such as sporadic amyotrophic lateral sclerosis, most likely result from the interaction of several genes with environmental factors. Work is rapidly progressing in identifying genes and gene products and function, which will eventually lead to prophylactic as well as therapeutic intervention for these disorders.

[PreviousNext](#)

UPPER AND LOWER MOTOR NEURON DEGENERATION DISORDERS

Amyotrophic Lateral Sclerosis

Amyotrophic lateral sclerosis (ALS), which is also called motor neuron disease, Charcot's disease, or Lou Gehrig's disease, is an age-dependent fatal paralytic disorder caused by the degeneration of motor neurons in the motor cortex, brain stem, and spinal cord. About 10 percent of cases are familial (FALS) and the rest are sporadic (SALS).

Pathogenesis and Pathophysiology. ALS is a combined gray and white matter disease, affecting motor cells and motor fiber tracts. The hallmark of ALS is atrophy, degeneration, and loss of anterior horn neurons, followed by glial replacement. There is loss of pyramidal cells from the precentral cortex and large myelinated fibers of the anterior and lateral columns of the spinal cord, the brain stem, and the cerebrum. The posterior columns are usually spared in sporadic ALS. Lower brain stem nuclei are more often and more extensively involved than upper nuclei ([Fig. 36-1](#)). Therefore, oculomotor nuclei loss is modest and rarely demonstrable clinically, whereas the hypoglossal nuclei are prominently degenerated. Previously, it was thought that Clarke's nucleus was unaffected, but it is now recognized that those neurons may also degenerate. In patients who have an extended disease course due to parenteral

Figure 36-1 Spinal cord section from J-M Charcot's original presentations on amyotrophic lateral sclerosis, showing the combined anterior horn cell degeneration (f) and the sclerosis of the lateral columns (a). c and p designate anterior and posterior horn regions as normal anatomical landmarks inserted as reference points by Charco(From Charcot J-M: Oeuvres Completes. Paris, Bureau du Progres Medical, 1873.)

nutrition and artificial ventilation, there may be late involvement of oculomotor and sacral nuclei.

Several cytoplasmic and ultrastructural abnormalities are associated with ALS. Spheroids with a strongly argentophilic fibrillary pattern develop in conjunction with cell soma atrophy, suggesting they may be complementary processes. Ultrastructurally, the spheroids are neurofilament bundles that may contain other cytoplasmic structures, such as mitochondria. Some investigators hypothesize that the reported increase in phosphorylated neurofilaments identified using monoclonal antibodies suggests premature or excessive neurofilament phosphorylation, which may be associated with impaired neurofilament transport. Other identified structures include Bunina bodies, tiny round eosinophilic structures that may be found in neuronal cytoplasm, and Lewy body-like eosinophilic inclusions found in both SALS and FALS. The latter are immunoreactive to neurofilaments, ubiquitin, and the gene encoding Cu/Zn superoxide dismutase (SOD1). ^[1]

Genetic linkage has identified SOD1 at 21q22.1 as the cause in 20 percent of autosomal dominant familial cases (genetic nomenclature, ALS1). This has provided the first opportunity to study any type of ALS with a proven etiology. Because SALS is not associated with mutations in SOD1 but it is clinically indistinguishable from ALS1 and pathologically very similar, authorities assume there is a common pathway involved in the two diseases. Therefore, the ALS phenotype may result from a variety of disruptions in the events required for motor neuron maintenance. Consequently, much research on the pathogenesis of motor neuron disease has focused on SOD1, an endogenous free radical scavenger enzyme. It functions as a dismutase, converting superoxide to oxygen and hydrogen peroxide, and is thought to have peroxidase and sequestration properties. Superoxide is an unstable and highly active molecule that causes oxidation of cell constituents either directly or through toxic and stable derivatives. There is a 35 to 75 percent reduction in activity of mutant SOD1 in ALS1, but there is no reduction in SOD1 activity in non-chromosome 21 FALS. In most instances, loss of SOD1 enzyme activity appears to be due to enzymatic structural instability, resulting in a shortened half-life of the mutant SOD1 protein.

Exploration of mechanisms by which mutant SOD1 causes motor neuron degeneration have focused on exaggerated or disturbed functions of SOD1. Experiments with transgenic mice expressing different mutations suggest that it is unlikely that the disease phenotype is caused by a position effect of the mutant SOD1 gene. Rather, it is more likely that a toxic effect of mutant SOD1 leads to motor neuron death. Such a toxic mechanism may also underlie FALS in humans. ^[2]

Although SOD1 activity serves as an antioxidant defense, the effects of conversion of O_2^- to H_2O_2 on the viability of cells may be double edged. Hydrogen peroxide and its derivatives are directly toxic to the cell and may signal apoptosis. Because SOD1 activity is reduced in ALS1, it is conceivable that increased superoxide free radical could be responsible for the disease. Although this hypothesis is supported by a number of in vitro studies, it is not fully defensible. First, not all mutations of the SOD1 gene cause a decrease in the steady state of cytosolic SOD1 activity. Second, transgenic mice overexpressing FALS-linked mutations in the SOD1 gene on normal mouse background develop disease similar to ALS in humans, whereas those overexpressing normal SOD1 remained phenotypically unaffected. Observations from overexpression transgenic mouse models and those from SOD1 "knockout" mice strongly refute a loss of function hypothesis while supporting a gain of toxic function hypothesis. Firm conclusions are not yet possible, but increased peroxidase activity of mutant SOD1 may play a critical role in the pathogenesis of ALS1. ^[3]

Preliminary studies on protein structure using antibodies against SOD1 suggest that a common conformational change occurs in the mutants A4V, G37R, and H46R coded by exon 3 that may affect the lower rim of its electrostatic guidance channel. Crystallographic structural mapping predicts that ALS1 mutations lead to structural changes in SOD1 that may distort the lower rim of this channel, allowing the catalytic site to become shallower and more exposed. As a result, molecules normally excluded may gain access to the catalytic reactive site (rim hypothesis). ^[4] Beckman and colleagues have proposed that cell injury occurs when the mutant SOD1 reacts with peroxynitrite ($ONOO^-$) formed from superoxide and nitric oxide with resultant nitration of tyrosine residues of critical cytosolic proteins. ^[5] The access of peroxynitrite would be in keeping with the model of promiscuous accessibility to the copper site.

Finally, mutant SOD1 may exhibit metal-mediated cytotoxicities by disrupting the intracellular homeostasis of copper and zinc. It is well known that copper and zinc are potential neurotoxins, and sudden en masse release of zinc from SOD1 aggregates in motor neurons may lead to cell death. ^[6]

Different SOD1 mutations of ALS1 do not seem to influence age of onset, but they do influence the progression of the disease, with the A4V mutation duration averaging 1.2 years, the E100G mutation 4.7 years, and the H46R and G37R mutations averaging 18 to 20 years. ^[7]

In genetic research, the risk to relatives of an affected person as compared to the general population can be calculated with greater estimates corresponding to larger genetic control of trait variation. The estimated risk to siblings of ALS patients suggests that there is a significant genetic contribution. ALS1 represents a large genetic effect in a small ALS population (2.5 percent of ALS cases). Conversely, SALS may result from a genetic predisposition due to multiple small effects in larger ALS populations. Thus, newer techniques of identifying these effects, such as transmission disequilibrium testing, are being applied to SALS. Genes for glutamate transporters, calcium homeostasis, apoptosis, or intracellular protein cargo transport are reasonable candidates for evaluation. ^[8]

Rare recessive ALS (RFALS), which produces three different phenotypes classified according to type and timing of motor neuron involvement, has been identified in highly consanguineous families. RFALS type 3 (genetic nomenclature ALS2) has been linked to chromosome 2q33, and RFALS type 1 (genetic nomenclature ALS4) has been linked to another site that has not yet been published; several other families remain unlinked. ^[9]

FALS with dementia, a disinhibition dementia-parkin

sonism-amyotrophy complex has been linked to a region on chromosome 17q21-22 ^[10] (see [Chapter 33](#)).

A number of abnormalities in metabolism of the excitatory neurotransmitter glutamate have been identified in ALS, including alterations in tissue glutamate levels, transporter proteins, postsynaptic receptors, and indications of possible toxic agonists. Whether these are primary or secondary events and how they relate to the genesis of ALS is unclear but under intense investigation. ^[11]

Epidemiology and Risk Factors. Broadly, there are three types of ALS usually considered in epidemiological studies: SALS, FALS, and a variant of ALS, sometimes called Guamanian ALS, found in the Western Pacific, that is characterized by the co-occurrence of parkinsonism or dementia, or both, in some patients. Sporadic ALS has a worldwide incidence of 1 to 2 in 100,000 persons, with fairly uniform distribution worldwide and equal representation among racial groups. The occurrence of ALS before the age of 40 years is uncommon. The incidence is greatest between the ages of 50 and 70 years, and it seems to decline thereafter. The male-to-female

ratio is about 1.3:1. Clusters of the disease have been identified, particularly in the Kii peninsula of Japan and the Mariana Islands. The only indisputable risk factor other than age and gender is genetic susceptibility, with familial cases occurring in about 10 percent of most case series. Many isolated potential etiologies have been proposed for sporadic ALS, with the only consistent associations thus far being long-term exposure to heavy metals, particularly lead, and a family history of parkinsonism and dementia.^{1,2}

Clinical and Associated Disorders. ALS is a syndrome of upper and lower motor neuron dysfunction at several levels of the neuraxis without involvement of other neurological systems. There is no definitive test that can diagnose ALS. In 1994 the El Escorial criteria were developed to standardize its diagnosis ([Table 36-1](#)).^{1,2}

TABLE 36-1 -- SUMMARY OF EL ESCORIAL CRITERIA FOR THE DIAGNOSIS OF AMYOTROPHIC LATERAL SCLEROSIS (ALS)

The diagnosis of ALS requires the presence of signs of lower motor neuron (LMN) degeneration by clinical, electrophysiological, or neuropathological examination and signs of upper motor neuron (UMN) degeneration by clinical examination, and the progressive spread of these signs within a region or to other regions, together with the absence of electrophysiological or neuroimaging evidence of other disease processes that might explain these signs.

SUSPECTED ALS

LMN signs only in at least two regions

POSSIBLE ALS

UMN and LMN signs in only one region, or UMN signs only in at least two regions, or LMN signs rostral to UMN signs

Special cases: monomelic ALS, progressive bulbar palsy without spinal UMN and/or LMN signs, primary lateral sclerosis without spinal LMN signs

PROBABLE ALS

UMN signs in at least two regions, with some UMN signs above LMN signs

DEFINITE ALS

UMN signs and LMN signs in bulbar region and at least two spinal regions, or UMN and LMN signs in three spinal regions

Although the disease may present in many different ways and in different parts of the body, generally the patient seeks attention because of symptomatic weakness. Alternatively, there may be a history of muscle cramping and atrophy before weakness is apparent. A frequent diagnostic feature is the presence of hyperreflexia in segmental regions where muscles are starting to atrophy and an absence of sensory disturbance in the same distribution. Limb involvement occurs more often than bulbar involvement, and upper limbs are more often affected than lower limbs in SALS; this pattern is reversed in FALS. However, the pattern of involvement is frequently asymmetrical or focal. If more upper motor neurons are affected, the symptoms will be primarily clumsiness and stiffness, whereas lower motor neuron degeneration will present as weakness or atrophy and occasionally fasciculations. Bulbar symptoms include hoarseness, slurring of speech, choking on liquids, and difficulty initiating swallowing. Paresthesias and sensory symptoms affect up to 25 percent of patients, but if present, these complaints are mild. There is wide variation in disease progression and duration, neither of which can be predicted from age or site of onset. Generally, bowel, bladder, and sexual functioning are spared, with about 4 percent of patients experiencing loss of sphincter control. ALS patients have diminished skin elasticity and rarely develop bedsores, seemingly because of the accumulation of a basic protein there.^{1,2} Although fasciculations, especially of the tongue, are considered by some to be specifically associated with anterior horn cell disease, they may actually be seen in any disorder affecting the motor neuron, including the axon.

There has been controversy over the years whether syndromes that are confined to one type of motor neuron are distinct from ALS or are a variant of ALS. Primary lateral sclerosis and progressive pseudobulbar palsy are both syndromes confined to the upper motor neuron, whereas progressive muscular atrophy and progressive bulbar palsy affect only the lower motor neuron. Because all of these phenotypes are sometimes produced by the same mutation in the SOD1 gene, it is generally now accepted that these phenotypes are different manifestations of the same disease process.

FALS with dementia (see [Chapter 33](#)), characterized by the association of frontal lobe dementia with parkinsonism and amyotrophy, has a variability of clinical symptoms among patients as a striking feature. Whereas disinhibition and frontal lobe dementia are common features, the amyotrophy may be the most prominent feature in some patients and absent in others.^{1,2}

Guamanian ALS was first described in the early 1950s when it was detected in epidemic proportions in Guam, Kii peninsula, and Western New Guinea (see [Chapter 34](#)). It is associated with parkinsonism and dementia in some patients. The incidence has been declining in the intervening years, but there has been an increase in the number of recognized persons with parkinsonism and dementia. This syndrome may include supranuclear gaze palsy. Its etiology is unclear. There was interest in cycad flour as the source of an excitatory amino acid, which causes a motor neuron disease in cynomolgus monkeys, but the amounts eaten by Guamanians in their flour appear insufficient to cause the disease. It has also been proposed that low levels

of calcium and magnesium in the local environment may lead to chronic mild hyperparathyroidism with intraneuronal depositions of calcium hydroxyapatite and aluminum.^{1,2} Only recently has examination into the possible genetic origins of the syndrome begun (see [Chapter 33](#)) and [Chapter 34](#)).

Differential Diagnosis and Evaluation. Within disorders of the motor neuron, the most difficult distinctions are among progressive muscular atrophy, spinal muscular atrophy (SMA), primary lateral sclerosis, and familial spastic paraplegia (FSP) when there is no clear family history. Generally, progressive muscular atrophy is a progressive, asymmetrical lower motor neuron degeneration that has a later onset and can affect distal and proximal muscle, resulting in severe disability in about 5 years. SMA usually occurs in younger people and is symmetrical (see later discussion in this chapter). FSP may be distinguished from primary lateral sclerosis early on by gross lower extremity spasticity in the presence of normal strength, hyperreflexia in the presence of flexor plantar response, and brisk superficial abdominal reflexes. Generally, primary lateral sclerosis is a disease of later onset that is sometimes asymmetrical.

Electromyographic (EMG) features commonly seen include fibrillation, positive sharp waves, and complex repetitive discharges that indicate denervation. Simultaneously, reduced numbers and increased amplitude and duration of motor unit potentials indicate reinnervation. Increased jitter and fasciculations are also characteristic of the disease. Cerebrospinal fluid examination either is normal or shows mildly elevated protein (less than 200 mg/dl). There may be moderate increases in creatinine kinase of the muscle enzyme type.

Muscle biopsy demonstrates small angulated fibers, small groups of atrophic fibers, and evidence of type grouping.^{1,2}

Management and Future Perspectives. Thus far, only the benzothiazole riluzole has been shown to extend lifespan, although the extension averages only 3 months and mortality rates are unaffected. Riluzole acts to block voltage-activated sodium channels and to protect against glutamate toxicity.^{1,2}

Although there is no truly effective pharmacological treatment yet available for ALS, a supportive multidisciplinary team can provide care and symptom management that significantly improves the patient's quality of life. Drugs such as baclofen, quinine, and phenytoin can be used to reduce cramping; anticholinergic agents can be used to control sialorrhea. Amitriptyline may help control pseudobulbar symptoms in some patients. Occupational therapy can provide splints and aids that can extend the patient's ability to function independently. A speech therapist can provide instruction to prolong the patient's ability to communicate and swallow, as well as assistance in procuring needed communication tools. Open, sympathetic discussion of feeding and ventilatory support options is required with the patient and family. Bilevel positive airway pressure may provide at least short-term symptomatic relief of respiratory fatigue and sleep apnea. ALS remains a fatal disease, with a mean survival of 3 years after the onset of symptoms.^{1,2}

Spinal Muscular Atrophies

The spinal muscular atrophies are diseases of the anterior horn cells of the midbrain, pons, medulla, and spinal cord that most often present with muscle weakness in infancy and childhood. They may present with either proximal or distal weakness from the antenatal period onward. The inheritance pattern is most commonly autosomal recessive, but there are forms that are dominant and X linked ([Table 36-2](#)).

Pathogenesis and Pathophysiology. Information about the molecular basis for these disorders has exploded in the last 5 years. Both the severe and milder forms of

TABLE 36-2 -- TYPES OF SPINAL MUSCULAR ATROPHY

Type	Inheritance Pattern	Age of Onset	Presenting Symptoms	Hallmark	Prognosis
SMA type I (severe infantile SMA, acute or fatal SMA, Werdnig-Hoffman atrophy, Oppenheim disease, amyotonia congenita)	AR	In utero to 6 months	Hypotonia and weakness, problems with sucking, swallowing, and breathing	Never able to sit	Average life expectancy is 8 months, 95% dead before the age of 1 year
SMA type 11 (intermediate)	AR	Generally between 3 and 15 months	Proximal leg weakness, fasciculations, fine hand tremor	Never able to stand, facial muscles spared	Dependent on extent of timing of respiratory
SMA type III (chronic SMA, Kugelberg-Welander disease)	AR, AD	15 months to teen years	Proximal leg weakness, delayed motor milestones		Dependent on extent and timing of respiratory complications
SMA type IV (adult-onset SMA)	AD, AR, or very rarely X-linked recessive	Median age of onset 37 years	Proximal weakness, variable within families, more severe in AD form		Life expectancy not markedly reduced
Distal SMA (progressive SMA, Charcot-Marie-Tooth type-SMA)	AR, AD	AR: birth or infancy; AD: adulthood	Distal weakness		Very slow clinical progression; does not alter lifespan

AD, Autosomal dominant; AR, autosomal recessive.

autosomal recessive SMA have been linked to chromosome 5q11.3-13.1, a region that contains multiple copies of genes and pseudogenes and is characterized by instability. Deletions, truncations, or point mutations in what is now called the gene for survival of motor neurons (SMN) have been identified in SMA types I, II, and III.^[10] Its protein product has no known homolog, and its function is not yet known. Although there is no correlation between genotype and phenotype, most affected siblings exhibit the same phenotype, suggesting that there may be additional modifying factors, one of which could be another gene tightly linked to the pathogenic gene. One possibility is the neuronal apoptosis protein gene, located within the linked region, because more severely affected patients have fewer copies of it.^[11] Another possibility is SMN's closely flanking, nearly identical copy gene, *c* SMN, which can produce an alternatively spliced form that may alter its structure. It is conceivable that the number of copies of *c* SMN, in addition to individual or tissue-specific influences on its transcription, may determine phenotype when there is a homozygous SMN deletion.^[10], ^[12] Ultimately the amount of SMN gene product may determine the severity of disease.

Epidemiology and Risk Factors. The autosomal recessive SMAs are the most common cause of death in infancy, with incidence estimates of 1 in 10,000 to 25,000 for type I in the Western world. Similar numbers are affected with the milder forms and forms with a later onset. Distal SMA of recessive inheritance is more common with consanguineous parents, whereas the dominant form is rare. The X-linked adult SMA is also rare.^[13]

Clinical Features and Associated Disorders. The three clinical hallmarks of this disorder are hypotonia, weakness, and cranial nerve palsies (Fig. 36-2). Generally, SMA has an insidious onset of symmetrical weakness. Proximal muscles are weakened more than distal ones, and the legs become markedly weak before the arms are severely involved. Patients with the later onset forms decline less rapidly than those with earlier onset. An interesting difference between the SMAs and other neurodegenerative disorders is that in the SMAs the greatest decline in muscular power occurs at onset and then slows, implying great loss of motor neurons initially, followed by a stabilization in any

Figure 36-2 A baby with spinal muscular atrophy, showing the flaccid head lag in the supine position (From Dubowitz V: *Muscle Disorders in Childhood*. Philadelphia, W.B. Saunders, 1995.)

remaining neurons. This phenomenon results in a large number of complications owing to greater demands on remaining strength, such as scoliosis, contractures, and disuse atrophy, as well as respiratory, nutritional, and sleep problems. Arthrogryposis multiplex congenita, a disorder characterized by congenital limitation of motion in all joints except the temporomandibular and vertebral joints, is sometimes secondary to loss of anterior horn cells. A deletion of SMN has been found in half of such cases examined thus far.^[14]

Progressive bulbar palsy of childhood, or Fazio-Londe disease, involves brain stem motor neuron degeneration that presents most often with stridor followed by ptosis, dysarthria, facial palsy, and dysphagia. Death generally occurs in early childhood.

An autosomal dominant scapuloperoneal SMA has been reported with fasciculations, weakness, and atrophy in that distribution. Autopsy findings included degeneration of anterior horn cells and motor neurons of cranial nerves VII, IX, and X. A few families with adult-onset, autosomal dominant facioscapulohumeral and scapulohumeral distribution SMA have been reported.^[15]

Kennedy's syndrome, a spinobulbar neuropathy with midlife onset, normal lifespan, and gynecomastia that affects males, is caused by the expansion of trinucleotide repeats in the androgen receptor gene located on the X chromosome.^[16] This was a particularly important discovery because it paved the way for identification of trinucleotide repeats as the cause of several other neurological diseases.

Differential Diagnosis and Evaluation. Because many disorders can mimic the clinical picture of the SMAs, it is essential to verify a neurogenic process via EMG and muscle biopsy. In children, the differential diagnosis is particularly wide (Table 36-3).

Homozygous deletion of SMN is a sensitive test for confirming the clinical diagnosis in almost all cases, including isolated cases and those with unusual features. After genetic testing, the most revealing studies are EMG and muscle histochemistry, both of which will confirm a neurogenic process involving muscle. Fibrillation and normal-sized residual motor units are commonly seen in the acutely denervated muscle fibers of SMA I. Additionally, there is an abnormal rhythmical motor unit discharge during sleep. SMA II and III produce very large motor units and absence of spontaneous activity. Serum creatine kinase (CK) can be elevated, and it correlates positively with duration of illness.

Management and Future Prognosis. There is no specific treatment for any of the SMAs. A multidisciplinary approach aimed at preventing contractures, skeletal deformities, respiratory complications, and social isolation is imperative. Genetic counseling of parents of young SMA patients or SMA patients approaching childbearing age is appropriate. Thus far, prenatal testing for SMN deletion is available only on a research basis. The prognosis varies according to type, ranging from the early fatality of SMA I to the basically unaltered lifespan of SMA III.

Familial Spastic Paraplegias

The FSPs, also known as Strumpell-Lorrain syndrome and hereditary spastic paraplegias, are a broad group of

--	--

genetically and clinically diverse disorders characterized by lower extremity spasticity and weakness. Generally, they are classified according to mode of inheritance and symptoms. The more common uncomplicated or so-called pure FSP indicates progressive spasticity of the lower extremities that may be accompanied by a mild decrease in proprioception and urinary sphincter dysfunction, whereas complicated FSP denotes the presence of other neurological problems.

Pathogenesis and Pathophysiology. Information about the genetic basis for these disorders is mushrooming. It has been established that uncomplicated autosomal dominant, autosomal recessive, and X-linked FSPs are heterogeneous disorders. Because families with strong similarities in phenotype are linked to different genetic loci, there may be various points of disturbance in a common biochemical pathway that leads to degeneration of the most distal portions of the longest ascending and descending central nervous system axons, particularly the corticospinal tracts from the motor cortex to the legs, the fasciculus gracilis fibers, and the spinocerebellar fibers ([Table 36-4](#)). Genetic penetrance is age dependent and nearly complete. ^[17]

Clinical Features and Associated Disorders. The patient generally presents with leg stiffness, weakness in the hip flexors, and impaired foot dorsiflexion in the second through fourth decades, although symptoms may be apparent in infancy or not until late adulthood. The gait disturbance progresses insidiously and continuously. Patients may also have paresthesia and mildly decreased vibratory sense below the knees, and urinary urgency and incontinence late in the disease. On neurological examination, generally there are no abnormalities of the corticobulbar tracts or upper extremities, except possibly brisk deep tendon reflexes. In the lower extremities, deep tendon reflexes are pathologically increased and there is decreased hip flexion and ankle dorsiflexion. Crossed adductor reflexes, ankle clonus, and extensor plantar responses are present. Hoffman's and Tromner's signs, as well as pes cavus, may be present. Occasionally, slight dysmetria may be seen on finger-to-nose testing in patients with longstanding disease.

The designation complicated FSP indicates spasticity with additional neurological impairment, such as optic neuropathy, retinopathy, extrapyramidal disturbance, dementia, ataxia, ichthyosis, mental retardation, and deafness. ^[17]

Differential Diagnosis and Evaluation. The FSPs are diagnoses of exclusion. Particular care is necessary if the family history is not revealing or if there are numerous complications or atypical features. Because FSP can mimic treatable disorders, such as vitamin B₁₂ deficiency, dopa-responsive dystonia, cervical spondylosis, or multiple sclerosis, exhaustive evaluation is justified. ^[17]

Molecular diagnosis is available only to family members within kindreds who have been linked to one of the identified loci. Electrophysiological studies are the most revealing. Somatosensory evoked potentials of the lower extremities show conduction delay in the dorsal column fibers, whereas cortical evoked potentials show reduced conduction velocity and amplitude in lumbar spinal segment muscles. Cortical evoked potentials of the arms are either normal or mildly slow. Nerve conduction studies are most often normal, although there may be subclinical sensory impairment of peripheral nerves and spinal pathways.

MRI of the brain and spinal cord as well as plasma long chain fatty acid analysis should be performed. ^[17]

Management and Prognosis. There is no treatment available to address the underlying process in FSP. Treatments to combat the problems associated with chronic paraplegia can be helpful, particularly oral or intrathecal baclofen or oral dantrolene for the lower extremity spasticity, and oxybutynin for bladder spasticity. Caution should be exhibited in counseling regarding the course of the disease because there is variation in severity of phenotype reported.

At this time, although the phenotypes of the various autosomal dominant FSPs are very similar, it does seem to be more severe in the families linked to chromosome 15q, in which more patients require wheelchairs by the fourth decade. The families linked to chromosome 2p showed more variation, including a less common childhood onset and a relatively nonprogressive course. ^[18]

DEGENERATIVE MUSCULAR DISORDERS

The muscular dystrophies are hereditary, degenerative dystrophinopathies and disorders of dystrophin-associated proteins. In 1987, with the identification of a defect in the dystrophin gene as the cause of Duchenne muscular dystrophy (DMD), Monaco and Kunkel opened the door

for research into its role in muscle function and maintenance. [19]

Dystrophin is controlled by a very large gene, at least 2300 kb and 79 exons, that encodes a 3685 amino acid protein product with four distinct domains. It has an I-beam shape with globular domains at each end and a rodlike segment in the middle (Fig. 36-3). At the aminoterminal end, it binds to cytoplasmic actin filaments, whereas at the other end, it binds to a complex of proteins and glycoproteins called dystrophin-associated proteins and dystrophin-associated glycoproteins. Transcripts, each with its own promotor, suggest that dystrophin influences a number of distinct functions. Muscle dystrophin is found on the plasma membrane surface in skeletal muscle fibers, on the surfaces of plasma membrane and transverse tubules of cardiac muscle fibers, and on smooth muscle membranes. Cortical dystrophin is found in the hippocampus, amygdala, thalamus, hypothalamus and neocortex, and a

Figure 36-3 Localization of dystrophin and utrophin in the muscle cell. Dystrophin is found throughout the sarcolemma, whereas utrophin is confined to the neuromuscular junction. Both proteins are associated with a glycoprotein complex that binds to the extracellular matrix.(Reprinted with permission from Campbell KP, Crosbie RH: The structure of dystrophin. Nature 1996;384:308. Copyright 1996 MacMillan Magazines Limited.)

Purkinje cell isoform is found in the cerebellum. [20] [21] [22] A second protein product of the DMD gene, which is structurally different from dystrophin, has not been found in muscle, but its level in other tissues is comparable to that of dystrophin in muscle. [23]

It is now known that there are at least three subcomplexes that form the glycoprotein complex involved with dystrophin in muscle support. Several components of these subcomplexes have now been identified and some of their relationships determined. The dystroglycan subcomplex consisting of -dystroglycan and beta-dystroglycan functions as a connecting axis, called the dystrophin-axis, between the extracellular matrix and the subsarcolemma cytoskeleton. These dystroglycans are ubiquitously expressed in various tissues. The basal lamina is a network of several components, including laminin, that surrounds each muscle fiber in fixed contact with the sarcolemma and provides protection from mechanical damage. beta-Dystroglycan is an extracellular protein that binds to the laminin subunit merosin in the basement membrane, as well as to beta-dystroglycan, a transmembrane protein, which, in turn, binds to the cysteine-rich and carboxyl-terminus domains of dystrophin within the cell. Then the N-terminus domain of dystrophin binds to actin filaments, which forms the cytoskeleton of the subsarcolemma. [22] Utrophin, a dystrophin homolog, binds to actin and most likely the dystroglycan complex. [24] It is possible that utrophin and these proteins form a utrophin axis similar to the dystrophin-axis.

Four other transmembrane glycoproteins, called the sarcoglycans, have been identified:

-sarcoglycan (in some sources called 50DAG, A2, and adhalin), beta-sarcoglycan (43DAG, A3b), gamma-sarcoglycan (35DAG, A4), and delta-sarcoglycan. It has been proposed that the sarcoglycan complex is fixed to the dystrophin-axis by lateral association, although the binding site is not yet known. The sarcoglycan complex is expressed specifically in skeletal and cardiac muscle. [21]

Finally, the components of the syntrophin complex (alpha-syntrophin, which is specific for muscle; beta₁-syntrophin, which is ubiquitous, and beta₂-syntrophin, which is localized to the neuromuscular junction) bind to the distal part of the carboxy-terminal domain of dystrophin. [21]

In the last few years, disruptions in these proteins and glycoproteins have been implicated in several types of muscular dystrophy(Table 36-5).

Dystrophinopathies

Different mutations in the dystrophin gene produce different allelic disorders, most commonly either the lethal DMD or Becker muscular dystrophy (BMD), a milder myopathy. Very rarely, patients with cardiomyopathy with mild weakness, dilated cardiomyopathy without weakness, exercise intolerance associated with myalgias, muscle cramps, or myoglobinuria, and asymptomatic elevation of serum CK have also been identified. [25]

Pathogenesis and Pathophysiology. Large mutations in the dystrophin gene are identified in about 75 percent of patients with DMD and 87 percent of patients with BMD. Most large mutations are deletions, and they tend to occur in regions where the introns are longer. The deletion breakpoints seem to be at sites where recombination events occur in healthy individuals. Large deletions are also common in BMD, whereas large duplications are rare. Small mutations account for about 30 percent of DMD cases and 15 percent of BMD cases. Mutations that shift the mRNA transitional reading frame usually produce a truncated dystrophin molecule, missing the carboxy terminus, which in turn does not bind adequately to dystrophin-associated proteins at the cell membrane, resulting in severe dystrophin deficiency in the Duchenne phenotype. Either no dystrophin is made or the aborted molecule is degraded rapidly. Nonframeshifting mutations produce a dystrophin molecule with a preserved carboxy terminus in which more dystrophin remains and the phenotype is the milder form of BMD. [22] In-frame deletions alter the clinical presentation depending on where they occur. Deletions that involve the cysteine-rich and carboxy-terminus domains required for attachment to the dystrophin-associated proteins confer the Duchenne phenotype, whereas deletions in the proximal portion of the rod domain produce a very mild phenotype. [22] Deletions in the distal region present the BMD phenotype and produce 40 to 70 percent of the normal amount of dystrophin. [25] There are rare cases to which these generalizations do not apply: There are out-of-frame deletions that can result in DMD, BMD, or an intermediate phenotype, and there are even situations in which there is no correlation between the degree of dystrophin deficiency and the severity of phenotype. [25], [26]

Epidemiology and Risk Factors. DMD is the most common neuromuscular disease of childhood, with an estimated overall prevalence of 63 cases per million, whereas BMD has an overall prevalence of 24 cases per million. [25] Because dystrophin is at Xp21.1, nearly all patients are male. As many as 20 percent of new DMD cases and an unknown number of BMD cases are caused by gonadal mosaicism. [25]

Clinical Features and Associated Disorders. The hallmarks of DMD are progressive proximal muscle weakness with pseudohypertrophy of the calves. The myocardium is involved, whereas bulbar muscles are spared. There may be mild mental retardation. DMD is universally fatal, usually either from respiratory or cardiac

complications.

As early as 1868, Duchenne had established criteria for the diagnosis of what would later be called DMD that still serves as an accurate description of its clinical picture: (1) weakness, appearing first in the lower extremities; (2) wide-based gait and stance, with lordosis; (3) subsequent hypertrophy of weakened muscles; (4) loss of muscle contractility with electrical stimulation; and (5) intact sensation and bowel and bladder function, with a (6) progressive, deteriorating course.

Usually, the child is asymptomatic in the neonatal period, with the earliest problems perceived by caregivers being developmental delays, particularly in walking and climbing, and the appearance of enlarged calf muscles. Between the ages of 3 and 6, the gait becomes waddling and lordotic. Gowers' sign appears, in which the child stands from a prone position by a process of climbing up the legs, using the hands first on the knees and then on the thighs to support her- or himself ([Fig. 36-4](#)). Usually by the age of 6 years, there is enlargement of calf, gluteal, lateral vastus, deltoid, and infraspinatus muscles, and weakness is readily

Figure 36-4 Gower's sign. (From Siegel IM: *Muscle and Its Diseases: An Outline Primer of Basic Science and Clinical Method*. Chicago, Yearbook Medical Publishers, 1986.)

apparent, with the proximal extremities more severely affected than the distal extremities, and lower extremities and torso more severely affected than the upper extremities ([Fig. 36-5](#)). Weakness of the arms may be present but is not obvious without careful examination. The strength of limb and torso muscles continues to decline steadily from ages 6 through 11 years. Proximal muscles continue to be more severely affected than distal muscles, with neck flexors becoming more involved than extensors, wrist extensors more than flexors, biceps and triceps more than deltoid, quadriceps more than hamstrings, and the tibialis anterior and peronei more than the gastrocnemius, soleus, and tibialis posterior. Tendon reflexes decrease and disappear as muscle weakness progresses. By the age of 10 years, 50 percent of patients have lost biceps, triceps, and knee reflexes, in contrast with the ankle reflex, which remains in one third of patients even in end-stage disease. Significant contractures of the iliotibial bands, hip flexors, and heel cords are present in 70 percent of the children by the age of 10 years. The children tend to have relatively mild functional impairment until they are about 8 years old, when they then decline more rapidly over the next 2 to 3 years. The second decade brings progressive kyphoscoliosis from weakened paraspinal muscles, and decreased vital and total lung capacities and maximal inspiratory and expiratory pressures from weakened respiratory muscles. These problems first appear between the ages of 8 and 9 years, and progress as functional status deteriorates.

The mean age of death in a survey of 176 patients who died between 1970 and 1984 was 18.3 +/- 3 years. It was slightly increased to 20 +/- 3.9 years in the subset of 48 patients who died between 1980 and 1984. About 40 percent died of respiratory failure, and 10 to 40 percent died of cardiac complications. Although cardiac rate, rhythm, and conduction defects occur in up to 90 percent of DMD patients, they tend to be stable or slowly progressive problems. ^[25]

In BMD, disease is later in onset and slower in progression. As early as the mid-1950s, Becker proposed that these cases represented a variation of DMD. Now that it is known that DMD and BMD are allelic disorders, it is apparent that BMD phenotypes range from myalgias and muscle cramps to symptoms clinically indistinguishable from DMD.

Age of onset ranges from 1 to 70 years of age, with a mean of 12 years. Ninety percent of patients are affected by age 20. Lower extremity weakness appears on average by age 11, with upper extremity weakness by age 20. Loss of ambulation generally occurs around 40 but can occur as early as age 12. Age at death ranges from 23 to 89 years of age, with the average being 42.

Cardiac problems similar to that associated with DMD are present in about half of the patients with BMD. The extent of cardiac involvement does not correlate with degree of myopathy. Myocardial pathology includes degeneration of cardiac muscle and fibrous replacement of myocytes, particularly in the posterobasal region and the adjacent lateral wall of the left ventricle.

When compared with unaffected brothers, fertility ranges from 10 to 79 percent, correlating positively with severity of phenotype. Fatty infiltration of smooth muscle may result in delayed gastric emptying with emesis, abdominal pain, and distention. Adverse reactions to succinylcholine and halothane have been reported, which ranged from

Figure 36-5 Enlarged calf muscles in a patient with Duchenne muscular dystrophy. (From Fenichel GM: *Clinical Pediatric Neurology*. Philadelphia, W.B. Saunders, 1997.)

marked elevation of CK in the postoperative period to cardiac arrest. ^[25]

Differential Diagnosis and Evaluation. The diagnosis of DMD and BMD has become considerably more reliable with the advent of molecular genetics. When the clinical presentation, elevation of CK, muscle biopsy, EMG findings, and inheritance pattern are consistent with a dystrophinopathy, the patient's white blood cells or muscle should be examined for deletions or duplications in the dystrophin gene. Multiplex polymerase chain reaction (PCR) amplification of commonly deleted exons detects 98 percent of the deletions that cause more than 65 percent of the dystrophinopathies. Quantitative Southern blot analysis may be needed to detect partial gene duplication because it is more sensitive. ^[30], ^[31]

Immunoblot analysis of muscle homogenates with dystrophin antibodies confirms abnormalities in at least 95 percent of DMD patients and differentiates DMD from BMD. Analysis of restriction length polymorphisms and a nonradioactive direct test based on PCR amplification provides rapid, precise carrier diagnosis in women whose relatives have a known deletion. Sisters and daughters of mothers who have given birth to boys with isolated cases of DMD or BMD should also be tested and counseled. Such mothers should also consider prenatal diagnosis because the risk for recurrence in additional sons is estimated at 7 percent. Prenatal diagnosis can be performed as early as 8 weeks' gestation. ^[32]

The EMG changes seen are those common to all myopathic disorders. Motor units fire at a relatively high rate for the degree of effort, with a higher number activated than would be in a muscle of comparable strength in a neurogenic problem. As the disease progresses, fewer and fewer motor units can be activated. An increased number of motor unit potentials are polyphasic with one or more late components, as well as components reduced in duration. Fibrillation potentials are often observed. Nerve conduction velocities are normal.

Similar pathological changes are present in BMD and DMD, particularly necrotic and regenerating fibers, branching fibers, abnormal fiber size, and endomysial fibrosis. Generally there are more necrotic, hypercontracted, and regenerating fibers with a more severe phenotype. Additionally, inflammatory cells are evident at perivascular, endomysial, and perimysial sites in DMD. Plasma membrane defects that lead to segmental fiber necrosis and eventual regeneration are observed with electron microscopy. Extensive discussion of morphological and electron microscopy studies is available in Engel (see reference ^[25]).

Serum CK is the most useful of the serum enzyme tests, with CK increased up to two orders of magnitude during the first 3 years when it peaks and then declines exponentially by about 20 percent annually. Myoglobinemia is roughly correlated with elevations in CK. Ambulatory DMD patients have diurnal fluctuations in myoglobin and CK, with increases corresponding to physical activity. ^[33] In the cerebrospinal fluid, protein fractions are increased in most dystrophies and epsilon-globulin is decreased. Because excretion of total creatinine declines with decreasing functional muscle mass, urinary creatinine is 40 to 90 percent below normal. ^[34] Urinary creatine excretion is about twice normal between ages 6 and 11, and it increases with age.

It is essential to evaluate the heart. Ninety percent of patients with DMD have myocardial fibrosis, revealed by elevated right precordial R waves and deep Q waves in left precordial and limb leads on EKG. ^[35] Persistent or labile sinus tachycardia, sinus arrhythmias, and interatrial conduction defects are also common abnormalities. Echocardiography demonstrates small internal ventricles, hypokinesis of the posterobasal ventricular wall, and slowed ventricular relaxation.

Examination of dystrophin can prevent misdiagnosis in patients with disorders that mimic the clinical presentation of DMD and BMD, particularly the spinal muscular atrophies, congenital muscular dystrophy, acid maltase deficiency, and Emery-Dreifuss muscular dystrophy (ED MD). Dystrophin should also be evaluated in males

with dilated cardiomyopathy, even in the absence of muscle weakness, and in girls with symptoms of DMD.

Management and Prognosis. Thus far, the only medication to improve functioning of boys with DMD when evaluated in carefully controlled trials is a regimen of alternate-day prednisone with a dosage range of 0.75 to 1.5 mg/kg/day. Improvement began about 1 month after beginning treatment and peaked by 3 months, with significant and sustained benefits still evident at 3 years. The decrease in muscle strength and increase in muscle mass was slower than expected, and the extent of disability was less. Side effects included those common to all steroids: altered behavior, Cushinoid appearance, gastrointestinal disturbance, rashes, and hirsutism. [36]

Effective gene therapy remains elusive. A carefully controlled study determined that injecting normal myoblasts

into affected muscle did not increase muscle force generation or the amount of dystrophin in muscle. [37]

Much of the management of the dystrophinopathies remains supportive, and there is controversy regarding appropriate active exercise regimens in the dystrophinopathies. The review by Spenser and Vignos provides a balanced discussion of the role of active exercise in DMD. [38] In one short-term controlled study, resistance exercises neither hastened physical deterioration, as has been proposed, nor maintained strength any better than free exercises. More clearly, passive exercises and joint stretching are important in delaying the onset of contractures. Maintaining ambulation as long as possible is crucial because its loss is associated with contractures and scoliosis, which, in turn, is associated with restrictive respiratory syndrome. Release of hip and ankle contractures by subcutaneous tenotomy while the patient is still ambulatory has been shown to preserve ambulation for about 2 additional years. [39]

Inspiratory resistive exercises have been shown to increase endurance of respiratory muscles but not vital capacity. [40] When indicated, intermittent ventilatory assistance ameliorates symptoms of hypoventilation but does not slow the deterioration of respiratory function. If assisted ventilation is employed when vital capacity falls below 10 percent of normal, it can prolong survival by 3 to 4 years. [25]

Bregman has outlined strategies families can employ to result in more effective management of the childhood neuromuscular disorders: (1) maintaining a regular schedule of activities for both the affected child and other family members, (2) providing interesting activities appropriate to the degree of disability that enhance the affected child's experiences, (3) assisting the affected child in setting realistic goals, (4) encouraging as much independence as possible in the affected child, (5) employing stress reduction strategies, (6) including all family members in decision making, and (7) maintaining active relationships with the primary physician and support groups in the community. [41]

Data indicate that DMD patients are living somewhat longer than they used to, probably because of more aggressive respiratory and cardiac care, but as yet, there is nothing that reverses the basically relentless course of either the Duchenne or Becker phenotype.

Future Perspectives. Recent work suggests that a disruption of basement membrane organization occurring in rare homozygotes for a null allele of dystroglycan may be the common feature of muscular dystrophies associated with the dystroglycan complex. [42] Effective treatment may involve either replacement of dystrophin or upregulation of a related protein, such as utrophin. Two recent papers report the development of adenoviral vectors from which protein-producing genes have been removed, allowing transport of more DNA and eliminating proteins that trigger the host response. [43], [44] Although upregulation of utrophin theoretically could occur pharmacologically, recent work with the utrophin transgene is very exciting. High expression of the utrophin transgene in skeletal and diaphragmatic muscle of the dystrophin-deficient *mdx* mouse markedly reduced dystrophic pathology. [45]

Limb Girdle Muscular Dystrophies

The limb girdle muscular dystrophies (LGMDs) are being reclassified on a genetic basis as their underlying pathologies are unraveled. The genes and their products or actions identified thus far again point to disturbances in the structural support system of muscle, particularly of the sarcoglycan complex. It may be that a disturbance in the sarcolemma-extracellular matrix interaction is the molecular basis for muscle fiber necrosis (Table 36-5). Emery estimates LGMD prevalence to be 1 in 100,000. As early as 1960, Morton proposed that homozygosity at either of two loci could produce LGMD and that about 1.6 percent of the normal population is heterozygous for an LGMD gene. [46]

With the exception of the severe childhood autosomal recessive muscular dystrophy (SCARMD) found primarily in northern Africa, the LGMDs all fall within a clinical spectrum that includes weakness of proximal lower extremities, which is usually symmetrical, appearing any time from the first decade until middle age, and generally followed by weakness in the shoulder girdle region. Occasionally, shoulder girdle weakness may precede the pelvic girdle weakness. Facial muscles are uninvolved. The progression is generally slow, with loss of ambulation occurring 10 to 30 years after onset. Cardiac involvement is not reported, except in the newly recognized autosomal dominant form reported from the Netherlands, known as LGMD-1B.

The features of SCARMD have been well described by Ben Hamida and associates. [47] Pelvic girdle weakness precedes pectoral girdle weakness, with onset occurring between ages 3 and 12. Abdominal, neck flexor, and intercostal muscles are often affected, whereas external ocular, facial, lingual, and pharyngeal muscles are spared. Seventyfive percent of patients are unable to walk by their 30s. Contractures form and reflexes are lost as the disease progresses. Cardiomegaly and EKG abnormalities are common by the intermediate stages of the illness. There is no cognitive impairment.

If sufficient informative family members are available, linkage analysis can provide a genetic diagnosis if the patient has one of the previously linked types of LGMD. SCARMD can be diagnosed by a negative sarcolemmal immunostain for adhalin. [48]

TABLE 36-5 -- LIMB GIRDLE MUSCULAR DYSTROPHY

Type	Inheritance	Gene Locus	Gene Product	Unusual Symptoms
1A	AD	5q31-33	?	Palatal weakness
1B	AD	?	?	?
2A	AR	15q	Calpain-3	
2B	AR	2p13	?	Some Canadians had distal extremity weakness and wasting (Miyoshi myopathy)
2C	AR	13q12	gamma-Sarcoglycan	Cardiac involvement, abdominal, neck flexor and intercostal muscles affected, malignant course
2D	AR	17q.33	alpha-Sarcoglycan (adhalin)	
2E	AR	4q12	beta-Sarcoglycan	

AD, Autosomal dominant; AR, autosomal recessive.

There are several nonspecific findings associated with the LGMDs. Serum CK is mildly to moderately elevated, except in SCARMD, in which the levels may rival those of DMD. [49] Creatinuria and hypocreaturinuria are nonspecific indicators of muscle destruction that may be present. The EMG shows nonspecific myopathic changes, including short duration, low-amplitude motor unit potentials, increased proportion of polyphasic potentials, and rapid recruitment. Fibrillation and positive sharp waves may occur with denervation caused by muscle fiber necrosis. Muscle biopsy pathology also is nonspecific, with morphology like that of other myopathies. [46]

The LGMDs have relatively common and nonspecific clinical and laboratory findings that may be seen in other neuromuscular disorders. Therefore, care must be taken in evaluation. As an example, in a Japanese series, 17 percent of patients with clinically diagnosed LGMD actually had a dystrophinopathy when muscle dystrophin content was analyzed, which emphasizes the need for examination of dystrophin protein and gene studies for accurate diagnosis (Table 36-6). [49]

There are no specific treatments for any of the LGMDs. The physician's goal is to preserve as much function for as long as possible through the use of physical and

occupational therapy and psychological support. Research into the pathogenesis of these disorders is proceeding rapidly. Recently, a missense mutation in the gene at 5q33 that encodes for delta-sarcoglycan, which is homologous to epsilon-sarcoglycan and has a striated muscle-specific expression of mRNA similar to that of delta-sarcoglycan and epsilon-sarcoglycan, has been associated with yet another mild autosomal-dominant myopathy.^[50] As the relationships and workings of the dystroglycan and sarcoglycan complexes are better understood, it may be possible to offer a rational treatment for these disorders.

Facioscapulohumeral Muscular Dystrophy

Facioscapulohumeral muscular dystrophy (FSH MD), or Landouzy-Dejerine muscular dystrophy, is slowly progressive degenerative myopathy that affects particular facial, torso, and extremity muscles. There are at least two loci for FSH MD. Most large families thus far are linked to 4q35, in which no gene has been found. About 15 percent of other clinically indistinguishable families remain unlinked.^[51] Although isolated cases have been identified, generally

TABLE 36-6 -- DIFFERENTIAL DIAGNOSES IN LIMB GIRDLE MUSCULAR DYSTROPHY

Emery-Dreifuss muscular dystrophy	Sarcotubular myopathy
	Scapuloperoneal dystrophy
Facioscapulohumeral dystrophy	Spinal muscular atrophy

with careful evaluation of the family, there is a clear autosomal dominant inheritance pattern with a penetrance of 95 percent by the time the individuals reach their 20s. Prevalence is about 1 in 20,000.^[52]

Onset has been reported from infancy until middle age. There is significant variability of the severity symptoms within families, with some individuals having symptoms that are so mild that they are unaware they have the disease until other family members are diagnosed. Generally, the patient first notices asymmetrical weakness in an upper extremity, although facial weakness may have been present for some time. The facial weakness appears insidiously in the orbicularis oculi, zygomaticus, and orbicularis oris muscles. The weakness generally progresses slowly and in a descending pattern from facial muscles to shoulder girdle to upper arms and then pelvic girdle muscles ([Fig. 36-6](#)). There may be plateaus and even occasional arrest of the disorder.

Emery recommends that four criteria be present for the diagnosis of FSH MD: (1) onset in facial and shoulder muscles, with sparing of extraocular, pharyngeal, lingual, and cardiac muscles, (2) autosomal dominant inheritance pattern, (3) facial weakness in half or more of affected family members, and (4) myopathic changes, including polyphasic motor units of low amplitude and short duration on EMG and variation in fiber diameter, centrally located nuclei, and moth-eaten fibers on muscle biopsy. The unevenness of the disease process may extend to individual muscles.^[53]

Several other problems have been identified in FSH MD, particularly in patients with early onset and relatively rapid progression. Hearing loss in the 4000 to 6000 Hz range and retinal capillary abnormalities (Coat's disease) have been reported. Although it is not usually clinically apparent, abnormal AV node or intranodal conduction also occur.^[54]

There is no definitive treatment for FSH MD. Steroids may provide transient benefit if there are inflammatory changes on the muscle biopsy. Physical and occupational therapy are useful for maintaining optimal functioning. Orthotics and bracing may be helpful, as may surgical stabilization of the scapulae. Early photocoagulation of retinal abnormalities is recommended.^[53] Large families who have been linked to the chromosome 4 locus may have their diagnosis verified by genetic testing. The course is relatively benign; most patients remain ambulatory, and lifespan is not significantly decreased.^[54]

Scapuloperoneal Syndromes

The scapuloperoneal syndromes (SPSs) are heterogeneous disorders characterized by weakness of both shoulder girdle and peroneal muscles. Both a neurogenic form (scapuloperoneal spinal muscular atrophy [SPSMA]) and a myopathic form (scapuloperoneal muscular dystrophy [SP MD]) have been identified. The neurogenic SPSMA was linked to chromosome 12q24.1-q24.31, which is a region about 20 cM telomeric to the location of the gene for the myopathic SP MD.^[55]

These are uncommon disorders, with heated debate as to whether the scapuloperoneal syndromes are all distinct

Figure 36-6 Facioscapulohumeral dystrophy in a 15-year-old boy. There is marked facial weakness on frontal view and dramatic scapular winging with arm abduction on the posterior. (From Dubowitz V: *Muscle Disorders in Childhood*. London, W.B. Saunders, 1995.)

entities. Autosomal dominant, autosomal recessive, and sex-linked recessive patterns of inheritance have been reported, as well as sporadic cases. Genetic studies will undoubtedly eventually clarify the situation.

The clinical features of both the myopathic and neurogenic types are similar. Age of onset reported ranges from infancy to adulthood, most commonly late childhood or young adulthood. The usual presentation is weakness in shoulder girdle muscles, progressing to weakness in the anterior tibial muscles, followed by weakness in pelvic girdle muscles. When facial involvement occurs, it is mild and late in onset.

Although there are a few neuromuscular disorders that may present with weakness in the scapuloperoneal distribution, particularly Charcot-Marie-Tooth disease and FSH MD, a comprehensive neuromuscular work-up based primarily on EMG and muscle and nerve biopsies screens out most of them.

Davidenkow's syndrome, which includes scapuloperoneal weakness, may be confused with the SPSs. However, it also has pes cavus deformities and progressive distal sensory loss with early depression of reflexes, as well as impaired sensory and motor nerve conduction velocities.^[56]

ED MD may also produce weakness in the scapulohumeral distribution, but it has characteristic contractures and cardiac conduction abnormalities not present in the SPSs. The weakness tends to progress very slowly, and patients become only mildly disabled. It generally does not affect the lifespan.^[57]

Myotonic Dystrophy

Myotonic dystrophy (DM), or Steinert's disease, is an autosomal dominant multisystem degenerative disease characterized by myotonia, progressive muscular weakness, gonadal atrophy, cataracts, and cardiac dysrhythmias.

Pathogenesis and Pathophysiology. The molecular basis of DM is an unstable trinucleotide repeat sequence, cytosine, thymine, and guanidine (CTG) in the protein kinase-encoding gene (DMK), located at 19q13.3. The repeat is present 50 to several thousands of times in patients with DM rather than the 5 to 30 times in the

normal population. The size of the repeat is correlated roughly with severity of symptoms, with more-affected patients having greater numbers of repeats.^[58] The repeat expansion also may account for the anticipation seen in families with DM, in which the severity of symptoms increases and the age of onset decreases with subsequent generations.^[59] It was demonstrated that DMK protein is localized to the postsynaptic side of the neuromuscular junction in skeletal muscle and the intercalated discs in cardiac muscle in humans. Additionally, DMK protein is present in specific structures in rat brain, supporting the hypothesis that it may have selective actions in the central nervous system.^[60]

There have been widely conflicting results in the effort to unravel the precise effect of the expanded repeats; some data support the theory that there is a loss of function of the mutant allele, whereas other data favor increased expression of the allele. Recent work supports a new interpretation of the data. Both normal and expanded DM kinase genes are transcribed in patient muscle, but the expanded RNA has a dominant effect on RNA metabolism by preventing accumulation of poly(A)+ RNA.^[61]

Epidemiology and Risk Factors. There is an estimated prevalence of 3 to 5 per 100,000 population and an incidence of 1 in 8,000 live births, making it the most common adult muscular dystrophy. Although a few isolated

populations have an exceptionally high prevalence, DM has been found in all racial groups.^[62]

Clinical Features and Associated Findings. The phenotype is correlated with the length of the CTG repeat and thus is widely variable, ranging from the single manifestation of cataracts that present in the middle years to severe neonatal hypotonia that can lead to death if respiratory support is not provided. Traditionally, these different types of symptoms have resulted in the designation of either congenital or noncongenital DM.

The classic presentation of noncongenital DM, which is well described by Harper, includes marked weakness in the face, jaw, and neck muscles and milder distal extremity weakness (Fig. 36-7).^[62] Weakness of the extremities is often the first problem perceived by the patient, even when a careful evaluation may reveal a clear history of myotonia (sometimes termed muscle stiffness or cramping by patients), facial weakness, and nasal speech. Patients frequently seem unaware of their illness and symptoms, both in themselves and in family members. Using a percussion hammer, myotonia can be elicited in patients with DM with a brisk tap on the thenar muscle, causing flexion-opposition of the thumb with slow relaxation.

The person with advanced DM has a characteristic appearance: a long, thin face with sunken cheeks due to temporal and masseter wasting, a so-called swan neck because of sternocleidomastoid wasting, and ptosis, with relatively strong muscles in the posterior neck and shoulder girdle.

Congenital DM presents a distinctive picture that is different from other disorders. Facial diplegia and jaw weakness without concomitant extremity weakness are hallmarks. Weakness of the respiratory muscles with respiratory distress is present in at least 50 percent of patients and is the most common cause of death in these infants. Hypotonia is present in severely affected neonates but it may disappear within weeks. Clinical myotonia is generally absent and is usually detectable only by EMG.^[62]

A recent prospective study followed patients of both types for 10 years, with the conclusion that muscle weakness

Figure 36-7 Myotonic dystrophy with typical myopathic facies, frontal balding, and sunken chee (From Dubowitz V: *Muscle Disorders in Childhood*. London, W.B. Saunders, 1995.)

was relatively mild in both types, although it was progressive in the noncongenital form. Weakness was generalized in both types, with no significant differences found in distribution. Additionally, 75 percent of the noncongenital patients and 81 percent of the congenital patients had cardiac abnormalities, primarily conduction defects, demonstrated on EKG. Intellectual function was frequently and severely impaired in the congenital type, whereas only about a third of the noncongenital patients were mildly impaired.^[63]

It cannot be overemphasized that DM is a multisystem disorder. The heart is prominently involved, and the severity of cardiac symptoms does not correlate with severity of other symptoms in this disorder. All patients with DM need to undergo EKG evaluation, because sudden death is well documented, and as many as 90 percent of patients have conduction defects, particularly first-degree heart block and atrial arrhythmias. Both the diaphragm and intercostal muscles may be myotonic and weak, which leads to alveolar hypoventilation. In addition, there are smooth muscle abnormalities throughout the gastrointestinal system. Particularly important are the delayed relaxation of the pharynx and reduced motility in the esophagus that may lead to aspiration, constipation, and anal sphincter abnormalities in children.

Central nervous system involvement includes generalized atrophy and ventricular dilatation, but structural changes in the brain do not seem to be common, even in patients with congenital disorders. However, there are well-known behaviors associated with DM that range from apathy and inertia, with concomitant lower socioeconomic status, to hypersomnolence that is often present without detectable respiratory problems. In addition, numerous endocrinological abnormalities have been reported, several with clinical importance. Hyperinsulinism and reduced numbers of insulin receptors are common, but diabetes is not. Elevations of pituitary FSH and LH occur frequently.

In males, testicular atrophy, Leydig cell hyperplasia, and slightly reduced serum testosterone is common. In females, no consistent ovarian problems have been documented, but the spontaneous abortion rate is high. Fertility in both sexes seems to be reduced to about 75 percent of normal. Finally, in the ocular system, cataracts with characteristic multicolored crystalline subcapsular opacities have been documented since the recognition of DM as an entity. Retinal degeneration, low intraocular pressure, and saccadic eye movement defects have been reported.^[62]

Evaluation and Differential Diagnosis. Faciohumeral dystrophy may have the same distribution of weakness, but there is no myotonia. More rarely, some of the LGMDs may have a similar distribution of weakness, again without myotonia. Molecular analysis can distinguish DM from these disorders, as well as those with marked myotonia, such as myotonia congenita and paramyotonia.

Sometimes the clinical presentation of DM is so distinctive that the experienced clinician uses tools only to confirm a diagnosis already made. EMG should be employed in suspected DM when myotonia is clinically equivocal or absent. The typical pattern is of long-lasting runs with declining frequency and amplitude, with the distal muscles of the upper extremities and the orbicularis orbis most often being involved. A careful slit lamp evaluation will

ascertain characteristic opacities and should be performed on any patient suspected of having this condition. Muscle biopsy may show a constellation of abnormalities, including increased central nuclei, nuclear chains, ringed fibers, sarcoplasmic masses, atrophy of type I fibers, increased numbers of fibers in spindles, and increased arborization at the terminal.^[62] Nerve biopsy shows increased arborization. Other conditions associated with myotonia, such as myotonia congenita (see Chapter 37) and drug-induced myotonia (see Chapter 55), need to be considered.

Management and Prognosis. Because there is no cure for DM, current management focuses on treatment of the myotonia and associated systemic problems, monitoring of pregnancy, and genetic counseling. Because patients frequently do not perceive their myotonia as being problematic, they may not follow a treatment plan. However, 100 mg of phenytoin taken three times daily is effective in reducing myotonia and does not produce the cardiopressive complications of either quinine or procainamide. Anesthesia should be used for these patients only when it cannot be avoided. Myotonia may be increased by the depolarizing relaxants used for inducing anesthesia or the anticholinesterases used to terminate relaxation, although the barbiturates, benzodiazepines, and opiates may produce apnea. Cases have been reported in which the diagnosis of DM has been made only after the patient experienced postoperative apnea. Harper provides a comprehensive discussion of anesthetic management in DM.^[62] A bracelet that identifies the patient as having DM may be helpful.

Because cardiac complications may be life threatening, careful evaluation, including a His bundle electrogram, must be performed to ascertain conduction defects that need pacemakers. Some respiratory problems may be avoided by upright positioning during meals and by spacing meals well ahead of bedtime.

There is increased risk of spontaneous abortion in myotonic mothers, as well as complications during labor and delivery. There may be incoordination of contractions during labor that prolong the first stage, a retained placenta, and postpartum hemorrhage, as well as the previously cited anesthetic sensitivity.

Presymptomatic and prenatal genetic counseling, including a discussion of the increased risks of pregnancy to an affected or carrier mother as well as to the fetus, the phenomenon of anticipation, and congenital DM, should be provided to families with a history of DM. It should be remembered that although a significant number of persons with DM are mentally impaired, some who are not may be perceived as such because of facial weakness.

Oculopharyngeal Muscular Dystrophy

Oculopharyngeal muscular dystrophy is a disorder of late adult onset characterized by progressive ptosis and dysphagia. The region of chromosome 14q11.2-q13 with the cardiac

and beta myosin heavy chain genes is the locus of the causative gene in three French Canadian families.^[64] Although the highest prevalence of oculopharyngeal muscular dystrophy continues to be in Quebec, which is most likely the result of a founder effect, families have now been identified in more than 20 countries. Inheritance is autosomal dominant with complete penetrance.

Asymmetrical weakness of the levator palpebrae and pharyngeal muscles is the initial presentation, generally after the age of 50. Eventually all extraocular muscles may become involved. There is no cardiac involvement. The EMG shows myopathic changes. Muscle biopsy reveals changes found in other muscular dystrophies: loss of muscle fibers, variation in fiber size, increased numbers of nuclei and internal nuclei, and increased fibrous and fatty connective tissue. On histochemistry, there are small angulated fibers that react strongly for oxidative enzymes and "rimmed" vacuoles, particularly in type I fibers from extremity muscles rather than extraocular muscles. On electron microscopy, there are unique intranuclear tubular filaments.^[65]

Oculopharyngeal muscular dystrophy can be distinguished from inclusion body myositis, which presents as dysphagia. It also has rimmed vacuoles, but the filaments seen are larger and are present in the cytoplasm as well as the nucleus and there are no ocular palsies. Ocular myasthenia gravis without waxing and waning of symptoms may produce weakness in the same distribution as oculopharyngeal muscular dystrophy, but it generates demonstrable neuromuscular junction transmission defects on EMG and neuromuscular junction abnormalities on morphological studies. Although late onset of the mitochondrial myopathy, Kearns-Sayre syndrome, or oculocraniosomatic disease may present with ptosis, histochemical and ultrastructural studies of muscle show biochemical defects in the respiratory chain and mitochondrial DNA deletions.

Interventions, such as eyelid crutches to alleviate the ptosis and a feeding tube to provide adequate nutrition, are palliative. If the patient does not receive a feeding tube, the dysphagia will lead to early death by malnutrition and starvation.

Emery-Dreifuss Muscular Dystrophy

ED MD, which is characterized by early contractures and cardiomyopathy, was first identified as a distinct form of muscular dystrophy in a large Virginia family in 1966.^[66] Generally it is X-linked recessive, although there is an autosomal dominant form, sometimes called Hauptmann-Tannhauser muscular dystrophy.^[67] The incidence of the X-linked type is estimated to be about 1 in 100,000, with the autosomal dominant form being even more rare. One of 10 new X-linked cases may be a new mutation.^[68]

In 1994, the gene for the X-linked type of ED MD was identified as STA at Xq28.^[68] It codes for emerin, a serine-rich protein of 254 amino acids, which resembles membrane proteins of the secretory pathway involved in vesicular transport.^[69] Several different mutations have been reported that result in lack of emerin in skeletal and cardiac muscle.^[70],^[71] Although the lack of emerin seems to cause the disease, the pathway remains to be established.

The classic symptoms of ED MD include (1) contractures of elbows, Achilles' tendon, and post-cervical muscles before weakness is present; (2) slowly progressive

weakness and muscle wasting, generally starting in the humeroperoneal muscles; and (3) a cardiomyopathy that frequently presents as heart block. A similar disorder, X-linked scapuloperoneal syndrome, that includes color blindness has been linked to Xq28 and may be allelic to ED MD.^[70]

The early contractures and conduction block are features that are helpful in distinguishing this from other muscular dystrophies that may have weakness in the same distribution and the same pattern of inheritance. The main features of the cardiac involvement are impairment of impulse generating cells, variable sinoatrial and atrioventricular conduction defects, increased atrial and ventricular heterotopia, and functional impairment of the myocardium.^[71] Rigid spine syndrome, which occurs sporadically, also has early contractures, but they are limited to the spinal musculature. It usually does not involve cardiac problems.^[72]

The muscle biopsy has nonspecific myopathic or dystrophic changes, including variation in fiber size and fiber necrosis, and endomysial and perimysial fibrosis. Unlike DMD and BMD, there is no alteration in dystrophin.^[73]

The care provided to the patient is similar to that for the other muscular dystrophies, with the notable exception of cardiac intervention. Merlini documented that up to 40 percent of patients with ED MD die suddenly, many of them without any preceding cardiac symptoms. Therefore, a thorough cardiac evaluation, and insertion of a pacemaker when indicated, is essential. Asymptomatic female carriers should be evaluated because they may also have cardiac abnormalities.^[74]

The function of emerin needs to be determined. A recent paper suggests the small size of the STA gene and its housekeeping pattern of expression may make gene therapy possible in ED MD.^[75]

Distal Myopathies

The distal myopathies are a rare heterogeneous group of disorders characterized by progressive muscular weakness and atrophy beginning in the hands or feet (... [Table 36-7](#)). Several types of distal myopathies have been differentiated clinically, distinguished either by site of onset or mode of inheritance or by differences seen on muscle biopsy.

The late adult-onset distal autosomal dominant myopathy that first appears in the hands, also called Welander distal myopathy or Swedish-type distal myopathy, has been linked to chromosome 14.^[76] It has a mean onset of 47 years (range, 20 to 77 years), with weakness in the hands that generally presents as clumsiness in the thumb and forefinger that spreads to other fingers. Eventually, patients develop distal leg weakness, more often in the extensors. Fewer than 20 percent of patients develop proximal extremity weakness, while more than 90 percent complain of vasomotor disturbances, primarily a sensation of cold, in the hands and feet. Another late adult-onset autosomal dominant disease found in Finland first involves weakness in the anterior tibial muscles, followed by weakness of the long toe extensor muscles and proximal leg weakness in about half the patients. There is no weakness in the hands. Yet another late-onset autosomal dominant distal myopathy,

TABLE 36-7 -- DISTAL MYOPATHIES: DISTINCTIONS IN DIFFERENT TYPES

Age of Onset	Type	Mode of Site of Onset	Inheritance
Late adulthood	Welander	Hands	AD
	Finnish	Legs	AD
	Markesberry- Griggs	Legs	AD
Early adulthood	type I: Nonaka	Anterior compartment of legs	AR
	type II: Miyoshi	Posterior compartment of legs	AR
	type III: Laing	Anterior compartment of legs, distal weakness with sternocleidomastoid weakness	AD

Childhood (ages 5 to 15)	Desmin storage	Distal weakness with respiratory and bulbar involvement	AD
	Juvenile	Feet, then hands	AD
Infancy (<2 years)	Infantile	Hands and feet	AR

AD. Autosomal dominant: AR, autosomal recessive

known as Markesberry-Griggs myopathy, has been described in which proximal weakness is also common and the intrinsic foot muscles are affected. Cardiomyopathy in non-Scandinavian middle-aged adults can also occur.

The early adult-onset autosomal recessive myopathies begin with leg weakness. Type I starts in the anterior compartment, usually presenting with foot drop, whereas type II starts in the gastrocnemius muscles. At this time, these types are assumed to be different entities owing to differences seen on muscle biopsy. There are two other early adult-onset forms that are autosomal dominant. Laing's myopathy, linked to chromosome 14, includes facial and shoulder weakness in addition to distal weakness. Desmin storage myopathy has respiratory and bulbar musculature involvement as well as prominent hand and foot involvement.

Two early onset forms have also been described in Dutch and British families. The infantile onset form spreads from the feet to the hands but does not progress after age 18. The juvenile onset form starts simultaneously in the hands and feet and slowly progresses until about age 50 years. ^[77]

The differential diagnosis includes myopathies and neuropathies. Whereas most myopathies predominantly affect proximal muscles, a few that can present distally include various metabolic myopathies and inclusion body myositis. Laing's myopathy can resemble FSH MD. Although distal weakness may suggest neuropathic disorders, EMG and muscle studies determine that these conditions are myopathic. Serum CK activity is markedly increased, often 50 times the normal value. Electrical studies demonstrate signs of myopathy in the involved areas of weakness, where nerve conductions are normal. Muscle biopsy shows dystrophic changes of variable severity. Rimmed vacuoles are

77

frequently observed, suggesting a link between distal myopathies and inclusion body myositis. Patients with Welander's disease also show angulated fibers, whereas desmin storage is typical of the early adult-onset form with respiratory muscle involvement. DM can present without clinically apparent myotonia, and the neuronal late-onset type of Charcot-Marie-Tooth disease (CMT) may look similar. ^[77]

Thus far, no medical interventions have improved these conditions. Appropriate orthotics and physical and occupational therapy provide the most assistance. By and large, these are slowly progressive disorders that sometimes plateau, and they are not life threatening.

DEGENERATIVE NEUROPATHIES

Hereditary Sensory and Motor Neuropathies

In general, the hereditary sensory and motor neuropathies are peripheral neuropathies that affect either autonomic nerves, sensory nerves, motor fibers, or a combination thereof. The molecular genetics of these disorders is being ardently pursued and the mechanisms underlying them are rapidly being unraveled. However, to date there is overlapping terminology used when they are described ([Table 36-8](#)). This discussion is organized according to the classification that is emerging based on genetics ([Table 36-9](#)). CMT is the most common hereditary sensory and motor neuropathy, and CMT type 1A is the most common form of CMT, accounting for more than 50 percent of all cases of CMT.

Pathogenesis and Pathophysiology. Pathological changes seen in CMT include loss of myelinated fibers and sclerosis in the posterior column of the spinal cord, particularly in the fasciculus gracilis in its upper regions. Peripheral nerves show fewer myelin sheaths, with the extent of the decrease correlating with the severity of clinical disease. There is also an increase in transverse fascicular area, especially in the auricular and sural nerves. Onion bulbs, made up of circumferentially directed Schwann cells and their processes, can be seen at myelinated internodes, demyelinated internodes, or former sites of myelinated fibers.

There has been considerable controversy over the years whether the primary defect in CMT originates in the neuron and its axon or in the Schwann cell. The histopathological changes seen emphasize demyelination, whereas the clinical picture of muscle weakness and atrophy is evidence

TABLE 36-8 -- TYPES OF HEREDITARY SENSORY AND MOTOR NEUROPATHY (HSMN)

Type	Other Names	Particular Characteristics
HSMN I	CMT I	Hypertrophic demyelinating neuropathy
HSMN 11	CMT 11	Axonal neuropathy with normal or near normal nerve conduction Velocities
HSMN 111	Dejerine-Sottas disease	Severe hypertrophic demyelinating neuropathy with onset in infancy

TABLE 36-9 -- GENES AND GENE PRODUCTS IN THE HEREDITARY SENSORY AND MOTOR NEUROPATHIES

Disorder	Mode of Inheritance	Gene Gene Locus	Product
CMT1A	AD	Duplication (or rarely, point mutation) at 17p11.2-12	PMP22
HNPP	AD	Deletion at 17p11.2	PMP22
Dejerine-Sottas syndrome A	AD	Point mutation at 17p11.2	PMP22
Dejerine-Sottas syndrome B	AD	Point mutation at 1q22.3	Myelin protein zero (PO)
CMT 1B	AD	1q22.3	PO
CMT 1C	AD	?

CMT 4B	AR	1q231	?
CMT 4C	AR	5q23-33	?

AD autosomal dominant AR autosomal recessive CMT, Charcot-Mane-Tooth disease; HNPP, hereditars neuropathy with liability to pressure palsies; PO, myelin protein zero; PMP, peripheral myelin protein.

of muscle denervation and axonal loss and of axons with calibers reduced out of proportion to the extant of myelin loss. ^[78]

The gene defects and their products associated with the CMTs are beginning to clear this up. Peripheral myelin protein 22, which has been implicated in several of the CMTs (see [Table 36-9](#)), is present as a protein in all myelinated fibers of the peripheral nervous system and is localized to compact myelin. Studies in the trembler mouse, which also has a gene defect in peripheral myelin protein 22, indicate that Schwann cells can modulate axon caliber, neurofilament phosphorylation, and neurofilament density within the axoplasm. Therefore, abnormal expression of peripheral myelin protein 22 could account for both the neuronal and Schwann cell alterations seen in CMT. ^[79]

Myelin protein zero (P0) is the major component of peripheral nervous system myelin. It is an integral membrane glycoprotein, and its expression is confined to myelinated Schwann cells. A major role of the P0 extracellular domain is compaction of peripheral myelin, while the cytoplasmic domain is thought to interact with a component of the opposing membrane of the compact myelin, holding these membranes together. ^[80]

Connexin 32 is a gap junction protein. Before its identification as a gene for X-linked CMT (CMT X), it was not known there were gap junctions in human peripheral nerve. It has now been detected at the nodes of Ranvier and the Schmidt-Lanterman incisures, which may mean it forms intracellular gap junctions between the folds in Schwann cell cytoplasm. ^[81]

Epidemiology and Risk Factors. The hereditary sensory and motor neuropathies occur worldwide, with an estimated prevalence ranging from 4.7 to 36 per 100,000, and an approximate incidence of 1 in 25,000 persons. Autosomal dominant, autosomal recessive, and X-linked dominant and recessive inheritance patterns have been

reported. [Table 36-9](#) identifies the known genetic loci and known gene products.

Clinical Features and Associated Disorders. Although there is wide intrafamilial variability in phenotype, it is generally accepted that clinical presentation of CMT 1A and 1B are similar, although they are distinguishable, and CMT 1A may have a milder clinical course than 1B. Age of onset ranges from childhood to early adulthood, with symmetrical insidious weakness and atrophy of the intrinsic foot and peroneal muscles occurring first, associated with varus deformity of the feet and a steppage gait. Calf, intrinsic hand, and thigh muscles may be involved later ([Fig. 36-8](#)). Atrophy tends to occur at the distal ends of the gastrocnemius, soleus, and quadriceps muscles. Cramps and fasciculations are often reported after exercise. Stretch reflexes disappear first in the gastrocnemius and soleus, then the quadriceps, and finally the arms.

Although patients generally do not report sensory disturbances, a careful examination reveals abnormalities in all modalities. Pes cavus and hammer toes are present in up to two thirds of patients. Decreased skin temperature over the distal leg is common, and decreased sweating has been reported. Enlargement and hardening of nerves, particularly those between the shoulder and elbow, have been observed in up to one fourth of patients.

Hereditary neuropathy with liability to pressure palsies, also called tomaculous neuropathy, is a syndrome characterized by a tendency toward the development of

recurring sensory and motor nerve palsies brought on by mild pressure

Figure 36-8 Patient with Charcot-Marie-Tooth disease showing marked wasting of calf muscles and intrinsic foot muscles (From Dubowitz V: *Muscle Disorders in Childhood*. London, W.B. Saunders, 1995.)

or trauma to a particular peripheral nerve bundle. An insult from which a normal person would quickly recover results in residual nerve damage that may take days or even months to resolve. Some of these patients go on to develop CMT, whereas other family members may have only the CMT phenotype.

Dejerine-Sottas syndrome, sometimes called progressive hypertrophic neuropathy, is a more severe form of peroneal muscular atrophy with presentation in infancy of progressive generalized muscle weakness, severe sensory loss, limb ataxia, and marked hypertrophy of peripheral nerves. Both dominant and recessive inheritance patterns have been reported. Molecular genetic studies indicate that Dejerine-Sottas syndrome is a variation of CMT with a generally more malignant phenotype.

About 10 percent of cases of CMT are X-linked, in which primarily male family members are affected through maternal transmission. Again there is intrafamilial variation in severity, but generally, onset occurs in childhood, with slowly progressive distal weakness and sensory disturbance that tends to be more severe than that seen in CMT 1. Carrier females may have mild, variable clinical disease.

In Roussy-Levy syndrome, peroneal muscular atrophy is associated with essential tremor. The gene locus has not been identified. [78]

Differential Diagnosis and Evaluation. Other mixed polyneuropathies of nutritional, infectious, toxic, autoimmune, and vasculitic origin should be considered. Both axonal and demyelinating neuropathies need to be included in the differential diagnosis. At present, genetic confirmation of this disorder is available only for CMT 1A, hereditary neuropathy with liability to pressure palsies, Dejerine-Sottas syndrome, and X-linked CMT. CK is normal. On EMG, nerve conduction velocities are slowed in peripheral nerves. The extent of velocity reduction is no longer an accepted criterion for diagnosing the type of CMT. On nerve biopsy, there is a moderate increase in epineurium and perineurium and a variable decrease in the number of myelinated fibers that correlates with the severity of disease. Onion bulb formation is visible around myelinated and demyelinated internodes. [79]

Management. There is no cure or effective treatment for these disorders. Physical therapy, occupational therapy, and orthotic devices can help maintain optimal function. Genetic counseling is an obvious and important component of care for these patients.

Prognosis and Future Perspectives. Although large studies are not available, several series conclude that life expectancy is not reduced in CMT1 and that generally those with CMT type 1A remain ambulatory throughout their lives. A 20-year follow-up study of a family with CMT type 1B demonstrated that patients remained ambulatory with a normal lifespan. Autopsy studies included a 92-year-old family member. [82]

Hereditary Sensory and Autonomic Neuropathies

The hereditary sensory and autonomic neuropathies (HSANs) are conditions in which primary sensory and

autonomic neurons either fail to develop or undergo system atrophy and degeneration. Dyck proposes the comprehensive subdivision seen in [Table 36-10](#). These disorders have been called by a large variety of names because their symptoms were described by various investigators. Types I, II, and III are discussed here. Within this classification there are two large divisions: HSAN I is a progressive disorder with symptom onset usually occurring in the second decade or later with primarily lower extremities affected. HSANs II to V are static congenital disorders that are more generalized. A common thread among all the types is an insensitivity to pain. [83]

HEREDITARY SENSORY AND AUTONOMIC NEUROPATHY TYPE I

HSAN I is a disorder in which sensory disturbances and associated tissue complications outweigh its motor and autonomic manifestations. HSAN I is a rare disorder that is usually autosomal dominantly inherited, although recessive and X-linked pedigrees have been identified. [83] There is chronic axonal atrophy, myelin remodeling, and axonal degeneration with sparing of the central nervous system and non-neural tissues. Multipoint linkage analysis has mapped a gene for HSAN I to 9q22.1-q22.3, although the different modes of inheritance and phenotypes suggest that there may be other loci. [84]

Although there are different phenotypes, typically the disorder presents in one of the following ways: (1) foot complications, such as plantar ulcers, recurring paronychia of toes, stress fractures of foot bones, recurrent cellulitis, and resorption of foot bones; (2) spontaneous pain, either burning or aching of the feet that is worsened with weight

TABLE 36-10 -- HEREDITARY SENSORY AND AUTONOMIC NEUROPATHIES (HSANs)

Type	Hallmark	Inheritance Pattern
HSAN I (hereditary sensory radicular neuropathy)	Insensitivity to pain in feet and ensuing tissue complications	Primarily autosomal dominant
HSAN II (congenital sensory neuropathy)	Early onset of loss of sensation in all modalities	Autosomal recessive
HSAN III (familial dysautonomia, Riley-Day syndrome)	Early onset, predominantly autonomic symptoms, absence of fungiform papillae on the tongue	Autosomal recessive, predominantly Jewish (gene on D9S58)
HSAN IV (familial sensory neuropathy with anhydrosis, congenital insensitivity to pain)	Mild mental retardation, episodes of fever related to environment rather than infection	Rare
HSAN V (congenital sensory neuropathy with selective loss of small myelinated fibers)	Congenital insensitivity to pain in extremities normal strength and tendon reflexes, abnormality of nociception	Fewer than 10 cases reported

bearing and decreased at night, or disabling lancinating pain in deep tissues of the feet, legs, or shoulder; or (3) symptoms of sensory and autonomic neuropathy.

The complications of HSAN I may be of sudden, overwhelming onset, with ulcers first developing over pressure points on the foot. When these ulcers are neglected, they do not heal and are associated with the complications previously described. Phenotypes have been reported in which HSAN is associated with deafness, leg weakness and atrophy, burning feet, restless legs, and neuropathic atrophy. HSAN is a slowly progressive disorder that does not seem to decrease the lifespan. It cannot be emphasized enough that proper foot care can prevent complications that can lead to foot amputation and sepsis.

HSAN I may be distinguished from other varieties of HSAN because it starts later, usually in the second or third decade; is slowly progressive; and preferentially affects lower limbs. It is closest in presentation to HSAN II, although in that condition, the motor and autonomic symptoms outweigh the sensory symptoms and deficits of type I. Spinocerebellar degeneration can be distinguished from HSAN I because of its kinesthetic and mechanoreceptor loss, cerebellar ataxia, and relatively less small fiber sensory and autonomic dysfunction. Familial amyloidosis may include sexual and sphincter dysfunction, which are not found in HSAN I, and porphyria with neuropathy, which has a more acute onset associated with changes in mental status.

Typically, touch-pressure threshold, thermal discrimination, and nociception are abnormally elevated in the foot and leg, although they may be altered in the arm and hand as well. Paresthesias are not present. Loss of sweating in the distal leg is common. Sural nerve amplitudes are reduced, with small myelinated fibers being primarily affected. A decrease in the Achilles tendon reflex is common, followed most often by a decrease in the quadriceps reflex. [83]

There is no effective treatment. The main goal is the prevention of foot ulcers. The feet should be inspected regularly for signs of pressure points, soaked daily, and treated with petrolatum lotion applied to seal in moisture. Shoes should be chosen carefully to avoid pressure points. Any ulcers should be treated promptly with cleaning and debridement, if necessary. The appropriate antibiotic should be used for cellulitis or septicemia. Genetic counseling should include information about

phenotypic variation and degree of risk.

HEREDITARY SENSORY AND AUTONOMIC NEUROPATHY TYPE II

HSAN II is characterized by an early onset of loss of sensation in all modalities. This is a rare disorder, in which cases reported are either sporadic or within a sibship, suggesting an autosomal recessive pattern of inheritance. There is profound loss of myelinated fibers in cutaneous nerves, especially the sural nerve. Dyck proposes that the degenerative process begins in utero or in infancy.^[83] There are fewer nerve fibers at the ankle than the midcalf, marked denervation of the extensor digitorum brevis, evidence of segmental demyelination and remyelination, and

electron microscopic abnormalities within axis cylinders.^[83] As yet, no gene locus has been identified.

Symptoms first appear in infancy or early childhood and may be widespread. Paronychia, whitlows, ulcers of the fingers and feet, and previously undetected fractures of the foot and hand are common and result directly from underlying sensory disturbance ([Fig. 36-9](#)). There have been pedigrees reported with HSAN II and other dysautonomic features, as well as retinitis pigmentosa or tonic pupils. There is sensory loss affecting all modalities in the lower and upper limbs and sometimes in the trunk. Tendon reflexes are generally absent or diminished in all limbs. There is loss of sweating over acral parts. However, there is no prominent muscle weakness, postural hypotension, or sphincter disturbance.

Generally, there are no sensory nerve action potentials elicitable in the ulnar, median, or sural nerves, while the conduction velocities of motor fibers of the same nerves are at or just below the lower end of normal. Minimal fibrillation may be found in the extensor digitorum brevis, which has a decreased number of motor unit potentials, a large number of which are polyphasic.^[83]

Complications are much more difficult to prevent in HSAN II owing to its early onset at an age when patients cannot understand the problem or cooperate with preventive regimens. In addition, complications are frequent because the hands are so seriously affected. Preventive care, which is similar to that of HSAN I, needs to be as aggressive as possible because complications may be life threatening. Special attention should be given so that these children have adequate educational opportunities to develop their intellectual potential in spite of severe physical handicaps. Genetic counseling should be provided.

HEREDITARY SENSORY AND AUTONOMIC NEUROPATHY TYPE III (RILEY-DAY SYNDROME)

HSAN III is present almost exclusively in Ashkenazi Jews. Some investigators argue that those who are not Jewish in fact have a different type of neuropathy. The gene frequency has been estimated at 0.01 per 100,000 Jews in the United States.^[85] Decreased levels of dopamine-beta-hydroxylase, the enzyme that converts dopamine to norepinephrine, and increased levels of antigen of the beta unit of nerve growth factor (NGF) have been identified. However, the structural gene for beta-nerve growth factor and the gene for the receptor for nerve growth factor were both excluded as the site of mutation in HSAN III. Rather, it has been linked to D9S58, which has an unknown gene product.^[86] Postmortem studies have varied widely; some have shown no nervous system lesions at all, whereas others show extensive damage, particularly in the brain stem reticular formation, the cortex, and the long tracts of the cord. There is a marked decrease in the number of unmyelinated fibers of the cutaneous nerves.^[83]

Usually, HSAN III presents at birth. Axelrod proposes that it should be suspected in a child of Eastern European Jewish extraction with breech delivery, meconium staining, poor suck, hypotonia, or hypothermia. There is difficulty feeding and a failure to thrive, along with unexplained fevers, lack of tearing, paroxysmal hypertension, increased sweating, cold hands and feet, erythematous blotching of the skin, and drooling. There is also a lack of fungiform papillae on the tongue, a feature that is highly distinctive of this disorder. Although there is overlap between symptoms and signs of this and other types of HSAN, examination of the tongue leads to the exclusion or inclusion of this diagnosis. If the disorder presents later, it may be observed as delayed development or stunted growth with decreased pain sensation and ataxia. Abnormalities in cutaneous temperature discrimination and nociception are present in most patients, whereas fewer have abnormalities in joint position and vibratory sensation.

Recurrent vomiting is common in the early years. Several gastrointestinal abnormalities have been identified: megaesophagus, pylorospasm, gastric ulcer, jejunal distention, and megacolon. Corneal abrasions may occur secondary to corneal insensitivity, whereas neuropathic or Charcot's joints may occur secondary to pain insensitivity. About half of the patients develop kyphosis, scoliosis, or both. Pulmonary complications, profound hypotension, and prolonged respiratory depression from the administration of anesthesia have been reported.^[83]

Clinical and laboratory diagnosis may be based on the presence of five signs: (1) lack of the normal flare after intradermal injection of histamine, (2) absence of fungiform papillae on the tongue, (3) miosis of the pupil after conjunctival instillation of 2.5 percent methacholine chloride, (4) absent deep tendon reflexes, and (5) diminished tear flow. Sural nerve biopsy shows markedly decreased unmyelinated fibers, no active fiber degeneration, and fewer Schwann cell cytoplasmic clusters than other types of neuropathy. Nerve conduction velocity studies have mixed nerve velocities within the normal range.^[87]

Treatment remains supportive and is best provided by

an interdisciplinary team that includes a genetic counselor. Prenatal diagnosis is available for informative families.^[88] Most patients do not survive to adulthood, succumbing to either recurrent infections or hyperpyrexia. The oldest surviving patient in one series was 38 years old, with one third of the patients in that series being 20 years or older.^[89]

Autonomic Neuropathy of Multiple System Atrophy (Shy-Drager Syndrome)

In 1960, Shy and Drager first described the combination of progressive autonomic failure and multiple system atrophy that manifested as orthostatic hypotension, akinesia, and rigidity that led to incapacity in a few years (see [Chapter 34](#)). In the ensuing years, conditions including striatonigral degeneration and forms of olivoponto-cerebellar atrophy have been combined with Shy-Drager syndrome under the larger category of degenerative processes called multiple system atrophy. This discussion focuses on the phenotype with prominent dysautonomia that was described by Shy and Drager.

Shy-Drager syndrome affects men more often than women, most often in middle age or later. A Japanese series calculated the prevalence to be 0.3 per 100,000.^[90] There have been reports of families with autosomal dominant inheritance. A genetic basis was postulated in 1983 when an association was found between HLA antigen Aw32 and autonomic failure.^[91] Thus far, no gene has been identified.

There is degeneration of both pigmented catecholamine-containing cells in the brain stem and cholinergic cells in the intermediolateral columns, along with distal ganglionic and postganglionic degeneration. The abnormality in sympathetic function leads to depressed circulating norepinephrine responses to standing and exertion. There is enhanced blood pressure response to norepinephrine administration, along with evidence of increased and beta receptor concentrations, which correlates to supersensitivity to norepinephrine. Basal norepinephrine levels are normal. Generally, catecholamine is depleted in sympathetic nerve endings around blood vessels.^[92]

Often in the male, the first symptom is impotence and loss of libido, with disturbance in micturition being common in both sexes. The characteristic orthostatic hypotension may be seen either as so-called drop attacks or as a gradual loss of consciousness over about a minute that is often associated with a neckache that radiates to the occiput and shoulders. Generally, there is at least partial loss of thermoregulatory sweating. Respiratory disturbance occurs as involuntary gasping, cluster breathing, and laryngeal stridor that may lead to obstructive sleep apnea and even death, or to central sleep apnea.

On neurological examination, abnormalities of the pupil, including Horner's syndrome, alternating anisocoria, and abnormal responses to drugs may be seen. Mild parkinsonian features or cerebellar ataxia may accompany the condition, but dysautonomia is the predominant dysfunction. In the striatonigral degeneration variant, or multiple system atrophy, rigidity with little tremor, progressive loss of facial expression, limb akinesias, anterocollis, and gait instability predominate (see [Chapter 34](#)). There is difficulty walking, standing, turning, and feeding oneself, and the speech is faint and slurred. With pyramidal lesions, there may be an increase in tone, along with impaired rapid hand and foot movements and exaggerated deep tendon reflexes and bilateral extensor responses. Primitive reflexes may be present, and amyotrophy is common. Dementia is not seen more often than would be expected by chance owing to the age of this population. When the olivopontocerebellar variant is present, ataxia and limb tremor develops.

Differential Diagnosis. Pure autonomic failure (Bradbury-Eggleston syndrome) may present with the same autonomic disturbance as Shy-Drager syndrome, but it does not have any other neurological symptoms. Amyloidosis may also look similar but generally is associated with a greater degree of bowel involvement (see [Chapter 21](#)). Familial dysautonomia (Riley-Day syndrome, or HSAN III) presents in children and therefore is distinguishable from Shy-Drager syndrome.

Management. Several general actions may help the patient avoid aggravation of orthostatic hypotension: maintenance of adequate blood volume with fluid intake of 2 to 2.5 L/day, sleeping in a semirecumbent position, and rising slowly to standing. In addition, patients should avoid excessive warmth (in bathing and climate); do moderate rather than vigorous exercise; eat small, frequent meals; and avoid vasodilators, such as alcohol and nitroglycerin. Mechanical support may be provided by Jobst's stockings in combination with abdominal binding. Severe orthostatic hypotension has been successfully managed with an air force anti-gravity suite. The most common pharmacological agent used is fludrocortisone, which increases blood volume and maintains venous return to the heart. Second-line drugs are the vasoconstrictors, such as phenylephrine and ephedrine, with the prostaglandin inhibitors being the next choice, followed by beta-1 agonists. Early tracheostomy for laryngeal stridor may prevent premature death.

A recent Japanese study concluded that 90 percent of patients are alive 3 years after their first symptoms and 54 percent are alive after 6 years. Earlier onset of more extensive autonomic disturbance was associated with a poorer prognosis.

MUSCLE DISORDERS

Channelopathies (Myotonias and Periodic Paralysis)

The channelopathies are disorders of ion channels that result in altered excitability of cellular membranes. At present, more is known about muscle and peripheral nerve than central nervous system channelopathies. Most of the well-characterized channelopathies are disorders of muscle membrane ion channels. A disturbance of ion channel function may result in muscle membrane hyperexcitability leading to myotonia as the dominant feature, or, alternatively, it may result in muscle membrane hypoexcitability leading to the episodic weakness seen in periodic paralysis. The muscle channelopathies can be grouped into sodium, calcium, and chloride channel disorders ([Table 37-1](#)). This chapter focuses on the inherited channelopathies, but it is important to be aware that there are acquired, usually autoimmune, channelopathies that also result in nerve and muscle disease.

Traditionally, the myotonias have been divided into dystrophic and nondystrophic disorders. In the dystrophic myotonias, myotonia is one of several muscle symptoms, with muscle atrophy and weakness being most prominent. These diseases include dystrophia myotonica and proximal myotonic myopathy (see [Chapter 36](#)). [1](#) , [2](#) In contrast, in nondystrophic myotonias the most prominent symptom is myotonia, and it is these disorders that have been shown to result from a gene lesion in a muscle channel protein. Those nondystrophic disorders are the focus of this chapter.

The periodic paralyzes have been traditionally divided into those associated with a high or normal serum potassium concentration (i.e., hyperkalemic periodic paralysis) and those associated with a low serum potassium concentration (i.e., hypokalemic periodic paralysis). In fact, however, the abnormal serum potassium concentration is clearly the consequence rather than the cause of the peri

odic paralysis. Recent advances in physiology and genetics have vindicated this traditional nosologic separation of diseases by demonstrating that they are due to disorders of entirely different ion channels. [1](#) [2](#) [3](#) [4](#) [5](#)

Pathogenesis and Pathophysiology--Sodium Channelopathies. Most, if not all, of the sodium channelopathies result from allelic point mutations in the same channel gene, which is situated on the long arm of chromosome 17. To date, 16 different point mutations have been found that result in amino acid substitutions in conserved portions of the gene. Strict phenotypic-genotypic correlations for these point mutations are not yet defined because many have variable phenotypic expression. Physiologically, these mutations result in reduced inactivation of the sodium channel, followed by either increased muscle excitability with myotonia or increased muscle inexcitability with hyperkalemic periodic paralysis. In cases of hyperkalemic periodic paralysis, this physiological abnormality is accentuated by an increase in the extracellular potassium concentration, whereas in paramyotonia congenita, it is sensitive to cooling, thus accounting for the worsening of symptoms with these factors.

Pathogenesis and Pathophysiology--Chloride Channelopathies. In both forms of myotonia congenita, the characteristic feature is that of reduced muscle membrane chloride conductance resulting in muscle membrane hyperexcitability with after-depolarization and repetitive firing, which leads to the myotonia. This abnormal physiology can be reproduced by chloride channel blockers or the substitution of impermeable ions for chloride. These diseases are linked to chromosome 7q32 in a region that encodes a chloride channel gene (CLC9). Thomsen's and Becker's diseases are allelic disorders in which a number of point mutations have been described. However, these mutations account for only 30 to 40 percent of cases, and undoubtedly other chloride channel mutations will be discovered. [1](#)

Pathogenesis and Pathophysiology--Calcium Channelopathies. In hypokalemic periodic paralysis, the weakness results from an abnormality of muscle membrane excitability related to the calcium channel. There is an influx of potassium into the muscle fiber with an accompanying influx of extracellular water. These patients have an increased sensitivity to the effect of insulin on the movement of potassium into cells independently of the glucopenic action of insulin. This influx of potassium may account for the precipitation of hypokalemic periodic paralysis with large carbohydrate meals. In contrast to the reaction in normal muscle fibers, the influx of potassium in hypokalemic periodic paralysis causes the muscle fibers to become depolarized and inexcitable. Hypokalemic periodic paralysis has been linked to chromosome 1q at the site of a skeletal muscle dihydropyridine receptor alpha-1 subunit that functions as a calcium channel (CACNL1A3). Three mutations account for over 50 percent of cases of hypokalemic periodic paralysis, and these mutations are in a highly conserved region of the gene that codes for the voltage sensor region of the calcium channel. [1](#) The dihydropyridine receptor has a primary role in electrocontraction coupling, opening the calcium channels of the sarcoplasmic reticulum and allowing an influx of calcium into the muscle sarcoplasm and triggering muscle contraction. Although the mutations described in hypokalemic periodic paralysis do lead to loss of function of the dihydropyridine receptor, it is not yet clear how this results in the abnormal response of muscle fibers to insulin with consequent hypokalemia and weakness.

Pathogenesis and Pathophysiology--Possible Channelopathy. Schwartz-Jampel syndrome is a rare myotonic disorder of unknown etiology. Some cases that were initially thought to be Schwartz-Jampel syndrome have demonstrated a different EMG picture (see later discussion) and have been subsequently shown to be due to a sodium channel mutation such as that seen in myotonia permanens. [1](#) It is possible that a channel disorder will be found that accounts for other cases of Schwartz-Jampel syndrome.

Epidemiology and Risk Factors. Autosomal dominant myotonia congenita (Thomsen's disease) has an incidence of between 0.25 and 4.0 per 100,000. [1](#) Finnish and Danish studies of hypokalemic periodic paralysis have yielded an incidence of between 0.4 and 1.25 per 100,000. [1](#)

Clinical Features and Associated Disorders-- Sodium Channelopathies. Disorders of the alpha subunit of the muscle sodium channel result in three major distinct

disorders: paramyotonia congenita, hyperkalemic periodic paralysis, and sodium channel myotonias. There is some phenotypic overlap among the sodium channelopathies, suggesting that these may be part of a continuum rather than rigidly demarcated clinical entities. The literature also includes normokalemic and myotonic periodic paralyses in this category, but since most, if not all, of these are potassium sensitive in exactly the same way as hyperkalemic periodic paralysis, it is likely that they represent sodium channel disorders.

Paramyotonia Congenita. This disease is autosomal dominant, inherited with complete penetrance. The predominant symptom is paradoxical myotonia, which is usually present from birth and persists throughout life. The myotonia is paradoxical because unlike classic myotonia, it increases with repetitive movements. It is also exacerbated by cold temperatures, which also cause weakness. The myotonia particularly affects the face, neck, and forearms. Typically, on relief of the myotonia, either spontaneously or with warming of the muscles, a variable degree of weakness occurs, which can persist for several hours. In a warm environment, patients may have no symptoms at all. In some families with this disorder, there is a tendency for attacks of paralysis to occur independently of the myotonia. In many patients, these attacks are precipitated by potassium ingestion, in much the same way as hyperkalemic periodic paralysis. Occasional patients are weakened by hypokalemia.

Hyperkalemic Periodic Paralysis. As with paramyotonia congenita, hyperkalemic periodic paralysis normally appears in infancy or early childhood with frequent episodes of paresis that are generally brief and mild, lasting between 15 minutes and 4 hours. Attacks are often precipitated by rest following exercise, by ingestion of potassium-rich foods, or by administration of potassium compounds. The attacks commonly start in the morning before breakfast, and stress tends to provoke them more easily. Weakness is mainly proximal, but distal muscles can be involved. There is usually no ocular or respiratory muscle weakness. Examination of a patient who is having a severe attack

reveals a flaccid tetraparesis with absent reflexes and normal sensory examination. The potassium level may rise during the attack but not necessarily above the upper limit of normal range and rarely to levels that cause cardiac dysrhythmias. Generally, between attacks, most patients maintain normal strength, but a few have persistent mild weakness. The frequency of attacks may decline as the patient grows older. In some families with hyperkalemic periodic paralysis, there is a coexisting myotonia, which is usually mild. In these patients, cooling may provoke weakness but does not cause worsening of the myotonia.

Sodium Channel Myotonias. Sodium channel myotonias are a group of recently classified myotonias that have been shown to be due to sodium channel gene mutations but do not have the classic features of paramyotonia congenita or episodes of periodic paralysis. In some cases, the myotonia becomes worse with cold, but it is not associated with weakness and responds to acetazolamide (acetazolamide-responsive myotonia).^[9] In other families, myotonia fluctuates on a daily basis and is provoked by exercise (myotonia fluctuans).^[9] A third form of sodium channel myotonia consists of permanent very severe myotonia (myotonia permanans).^[9]

Clinical Features and Associated Disorders-- Chloride Channelopathies. There are two similar forms of myotonia congenita that are now known to be due to disorders of the chloride channel. Both are inherited--one as an autosomal dominant disease (Thomsen's disease) and other as an autosomal recessive disease (Becker's disease).

Autosomal Dominant Myotonia Congenita (Thomsen's Disease). The main symptom in this disorder is painless generalized myotonia, which is perceived as muscle stiffness. It usually appears in the first and second decades of life and is provoked by exertion following rest. It may be demonstrated by asking the patient to rise from a chair after a period of quiet sitting. This myotonia improves with exercise. Patients have well-developed muscles with particular hypertrophy of the lower limbs, giving them an athletic appearance. Muscle strength may be normal, or possibly even stronger than normal. This attribute results in an advantage in power sports in which speed is not a requisite. The patients have normal reflexes, and eyelid, grip, and percussion-induced myotonia can usually be demonstrated.

Autosomal Recessive Myotonia Congenita (Becker's Disease). This disorder is very similar to Thomsen's disease except that myotonia appears later in the first decade. However, Becker's disease can be more severe, and patients may have, in addition to severe myotonic stiffness, a disabling phenomenon of transient weakness not seen in Thomsen's disease. In Becker's disease, the patient's muscles are initially weak, and a period of activity is required before full strength returns. At times, this weakness is so severe that the patient requires assistance with ambulation; persistent weakness may occur. As in Thomsen's disease, these patients may have muscle hypertrophy, particularly of the legs and buttocks, with some hyperlordosis of the spine.

Hypokalemic Periodic Paralysis. Primary hypokalemic periodic paralysis is an autosomal dominant disorder that is more common in males and has a variable penetrance in females. Attacks usually begin by the time of adolescence and often occur at night, such that the patient awakens with weakness. These episodes may be precipitated by carbohydrate or alcohol intake, rest after exercise, or emotional stress. The frequency of attacks is generally less than that seen in patients with hyperkalemic periodic paralysis and may vary from daily to only once or twice in a lifetime. Typically, attacks last between 1 and 4 hours, but occasionally they persist for up to 3 days. Prodromal symptoms of muscle stiffness, heavy limbs, or sweating may occur followed by proximal lower limb weakness, which spreads to become a tetraparesis. Ocular or bulbar involvement is rare. Fatalities are rare and usually result from injudicious treatment or hypokalemia-induced cardiac dysrhythmias. Oliguria is typical during attacks and results from the sequestration of water intracellularly.

In younger subjects the only detectable interictal abnormality is eyelid myotonia, which is seen in approximately 50 percent of patients. In older subjects, the frequency of attacks often decreases, but patients may have persistent weakness. During severe attacks patients are flaccid and areflexic.

Clinical Features and Associated Disorders--Possible Channelopathy Schwartz-Jampel Syndrome. Onset of this disorder occurs before the age of 3. It becomes manifest with severe continuous motor activity and muscle stiffness, particularly in the face and thighs. Patients have an unusual masklike face with blepharospasm and continuous motor activity of the chin and lips. Hypertrophy of the thigh muscles also occurs. Patients may also have a variety of skeletal malformations including contractures and short stature.^[10]

Differential Diagnosis Myotonias. The principal symptom of myotonia is that of muscle stiffness and an inability to relax contracted muscle (usually sodium channel myotonia is not painful). Stiffness may be confused with increased muscle tone related to spasticity or rigidity. Muscle cramps, which must be distinguished from this stiffness, are often a feature of a peripheral nerve disorder and are readily differentiated on EMG. Dystonia should be considered in these patients, but this disorder results in abnormal postures and is the result of discharges of whole motor units rather than individual muscle fibers. Painless but electrically silent contractures may be a feature of metabolic myopathy such as McArdle's disease and may be mistaken for myotonia. In patients who are taking neuroleptics or those who have been withdrawn from levodopa, neuroleptic malignant syndrome should be considered in the presence of muscle rigidity or stiffness with fever, an elevated creatine kinase (CK) level, and a high white blood cell count. The term pseudomyotonia has been used to refer to impaired relaxation without electrical evidence of myotonia, and this phenomenon occurs in patients with acid maltase deficiency and Brody's disease. True myotonia may be part of a generalized disorder, as in dystrophia myotonica, but is not usually the presenting symptom. The different nondystrophic myotonias can usually be distinguished clinically, but sometimes gene analysis is needed for a final diagnosis.

Periodic Paralysis. In a patient with a first attack of periodic paralysis, the differential diagnosis must include other causes of a flaccid, areflexic tetraparesis without sensory signs. Metabolic causes such as hypercalcemia, hypocalcemia, hypophosphatemia, hypomagnesemia, and rhab

domyolysis need to be excluded. Disorders such as Guillain-Barre(c) syndrome, myasthenic syndrome, and acute poliomyelitis can produce a similar clinical picture. In these cases, the history and associated features will point to the correct diagnosis. Secondary hypokalemic periodic paralysis usually results from intracellular potassium depletion from either renal, endocrine, gastrointestinal, or drug-induced mechanisms [Table 37-2](#) . Usually these underlying conditions are obvious, but sometimes recurrent episodes of transient weakness can be difficult to distinguish from primary hypokalemic periodic paralysis. Late-onset hypokalemic periodic paralysis should raise a strong suspicion of a secondary disorder rather than the primary form. Thyrotoxic periodic paralysis results from an alteration in muscle membrane permeability and is most common in Japanese, Chinese, and other Asian populations but does occur in Caucasians. The clinical presentation is often indistinguishable from that of hypokalemic periodic paralysis but with the additional, sometimes subtle, evidence of hyperthyroidism.^[11] Rarely, paralytic episodes may precede the occurrence of any other clinical feature of hyperthyroidism.

Evaluation Myotonias. Laboratory evaluations should include a serum CK level, which is usually normal but may be elevated two to five times in Thomsen's and Becker's diseases, perhaps reflecting the degree of muscle hypertrophy. The EMG in these disorders shows spontaneous myotonic discharges, but in patients with paramyotonia congenita, provocation by cooling of the examined limb may be required to demonstrate this finding. The EMG also shows a decrement in the compound motor action potential (CMAP) with exercise or with high-frequency 30-Hz stimulation, particularly in patients with myotonia congenita.^[12], ^[13] The

decrement in the CMAP is particularly marked in Becker's disease, and this finding is presumably the cause of the transient weakness seen in patients with that condition.^[13] In the Schwartz-Jampel syndrome, the EMG shows continuous spontaneous motor activity with few of the fluctua

tions in frequency and amplitude seen in patients with other myotonias. In phenotypically similar cases, in which the electrical activity closely resembles that noted in myotonia, the likely diagnosis is myotonia permanans.^[14] In all these conditions, muscle biopsy shows few abnormalities, although there may be variations in fiber size with fiber hypertrophy and increased central nuclei. In paramyotonia congenita with hyperkalemic periodic paralysis, vacuolated and necrotic fibers may occur. In myotonia congenita, there may be a lack of 2B fibers. Study of family members may be valuable, since clinical or EMG evidence of disease in apparently asymptomatic individuals can clarify the mode of inheritance.

Periodic Paralysis. When periodic paralysis is considered, serial blood tests for potassium, calcium, magnesium, phosphate, and CK should be obtained during an episode of weakness. Each time a blood sample is taken, muscle strength should be tested. Potassium levels should be checked sequentially every 15 to 30 minutes to determine the direction of change when muscle strength is decreasing or improving. The potassium level may be normal during hyperkalemic periodic paralysis and occasionally in hypokalemic periodic paralysis. An electrocardiogram (ECG) may show changes consistent with hypokalemia or hyperkalemia and may also give forewarning of cardiac complications. EMG in these patients shows reduced CMAP proportionate to the degree of weakness. Nerve conduction studies are normal. Neurophysiological tests also serve to exclude other causes of paralysis such as the Guillain-Barre(c) syndrome or myasthenia gravis.

Patients who are seen between attacks require a thorough investigation to exclude a diagnosis of secondary causes of hypokalemia. EMG may be helpful in showing evidence of myotonia that favors a diagnosis of hyperkalemic periodic paralysis. In patients in whom fixed weakness has developed, the EMG may reveal myopathic changes. Even in patients in whom the EMG is initially normal, there may be an exaggerated increment followed by a decline in CMAP with high-frequency 30-Hz stimulation or following repetitive muscle contraction.^[14] Muscle biopsy is often abnormal between attacks in patients with hypokalemic periodic paralysis, demonstrating pathognomonic changes of large central vacuoles and occasional necrotic fibers. In patients with hyperkalemic periodic paralysis, smaller vacuoles may be present, and tubular aggregates may be seen. Provocative testing may be required to confirm the diagnosis. This must be performed under careful supervision including monitoring of the potassium level and the ECG. Hypokalemic challenge can be performed by giving intravenous glucose with or without insulin.^[14] Hyperkalemic challenge can be performed by giving repeated doses of oral potassium.^[14]

Management Myotonias. Because myotonia can be exacerbated by several muscle relaxant drugs and by anticholinesterase drugs, anesthesia for these patients should be planned accordingly. Because potassium administration can exacerbate myotonia, potassium supplements should be given only when necessary and always with caution. The treatment of myotonia congenita relies on membrane-stabilizing drugs such as procainamide and quinine, and these can be used intermittently as necessary. Phenytoin is more useful

for chronic administration and is less likely to produce cardiac side effects. Occasional cases of myotonia are responsive to acetazolamide, and mexilitine is useful for both the myotonia and the weakness associated with paramyotonia congenita.

Periodic Paralysis. Attacks of hypokalemic periodic paralysis may be partially prevented by a low-carbohydrate, low-sodium diet. Acetazolamide prevents paralytic attacks and improves residual weakness between attacks. When hypokalemic periodic paralysis is secondary to thyrotoxicosis, the primary thyroid disease should be treated. In the interim, the paralytic attacks and persistent weakness can be treated very effectively with beta-adrenergic blocking agents. During acute attacks, emergency treatment may be required. In these cases, oral potassium is preferred because its concentration usually declines with parenteral potassium owing to the diluents employed. The ECG should be carefully monitored during attacks and when treating patients because of the risk of cardiac dysrhythmias.

In patients with hyperkalemic periodic paralysis, attacks are usually mild but should be treated to prevent the onset of permanent weakness; thiazide diuretics are effective in these patients. During acute attacks, treatment is seldom needed. Carbohydrate-containing foods and fluid may aggravate the weakness, and potassium-containing foods should be avoided. Inhaled beta-adrenergic agonists such as salbutamol are effective treatments in acute situations but may be contraindicated if the patient has a coexisting cardiac dysrhythmia.

Congenital Myopathies

The initial definition of the so-called congenital myopathies implied the onset at birth of a nonprogressive primary myopathy, that could not be explained on the basis of a dystrophic or metabolic abnormality. However, in some morphologically and genetically identical cases, no symptoms are not present at birth and instead occur later. Furthermore, some cases of congenital myopathies such as nemaline myopathy and centronuclear myopathy are characterized by progressive weakness with a fatal outcome. The assumption that all of these congenital myopathies had no metabolic basis reflected ignorance about their etiology. The various congenital myopathies continue to be diagnosed in most instances on the basis of their morphological characteristics as seen on muscle biopsy. For some of these diseases, there is a large body of literature defining a clear phenotype, but others have been described in only one or two case reports, and the specificity of the morphological changes described and their validity as a disease entity must remain doubtful. The recent descriptions of the gene lesion for most of the disorders are rapidly changing the classification of these conditions. All of the congenital myopathies are rare, with an incidence of less than 1 per 100,000.

Since many of the congenital myopathies have a similar clinical picture, their differential diagnosis, evaluation, and management are also similar. The specific distinguishing clinical features of the individual congenital myopathies are described. Although the diagnostic label of congenital myopathy has historically implied that muscle weakness is present at birth, there are several exceptions. Presentation may occur in utero with reduced fetal movements, and there may be a delayed second stage of labor. Additionally, a higher incidence of assisted delivery with its consequent complications resulting from fetal hypotonia is reported. The commonest

presentation in these disorders is a floppy baby who has delayed motor milestones. In school, these individuals usually have difficulty in keeping up with their peers, either in sports or simply in walking. Some patients may present in later childhood or even as adults. Early weakness usually becomes manifest as difficulty in rising from a chair or the floor and in climbing stairs. In some patients with congenital myopathies, facial weakness or ophthalmoplegia is seen. In those in whom the disease has an early onset, the muscle weakness can lead to skeletal defects, causing dysmorphic features, kyphoscoliosis, and pes cavus. Diaphragmatic or chest wall involvement can give rise to respiratory weakness with carbon dioxide retention, particularly at night, causing morning headaches or daytime somnolence. Such respiratory weakness is usually a late feature of the congenital myopathies, but in nemaline myopathy it occurs early. As a rule, the congenital myopathies are stable or only slowly progressive, and many patients are remarkably active despite their weakness.

NEMALINE MYOPATHY

This particular congenital myopathy is defined by the presence of rods in the muscle biopsy. These structures stain red using Gomori trichrome stain, and it is their threadlike appearance that gives this condition its name, *nema* being Greek for thread. Electron microscopy shows that the rods represent an abnormal deposition of Z-band material. The cause of this and its relevance to the subsequent development of nemaline myopathy are unknown. Rods are not exclusive to nemaline myopathy and can be seen in other muscle disorders, including polymyositis, human immunodeficiency virus (HIV)-related myopathy, and muscle injured by tenotomy. Nemaline myopathy occurs sporadically quite often, but autosomal dominant inheritance linked to chromosome 1q (alpha tropomyosin), ^[15] and autosomal recessive cases linked to chromosome 2q^[16] have been demonstrated.

The usual clinical picture of nemaline myopathy is one of mild and progressive myopathy present from birth; however, some individuals are more severely affected, and early death is associated. In addition, some patients with adult-onset disease appear to have profuse rods on muscle biopsy but lack the usual clinical phenotype. Typical clinical signs include generalized reduction of muscle bulk, generalized limb weakness, and mild facial weakness but no ocular signs. Cardiac involvement is unusual. The facial appearance is characteristic and is marked by a high arched palate and a long thin face. Respiratory failure, due to involvement of the diaphragm, is an early feature that can have a major impact on the prognosis.

MYOTUBULAR-CENTRONUCLEAR MYOPATHY

The key morphological abnormality in this disorder is the presence of central nuclei, which occupy between 25

and 80 percent of the muscle fibers, more often the type 1 fibers. A halo around the central nuclei is often present, which shows increased oxidative enzyme activity, and glycogen staining, but reduced amounts of ATPase staining. The original term, myotubular myopathy, was based on the resemblance of these morphological abnormalities to that of myotubes. The later and preferred term of centronuclear myopathy is more descriptive and avoids assumptions about the cause of the abnormality. Because of the resemblance to myotubes, the findings in this disorder were thought to represent a maturational arrest with failure of the normal peripheral migration of nuclei during differentiation. However, the morphological similarities of this disorder to myotubes are only superficial, and central nuclei can appear after infancy. Many of these cases are hereditary, and autosomal recessive, autosomal dominant, and X-linked varieties have been described. The X-linked variety has been linked to chromosome Xq28 (myotubularin).^[19]

Prominent ptosis and ophthalmoplegia distinguish this disease from the other congenital myopathies. Cardiac involvement is not common. A variety of skeletal malformations occur, resulting in a Marfanoid habitus with a long narrow face and a high arched palate. A more severe X-linked variety that has an in utero and neonatal presentation is recognized. These patients have severe generalized weakness with bulbar and respiratory involvement but less ptosis and ophthalmoparesis.^[17] With intensive initial support, some improvement may occur, but these patients remain severely disabled and are prone to sudden death from aspiration. A late childhood or adult-onset variant is also seen; these patients present with mild limb weakness without ptosis, ophthalmoparesis, or dysmorphic features.

CENTRAL CORE DISEASE

The key morphological abnormality in this disorder is the presence of central or eccentric cores that do not stain for glycogen or oxidative enzymes but sometimes do stain with ATPase. The cores have a predilection for type 1 muscle fibers, which are the predominant fiber type on biopsy. The cause is unknown. The resemblance of the cores to the target fibers, seen in denervating muscle, suggests that central core disease may be a disorder of innervation, but unlike the targets, cores run the whole length of the fiber. The disease is inherited in an autosomal dominant fashion or is occasionally sporadic. This disease may be allelic because malignant hyperthermia also has point mutations of the ryanodine receptor on chromosome 19q13.1.^[19], ^[20]

Distinguishing features are the lack of cranial involvement apart from an occasional mild facial weakness, the frequency of congenital dislocation of the hip, and the occasional coexistence of malignant hyperthermia. As in patients with malignant hyperthermia, anesthetic precautions are required.

OTHER CONGENITAL MYOPATHIES

A variety of other morphological abnormalities have been described in cases marked by a presentation typical of congenital myopathy, and they have names to match--minicore, multicore, finger print body, zebra body, sarcotubular, and hyaline body myopathies. There are too few case reports of these myopathies to be sure that they are necessarily distinct myopathies or to discern a distinct phenotype.

CONGENITAL FIBER-TYPE DISPROPORTION

There is considerable doubt about whether this entity represents a distinct type of congenital myopathy. The description of congenital fiber-type disproportion arose from a survey of congenital myopathies by Brooke, who found several patients in whom the type 1 fibers were at least 12 percent smaller than type 2 fibers.^[21] This was an isolated finding in some cases, while in others it coexisted with other more striking pathological abnormalities. Later work suggested that the pathological criteria should be refined to include the requirement that type 2 fibers be of normal or increased size to distinguish this disorder from mild spinal muscular atrophy.^[22]

Initially, it was suggested that these pathological appearances had some prognostic value in that all the patients in Brooke's original series showed no progression of muscle weakness after 2 years of age, and some even improved. This has not been borne out by subsequent studies. No specific pathophysiological explanation has been advanced for the pathological picture, and there is no genetic marker for it.

Differential Diagnosis. The differential diagnosis of all congenital myopathies involves the evaluation of a floppy infant. There are a wide range of causes of this condition, most of which are central or neurogenic rather than myopathic. The neurogenic causes are usually central, although hereditary neuropathies causing dysmyelination or hypomyelination as well as anterior horn disease (i.e., spinal muscular atrophy) may also present with the appearance of a floppy baby. Central nervous system disorders may be marked by upper motor neuron features, seizures, or intellectual impairment, but recognition of some of these features may be difficult. Among the myopathic causes, a distinction should be made between the congenital muscular dystrophies, congenital myotonic dystrophy, congenital myasthenia (see later discussion), and the metabolic myopathies.

Evaluation. Creatine kinase levels are normal or only mildly elevated in patients with the congenital myopathies. Neurophysiological studies are useful in excluding the neuropathies and myasthenias. In the congenital myopathies, nerve conduction studies are normal, and the EMG may show only mild, nonspecific myopathic features. Definitive diagnosis of a congenital myopathy rests on the morphological characteristics seen on muscle biopsy. These morphological abnormalities must be present in substantially increased numbers to make the diagnosis. Any of the pathological findings may be nonspecific findings in other neuromuscular disorders. In some cases of congenital myopathy, the muscle biopsy may show only minor nonspecific myopathic features. This may reflect a selectivity of muscle involvement, and when other causes have been excluded, a label of "nonspecific congenital myopathy" may be applied.

Management. There is no specific treatment for any of the congenital myopathies. The association of central core disease with malignant hyperthermia makes it prudent to avoid precipitating factors such as the volatile gases used in general anesthesia. Otherwise, management of patients with the congenital myopathies is

supportive, and particular regard should be paid to the prevention of secondary complications such as contractures and progressive kyphoscoliosis. Bracing may be an effective means of maintaining ambulation but is usually unsatisfactory. Respiratory and cardiac function should be regularly assessed and appropriate support given.

Malignant Hyperthermia

Malignant hyperthermia is a hereditary skeletal muscle disease characterized by a hypercatabolic reaction of muscle to anesthetic agents or to physical or emotional stress.

Pathogenesis and Pathophysiology. The central event in malignant hyperthermia appears to be an increase in the calcium concentration, which results in continuous activation of the actin-myosin contraction apparatus and sustained muscle contraction. This increase in calcium level is due to an increased release of calcium from the sarcoplasmic reticulum of the muscle combined with a reduction in calcium reuptake. The continuous muscle activity results in muscle rigidity, muscle necrosis, hyperpyrexia, and hypermetabolism. Linkage has been found to chromosome 19q13.1. A ryanodine receptor gene in this region has been shown to have mutations in a proportion of cases. The ryanodine receptor is a calcium-releasing channel involved in calcium homeostasis. Linkage has also been found to chromosome 17q1.2-24, which codes for the alpha subunit of the sodium channel, and to chromosomes 7q and 3q.^[23], ^[24]

Epidemiology and Risk Factors. Malignant hyperthermia has a worldwide distribution and an incidence of 1 in 12,000 anesthetic incidents in children and 1 in 50,000 anesthetic events in adults.^[25] However, it is possible that many mild cases are unrecognized and are mistaken for other anesthetic complications. Males are more often affected than females, and there is a peak incidence at the age of 30 years. Thereafter, the incidence declines, and cases are virtually unheard of beyond the age of 75 years.^[25]

Clinical Features and Associated Disorders. The most common precipitating event is halothane general anesthesia. The muscle relaxant succinylcholine is a milder trigger of attacks when administered alone but is more potent when combined with halothane. The likelihood of triggering an attack with these agents is increased if the patient has been exercising vigorously beforehand or is under stress at the time of anesthetic induction. Between attacks of malignant hyperthermia, patients rarely have any muscle symptoms, although some muscle diseases, such as congenital myopathies, are associated with attacks of malignant hyperthermia. In 50 percent of cases of malignant hyperthermia, patients may have had previous anesthesia without complications.^[25] Attacks often start with jaw spasm followed by generalized muscle spasm and rigidity. These signs are associated with hyperventilation, tachycardia, and an unstable blood pressure. A mottled, flushed, and cyanotic skin rash may appear. After an interval of 15 to 16 minutes, the body temperature may start to rise precipitously. Metabolic and respiratory acidosis, hypoxemia, generalized vasoconstriction, and an increased cardiac output occur. The serum potassium may rise, and the CK may rise 100-fold. Consequent complications of myoglobinuria and disseminated intravascular coagulation may occur, either of which can lead to renal failure. During recovery, patients may experience a further relapse with signs and symptoms.

Differential Diagnosis. The condition that most closely resembles malignant hyperthermia is the neuroleptic malignant syndrome (NMS), in which patients have an abnormal response to dopamine-blocking agents or levodopa withdrawal. Patients with NMS develop rigidity with hyperthermia and have many of the same biochemical features seen in malignant hyperthermia. Neuroleptic malignant syndrome usually occurs in patients with psychiatric disease who are undergoing neuroleptic drug treatment or, rarely, with the abrupt cessation of levodopa. Acute dystonic reactions to drugs such as neuroleptics or antiemetics may produce a similar picture of increased muscle tone. Patients with myotonia may also develop rigidity with the use of depolarizing agents during anesthetic induction.

Evaluation. During the acute illness the main emphasis of the evaluation is on monitoring possible hyperkalemic, cardiac, respiratory, or renal complications, so that appropriate measures can be taken. Evaluation of well patients thought to be at risk of developing malignant hyperthermia can be difficult. Only a few have a raised CK level. The genetic heterogeneity of the disease and the fact that even the recognized point mutations cover only a small percentage of the patients at risk limit the value of genetic testing. A variety of in vivo tests have been purported to highlight individuals at risk, but these are not particularly reliable. The screening test typically used is the in vitro caffeine and halothane contracture test. In this study an exaggerated response to these agents in freshly isolated muscle is observed in patients with a predisposition to malignant hyperthermia. This test is performed only in specialized centers. Unfortunately, an overlap between normal and affected individuals occurs, and false-positive tests are possible.^[36]

Management and Prognosis. Preventive measures include the avoidance of precipitating agents, namely, halothane and succinylcholine, but many other agents pose some risk in susceptible individuals. Patients should be advised to wear Med-Alert bracelets to warn of their susceptibility to malignant hypothermia. Narcotics, barbiturates, benzodiazepines, nitrous oxide, and nondepolarizing muscle relaxants are generally safe. Acute management consists of removal of the triggering agents and supportive measures as required. Body cooling may be required in response to the hyperthermia, which if allowed to continue aggravates the metabolic derangement. Dantrolene is the mainstay of treatment; when given intravenously, it results in the reversal of the abnormalities. The mortality rate has dropped since the use of this agent has been instituted. Improved recognition of this complication and better supportive measures with the availability of dantrolene have

728

resulted in a dramatic drop in mortality from 65 to 2 percent.

Brody's Disease

This disorder was first described by Brody in 1969.^[27] Although it resembles myotonia clinically, the crucial difference is that the EMG of affected muscle shows no myotonic discharges. This is a rare disorder, and only about 21 cases have been recorded in the literature.^[28]

This disorder usually begins in childhood, and patients often have difficulty in keeping up with their peers in physical activities. They have poor relaxation of muscles, initially in the limbs but later in the face and trunk as well. This pseudomyotonia is made worse by exercise and cold weather, and myoglobinuria occurs in some. On examination, these patients are found to have eyelid and grip but not percussion myotonia. There may be mild muscle atrophy and weakness in the final stages of the disease.

This pseudomyotonia is thought to result from abnormalities in sarcoplasmic reticulum Ca²⁺ ATPase, a transmembrane protein responsible for extruding calcium out of the cytoplasm and into the sarcoplasmic reticulum. This 100-kD protein is coded for on chromosome 16 and is deficient in amount or activity, particularly in type 2 muscle fibers.^[29] Genetic heterogeneity is suggested by reports of autosomal dominant and either autosomal or X-linked recessive inheritance.

The differential diagnosis of Brody's disease includes myotonia and pseudomyotonia as described earlier. The CK level may be normal or slightly elevated, particularly in patients with associated myoglobinuria. Muscle biopsy shows type 2A and B atrophy with angulated fibers. EMG shows electrical silence during the time of apparent myotonia. Biochemical and immunological assays of sarcoplasmic reticulum Ca²⁺ ATPase may be employed to make the diagnosis.

Empirical treatment with dantrolene and calcium channel blockers has been used with varying success. The disease is slowly progressive or stationary, but in some individuals exercise-induced pseudomyotonia becomes worse as they get older.

NEUROMUSCULAR JUNCTION DISORDERS

Congenital Myasthenias

The onset of myasthenic symptoms at birth or in patients with a family history of this disease has always made congenital forms of myasthenia a diagnostic possibility. With the advent of the acetylcholine receptor (AChR) and the calcium channel antibody test as markers for myasthenia gravis and Lambert Eaton myasthenia, it has become apparent that congenital myasthenia, like the congenital myopathies, may present later in life and, in some cases, without a family history.

Pathogenesis and Pathophysiology. Congenital defects of the neuromuscular junction can be divided into presynaptic, synaptic, and postsynaptic defects ([Table 37-3](#)). Presynaptic disorders include defects in the synthesis of acetylcholine or in its packaging into the presynaptic vesicles, which reduces the amount of acetylcholine available for release. Synaptic defects involve a deficiency of acetylcholinesterase. Postsynaptic defects consist of abnormal function or numbers of acetylcholine receptors. Not all the congenital myasthenic syndromes have a well-defined cause. Some appear to be sporadic, but among the inherited cases, autosomal recessive inheritance is most common. The slow channel syndrome is inherited as an autosomal dominant trait.

Epidemiology and Risk Factors. Precise incidence figures are not available, but the congenital myasthenias represent a minority of patients with myasthenia and are rare diseases. Some patients with congenital myasthenia undoubtedly remain undiagnosed and later in life are presumed to have serologically negative autoimmune myasthenia, particularly if they respond well to anticholinesterase treatment.

Clinical Features and Associated Disorders. Only the broad clinical features of the congenital myasthenias are described; the individual syndromes are listed in [Table 37-3](#).^[29],^[31] Presentation of the congenital myasthenias can be similar to that of congenital myopathies, with presentation as a floppy baby. These patients may have difficulty with feeding, delayed motor milestones, and persistent or sometimes progressive limb weakness. Skeletal abnormalities can result from this weakness. Ocular, bulbar, and respiratory weakness may occur, but some of the syndromes are notable for the lack of ocular involvement. Other syndromes have a characteristically later time of onset, typically in the second or third decade. The distinguishing feature is fatigability or fluctuating weakness, usually becoming worse with activities such as feeding, crying, or moving. In patients with some of the myasthenic syndromes, episodic exacerbations occur with fever or emotional

TABLE 37-3 -- CLASSIFICATION OF THE CONGENITAL MYASTHENIAS

PRESYNAPTIC DEFECTS
Defect of ACh resynthesis or packaging
Paucity of synaptic vesicles and reduced quantal release
BOTH PRESYNAPTIC AND POSTSYNAPTIC DEFECTS
End-plate AChE deficiency
POSTSYNAPTIC DEFECTS
Kinetic abnormalities of AChR with AChR deficiency
Classic slow channel syndrome
Epsilon subunit mutations
AChR deficiency and short channel open time
Kinetic abnormalities of AChR without AChR deficiency
High-conductance fast channel syndrome
Syndrome attributed to abnormal interaction of ACh with AChR
PARTIALLY CHARACTERIZED SYNDROMES
Other AChR deficiencies
Congenital myasthenic syndrome resembling LEMS
Congenital myasthenic syndrome with facial malformations
Familial limb girdle myasthenia

LEMS, Lambert-Eaton myasthenic syndrome; ACh, acetylcholine; AChR, acetyl-choline receptor; AChE, acetylcholinesterase.

upset and at times with no obvious reason. The physical examination is characterized by fatigable weakness. Fixed weakness is usually generalized, but very selective weakness is described. Delayed pupillary responses occur in some cases. Reflexes are generally but not invariably preserved.

Differential Diagnosis. The same differential diagnosis applies to these conditions as to the congenital myopathies. Clinical distinction from mitochondrial myopathy may be difficult because this latter disorder can also present with fatigable weakness. Neonatal botulism must be excluded. Once the diagnosis of a myasthenic syndrome has been made, a differentiation of congenital from acquired autoimmune myasthenia may be required, particularly in patients with late-onset disease who lack a family history. Neonatal myasthenia due to passive placental transfer of AChR antibodies usually occurs in offspring of obviously affected AChR antibody-positive mothers.

Evaluation. A positive AChR antibody test excludes a congenital myasthenia, but because cases of AChR antibody-negative myasthenia gravis exist, a negative test is less helpful. A positive edrophonium (Tensilon) test confirms the presence of a myasthenic syndrome but does not differentiate congenital myasthenia from myasthenia gravis. It may be negative in some patients with congenital myasthenia in whom there is a deficiency of acetylcholinesterase. EMG studies may show a decrement in the compound muscle action potential to repetitive stimulation but at 10 Hz rather than the typical 3 Hz. Single-fiber EMG may show excess jitter and blocking. Morphological, immunostaining, and immunochemical techniques and in vitro neurophysiological tests on intercostal muscle containing motor end plates are research methods for confirming and characterizing the nature of a congenital myasthenia.^[29],^[31] Genetic analysis may show, for example, mutations of genes encoding for subunits of AChR.^[29]

Management. Respiratory and bulbar complications require appropriate supportive measures. Depending on the precise nature of the congenital myasthenia, some patients may respond to anticholinesterase treatment. Those patients who do not respond to anticholinesterases may benefit from treatment with 3,4,-diaminopyridine.^[32]

NEURONAL DISORDERS

Familial Amyloid Polyneuropathy

In amyloidosis, extracellular deposition of amyloid occurs in a variety of organs such as the heart, intestinal tract, liver, and kidneys. In amyloid neuropathy, deposition of amyloid in peripheral nerves predominates. Amyloid neuropathy may be due to acquired, usually immunoglobulin-derived, amyloid, or it may be hereditary, as in familial amyloid polyneuropathy. Amyloid is a class of glycoproteins that have a fibrillar beta sheet structure and may be derived from a variety of precursor proteins. In familial amyloid polyneuropathy, the dominant form of amyloid is derived from transthyretin (TTR), but it may also be derived from apolipoprotein A1 and gelosin. Initially, familial amyloid polyneuropathy (FAP) was described on a clinical basis, and four types were recognized. Despite overlap with the recent and increasing discoveries of specific gene mutations, this original classification is still useful ([Table 37-4](#)).

Pathogenesis and Pathophysiology. To date, 36 mutations of the TTR gene have been described as well as mutations of the apolipoprotein A1 and gelosin protein genes. These are all autosomal dominant conditions with reduced penetrance, and most individuals are heterozygous for the given mutation. Some individuals who are homozygous for the Met 30 TTR mutation have been described, but there are no differences in their clinical phenotype compared to that of heterozygous individuals. The Met 30 mutation has arisen spontaneously in different parts of the world.^[33] In contrast, the Ala 60 TTR mutation, which was first described in a family in the Appalachian region, has been found to be due to a founder effect, which originated in Ireland.^[34]

The deposition of amyloid may occur within the nerve rather than being derived from circulating amyloid. In the TTR-associated FAP with the Met 30 mutation, axonal loss that affects unmyelinated and small unmyelinated fibers and subsequently larger fibers is seen. Although axonal degeneration is the predominant pathological finding, segmental demyelination is also evident. The amyloid may have a diffuse or patchy distribution. On biopsy, amyloid deposition may be present only in proximal nerves and absent in distal nerves. Three patterns of amyloid deposition are seen: in the connective tissue of the peripheral nerves, in the endoneurial tissue, and in the vasa nervorum. The mechanism by which amyloid deposition leads to neuropathy is unclear. Some researchers have argued that the neuropathy results from a generalized metabolic disorder and that amyloid deposition is a secondary event. Deposition within the endoneurial vessels might result in ischemic nerve but would not fully explain the selectivity of small fiber involvement. Endoneurial blood vessel deposition of amyloid might alter vascular permeability, with consequent endoneurial edema contributing to the compressive damage of the nerves. Compressive damage may also result

TABLE 37-4 -- CLASSIFICATION OF FAMILIAL AMYLOID POLYNEUROPATHIES (FAP)

FAP Type	Clinical Phenotype	Amyloid Precursor	Common Mutation
Type 1 (Portuguese)	Lower limb neuropathy	Transthyretin	Met 30 (plus others)
(Irish/Appalachian)		Transthyretin	Ala 60
Type 2 (Indiana)	Upper limb neuropathy	Transthyretin	Ser 84, His 58 plus others
Type 3 (Iowa)	Lower limb neuropathy	Apolipoprotein A1	Arg 26
	Nephropathy		
	Gastric ulcers		
Type 4 (Finnish)	Cranial neuropathy	Gelosin	Asp 187, Tyr 187
	Corneal dystrophy		

from the deposition of amyloid in the connective tissue surrounding the peripheral nerve. The presence of segmental demyelination favors a compressive etiology but is not the dominant pathology.

Epidemiology and Risk Factors. The most common FAP, the TTR-associated FAP with a Met 30 mutation, has been described in 500 Portuguese families, and the gelosin-derived FAP has been reported in 200 Finnish families. In contrast, some FAP mutations have been confined to a single family.

Clinical Features and Associated Disorders FAP Type 1 (Portuguese). This TTR-derived FAP was originally described in Portugal but has now been found in a wide variety of locations including Scandinavia and Mediterranean countries as well as North and South America and Japan. The age of onset varies with ethnic origin. The Portuguese develop symptoms in their twenties or thirties, whereas the Swedes and the French become symptomatic in their late fifties. The initial symptom is painful dysesthesia with attacks of stabbing pain in the lower limbs. With initial small fiber involvement, loss of pain and temperature sensation is reported. Patients are prone to foot ulcers, osteomyelitis, Charcot joints, and trophic skin changes. The neuropathy slowly progresses and eventually involves all nerve fiber types and all sensory modalities. Subsequent motor involvement results in muscle wasting and weakness with loss of reflexes. Months or years after the onset of disease in the lower limb, the upper limbs may become involved. Carpal tunnel syndrome may occur but is rarely a presenting feature. Autonomic neuropathy is frequent and is severe in some cases, with associated postural hypotension, impotence, gastrointestinal dysmotility, urinary difficulties, and dry skin. Cardiac amyloid deposition may be asymptomatic but can result in dysrhythmias and either a restrictive or hypertrophic cardiomyopathy. Renal involvement is occasionally severe.

The majority of patients with this clinical picture have the common TTR Met 30 mutation, but there are a large number of other point mutations in the TTR gene that give rise to a similar clinical picture. The Ala 60 Thr TTR point mutation gives rise to an Irish-Appalachian variant of FAP, which has the distinguishing features of a later onset (the sixth and seventh decades), prominent motor and large fiber sensory involvement, and more severe and symptomatic cardiac involvement.

FAP Type 2 (Indiana). This form was originally described in families of Swiss origin in Indiana and of German origin in Maryland. Patients present in middle life, commonly with bilateral carpal tunnel syndrome and vitreous opacities. Some patients, particularly males, have a more generalized neuropathy, with motor features in the upper limbs that then spread to the lower limbs. Autonomic neuropathy can occur, but both this and the generalized neuropathy are rarely disabling. Hepatosplenomegaly may occur. The vitreous abnormalities can cause severe visual impairment. The original cases had a Ser 84 or His 58 TTR point mutation, but a variety of other mutations have been described.^{[35], [36]}

FAP Type 3 (Iowa). This disorder has many features in common with FAP type I. Upper and lower extremities are affected, but usually there is no associated carpal tunnel syndrome. Peripheral neuropathy can be severe, but the autonomic neuropathy is less prominent. Peptic ulceration may occur, and renal involvement results in hypertension and uremia. Amyloid deposition also occurs in the liver, adrenal glands, and testes. This type of FAP is associated with apolipoprotein A1-derived amyloid, and a substitution of arginine for glycine has been found in nucleotide 26 of the gene.

FAP Type 4 (Finnish). This form of FAP was first described in a Finnish family but has since been reported in Dutch, Japanese, and Irish-American families. Corneal dystrophy begins in the thirties but is usually asymptomatic. A progressive cranial neuropathy then occurs that involves principally the facial nerve, although the trigeminal, hypoglossal, and vestibular nerves may also be involved. The facial skin becomes initially thickened and then atrophic. A mild generalized sensory and autonomic neuropathy then ensues. Although cardiac deposition of amyloid has been reported, this is rarely symptomatic. In these cases, the amyloid precursor protein is gelosin, and two mutations have been described in this gene thus far.^{[37], [38]}

Differential Diagnosis. The differential diagnosis of FAP varies with the presentation and is wider when there is no family history. Presentation with a painful, distal, and mainly sensory neuropathy of small-fiber type poses a differential diagnosis of leprosy, diabetes, vasculitis, or paraneoplastic associated neuropathies. Familial small-fiber neuropathies include type 1 hereditary sensory neuropathy and the neuropathy associated with Tangier's disease. Presentation with carpal tunnel syndrome requires differentiation from hypothyroidism, diabetes, osteoarthritis, and acromegaly. Carpal tunnel syndrome may also occur in patients undergoing hemodialysis, in whom there is deposition of beta-microglobulin derived amyloid. Presentation with prominent autonomic symptoms may require differentiation from other hereditary diseases such as familial dysautonomia (Riley-Day syndrome), dopamine beta-hydroxylase deficiency, and Fabry's disease.

Evaluation. Hematological and biochemical tests may reflect hepatic, renal, or gastrointestinal infiltration with amyloid. In isolated cases of amyloid neuropathy a careful search for monoclonal antibodies is required to exclude acquired amyloidosis. Urine and serum should be screened; they may be found positive in up to 85 percent of cases, gamma chains being the predominant monoclonal species. ECG may show evidence of cardiac involvement with conduction disturbances including

heart block or abnormalities such as widespread Q-wave and T-wave repolarization changes. Echocardiography can show either a restrictive or hypertrophic cardiomyopathy. Autonomic function tests typically reveal abnormal responses of blood pressure and heart rate to postural change and other provocative measures. Neurophysiological studies show an axonal neuropathy, but in the early stages when only small-diameter fibers are involved, the sensory nerve action potentials may be preserved. Sensory and motor conduction velocities are usually normal or only slightly reduced. EMG demonstrates evidence of chronic partial denervation in longstanding cases. In FAP type 4, electrophysiological studies show evidence of both axonal degeneration and demyelination. The histological diagnosis of amyloid requires pathological demonstration of amyloid deposition, detected by staining with Congo red, and the characteristic green bire

fringe with polarizing filters. Electromicroscopy can also reveal the characteristic fibrillar appearance of the protein. Rectal tissue is most accessible to sample. Immunohistochemistry can characterize the nature of the amyloid, although there may be technical difficulties in doing this when only small amounts of amyloid are present. TTR antibody immunohistochemistry is negative in some cases if TTR is not the precursor for the amyloid. It is also possible to detect variant TTR in the blood using autoimmune assay and enzyme-linked immunosorbent assay techniques. Screening tests for the common TTR mutations are available. When there is a high index of suspicion and evidence of a variant TTR is present, sequencing of the entire TTR gene may be justified in the absence of one of the common mutations.

Management. The mainstay of treatment is supportive in patients with autonomic, renal, gastrointestinal, and vitreous complications. Plasma exchange, in the hope of removing the circulating amyloid protein, has not been successful. Since over 90 percent of TTR is synthesized in the liver, some patients have undergone liver transplantation, resulting in a significant decline in the circulating TTR levels and reported stabilization of some symptoms, including the neuropathy. However, liver transplantation remains a hazardous procedure, particularly in those patients with autonomic involvement,^[39]^[40] and the optimal timing of such a procedure is unclear.

Prognosis and Future Perspectives. The prognosis of the different forms of FAP varies. In patients with FAP type 1, death from sepsis and systemic disease occurs about 15 years from the onset, but in late-onset cases, disease progression may be slower. In FAP type 2, peripheral neuropathy and autonomic involvement are not severe, and individuals may survive as long as 35 years with some disability. However, the vitreous disposition may lead to severe visual loss. In FAP type 3, peripheral neuropathy becomes disabling over the course of 10 years, and death is the result of renal failure over a 20-year period.

Undoubtedly, further mutations will be added to the 36 known mutations of the TTR gene, and further mutations for the other amyloid variants will be found as well. Already some knowledge of how these precursor variants become amyloidogenic is available, which may lead to ways of intervening in this process. A future suggested treatment is extracorporeal immune absorption onto TTR antibodies, which may be the subject of future clinical trials.^[41]

Giant Axonal Neuropathy

Giant axonal neuropathy is a rare condition. There is a high proportion of spontaneous cases, but reports of autosomal recessive inheritance exist.^[42] Symptoms begin in childhood with a slowly progressive peripheral motor and sensory neuropathy. Patients often have characteristically abnormal tight curly black hair. Central nervous system involvement can include intellectual impairment, optic atrophy, cerebellar ataxia and nystagmus, and corticospinal disturbance. Death usually occurs in adolescence.

The presence of intermediate filaments in a variety of cell types suggests that the abnormality is not confined to axons and hair. Decreases in disulfides and increases in thiol groups have been noted in hair samples from patients, but the primary cause of this disorder is unknown.^[43] Investigation may show mildly reduced motor conduction velocities and sensory nerve action potentials. Diagnosis is made by nerve biopsy, which shows evidence of axonal loss with focal swellings along the nerve, which on electron microscopy are seen to contain neurofilament accumulations. The management is supportive.

Isaac's Disease

In this syndrome, neuromyotonia or hyperexcitability of the peripheral nerves results in spontaneous and continuous muscle electrical activity. Although in some cases the disease is inherited, in the majority it is acquired. The continuous discharges may originate anywhere along the length of the peripheral nerve. There is some association between Isaac's syndrome and autoimmune disease, and it is thought that the acquired varieties are autoimmune in origin. In support of this idea, antibodies against potassium channels have been demonstrated. The hereditary disease is believed to be a genetic defect in the potassium channel, an assumption strengthened by the coexistence of myokymia in autosomal dominant episodic ataxia type I, which is a known genetic defect of the potassium channel.^[44] The syndrome is rare, and assessment of its frequency and its definitive clinical features is hampered by the variable names given to the disorder in the past. Typically, patients have muscle stiffness, cramps, and myokymia. They may also have generalized weakness and sweating. Onset occurs at any time during life, and the condition tends to be chronic. Motor features are most prominent in the limbs and trunk. Respiratory muscle involvement can cause breathing difficulties, and laryngeal involvement can cause stridor. Physical examination may reveal mild weakness with reduced or absent tendon reflexes and evidence of myokymia, which results in occasional muscle hypertrophy.

Myokymia can arise from peripheral nerve damage of any origin. It is also a feature of autosomal dominant episodic ataxia type I. The features of cramps and stiffness should raise the differential of Brody's disease, stiff person syndrome, and the myotonias. The EMG can confirm the diagnosis by showing doublet, triplet, or multiplet spontaneous motor unit discharges, which may be present even in the absence of visible myokymia. Nerve and muscle biopsies show nonspecific features, and in a few cases, oligoclonal IgG has been found in the CSF.^[45]

Anticonvulsant medications such as phenytoin and carbamazepine have been the first line of treatment. Plasma exchange may be appropriate when an autoimmune cause is thought to be likely. In some of these latter cases, immune suppression with corticosteroids and azathioprine has been tried.^[45]

ELECTROLYTE ABNORMALITIES

Sodium Disorders

Although dietary intake varies, body fluid composition and volume remain fairly constant, a reflection of multiple compensatory mechanisms. Although it is frequently cited that total body water (TBW) constitutes approximately 60 percent of body weight, the percentage varies with age, gender, and body habitus from 42 percent (obese, elderly female) to 75 percent (infant).^{1,2} The cell membrane serves as an interface between the intracellular fluid and extracellular fluid (ECF) compartments; their ratio is roughly 2 to 1. About three fourths of ECF is interstitial, while the remaining one fourth is intravascular (blood volume). The blood volume consists of plasma and formed elements, with plasma volume being approximately 95 percent water and 5 percent macromolecules (e.g., albumin). The interface between the interstitial and intravascular compartments is the capillary, which does not permit crossing of macromolecules. For that reason, the interstitial fluid is an ultrafiltrate of the plasma, and therefore their electrolyte concentrations are similar.

Starling forces determine the direction of water flow between compartments. Because the cell membrane is water permeable, whenever an intercompartmental osmolal gradient develops, water passively moves down its concentration gradient, from an area of lower osmolality to one of higher osmolality, thereby maintaining osmolal equilibrium. Solutes that are freely permeable across the membrane (e.g., urea) are referred to as ineffective osmoles, because they do not form significant osmolal gradients across the membrane. Conversely, membrane impermeable solutes (e.g., glucose, sodium [Na], mannitol, glycerol) are referred to as effective osmoles because they do create osmolal gradients across the membrane.^{1,2} Because the different fluid compartments are in osmolal equilibrium, the serum osmolality is a good reflection of the intracellular osmolality and can be approximated using the following formula^{1,2}:

$$\text{Serum osmolality} = 1.86 \text{ Na} + \text{BUN}/2.8 + \text{Glucose}/18 + 9,$$

where Na concentration is expressed in milliequivalents per liter (mEq/L) and blood urea nitrogen (BUN) and glucose concentrations are expressed in milligrams per deciliter (mg/dl). A discrepancy between *calculated* and *measured* osmolality indicates the presence of other serum osmoles. By monitoring the osmolality and volume of the ECF, the body maintains its fluid composition and volume fairly constant.^{1,2}

HYPONATREMIA

Pathogenesis and Pathophysiology. Hyponatremia reflects an excess of water, relative to Na. Because Na is an effective osmole, intercompartmental Na imbalances must be corrected by water movement. This can produce brain edema, which, in turn, may produce pulmonary edema, central diabetes insipidus (DI), cerebral infarction, cortical blindness, persistent vegetative state, respiratory arrest, and coma.^{1,2} Hyponatremic patients can be subdivided into hyperosmolal, normo-osmolal, and hypo-osmolal types. The hypo-osmolal type is the most frequent category and is

usually further subdivided, based on ECF volume, into hypervolemic, normovolemic, and hypovolemic ([Table 38-1](#)).

The neurological symptoms associated with hyponatremia primarily reflect central nervous system (CNS) involvement (e.g., encephalopathy, seizures) and are related to the rapidity of the onset of the lowered Na level. Brain cell compensatory mechanisms exist to counter hyponatremia (see Clinical Features and Associated Disorders) but require time to occur. When hyponatremia occurs acutely, water passively flows down its concentration gradient, resulting in its entry into the brain cells, thereby producing cerebral edema. The cause of peripheral neurological symptoms and signs (cramping, muscle twitching, and fasciculations) are most likely related to altered ion conductances and abnormal discharges of the peripheral nerves.

Epidemiology and Risk Factors. Among hospitalized patients, the incidence of hyponatremia is about 1 percent and its prevalence is about 2.5 percent.^{1,2} Postoperative patients account for roughly 25 percent of all hyponatremic episodes.^{1,2} It is important to note that although the incidence of hyponatremia is similar between the sexes, premenopausal women have a significantly greater incidence of brain damage than do men or postmenopausal women.^{1,2} This is a reflection of Na/K ATPase pump inhibition (which blocks the first line of defense against hyponatremia) and antidiuretic hormone (ADH) release stimulation (which contributes to water retention) by the sex hormones.^{1,2} Another significant risk factor for hyponatremia-induced brain damage is hypoxia, a reflection of its inhibitory effect on Na/K ATPase transport activity which, therefore, compromises the brain's ability to compensate for the hyponatremia.^{1,2} Other high-risk populations are patients with acquired immunodeficiency syndrome, syndrome of inappropriate antidiuretic hormone (SIADH; pulmonary disease, intracranial disease, drug-induced), adrenal insufficiency, and isotonic fluid loss (emesis, diarrhea).^{1,2} Among pregnant patients, the misuse of oxytocin is the most common cause of hyponatremia.^{1,2}

Clinical Features and Associated Disorders. The most common clinical features of hyponatremia are gastrointestinal (GI) (e.g., nausea, vomiting, anorexia) and neurological, with CNS abnormalities predominating. The CNS

TABLE 38-1 -- MAJOR CAUSES OF HYPONATREMIA

Iatrogenic
Factitious (blood drawn proximal to hyotonic infusion)
Hyperosmolal (glucose, mannitol, radiocontrast)
Normo-osmolal (hyperlipidemia, hypeproteinemia)
Hypo-osmolal
Hypervolemic (decreased cardiac output, increased vascular compliance, water shift)
Normovolemic (SIADH, drugs, hypothyroidism)
Hypovolemic (renal, extrarena[e g, gastrointestinal, cutaneous, hemorrhage])

Data from Votey SR, Peters. AL Hoffman JR. Disorders of water metabolism hyponatremia and hypernatremia. Emerg Med Clin North Am 1989;7:749769; and Riggs JE: Neurological manifestations of electrolyte disorder In Aminoff MJ (ed): Neurologyand Genera] Medicine 2nd ed New York,Churchhill Livingstone 1995,pp 321-331.

symptoms reflect cerebral edema due to the passive movement of water from the hypo-osmolal ECF into the brain cells. Initial water entry into the cell stimulates solute extrusion, initially by the Na/K ATPase pump, which limits the amount of water entry required to restore osmotic equilibrium and may render the patient asymptomatic.^{1,2} The most common CNS manifestation is encephalopathy, ranging from mild confusion to coma, depending on the degree of cerebral edema, its rapidity of onset, and its absolute magnitude. Sodium levels above 125 mEq/L are usually associated with GI symptoms, whereas seizures, coma, and permanent neurological sequelae are typically only observed with levels below 115 mEq/L. Neurological features due to hyponatremia of slow onset may be much less apparent, although impaired cognition is typical with Na levels below 120 mEq/L.^{1,2} Asterixis, ataxia, and multifocal myoclonus may also be observed in acute hyponatremic encephalopathy but are less frequent than in uremic encephalopathy (UE).^{1,2} Focal neurological features may also be seen and usually remit with correction of the hyponatremia. These findings may represent underlying focal pathologies with a resultant lower threshold for clinical expression. Other reported neurological features of hyponatremia include respiratory depression, bizarre behavior, nystagmus, increased tone, and hallucinations. Opisthotonic posturing, respiratory arrest, and fixed and dilated pupils suggest cerebral herniation.^{1,2} Muscle cramping may occur, but fasciculations, tremor, and twitching are uncommon.^{1,2} An associated disorder related to hyponatremia, or rather its treatment, is central pontine myelinolysis (discussed later).

Differential Diagnosis. The principal causes of hyponatremia include primary dilutional hyponatremia, SIADH, diuretic usage, and water intoxication. Dilutional hyponatremia can be seen in edematous states, such as cirrhosis, nephrosis, and congestive heart failure (CHF), as well as with excessive water intake in the presence of renal failure (RF), Addison's disease, myxedema, and nonosmotic ADH secretion. Among hospitalized patients, the most common cause of *acute* hyponatremia is iatrogenic overhydration (e.g., excessive intravenous [IV] fluid administration) in the presence of impaired water elimination.^{1,2} SIADH occurs with oat cell carcinoma of the lung, a variety of CNS and pulmonary disorders, the Guillain-Barre syndrome, acute intermittent porphyria, and may also be idiopathic. Before finding a low Na level, the differential diagnosis of the above-mentioned clinical neurological syndrome should include drug intoxications, infections, endocrinopathies, and other electrolyte disorders.

Evaluation. When hyponatremia is identified, the possibility of an error, either by the laboratory or by the phlebotomist (e.g., sampling proximal to a hypotonic fluid infusion), should be considered. If hyponatremia is verified, the patient's past medical history and medication profile should be reviewed, because it may suggest the cause. A careful physical examination should be performed, and if possible, the ECF volume status should be ascertained, along with serum electrolytes, BUN, creatinine (Cr), and osmolality. Uric acid is inversely proportional to the volume status and, therefore, may be helpful in determining hypervolemic and hypovolemic states. The serum osmolality should be calculated and compared with the measured

733

osmolality, and, if a discrepancy exists, the presence of an unidentified serum osmole (e.g., mannitol) is suggested. Other studies to consider include thyroid functions, adrenal studies, and the evaluation of urine Na, fractional excretion of Na, osmolality, and pH.

Management. In all cases of hyponatremia, the underlying cause must be identified and treated, and iatrogenic hyponatremia prevented (e.g., avoidance of free water and hypotonic solutions [D₅W, 1/2 normal saline (NS)] in postoperative patients). Initial management is based on the type of symptoms, their rapidity of onset, and the underlying etiology. Acute-onset hyponatremia is usually associated with a marked increase in brain water and a risk of cerebral herniation; for that reason, the condition requires rapid treatment. This is especially true if seizures or a decreased level of alertness is present. If the condition is left untreated, acute hyponatremia is nearly always fatal. Water restriction in acute hyponatremia is never indicated, and hypertonic saline is given in an intensive care setting. In patients with chronic hyponatremia, however, hypertonic saline is not always indicated and may even be dangerous. Its management should be based on the presence of symptoms. Asymptomatic patients with volume depletion require repletion (with NS), and those with hormone deficiency (e.g., hypothyroidism, adrenal insufficiency) require hormone replacement. Patients with drug-induced hyponatremia require the discontinuation of the offending agent. Water restriction may be appropriate for some patients with asymptomatic hyponatremia. Demeclocycline, a tetracycline antibiotic that produces nephrogenic DI, can be used for the long-term management of patients with stable asymptomatic hyponatremia (e.g., SIADH).^[10]

Hyponatremic-induced seizures can be treated with IV 3 percent hypertonic saline at a dose of 4 to 6 ml/kg body weight.^[11] This dosage rapidly raises the serum Na level by about 3 to 5 mEq/L and avoids the risk of respiratory embarrassment associated with benzodiazepines and phenobarbital. Hyponatremic-induced seizures are more commonly associated with acute hyponatremia, in which case rapid normalization to a level of 120 to 125 mEq/L can be accomplished without risk of neurological complications. The serum Na concentration need not be corrected to normal to obtain seizure control, and overcorrection can be harmful. Therapy with hypertonic saline should be discontinued when the patient becomes asymptomatic or the plasma Na concentration increases by 20 mEq/L or reaches a value in the range of 120 to 125 mEq/L.^[1] To avoid potential complications, the plasma Na should never be acutely elevated to normonatremic levels and should not be increased by more than 25 mEq/L during the first 48 hours of therapy.^[12] In the setting of chronic hyponatremia, seizures are less common. Loop diuretics (e.g., furosemide) result in solvent loss greater than solute loss (i.e., net water loss) and can be used, in addition to the hypertonic saline, to raise the serum Na concentration.

Central pontine myelinolysis refers to the demyelinating lesions noted in the pons of patients with hyponatremia, which were previously believed to occur when the serum Na concentration was corrected too rapidly (discussed later; Fig. 38-1 (Figure Not Available)). Because myelinolysis also occurs outside of the pons, the term *osmotic myelinolysis* is also used by some physicians.^[13] Central pontine myelinolysis was first described in 1959^[14] in malnourished alcoholics and was later noted in hospitalized patients undergoing hydration.^[15] In 1980, Leslie and colleagues^[16] suggested that central pontine myelinolysis was due to rapid correction of hyponatremia. This led some physicians to suggest that the rate of hyponatremia correction should not exceed 12 mEq/L

Figure 38-1 (Figure Not Available) A 30-year-old woman with a history of alcoholism presented with confusion and disorientation following a seizure. The patient's serum sodium was 99 mmol/L, and she was treated with an infusion of normal saline. This resulted in a sodium value of 125 mmol/L 24 hours later. The patient initially had dysarthria, slow response on finger-to-nose testing, and was interactive on examination. On day 7 of admission, the patient became unresponsive and had new Babinski's signs. Brain magnetic resonance imaging demonstrated central pontine myelinolysis with a region of low signal intensity on a sagittal T1-weighted image (A) and high signal intensity on an axial T2-weighted image, which is marked by the arrow (B). The arrowheads in E show the relative preservation of the corticospinal tract (From Hart BL, Eaton RP: Images in clinical medicine--Osmotic myelinolysis. N Engl J Med 333:1259, 1995.)

734

per day.^[17] Others have suggested that the magnitude of correction determines whether or not neurological complications occur.^[12] Based on several prospective studies, Griggs proposed that cerebral demyelination is not a manifestation of the rapid correction of acute hyponatremia^[1] and studies have not confirmed that the demyelination associated with hyponatremia is related to rapid correction.^[18] In fact, the majority of brain lesions observed among patients with symptomatic hyponatremia result from a delay in the initiation of therapy, which, in turn, results in respiratory insufficiency.^[19] Cerebral demyelinating lesions also occur with improper therapy, but they are unrelated to its rate of correction.^[12] A recent review of hyponatremia reported that cerebral demyelination occurs only when patients with hyponatremia are overcorrected (i.e., patients are made hypernatremic), have an absolute increase in plasma Na concentration exceeding 25 mEq/L during the first 24 to 48 hours of therapy, suffer a hypoxic event, or have underlying severe liver disease.^[1] The most recent review on myelinolysis suggested that chronic hyponatremia should be corrected at a rate below 10 mEq/L during any 24-hour period.^[20]

Prognosis and Future Perspectives. The prognosis is much better for patients with chronic hyponatremia than for those with acute hyponatremia. Acute hyponatremia is associated with substantial morbidity and mortality, with a mortality rate of 50 percent in one series.^[2] In addition to a higher mortality, patients with hyponatremia-induced seizures frequently show persistent neurological deficits.^[2] Diuretic-induced hyponatremia, hypoxia, alcoholism, malnutrition, liver disease, and female gender are risk factors for a poor neurological outcome.^[3] Because volume-induced ADH release occurs with significant blood volume reductions, treatment of hypervolemic hypo-osmolal hyponatremia carries an ominous prognosis.^[3]

HYPERNATREMIA

Hypernatremia is defined as a serum Na concentration above the normal range (135 to 145 mEq/L) and represents a relative increase in total body Na relative to TBW. This may be caused by either water loss or Na gain and is usually encountered when water losses exceed Na losses along with decreased water intake (e.g., limited access to water; loss of thirst).

Pathogenesis and Pathophysiology. The primary cause of hypernatremia is water loss, either renal, extrarenal, or both, along with limited water intake (e.g., decreased thirst, or a comatose or debilitated condition). Disorders causing renal water loss include DI, osmotic diuresis, hypokalemia and hypercalcemia (which may impair the concentrating capacity of the kidney), and renal parenchymal disease (e.g., sickle cell anemia). Those disorders causing nonrenal water losses include excessive sweating and other insensible losses, diarrhea, and disordered thirst. Central DI (i.e., pituitary deficiency of ADH) most commonly results from pituitary region tumors, their surgical treatment, and cranial trauma,^[21] and less frequently from infiltrative disorders (e.g., sarcoidosis). Impaired ADH synthesis is the underlying problem in some patients, whereas others have impaired ADH release in response to osmotic stimuli. Nephrogenic DI (renal ADH unresponsiveness) is usually acquired (e.g., drugs, such as amphotericin B, lithium, and fluorocarbon anesthetics), and a transient form of DI can be seen in late pregnancy and tends to remit postpartum. Less common etiologies include excessive Na intake with limited water access (seen with water loss due to peritoneal dialysis), high dietary Na, seawater consumption, and iatrogenic errors in IV fluid delivery or total parenteral nutrition formulation. Essential hypernatremia has also been attributed to an impaired osmoreceptor set point.

Although the pathophysiology of hypernatremia is similar to that of hyponatremia (the movement of water along its concentration gradient to restore osmolal equilibrium), the pathology is different (cerebral dehydration occurs rather than cerebral edema). When the hypernatremia develops slowly, brain cells may be able to compensate by increasing the influx of electrolytes across the cell membrane, decreasing the intracellular electrolyte binding, and increasing the intracellular amino acid concentration.^[21]^[22]^[23] In doing so, the brain increases its intracellular osmolality to avoid water loss (dehydration).

Epidemiology and Risk Factors. The incidence of hypernatremia among hospitalized adults ranges from 0.7 to 2.3 percent and is even greater among children.^[7] It is usually seen among patients at the extremes of age, in whom it is most frequently caused by gastroenteritis (infants) and limited water intake due to debilitation.^[7] Common causes of hypernatremia among the elderly include surgery (21 percent), febrile illness (20 percent), infirmity (11 percent), and diabetes mellitus (11 percent).^[7] The elderly are at further risk because they have a diminished capacity for urine concentration and a depressed thirst response.^[7]^[24]

Closed head injury is also a risk factor for the development of DI and hypernatremia, with an incidence of 2 percent following severe closed head injury; the incidence is greater if the sella turcica region is involved.^[21] Additionally, hypernatremia is often induced by IV mannitol, which is used to decrease intracranial pressure (ICP); when mannitol therapy is discontinued, fluid therapy quickly restores the Na concentration.^[25]

Clinical Features and Associated Disorders. The most common neurological manifestations reflect CNS involvement and range from mild confusion to coma, the severity typically correlating with the degree of hypernatremia. A history of a strong sense of thirst and signs of dehydration should be sought. [1]

When the onset of hypernatremia is acute, early symptoms typically occur at an osmolality of 320 to 330 mOsm/kg body water, whereas coma and respiratory arrest more commonly occur at values exceeding 360 mOsm/kg body water. [1] As with hyponatremia, seizures are usually seen with acute-onset hypernatremia and tend to be generalized. Focal neurological features likely reflect focal dysfunction. In the setting of rapid brain dehydration, tearing of the bridging veins may result in subdural hemorrhages. Sub-arachnoid hemorrhage and intraparenchymal hemorrhages may also occur. Similar to other metabolic encephalopathies, myoclonus, asterix, and tremor occur and muscle cramping is frequently reported. Seizures are infrequent in chronic hypernatremia, except when it is too rapidly corrected.

Differential Diagnosis and Evaluation. With the clinical syndrome of confusion or coma, other disorders, in addition to hypernatremia, should be considered in the differential diagnosis including other electrolyte abnormalities, endocrinopathies, drug or toxin exposure, stroke, cerebral masses, trauma, and infection. The underlying cause of the hypernatremia should be identified and treated. In the case of nonrenal water losses, the etiology should be obvious, and the urine should be concentrated and of low volume. A history, thorough physical examination, and the same laboratory tests used in the evaluation of hyponatremia should be obtained. The presence of a hypotonic urine in the face of dehydration and hypernatremia is diagnostic of DI, either central or nephrogenic. In nonketotic hyperosmolar hyperglycemia (NKH), the serum osmolality and glucose are markedly elevated, ketone bodies are absent, and the patient is dehydrated (see Hyperglycemia). Because focal neurological findings may be produced by intraparenchymal, subdural, or subarachnoid hemorrhages, brain neuroimaging with computed tomography (CT) should be considered. In this setting, other etiologies associated with focal neurological signs should be contemplated, including stroke, arteriovenous malformation, and post-traumatic sequelae.

Management. After the patient is stabilized, water replacement is usually the initial management. Importantly, free water cannot be given IV, because the rapid lowering of plasma osmolality at the injection site causes massive hemolysis. D5W is roughly isotonic with plasma but isotonic saline solutions offer several advantages, including quicker correction of hypovolemia and a less rapid correction of serum Na concentration. A patient with a fixed urinary concentrating defect due to central or nephrogenic DI will develop the excretion of free water and worsening of hypernatremia when isotonic saline is administered. The amount of water deficit can be estimated by the following formula:

Water Deficit = TBW (1 - 140 mEq/L / actual Na),

where TBW is in liters, and Na concentration is in mEq/L. In acute hypernatremia, the risk of tissue dehydration (e.g., brain) is significant and fluid replacement should begin immediately. Importantly, among patients with chronic hypernatremia, correction should occur over a 48-hour period and not exceed a rate of 0.5 mEq/L per hour, otherwise seizures or cerebral edema might be precipitated. [1]

Prognosis and Future Perspectives. Hypernatremia, either acute or chronic in onset, is associated with a high rate of mortality and severe morbidity. [1] Among children with severe hypernatremia, an initial mortality rate of 20 percent, as well as an incidence of permanent brain damage exceeding 33 percent, has been reported. [1, 26] The mortality rate from hypernatremia in hospitalized adults is about 50 percent, [1] although the existence of severe concomitant disease makes it difficult to determine the exact cause of the mortality.

Potassium Disorders

The total body content of potassium (K) is about 3500 mEq, [27] and roughly 98 percent is intracellular, two thirds of which is intramuscular. [1] Because cell membranes are more permeable to K than to Na and Cl, K is primarily responsible for the resting transmembrane potential and is therefore critical to the function of excitable tissue.

HYPOKALEMIA

Hypokalemia, the most frequent electrolyte disorder encountered by the clinician, is defined as a plasma K concentration below the normal range (3.5 to 5.5 mEq/L).

Pathogenesis and Pathophysiology. Whenever K losses exceed intake, total body K decreases and hypokalemia results. Each 1-mEq/L decrement in the plasma K level roughly correlates to a total body K decrease of 100 to 300 mEq (Table 38-2). K influx increases intracellular positivity, thereby producing a mild depolarization. This lessened state of electrical excitability underlies the muscle weakness and hyporeflexia that can be seen clinically.

Epidemiology and Risk Factors. Approximately 2 percent of normal adults, 21 percent of hospitalized patients, 25 percent of patients taking 50 mg of hydrochlorothiazide daily, and nearly 100 percent of patients taking more than one class of diuretic have hypokalemia. [27] Although acute hypokalemia is an uncommon cause of weakness, certain scenarios increase its risk of development, including rapid correction of systemic acidosis (e.g., hyperventilation, bicarbonate administration), postoperative patients unable to take food by mouth (because K excretion cannot be stopped), and the chronic use of beta-2 agonists (e.g., asthmatics).

Clinical Features and Associated Disorders. The clinical features of hypokalemia are predominantly muscular and occur more frequently when the extracellular K level changes rapidly. The magnitude is also influential. [1] K levels of 3 to 3.5 mEq/L are associated with weakness, myalgias, and easy fatigability; those of 2.5 to 3.0 mEq/L are associated with more pronounced weakness; and those below 2.5 mEq/L (and especially if below 2.0 mEq/L) are associated with structural muscle damage (rhabdomyolysis and myoglobinuria). Areflexic quadriplegia and respiratory insufficiency may also occur at these lowest levels. The cranial musculature is rarely involved. Tetany may be observed in some hypokalemic patients, especially those with concomitant systemic alkalosis. Because hypokalemia can mask the tetany of hypocalcemia, tetany may appear as the hypokalemia is corrected. [1] Sensory disturbances and encephalopathic features are not expected in hypokalemia and, when present, should prompt a search for an underlying cause. Because hypokalemia can increase renal ammonia

production, it can aggravate a pre-existing hepatic encephalopathy (HE). [28]

Differential Diagnosis and Evaluation. Frequently, the cause of hypokalemia is apparent by history, and a full general and neurological examination, with particular emphasis on muscle strength and deep tendon reflexes, is necessary. The possibility of Cushing's syndrome or hyperaldosteronism is suggested by hypertension, and the presence of thyrotoxic periodic paralysis (TPP) is indicated by evidence of hyperthyroidism. Laboratory evaluation should include Na, K, Cl, bicarbonate, BUN, Cr, glucose, calcium (Ca), and magnesium (Mg), as well as an arterial blood gas (ABG) and an electrocardiogram (EKG). Thyroid function tests (TFTs) identify the rare TPP, and muscle biopsy may demonstrate vacuolar change but generally is not indicated.

Management. Therapy includes correction of the underlying cause and replacement therapy. Replacement therapy is usually recommended once the K level is below

3.5 mEq/L. Oral supplementation is preferred, but IV supplementation may be required when GI dysfunction exists or when the K deficiency is severe (with arrhythmias and neuromuscular manifestations).

Prognosis and Future Perspectives. Although respiratory failure and death can occur when hypokalemia goes unrecognized, complete recovery is expected when K replacement can be provided and the underlying disorder corrected. For disorders that cannot be corrected (e.g., aldosterone-secreting tumors), the prognosis is related to the underlying disorder.

HYPERKALEMIA

Pathogenesis and Pathophysiology. Hyperkalemia may result in three ways: (1) increased entry of K into the ECF, (2) intracellular K efflux, or (3) decreased K output. Of these three processes, intracellular K efflux and decreased K output predominate. Because the renal capacity for kaliuresis adapts to increasing K intake, hyperkalemia usually is not seen unless a massive amount of K is ingested, parenteral replacement is provided too rapidly, or co-existent adrenal or renal dysfunction exists. Even in the setting of complete RF, the rise in serum K is slow, ranging from 1 mEq/L per week to 0.5 mEq/L per day.^[29] In the setting of hyperkalemia, the chemical gradient for K efflux is lessened and, therefore, intracellular positivity increases. This results in a minimal depolarization which, in turn, makes the tissue less excitable by causing a reduction in Na influx.

Epidemiology and Risk Factors. Among hospitalized patients, the incidence of hyperkalemia approaches 10 percent, one fifth of which is above 6.0 mEq/L.^[27] Risk factors for the development of hyperkalemia include (1) renal or adrenal insufficiency, (2) K supplementation at rates and quantities above the suggested values, (3) situations resulting in tissue destruction (e.g., induction of chemotherapy), and (4) the use of beta-2 antagonists (e.g., propranolol) or other medications known to cause hyperkalemia (e.g., heparin, K-sparing diuretics).

Clinical Features and Associated Disorders. The usual manifesting feature of hyperkalemia is cardiac toxicity.^[3] EKG features include peaked T waves, increased PR (atrioventricular block) and QRS (interventricular block) intervals, and arrhythmias. Cardiac arrest represents the major problem and may be the initial symptom.^[27] Like hypokalemia, the major neurological manifestations of hyperkalemia are peripheral. Hyperkalemia may cause loss of strength and deep tendon reflexes, although this is observed less commonly than with hypokalemia. Muscle cramping is not uncommon, and both paresthesias^[27] and focal neurological signs^[30] have been reported.

Differential Diagnosis and Evaluation. Systemic acidosis and adrenal or renal insufficiency are the more frequently encountered etiologies of hyperkalemia. Once hyperkalemia is noted, an EKG must be obtained, followed by continuous cardiac monitoring until causes of pseudohyperkalemia are excluded. This requires a complete blood count (CBC) with smear for the presence of red blood cell hemolysis, thrombocytosis ($> 500,000/\text{mm}^3$), or leukocytosis ($> 50,000/\text{mm}^3$). Tourniquet-induced stasis and forearm exercise may also produce hyperkalemia.^[3]

Management. The treatment of hyperkalemia includes addressing its cardiac manifestations, reversing the underlying disorder, decreasing the K input, increasing the intracellular influx of K, and increasing K excretion.

Calcium Disorders

Ninety-nine percent of total body Ca is contained in bone, making the skeleton a Ca reservoir; the remaining 1 percent is distributed in the intracellular and ECF compartments. Because 1 percent of skeletal Ca is freely exchangeable with the ECF, it can help buffer acute changes in the serum Ca, whereas the kidney regulates calciuresis.^[31] Total serum Ca reflects dietary intake, GI absorption, calciuresis, and transfer from the bone to the ECF. Parathyroid hormone (PTH), 1,25-dihydroxycholecalciferol (DHCC), and calcitonin regulate both Ca absorption from the gut and calciuresis. PTH is released whenever the serum ionized Ca level falls; conversely, hypercalcemia suppresses the release of PTH. Because PTH promotes the synthesis of 1,25-DHCC, it indirectly influences GI absorption.

HYPOCALCEMIA

Although ionized Ca is the physiologically active form, total serum Ca is the laboratory parameter usually measured. This value reflects the ionized (unbound, 50 percent), the bound (mostly to albumin, 40 percent), and the chelated (10 percent) fractions. In the presence of normal serum protein levels, hypocalcemia exists when the total serum Ca value is below the normal range of 8.8 to 10.4 mg/dl. However, in the setting of hypoalbuminemia, although the measured total serum Ca is low, the patient is asymptomatic because the physiologically active, ionized fraction is normal.^[32] Although the total serum Ca value may be corrected for hypoalbuminemia (e.g., by adding 0.8 mg/dl to the measured Ca value for every 1.0-g/dl decrement in the serum albumin value), this correction formula may be inaccurate in critically ill patients.^[33] For that reason, it is best to measure the ionized Ca value in this patient population.

Pathogenesis and Pathophysiology. Hypocalcemia

TABLE 38-3 -- MAJOR CAUSES OF HYPOCALCEMIA

Hypoparathyroidism
Normal or increased parathyroid function (renal failure, vitamin D deficiency)
Protein-binding and anion-chelation of ionized calcium
Medications (anticalcemic and antineoplastic agents)
Multifactorial (gram negative sepsis)

Modified from Spiegel AM: The parathyroid glands, hypercalcemia, and hypocalcemia. In Bennett JC, Plum F (eds): Cecil Textbook of Medicine, 20th ed. Philadelphia, WB. Saunders, 1995, pp 1364-1373

may be caused by PTH or 1,25-DHCC deficiency, as well as by end-organ resistance to their actions and other conditions (Table 38-3). Ionized Ca is important for presynaptic neurotransmitter release and stabilization of nerve and muscle membranes (divalent cations stabilize the cell membranes of nerve and muscle).^[34] Thus, it is not surprising that disturbances of ionized Ca result in neuromuscular manifestations.

Neurologically, both the PNS and CNS may be involved. Tetany, a PNS manifestation, is thought to be caused by repetitively generated nerve fiber action potentials, possibly related to the spontaneous depolarization of the nerve cell membrane in the setting of hypocalcemia. When the rate of sequential muscle fiber depolarization does not permit Ca reuptake by the sarcoplasmic reticulum, tetany occurs. The instability of the neuromuscular membranes may explain why the clinical features of hypocalcemia are positive in nature (e.g., perioral and acral paresthesias, and muscle spasms).

Epidemiology and Risk Factors. Except in neonates and patients with RF, hypocalcemia is relatively rare. The most likely cause of hypocalcemia among patients presenting to an emergency room is hypomagnesemia.^[34] Risk factors include past thyroidectomy, neck trauma, a family history of hypocalcemia, malabsorption syndromes, antiepileptic drug usage, severe liver or kidney disease (decreased 1-alpha-hydroxylation of vitamin D), and pancreatitis. The incidence of postsurgical hypoparathyroidism (usually thyroidectomy) varies with the expertise of the surgeon.^[34] The decrease in total serum Ca during pregnancy reflects dilutional hypoalbuminemia and, for that reason, the ionized Ca concentration is unchanged.^[35]

Clinical Features and Associated Disorders. The clinical features of hypocalcemia are primarily neuromuscular, regardless of the underlying disorder, and are dependent on its rapidity of onset and magnitude. The earliest PNS symptoms include perioral and acral paresthesias, as well as tetany (tonic muscle spasms), the most characteristic and frequently recognized sign of hypocalcemia.^[3] Tetany can be overt or latent, and provocative tests may be necessary to elicit latent tetany. Provocative tests include Chvostek's sign, the contraction of ipsilateral facial muscles in response to light percussion over the facial nerve (just anterior to the ear); and Trousseau's sign, carpal spasm in response to ischemia (e.g., 3-minute application of blood pressure cuff maintained just above systolic pressure). The carpal spasm produced is first preceded by acral paresthesias, followed by sensations of spasm, and then carpal spasm, paralleling the sequence of development of tetany.^[36] Latent tetany may also become overt in the setting of alkalosis (e.g., hyperventilation or Na bicarbonate administration), a reflection of increased binding

between ionized Ca and albumin. When tetany is severe, lower extremity and pedal spasms, as well as laryngeal stridor, may be observed. Opisthotonos may occur if spasms involve the trunk. A history of preceding muscle cramps, or generalized muscle aching, is frequently obtained.

CNS manifestations include irritability, delirium, delusions, hallucinations, depression, and dementia. When the onset of hypocalcemia is slow and insidious, dementia may be the initial manifestation. Seizures may occur and can be the presenting sign when hypocalcemia is severe. They are usually generalized but may be focal.^[36] Intracerebral calcifications, seen most frequently with idiopathic hypoparathyroidism and pseudohypoparathyroidism, are usually asymptomatic. Although the basal ganglia are frequently affected, parkinsonism, athetosis, and chorea have been reported only rarely.^[37] When the condition is persistent, cataract formation may occur. CHF and papilledema with increased ICP (idiopathic intracranial hypertension) are rarely observed.^[34]

Differential Diagnosis. The etiologies of hypocalcemia are listed in [Table 38-3](#). The most common cause of hypoparathyroidism is surgical (e.g., thyroidectomy) and is usually transient, becoming permanent in less than 3 percent of patients. Severe hypomagnesemia may cause hypocalcemia by inducing deficient PTH secretion and causing end-organ resistance to PTH. This explains why hypomagnesemia causes many of the same clinical manifestations as hypocalcemia.

Evaluation. Serum electrolyte, BUN, Cr, Ca (total and ionized), Mg, phosphorus, alkaline phosphatase, and albumin levels should be determined. An ABG identifies whether a hyperventilation syndrome is present. An EKG and continuous cardiac monitoring may be required. More specific tests for intestinal malabsorption may also be necessary. In osteomalacia or rickets, the serum alkaline phosphatase is elevated. CT imaging of the head may reveal intracranial calcifications, especially in the basal ganglia region. When hypocalcemia and hyperphosphatemia co-exist in the presence of normal renal function, the diagnosis of hypoparathyroidism is strongly suggested and the appropriate laboratory evaluation is required. Hypocalcemia coupled

TABLE 38-4 -- MAJOR CAUSES OF HYPERCALCEMIA

Common causes

with a normal or low serum P level suggests vitamin D deficiency, malabsorption, or another cause of secondary hypoparathyroidism. Steatorrhea is frequently associated with hypomagnesemia and may serve as a clue to its presence.

Management. Acute, symptomatic hypocalcemia requires emergency treatment with IV Ca until symptoms resolve. Hypertension, bradycardia, cardiac conduction block, and digitalis toxicity may be precipitated if the infusion is provided too rapidly, and so monitoring is required.^[21] Because this form of treatment lasts only a few hours, it must be repeated, or the patient be provided with a continuous infusion. In less urgent settings (e.g., postsurgical hypocalcemia), elemental Ca may be given as a continuous infusion over 4 to 10 hours and Ca monitored. In the setting of mild hypocalcemia, treatment with oral Ca replacement alone may suffice. Ca carbonate, up to 1200 mg orally three times daily, may safely be given.^[21] Definitive resolution of hypocalcemia, however, requires identification and treatment of the underlying disease. For patients requiring long-term Ca supplementation, monitoring for evidence of toxicity is required (e.g., hypercalcemia, hypercalciuria).

HYPERCALCEMIA

Pathogenesis and Pathophysiology. Hypercalcemia occurs when serum Ca entry (from bone resorption and GI absorption) exceeds calciuresis. In the presence of normal serum proteins, hypercalcemia exists when the serum Ca concentration is above the normal range. However, physiological hypercalcemia is present only when the ionized Ca is above its normal range. The ionized Ca value can be calculated, based on the serum albumin level, or directly measured in most laboratories. In the setting of hypoalbuminemia, although the total serum Ca value may be normal, ionized Ca may be significantly elevated and require emergent treatment. In addition to serum protein binding, consideration of chelation (anions) and acid-base status is also important.

Epidemiology and Risk Factors. Approximately 40 percent of hypercalcemic patients develop neurological manifestations.^[9],^[38] Nearly all patients with hypercalcemia have a malignancy or hyperparathyroidism, or are using thiazide diuretics ([Table 38-4](#)). Malignancies are most common among hospitalized patients, and hyperparathyroidism is common among ambulatory patients.^[39] Malignancy-induced hypercalcemia occurs predominately in patients with bone metastases, such as lung (especially squamous cell), breast, ovarian, renal, hematological, head and neck, and GI cancers.^[31],^[40] Through increased calciuresis, the majority of these patients do not develop hypercalcemia. However, in the setting of renal dysfunction, hypercalcemia is readily provoked. Disorders that result in prolonged immobilization (paralysis, coma, or trauma) can cause hypercalcemia, especially in patients undergoing bone remodeling (normal growth in a young patient, osteoporosis in the elderly, Paget's disease). Infrequently, humoral hypercalcemia of malignancy (i.e., PTH-related peptide excretion by the tumor) is observed.

Clinical Features and Associated Disorders. The presentations of hypercalcemia vary with the patient's age, underlying disorder, magnitude of hypercalcemia, albumin level, and rapidity of onset. Individuals with mild hypercalcemia are frequently asymptomatic (identified by routine blood testing), whereas those with severe hypercalcemia may present in coma and rapidly progress to death. General features may reflect the underlying disorder, such as weight loss and cachexia with malignancy, or abdominal pain with acute pancreatitis. Less specific features include dehydration, polyuria, polydipsia, nocturia, hypercalciuria, urolithiasis, nephrolithiasis, nephrocalcinosis, renal impairment, GI disorders (anorexia, constipation, ileus, nausea, vomiting), pruritus, hypertension, and soft tissue deposition.

Neurologically, CNS symptoms predominate and can include headache, fatigue, apathy, depression, agitation, insomnia, hallucinations, psychosis, confusion, lethargy, obtundation, coma, and, rarely, seizures. The mental status changes are directly related to the degree of hypercalcemia and are more frequent at Ca levels exceeding 14 mg/dl. All CNS signs are reversible with treatment. PNS manifestations reflect decreased neuromuscular excitability, and although they are common, these manifestations are nonspecific. Weakness is generally subjective with few objective signs.^[39]

Differential Diagnosis and Evaluation. Before the realization that the observed clinical features reflect hypocalcemia, other etiologies must be considered. The particular cerebral manifestations, such as seizures and encephalopathic features, also dictate specific evaluation. The differential diagnoses of these central manifestations are lengthy and not addressed here (see [Chapter 52](#)). In the clinical setting of tetany, consideration should be given to disorders associated with cramping such as congenital myopathies and dystrophies (e.g., Duchenne's muscular dystrophy), cramp-myalgia syndrome (a dystrophinopathy), benign cramp syndrome (pseudotetanus), disorders producing contractures (e.g., McCordle's disease), and disorders producing continuous muscle activity (neuromyotonia).

The differential diagnosis of hypercalcemia is extensive. Frequently, the history, physical examination, initial laboratories, and routine radiographs identify the cause of hypercalcemia. A thorough examination may disclose features indicating the underlying disorder (e.g., breast mass, lymphadenopathy). Important laboratory evaluations include PTH, urine Ca, CBC, chemistries (ionized Ca, Mg, P), urinalysis, stool for occult blood, EKG, and chest x-ray study. Other considerations include tests of adrenal and thyroid function, serum and urinary immunoelectrophoresis (for myeloma), vitamin D metabolite levels, and immunoassay for PTH-related peptide. A bone scan may be required in some patients, including those with suspected multiple myeloma (e.g., abnormal serum protein electrophoresis, anemia, increased

plasma cells on blood smear).

Management. Prevention of hypercalcemia in immobilized patients includes early mobilization and hydration, which increases calciuresis and dilutes the urine. High Ca containing dietary products should be avoided. Although the underlying cause is the most important consideration for definitive treatment, the initial management of hypercalcemia depends on its magnitude and symptoms and may need to be initiated without a specific diagnosis. The major treatment modalities act by decreasing bone resorption,

decreasing GI absorption, and increasing calciuresis. Mild hypercalcemia (< 11.5 mg/dl) may require only recognition of the underlying disorder, recommendations to increase fluid intake, and careful follow-up. Conversely, in the setting of severe hypercalcemia (> 15 mg/dl or severe clinical signs), urgent treatment is usually required and, in the setting of normal renal function, typically consists of volume replacement using IV normal saline, furosemide, and careful monitoring of therapy.

Prognosis and Future Perspectives. The prognosis for patients with hypercalcemia is related to the underlying disorder resulting in the hypercalcemia. Although cancer patients with hypercalcemia have a poor prognosis and usually die within a few months, hypercalcemic treatment usually improves their quality of life.

Magnesium Disorders

Although magnesium (Mg) is the fourth most common cation in the body, less than 0.5 percent is present in the serum,^[41] of which about 30 percent is protein bound, 15 percent is chelated to serum anions, and 55 percent exists in the ionized (physiologically active) form.^[31] The amount of protein-bound Mg is directly proportional to the serum albumin concentration and the pH, and is inversely proportional to the serum anion concentration. In addition, transcellular shifting between the intracellular and extracellular compartments can occur. Although the Mg contained in bone is not readily exchangeable with that present in the serum, a shift of Mg from the ECF to the intracellular fluid occurs with insulin administration^[42] and the correction of acidosis.^[31] Intracellular Mg functions as an essential co-factor in hundreds of important enzymatic reactions. Mg balance is regulated by the GI tract and the kidney, which maintains the serum Mg concentration between 1.6 and 2.1 mEq/L. An interrelationship exists between Mg and Ca, as evidenced by the development of hypocalcemia in response to Mg depletion.^[43] In fact, Mg depletion is the most common cause of hypocalcemia in a general hospital population.^[44] An interrelationship also exists between Mg and K, and although the mechanism is unknown, it may be related to the Mg requirement of the Na/K ATPase enzyme system.^[45]

HYPOMAGNESEMIA

Because the serum Mg concentration contributes less than 0.5 percent of total body Mg, the terms hypomagnesemia and Mg deficiency are defined separately. Hypomagnesemia refers to a serum Mg concentration below the normal range, whereas Mg deficiency refers to a decrease in the total body or intracellular Mg contents. In the clinical setting of severe tissue Mg deficiency, the serum Mg may be normal or even elevated. Conversely, in the setting of normal tissue stores, hypomagnesemia may be present.

Pathogenesis and Pathophysiology. Mg affects both the PNS and CNS. Peripherally, Mg has a curare-like action at the neuromuscular junction, an action counteracted by acetylcholinesterase inhibitors and Ca.^[36] Mg is both a Ca channel antagonist (opposes Ca) and a membrane stabilizer (acts synergistically with Ca).^[31] Centrally, Mg has a depressant effect (interestingly, hibernating animals are hypermagnesemic), which is opposed by pentylenetetrazol (Metrazol).^[36]

Epidemiology and Risk Factors. Among hospitalized patients, the prevalence of hypomagnesemia is about 10 percent; it is approximately 20 percent when only intensive care unit patients are considered.^[44] Because Mg deficiency is more common than hypomagnesemia,^[31] the true incidence of Mg deficiency must exceed 10 percent. Risk factors for the development of hypomagnesemia include chronic diarrheal disorders, ketoacidosis, loop diuretic or digitalis usage, and alcoholism (Table 38-5).^[31] Among patients with steatorrheic states, the prevalence of Mg depletion is about one third; the correlation between fecal Mg and fat content suggests that Mg depletion may be due to formation of a complex between Mg and fat. The recommended daily allowance (RDA) of Mg (1200 mg) for pregnant and lactating women is 50 percent greater than that for nonpregnant women.^[46]

Clinical Features and Associated Disorders. Hypomagnesemia may be asymptomatic, yet when it is symptomatic, the neurological manifestations include agitation, tremor, myoclonus, seizures (rarely), confusion, coma, paresthesias, muscle fasciculations, weakness, presence of Chvostek's and Trousseau's signs, tetany, and hyperreflexia.^[21],^[44],^[47],^[48] In addition, a cardioskeletal mitochondrial myopathy has been described in association with chronic hypomagnesemia.^[49] Athetoid and choreiform movements have also been reported during hypomagnesemia, although these signs may have reflected co-existent liver disease.^[36] Unfortunately, the association of hypomagnesemia with hypokalemia, hypocalcemia, and other metabolic disorders makes it difficult to state with certainty which manifestations truly reflect hypomagnesemia. Importantly, the efficacy of Mg repletion in relieving manifestations of neuromuscular irritability may reflect its curare-like action (i.e., a therapeutic effect rather than reversal of deficiency symptoms). When the clinical manifestations of Mg deficiency are determined by induction of deficiency in human volunteers, GI features (anorexia, nausea, and vomiting), CNS features (lethargy, weakness, and personality change), PNS features (positive Trousseau's and Chvostek's signs, carpopedal

Saunders, 1995, pp 1137-1138.

spasm), tremor, and muscle fasciculations may be observed. Unfortunately, these features correlate with the development of hypocalcemia and hypokalemia.

Differential Diagnosis and Evaluation. Although the differential diagnosis of hypomagnesemia is long, it most commonly reflects an inadequate intake superimposed on impaired renal reabsorption or GI absorption. The two major problems in diagnosing Mg deficiency are that the serum Mg content represents only 0.5 percent of the total body content, and that the relationship between the serum level and the intracellular and total body content is poor. Thus, it is not uncommon to suspect hypomagnesemia and be faced with a normal serum Mg level. In this situation, an Mg loading test has been suggested.^[42] The presence of either hypokalemia or hypocalcemia, especially when it is resistant to treatment, makes the likelihood of symptomatic hypomagnesemia even greater, and for that reason, the concentrations of these two electrolytes should be determined. A urine Mg level helps differentiate renal from nonrenal etiologies.

Mg, like Ca, affects both the CNS and the PNS. Because Mg functions as a membrane stabilizer (synergistic with Ca), hypomagnesemia (like hypocalcemia) produces membrane instability. For that reason, it should always be considered in the neurological differential diagnosis of hypocalcemia, especially when hypocalcemia is

unresponsive to treatment. Diagnostic considerations to entertain vary with the clinical manifestations; they parallel those of hypocalcemia.

Management. The treatment of Mg deficiency depends on the underlying disorder, the clinical status of the patient, and the degree of deficit. In an emergency setting (e.g., seizure), Mg-sulfate heptahydrate solution may be infused.^[44] In the nonemergent setting, when hypomagnesemia is severely decreased, treatment may be IV or intramuscular. The intramuscular route is safer and preferred, when possible. Because serum Mg equilibrates with intracellular Mg slowly, rapid replacement may cause transient hypermagnesemia. Consequently, total body Mg repletion may require several days of treatment. Finally, in nonemergent settings when the degree of hypomagnesemia is not severe, oral replacement therapy can be undertaken using Mg-oxide. In mild, asymptomatic cases, dietary modification to include high Mg-containing foods (e.g., dried fruits, grains, legumes, green leafy vegetables, and unprocessed cereals) may suffice. During Mg replacement therapy, the serum Mg level should be monitored frequently and treatment continued until a normal serum Mg level is achieved. Because Mg is a neuromuscular depressant, tendon reflexes should be monitored for evidence of overtreatment (diminished reflexes); the infusion should be discontinued if either hypermagnesemia or hyporeflexia is observed.^[36] When Mg is replaced intravenously, Ca gluconate should be on hand to counteract transient hypermagnesemic-induced problems, such as apnea caused by respiratory muscle paralysis.^[9]

HYPERMAGNESEMIA

Because the kidney is the major regulator of serum Mg levels, hypermagnesemia is frequently observed in patients with renal impairment, especially when the condition is combined with increased Mg intake. By blocking the presynaptic Ca channels, Mg acts to limit depolarization-induced Ca influx. Because exocytosis of acetylcholine-containing vesicles is Ca dependent, neuromuscular depression occurs. Symptomatic hypermagnesemia is infrequently encountered.

In contrast to the neuromuscular irritability observed with hypomagnesemia, the neurological manifestations of hypermagnesemia are characterized by nervous system depression. The predominant neuromuscular manifestation is muscle weakness (or paralysis) due to neuromuscular junction transmission blockade.^[50] The manifestations of hypermagnesemia, both neurological and non-neurological, have been studied in experimental animals and human patients and reflect the degree of elevation of the serum Mg level. In general, patients are asymptomatic until the serum Mg level exceeds 4 mEq/L.^[44] Blood pressure depression begins at levels between 3 and 5 mEq/L,^[51] at which time the reflexes may be slightly depressed^[44] and responsiveness may be slightly impaired.^[36] As the serum Mg level increases further, hypotension becomes more pronounced. At levels between 7 and 10 mEq/L, the reflexes diminish and weakness and ataxia appear.^[36] At this level, lethargy and confusion have been reported,^[9] although this is controversial. In one study, levels as high as 12.4 mEq/L resulted in profound paralysis without significant changes in level of consciousness.^[52] Possible explanations for the mental decline observed in patients with hypermagnesemia include chronicity, which permits the CNS Mg level to rise; hypermagnesemia-induced hypoxic-ischemic encephalopathy; or neuromuscular junction blockade mistaken for mental status decline.^[31] At 10 mEq/L, respiratory impairment appears with resultant hypoxia and hypercapnia.^[36] At levels of 10 to 15 mEq/L, reflexes disappear and a flaccid quadriplegia may develop,^[44] and as respiratory embarrassment worsens, CNS narcosis results in coma and death. Other symptoms associated with hypermagnesemia include nausea, lethargy, dilated pupils, bradycardia and, rarely, complete heart block and cardiac arrest.^[44]

The underlying cause of the hypermagnesemia, as well as its neurological and cardiovascular manifestations, should be identified. Respiratory, cardiac, and renal status should be determined. In the setting of hypermagnesemia, sources of Mg should be identified and discontinued. In asymptomatic patients with normal or mildly impaired renal function, this action alone may suffice. Because natriuresis enhances urinary Mg excretion, furosemide may be administered and the urine volume replaced.^[44] Of course, this may induce hypocalcemia. In life-threatening situations, Ca salts can be administered to counteract the neuromuscular blockade and cardiotoxicity. Hemodialysis, using an Mg-free dialysate, is the most effective way of reducing serum Mg levels.^[44]

OXYGEN AND CARBON DIOXIDE ABNORMALITIES

Conditions causing hypoxemia include a low inspired oxygen (O_2) concentration, ventilation-perfusion mismatch, right-to-left shunting, impaired diffusion, and hypoventilation;

those causing hypercapnia include the breathing of a carbon dioxide (CO_2)-containing gas, ventilation-perfusion mismatch, and hypoventilation. Because neuromuscular dysfunction produces hypoventilation, which, in turn, produces both hypoxemia and hypercapnia, distinguishing which neurological features are related to which condition is difficult. Although isolated hypoxic encephalopathy is seldom seen in humans (e.g., mountain sickness), an understanding of its pathophysiological basis is important. Thus, this section is divided into three parts: hypoventilation, hypoxia, and hypocapnia.

Hypoventilation

The respiratory system consists of the lungs and chest wall and has two functions: ventilation and gas exchange. Ventilation refers to the movement of air into and out of the lungs and is required for effective gas exchange. Ventilation requires the synchronized activities of both nervous and muscle tissue. The muscles of respiration (and their innervation) are typically divided into the inspiratory group (diaphragm [C3-C5], external intercostals [T1-T12], and scalenes [C4-C8]) and the expiratory group (abdominals [T7-L1] and internal intercostals [T1-T12]). During quiet breathing, the inspiratory muscles are active, with the diaphragm generating most of the tidal volume, and expiration is predominantly passive. When quiet breathing is unable to keep pace with the metabolic demands of the body (e.g., during exercise or respiratory muscle failure), the accessory muscles of inspiration (trapezii, sternocleidomastoids, serrati, pectorals, levator scapulae, and the costal levators) are recruited and expiration becomes active; thus, ventilation increases.

All levels of the neuraxis are involved in respiration, and for the most part, it occurs without voluntary effort (i.e., it is automatic). Automatic respiration occurs via two neuronal groups located within the brain stem: one is situated near the floor of the fourth ventricle (the medullary center), and the other is located within the pons (the pontine pneumotaxic center). The medullary neurons have inherent automaticity, and the pontine neurons help coordinate the cyclical respirations. Through synapses with motor neurons innervating respiratory muscles, these neurons are responsible for spontaneous respiration. Voluntary respiration, which involves corticospinal tract innervation of the same respiratory motor neurons, can override automatic breathing. Under normal circumstances, respiratory regulation reflects the $PaCO_2$ and pH and, to a lesser extent, the PaO_2 . Chemoreceptors within the carotid and aortic bodies transmit this information to the respiratory centers in the brain stem (via cranial nerves IX and X, respectively), and respiration is adjusted accordingly.

The term *hypoxic encephalopathy* refers to the neurological findings resulting from impaired gas exchange or ventilation (e.g., anoxic anoxia, anemic anoxia, and histotoxic anoxia) and differs from the term *hypoxic-ischemic encephalopathy*, which refers to neurological dysfunction related to cerebral hypoperfusion (i.e., ischemic anoxia). With hypoxic-ischemic encephalopathy, in addition to hypoxia, there is loss of substrate (e.g., glucose) and impaired waste removal. Anoxic anoxia refers to reduced arterial partial pressure of O_2 (e.g., at high altitudes), whereas anemic anoxia relates to reduced hemoglobin availability for O_2 transport (e.g., in anemia and carbon monoxide intoxication). Histotoxic anoxia occurs when, in the setting of adequate O_2 availability, the tissue's ability to use O_2 is impaired (e.g., cyanide toxicity).

Pathogenesis and Pathophysiology. Ventilatory failure results in hypercapnia as well as hypoxemia, a combination that causes cerebral vasodilation, increased cerebral blood flow (CBF), and occasionally, increased ICP. Although hypoxemia probably contributes to the observed neurological features, the degree of CO_2 retention is more closely correlated. Acute, moderate hypercapnia (5 to 10 percent CO_2 in the inspired air) increases arousal and excitability. At higher levels of CO_2 , an anesthetic effect occurs, followed by a convulsant effect at the highest levels. Because CO_2 freely crosses the blood-brain barrier (BBB), thereby producing a cerebrospinal fluid (CSF) acidosis, respiratory acidosis is more neurologically disabling than is metabolic acidosis. Fortunately, several compensatory mechanisms exist to enhance the nervous system's tolerability of respiratory insufficiency. The CNS compensates by increasing O_2 extraction, CO_2 release, and CBF. These processes arise in conjunction with systemic alterations at the level of the kidney and with polycythemia. Should compensatory mechanisms fail, hypoxia, hypercapnia, and acidosis develop and produce neurological sequelae. Sustained hypoxia produces brain edema and cell death, abnormalities that can precipitate cardiac arrhythmias and hypotension. Again, isolated hypoxic encephalopathy is seldom seen in humans.

Clinical Features and Associated Disorders. Pulmonary disease causes both hypoxemia and hypercapnia, and distinguishing which neurological features are related to which state is difficult. The clinical features observed reflect the body's ability to compensate and the acuteness of the situation. The neurological manifestations are most closely related to the rapidity of onset and degree of hypercapnia, although hypoxia and cerebral edema may also contribute. Compensatory mechanisms may render individuals asymptomatic, even in the setting of significant degrees of hypoxia and hypercapnia. When these mechanisms cannot keep pace, clinical features of respiratory insufficiency manifest. Initially, patients with respiratory insufficiency may complain of sleep disturbances, daytime somnolence, and early morning headache, a reflection of nocturnal hypoventilation with resultant CO_2 retention and vasodilation; however, these symptoms are nonspecific and can occur with CHF or respiratory muscle weakness. Mental status changes are common early and include drowsiness, forgetfulness, and inattentiveness. Later, lethargy, obtundation, and coma may appear. Tremor and asterixis are frequently seen, whereas myoclonus and seizures are uncommon and are observed only with severe and prolonged respiratory insufficiency. Tendon reflexes may be brisk or depressed, upper motor neuron features may be present, and papilledema occurs in up to 10 percent of patients.

Differential Diagnosis and Evaluation. Respiratory impairment may be caused by dysfunction of gas exchange or ventilation ([Table 38-6](#)). Differentiation between these

TABLE 38-6 -- MAJOR CAUSES OF RESPIRATORY INSUFFICIENCY

EXTRAPULMONARY CAUSES

Central nervous system (parenchymal disorders, increased intracranial pressure, sleep apnea)

Neuromuscular disorders

Spinal cord: tetanus, trauma

Anterior horn cell: amyotrophic lateral sclerosis, poliomyelitis, rabies

Nerve: Guillain-Barre syndrome, diphtheria, porphyria, ciguatera, saxitoxin, tetrodotoxin, thallium intoxication, acute hyperkalemic paralysis, buckthorn polyneuropathy

Neuromuscular junction: myasthenia gravis, congenital myasthenic syndromes, botulism, hypermagnesemia, organophosphate poisoning, tick paralysis, snake bite

Muscle: polymyositis, inclusion body myositis, myotonic dystrophy, limb girdle muscular dystrophies, hypophosphatemia, stonefish myotoxin, nemaline myopathy, centronuclear myopathy, rhabdomyolysis

Other: kyphoscoliosis, ankylosing spondylitis, chest trauma, extreme obesity, pleural diseases

PULMONARY CAUSES

Chest bellows (non-neurological):

Primary muscle fatigue

Secondary muscle dysfunction: electrolyte disturbances, malnutrition, reduced respiratory drive: metabolic alkalosis, sedation

Other (e.g., pulmonary parenchymal or airway disorders, cardiac failure)

Modified from Jozefowicz RF: Neurologic manifestations of pulmonary disease. *Neurol Clin* 1989;7 605-616; and Bennett DA, Bleek TP: Diagnosis and treatment of neuromuscular causes of acute respiratory failure. *Clin Neuropharmacol* 1988; 11 303-347

two categories is important and is usually afforded by a thorough history, physical examination, and laboratory evaluation. Unlike motor unit disorders that produce hypoventilation, CNS disorders produce abnormal respiratory patterns, such as Cheyne-Stokes (forebrain and diencephalic damage), central neurogenic hyperventilation (hypothalamic and midbrain damage), apneustic (inspiratory breath holding related to pontine tegmental damage), cluster (irregular bursts of rapid breathing alternating with apneic periods), and ataxic (irregular breathing related to medullary damage) breathing patterns. The respiratory impairment associated with spinal cord disorders is predominantly a reflection of its location. Lesions at C3 affect diaphragmatic and intercostal function and spare only the accessory muscles of inspiration innervated by the eleventh cranial nerve. Lesions at C4 or C5 produce lesser degrees of diaphragmatic impairment. Low cervical and high thoracic lesions spare the diaphragm but affect the intercostal and abdominal muscles, thereby limiting full inspiration and active expiration. Midthoracic lesions affect only the abdominal muscles and therefore interfere only with active expiration. Respiratory impairment due to diaphragmatic weakness is worse in the supine position and improved in the erect position, a reflection of the effect of gravity on the abdominal contents. These features should be sought on physical examination. The electroencephalographic (EEG) changes associated with pulmonary encephalopathy are nonspecific and similar to those observed in patients with other forms of metabolic encephalopathy (i.e., diffuse slowing and slowing of the posterior dominant rhythm).

It is important to determine whether or not respiratory impairment reflects neurological dysfunction. Helpful studies for this discrimination include an ABG, pulmonary function tests, and electromyographic (EMG) examination. Neuromuscular system dysfunction impairs ventilation and is associated with both hypercapnia and hypoxemia. Non-neurological mechanisms of respiratory insufficiency (e.g., impaired gas exchange) initially produce hypoxemia without hypercapnia. This reflects the nonlinear hemoglobin dissociation curve of O₂ versus the essentially linear loading curve of CO₂. Thus, high ventilation areas of the lung are able to compensate for low ventilation areas until pulmonary disease is severe. In summary, hypoxemia in the presence of a normal or decreased PaCO₂ is indicative of a parenchymal process. Neurological versus non-neurological respiratory impairment may also be differentiated by determining the A-a gradient (i.e., the gradient between alveolar (A) and arterial (a) O₂ tensions), a value that is easily determined. The PaO₂ and PaCO₂ are obtained from the ABG, and the PAO₂ is obtained from the following equation:

$$PAO_2 = [(PB - 48) \times FIO_2] - PaCO_2 / R,$$

where PB is the barometric pressure (760 mm Hg at sea level), FIO₂ is the fraction of O₂ in the inspired air (0.21 in room air), and R is the respiratory quotient (0.8). On room air, an A-a gradient above 20 to 30 mm Hg always indicates intrapulmonary pathology, whereas an A-a gradient below 10 mm Hg suggests extrapulmonary causes of hypoxemia (e.g., hypoventilation). Pulmonary function test parameters indicative of respiratory muscle weakness include reduced vital capacity, reduced maximum voluntary ventilation, and increased residual volume. Of these parameters, only the vital capacity can be measured outside of the pulmonary function test laboratory. Maximum expiratory and inspiratory pressures are better parameters for identifying respiratory muscle weakness^[60]; maximum expiratory pressure is the most sensitive indicator for patients with neuromuscular disease. Although it is less useful for identifying respiratory muscle weakness, forced vital capacity is useful for the serial assessment of patients with known neuromuscular disorders. When the vital capacity drops below 25 ml/kg body weight, the ability to cough is impaired and oropharyngeal secretion accumulation occurs. Thus, the risk of aspiration pneumonia is significantly increased. Routine nerve conduction studies (NCS) (including phrenic NCS), repetitive nerve stimulation, and needle electrode examination (including the diaphragm) can be of great assistance in identifying both the nature (e.g., demyelinating neuropathy) and the site (e.g., nerve, neuromuscular junction, or muscle) of the underlying disorder.

Management. If the condition is left untreated, encephalopathy related to pulmonary dysfunction may lead to coma and death. The mainstays of treatment are to improve gas exchange and ventilation. In patients with chronic hypercapnia, in whom hypoxia-stimulated respiratory drive exists, high-concentration O₂ administration may produce clinical deterioration due to CO₂ retention. The O₂ affinity of hemoglobin and cytochrome is not as great as the affinity for carbon monoxide (CO) and cyanide, respectively. For that reason, CO and cyanide toxicity may require hyperbaric O₂ therapy.^{[59] [60] [61]}

Prognosis and Future Perspectives. Because cerebral

O₂ delivery depends on the mean arterial blood pressure and autoregulation, and because compensatory mechanisms exist, it is difficult to determine the severity of hypoxia a patient has experienced. When there is no loss of consciousness, there is rarely if ever any permanent nervous system damage.^[59] When hypoxia induces hypoperfusion (e.g., cardiac arrest), and hence ischemic anoxia, the prognosis worsens.

Hypoxia

Hypoxia increases CBF, glucose use, and brain lactate concentration, whereas energy metabolite (e.g., adenosine triphosphate [ATP], adenosine diphosphate [ADP], and adenosine monophosphate [AMP]) levels remain close to normal, even during severe hypoxia.^[62] Breathing 10 percent O₂ for 15 to 30 minutes increases the CBF by 35 percent, whereas breathing 7 percent O₂ (PaO₂ 35 mm Hg) for 15 minutes increases CBF by 75 percent.^[62] Once the PaO₂ drops below 25 mm Hg, ATP decreases, AMP and ADP increase, and the EEG is markedly slowed or nearly isoelectric.^[62] In addition, changes in ion homeostasis are induced by hypoxia. Unlike ischemic anoxia, in which Ca uptake is increased, hypoxia diminishes Ca uptake, thereby decreasing Ca-dependent acetylcholine release; this can be overcome by agents that enhance Ca uptake at the nerve terminals.^[63] Finally, neurotransmitter metabolism is also affected by hypoxia. Acetylcholine synthesis is O₂ dependent, and brain acetylcholine levels are decreased in the setting of hypoxia. However, because acetylcholine release in some brain regions is Ca dependent, the lowered brain acetylcholine levels may reflect the effect of hypoxia on Ca metabolism. Changes in amino acid, catecholamine, and serotonin neurotransmitter levels, as well as adenosine, cyclical nucleotides, and fatty acids, have also been reviewed.^[62]

Compensatory physiological mechanisms (e.g., increased erythropoiesis and O₂ dissociation curve shifts) permit adaptation to hypoxia, thereby making the effects of hypoxia time dependent and necessitating separate discussions for acute and chronic hypoxic states. Healthy human volunteers subjected to rapid decompression hypoxia (analogous to acute hypoxia, clinically) demonstrate an association between the PaO₂ level and the neurological features observed.^[53] New skill learning and the processing of complex information are the most vulnerable to hypoxia.^[62] At a PaO₂ of 80 mm Hg, impaired dark adaptation is noted; at 55 to 45 mm Hg, impaired learning and short-term memory occurs, whereas measures of selective attention are normal; at 40 to 30 mm Hg, loss of judgment, euphoria, delirium, and muscular incoordination occurs; additionally, twice as much light is required for visual perception; below 25 to 20 mm Hg, consciousness is rapidly lost.^[53],^[62] High altitude sickness begins shortly after ascending above 10,000 feet and is characterized by headache, decreased concentration, sleep disturbances, anorexia, nausea, and lassitude (see [Chapter 51](#)).

The clinical features of acute CO toxicity include prominent headache, nausea, vomiting, and encephalopathic features. The cherry-red lip appearance often described with this disorder is only present at high CO levels in comatose patients (see [Chapter 39](#)).

Several posthypoxic neurological syndromes have been described, including myoclonus, delayed anoxic encephalopathy, parkinsonism, and cerebral palsy. Global cerebral hypoxia of any etiology can result in myoclonus, as well as other neurological deficits. Posthypoxic myoclonus presents in two different clinical forms. Immediately following the hypoxic event, while the patient remains comatose, myoclonic jerks can appear. This acute form is transient and characterized by spontaneous jerks that involve the face predominately, yet may be generalized. Little is known about the electrophysiological properties of this acute posthypoxic myoclonus, but the prognosis associated with this sign is poor. In those patients who survive the hypoxic event and regain consciousness, a second type of delayed posthypoxic myoclonus may develop. Lance and Adams described this delayed form in patients demonstrating stimulus-sensitive intention or action myoclonus (posthypoxic action myoclonus [PHAM]) following cardiac or respiratory arrest.^[64] The characteristic feature of PHAM is the occurrence of myoclonus, both positive and negative, with voluntary movement, especially walking and movements requiring precision. Patients may be unable to walk when negative myoclonus occurs during ambulation. Fahn summarized the clinical findings of 88 patients (permanent in 87) with PHAM.^[65] All were acutely comatose with a median duration of unconsciousness of four days (range 1 to 120 days). The duration of coma did not correlate with the subsequent severity of the action myoclonus. Anesthesia-related mishaps were the single most common cause of cerebral hypoxia, with other etiologies including myocardial damage, drug overdose, and airway obstruction. Other neurological abnormalities, including cerebellar dysfunction, spasticity, dementia, and cortical blindness, were observed in these patients following the resolution of coma. EEG recordings may reveal generalized symmetrical or asymmetrical sharp waves, or spikes with slow waves may be detected. Alternatively, moderate to high-voltage fast activity, occurring centrally, can be observed. Other patients have slowing of the background or even normal EEGs. Somatosensory evoked potentials in patients with PHAM may initially be enlarged, yet decrease in size following initiation of therapy. The pathophysiological basis of PHAM is a matter of conjecture. Only a few pathological investigations exist and are not significantly helpful in the understanding of the pathophysiology of PHAM. 5-Hydroxytryptophan (5-HTP), the serotonin precursor, has been shown to be beneficial in PHAM, and has generated considerable interest in the possible role of brain serotonin in this form of myoclonus. 5-HTP alone and with carbidopa has been effective in reducing the amplitude of the myoclonic jerks. L-5-HTP is started at 100 mg/day in four

divided doses and is increased by 100 mg every 3-5 days, slower if side effects occur. Maximum daily dosage ranges from 1000 to 2000 mg. Carbidopa is given at 25 to 50 mg four times daily and should not be stopped before the discontinuation of 5-HTP. Lower doses of L-5-HTP (400 to 500 mg) may suffice when administered with either fluoxetine or paroxetine, serotonin uptake inhibitors, and carbidopa. Despite the use of carbidopa, systemic side effects are nearly universal and frequently necessitate 5-HTP dose reduction

744

or discontinuation. Common side effects include diarrhea, nausea, vomiting, abdominal pain, euphoria, insomnia, and blurred vision. Other medications with some utility in the treatment of PHAM, either alone or in combination, include valproate, piracetam, and clonazepam. The other benzodiazepines, phenobarbital, and phenytoin are usually of no benefit.

Postanoxic encephalopathy is an unexplained phenomenon that is observed during recovery (1 to 4 weeks) from an anoxic insult. It is characterized by irritability, confusion, apathy, and occasionally agitation or mania.^[66] Although most patients with this disorder survive for a period, serious mental and motor disturbances are reported, and many patients develop diffuse rigidity, spasticity, weakness, a shuffling gait, incontinence, coma, and death after 1-2 weeks.^[66] At autopsy, the major pathological finding is widespread cerebral demyelination.^[59] Uncommonly, rigidity, muteness, and helplessness develop over a period of weeks to months and, in these cases, autopsy reveals the basal ganglia to be more affected than the cerebral white matter and cortex.^{[59], [67]}

Parkinsonism following cerebral anoxia is usually accompanied by a large number of other neurological sequelae, a reflection of the cerebral structures most susceptible to anoxic insult (i.e., Sommer's sector of Ammon's horn, Purkinje's cells, the cerebral cortex [especially layer 3], the striatum, and the globus pallidus). For that reason, a "pure" parkinsonian syndrome is unexpected. It has been reported in CO intoxication, in both the acute and chronic settings.^[68]

Cerebral palsy refers to a syndrome of acquired, nonprogressive perinatal encephalopathy due to a variety of insults, including anoxia, hypoperfusion, trauma, vascular events, congenital abnormalities, and kernicterus (less common today). Asphyxia accounts for only a minority of cases, the most common cause reflecting prenatal factors that are difficult to identify with certainty.^[69] Cerebral palsy may be classified based on the type of motor impairment, and its distribution is segregated into spastic types and hypotonic types. Spastic types include spastic diplegia (legs more involved than arms), which is more common in premature infants; spastic hemiplegia, which is the most common form acquired after birth; and spastic quadriplegia (usually asymmetrical with arms more involved than legs), that is sometimes termed *double hemiplegia*. The hypotonic types include athetoid (predominant basal ganglia development) and ataxic (predominant cerebellar involvement). The spectrum of intellectual and motor deficit ranges from normal intelligence with mild motor deficits to severe retardation without the ability to walk.

Hypocapnia

Hyperventilation is defined as breathing in excess of metabolic demands and, therefore, is purely a respiratory disturbance. It produces hypocapnia, respiratory alkalosis, cerebral vasoconstriction (which, in turn, reduces the CBF), a reduction in the availability of O₂ peripherally (through shifts of the O₂ dissociation curve), a reduction in the level of ionized serum Ca, and when sustained, significant hypophosphatemia.^[55] Thus, neurological features are frequent, and patients with hyperventilation disorders are frequently referred to neurologists. Symptoms associated with hyperventilation vary widely and include lightheadedness, acral and perioral paresthesias (which may be painful), syncope and, less commonly, carpopedal spasms, muscle cramps, blurred vision, headache, dyspnea, and chest pain.^[54] ,^[55] Other reported symptoms include sweating of the hands, cold extremities, giddiness, ataxia, tremor, tinnitus, hallucinations, epigastric pain, a bloated feeling, vomiting, and unilateral somatic symptoms, which may result in the misdiagnosis of cerebral ischemia, seizure, or complicated migraine.^[70] Once it is induced, hypocapnia can be maintained with only an occasional sigh, thereby making its visual recognition difficult.^[71] These symptoms probably arise from a reduction in CBF and are associated with significant cerebral hypoxia.^[70] For every 1 mm Hg drop in PaCO₂, the CBF drops by 2 percent.

Disorders associated with hyperventilation can be subdivided into psychogenic (e.g., anxiety, panic, sighing, air hunger, or factitious disorders), organic (usually multifactorial including respiratory disease, CNS disorders, pain, aspirin overdose), and physiological (progesterone ingestion, prolonged conversation, hypoxic stimulation of chemoreceptors at high altitude, pyrexia).^[70] Hyperventilation is frequently reported in anxious individuals without any identifiable systemic disease.^[55] However, because isolated anxiety (i.e., in the absence of hyperventilation) has no effect on CBF, it should not produce these symptoms.^[72] Patients with organic disorders (e.g., asthma) can present with hyperventilation. Additionally, disorders producing anxiety (e.g., angina) can cause hyperventilation. Thus, the identification of hyperventilation should never be considered synonymous with anxiety, nor should these patients be taken less seriously. For that reason, whenever hyperventilation is recognized, organic etiologies should be excluded and treatment initiated.

ENDOCRINE ABNORMALITIES

An interdependence exists between the endocrine and nervous systems, as demonstrated by the influence of hormones on the nervous system and the requirement of an intact nervous system for endocrine activity. In the past, when early screening was not commonplace and treatment was not an option, the neurological features ascribed to endocrine dysfunction were much more pronounced. However, because these disorders are now diagnosed earlier, the clinical features are often much more subtle. The early recognition of endocrine-related neurological dysfunction is important because the condition is frequently reversible.

Thyroid Disorders

The thyroid gland synthesizes and secretes tetraiodothyronine (T_4) and, in much smaller quantities, triiodothyronine (T_3), which is at least two to four times more potent than T_4 . Both of these hormones regulate tissue metabolism. Iodine is bound to tyrosine residues of thyroglobulin in the thyroid gland (organification), and these iodinated

residues are then coupled to form T_4 and T_3 . Both protein-bound (inactive) and unbound (active) thyroid hormone fractions exist in serum. In the periphery, T_4 is deiodinated to T_3 , accounting for about 80 percent of T_3 production^[73]; otherwise it is converted into reverse T_3 (rT_3), a metabolically inactive product.

HYPOTHYROIDISM

Pathogenesis and Pathophysiology. Hypothyroidism can be related to thyroid gland dysfunction (i.e., primary hypothyroidism), to a disturbance outside of the thyroid gland (i.e., central hypothyroidism), or to peripheral resistance to thyroid hormone.^[74] Mechanisms of thyroid gland dysfunction include parenchymal destruction (viral or autoimmune), chronic inflammation with lymphocytic infiltration (Hashimoto's thyroiditis), cell death (radiation damage), or defective hormonogenesis. Defective hormonogenesis may occur due to inadequate iodine intake (i.e., endemic goiter), excessive ingestion of goitrogens (e.g., turnips), intrinsic defects in thyroid hormone production (e.g., rare enzymopathies), as well as medication-induced thyroid hormone synthesis disturbance (e.g., lithium, thionamides, amiodarone). In some patients, iodine loading may cause significant hypothyroidism (Wolff-Chaikoff effect).

Although the pathogenesis and pathophysiology of many of the peripheral neurological manifestations of the hypothyroid state are known, most of the CNS manifestations are unexplained. Although hypothyroid-induced seizures may be related to hyponatremia, coma likely represents a multifactorial process.^[75] Direct metabolic effects or entrapment by adjacent tissue (e.g., myxedematous infiltration) may cause peripheral and cranial mononeuropathies.^[73],^[74] Persistent percussion-induced local muscle contraction is referred to as myoedema and is caused by delayed Ca reuptake by the sarcoplasmic reticulum, thereby prolonging the contraction.^[76] A reduction in myosin ATPase activity contributes to slowed contraction, and delayed reuptake of Ca by the sarcoplasmic reticulum contributes to delayed relaxation.^[77] Also, a shift in muscle fiber type distribution from fast twitch to slow twitch may contribute to slowed muscle contraction and relaxation.^[78] In addition, a reduction in muscle mitochondrial oxidative capacity and beta-adrenergic receptors, as well as the induction of an insulin-resistant state, may contribute to weakness, fatigue, and exertional pain.^[79] The pathophysiology of the muscle enlargement, a feature more commonly observed in children (Kocher-Debre-Semelaigne syndrome), is uncertain, although work hypertrophy related to prolonged contraction is suspected.^[77]

Epidemiology and Risk Factors. The incidence of primary hypothyroidism is much greater in women than in men,^[73],^[79] especially among women between the ages of 40 and 60 years. Central hypothyroidism (e.g., hypothalamic-and pituitary-related), on the other hand, is more commonly observed among the neurosurgical population.^[25] Primary hypothyroidism is much more common than secondary hypothyroidism, and is usually caused by autoimmune destruction (e.g., Hashimoto's thyroiditis), irradiation, or surgically treated hyperthyroidism. Pituitary and hypothalamic disease contribute less than 10 percent of cases of hypothyroidism.^[75] Myxedema coma is extremely rare, and its incidence is higher in elderly women, especially those over 60 years.^[74] Risk factors for myxedema coma include noncompliance with levothyroxine therapy, infection, surgery, drugs, hyponatremia, and the winter months.^[74],^[76] Although complex changes in thyroid function occur during pregnancy, the normal pregnant woman is euthyroid,^[80] and the incidence of hypothyroidism is not influenced by pregnancy.^[35]

Clinical Features and Associated Disorders. Clinically, the onset of hypothyroidism may range from subtle and insidious findings to florid psychosis. The general examination features of hypothyroidism are numerous (Table 38-7). CNS features include forgetfulness, inattention, apathy, and slowing of speech, movement and mentation. These features may mimic depression. Seizures, personality changes, psychotic states, coma, and dementia may also be clinically apparent. Cerebellar ataxia is seen in 5 to 10 percent of patients,^[81] and may be the presenting sign (so-called myxedema staggers). A psychotic presentation (myxedema madness) characterized by agitation, disorientation, delusions, hallucinations, paranoia, and restlessness is observed in approximately 3 to 5 percent of patients.^[73] Myxedema coma is extremely rare, and its characteristic features include extreme hypothermia, seizures (the presenting manifestation in nearly 20 percent of patients^[75]), respiratory depression, and areflexia. Death can occur when early recognition and prompt treatment are lacking. Dementia may develop when hypothyroidism is severe. Except for the marked increase in the number of hours these patients remain asleep or resting, the clinical features of the dementia are similar to those secondary to other causes.^[82]

Peripheral neuromuscular features include cranial and peripheral neuropathies, prolonged reflex relaxation time (up to 85 percent of hypothyroid patients),^[73],^[74] and myopathy. Visual field defects can occur when pituitary enlargement causes hypothyroidism with concomitant chiasmal compression. A facial mononeuropathy, due to nerve entrapment in the fallopian canal of the temporal bone, may rarely occur.^[83] Although sensorineural hearing loss has been reported to correlate with the degree of hypothyroidism and has a high incidence among patients with congenital

TABLE 38-7 -- GENERAL FEATURES OF HYPOTHYROIDISM

Subjective	Objective
Fatigue, somnolence, cold intolerance, syncope, exertional dyspnea, weight gain, arthralgias, nausea, anorexia, indigestion, constipation, menstrual abnormalities	Bradycardia, hair changes (sparse, coarse, dry, brittle), puffy face, loss of lateral aspects of the eyebrows, periorbital edema, macroglossia, voice deepening and hoarsening, skin changes (scaly, thick, doughy, coarse, dry, carotenemia), brittle nails, nonpitting edema, galactorrhea, effusions
Data from Mitehell JM: Thyroid disease in the emergency department: Thyroid function tests and hypothyroidism and myxedema coma Emerg Med Clin North Am 1989;7:885-902; Mazzaferri EL: Adult hypothyroidism: 1. Manifestations and clinical presentation. Postgrad Med 1986;79:64-72; Myers L, Hays J: Myxedema coma. Crit Care Clin 1991;7:43-56; and Iqbal HJ, Ruff RL: Neurologic manifestations of endocrine diseases. Neurol Clin 7:489-508.	

hypothyroidism,^[82] its reported incidence among adult hypothyroid patients varies.^[84] Minor evidence of polyneuropathy, such as distal lower extremity sensory dysfunction and absent ankle jerks, is observed in approximately 10 percent of patients,^[77] and rarely, a moderately severe sensorimotor polyneuropathy has been described. Carpal tunnel syndrome (i.e., median mononeuropathy at the wrist) occurs in 15 to 30 percent of hypothyroid patients, is usually bilateral, and is the most common mononeuropathy encountered.

Myopathy can be a feature of hypothyroidism and manifests with proximal muscle weakness. Regardless of the cause of the hypothyroidism, weakness is observed in about one third of these patients.^[76] Increased muscle size and firmness, which is most obvious in the limb musculature, as well as slowed muscle contraction are important features to identify. Exertional pain, stiffness, and cramps may be noted, and myoedema may be observed. Myoedema, a mounding of the muscle in response to direct percussion, is painless and electrically silent, and occurs in one third of hypothyroid patients.^[76] Difficulty relaxing the hand grip and exacerbation by cold weather may suggest myotonia. However, unlike myotonia, hypothyroid myopathy involves a slowness of muscle relaxation and contraction, and resolves with correction of the hypothyroid state.^[82] Although sleep apnea is usually of the obstructive type, other possibilities include a central abnormality, chest muscle weakness, and blunted responses to hypoxia and hypercapnia.^[73] Reports have associated hypothyroidism with SIADH,^[25] idiopathic intracranial hypertension,^[85] and myasthenia gravis.

Differential Diagnosis. The differential diagnosis of hypothyroidism includes nonthyroidal illness (i.e., decreased T_3 or T_4 , or both, without clinical hypothyroidism), euthyroid hypothyroxinemia (decreased T_4 caused by decreased thyroid-binding globulin), and drugs that inhibit T_4 binding (salicylates, phenytoin, and phenobarbital). Once hypothyroidism has been diagnosed, the most important clinical distinction is between primary and secondary hypothyroidism. The clinical and

laboratory similarities between myxedema coma and other life-threatening causes of the comatose state may make its diagnosis extremely difficult. Regarding hypothyroid myopathy, the muscular appearance, stiffness, and exacerbation by cold may suggest a mild form of myotonia congenita, which can present in adulthood. Although the stiffness noted in patients with pyramidal and extrapyramidal diseases may appear similar to that of hypothyroid myopathy, the characteristic history, appearance, and laboratory studies usually permit the diagnosis of hypothyroidism.

Evaluation. The combination of a low T_4 level and an elevated thyroid-stimulating hormone (TSH) level is virtually diagnostic of primary hypothyroidism, because TSH elevation does not occur in central hypothyroidism. Further delineation between primary and secondary hypothyroidism is dependent on history, examination, and other laboratory studies. In addition to TFTs, other laboratory abnormalities have been described, including anemia (normocytic-normochromic, microcytic-hypochromic, or macrocytic) and hyponatremia (factitious due to hyperlipidemia or secondary to impaired free water excretion), as well as elevated serum creatine kinase, myoglobin,^[78] and prolactin. Because of the possibility of concomitant adrenal insufficiency, a serum cortisol level should also be obtained. The EEG may show slowing of the posterior dominant rhythm and a generalized voltage decrease, as well as triphasic waves that disappear with replacement therapy.^[86] CSF analysis may reveal an elevated protein content which may exceed 100 mg/dl.

Management. The treatment of hypothyroidism, regardless of cause, consists of thyroid hormone replacement. Even in the setting of hypothyroid-induced seizures, achievement of the euthyroid state facilitates control.^[81] Precipitants of myxedema coma (e.g., infection, cold exposure, certain drugs [phenothiazines, narcotics, and sedative-hypnotics, phenytoin, rifampin], and other stressors [surgery, trauma]) require correction.^[73]

Prognosis and Future Perspectives. With early recognition and treatment, as well as improved intensive supportive care, the mortality rate of myxedema coma has decreased from roughly 50 to 70 percent to around 15 to 20 percent.^[87] Without early recognition and prompt institution of replacement therapy, the prognosis is grave.^[88]

HYPERTHYROIDISM

Pathogenesis and Pathophysiology. Thyroid hormones affect mitochondrial oxidative capacity, protein synthesis and degradation, tissue sensitivity to catecholamines, muscle fiber differentiation, and capillary growth.^[89] Excess thyroid hormone produces accelerated muscle protein catabolism and enhanced lysosomal protease activity, and interferes with the anabolic effects of insulin on muscle.^[76] Despite this understanding, the exact pathophysiology of thyrotoxic myopathy remains unknown. CNS observations include elevated rates of cerebral circulation, faster posterior dominant rhythms, alterations in the sensitivity of some brain enzymes and neurotransmitter systems, and altered metabolic responses.^[89] At present, the specific pathophysiological processes causing these manifestations remain unknown. It has been proposed that alterations in central and peripheral beta-adrenergic tone may be responsible for hyperthyroid-related tremor and chorea, and that brisk tendon reflexes may reflect faster muscle contraction and relaxation times.

Epidemiology and Risk Factors. Hyperthyroidism is more common in women than in men (10:1 ratio) and often shows a strong familial predisposition. During pregnancy, hyperthyroidism occurs more commonly than hypothyroidism, with an incidence ranging from 0.05 to 0.2 percent, most commonly related to Graves' disease, acute (i.e., subacute) thyroiditis, toxic nodular goiter, and toxic adenoma.^{[35], [90]} The incidence of low-birth-weight infants is significantly increased, and neonatal mortality is slightly increased.^[89]

Clinical Features and Associated Disorders. The general clinical features of thyrotoxicosis are numerous ([Table 38-8](#)). Neuropsychiatric signs include impaired attention, concentration, and memory, as well as emotional lability, nervousness, hypervigilance, lethargy, depression (i.e., apathetic hyperthyroidism), mania, psychosis, insomnia, and agitated delirium.^[81] Apathetic hyperthyroidism most frequently occurs in the elderly, lacks the usual hyperadrenergic features, and may easily be confused with depression or dementia.

TABLE 38-8 -- GENERAL FEATURES OF THYROTOXICOSIS

Subjective	Objective
Impaired concentration and memory, emotional lability, nervousness, irritability, palpitations, heat intolerance, increased sweating and appetite, weight loss, frequent defecation, menstrual abnormalities, insomnia, headaches	Impaired attention span and memory, hypervigilance, systolic flow murmurs, skin changes (warm, moist, smooth), EKG changes (sinus tachycardia, atrial fibrillation), psychiatric problems (depression, mania, bipolar disorder, manic psychosis), chorea, thyrotoxic penodic paralysis, thyroid storm, ocular features
Data from Weiner WJ, Lang AE (eds): Movement Disorders: A Comprehensive Survey New York, Futura 1989 Kaminski HJ Rulf RL: Neurologic complications of endocrine diseases. Neurol Clin North Am 1989;7:489-508 Abend WK, Tyler HR Thyroid disease and the nervous system. In Aminoff MJ (ed): Neurology and General Medicine, 2nd ed. New York, Churchill Livingstone, 1995; 333-347; and Shahar E. Shapiro MS, Shenkman L: Hyperthyroid-induced chorea: Case report and review of the literature. Isr J Med Sci 1988 24:264-266.	

Although new-onset adulthood seizures are rarely related to hyperthyroidism, the seizure incidence among thyrotoxic patients ranges from 1 to 9 percent.^[78] Movement disorders, such as tremor (usually enhanced physiological tremor) and choreoathetosis, as well as upper motor neuron signs, including spasticity, hyperreflexia, clonus, and Babinski's signs, may also be observed.^{[89], [90]}

Peripheral neurological features include cranial and peripheral neuropathies, as well as neuromuscular junction and muscle disturbances ([Fig. 38-2](#)). Ocular features include lid lag, stare, widened palpebral fissures, extraocular

Figure 38-2 A 40-year-old woman who presented with complaints of double vision. This brain computerized tomography of the orbits demonstrates enlarged extraocular muscles bilaterally associated with Graves' ophthalmopathy (From Kennell T, Levy JM, Stegman CJ: Radiologic case. West J Med 146:241, 1987. Reprinted by permission of The Western Journal of Medicine.)

muscle dysfunction with diplopia, and optic nerve compression with visual impairment. Eyelid retraction manifests in several ways: (1) Stellwag's sign, a staring expression with infrequent blinking; (2) Dalrymple's sign, a widened palpebral fissure due to retraction of both the upper and lower lids; (3) von Graefe's sign, a larger than normal portion of visible sclera with downward eye movement; (4) Joffroy's sign, a lack of frontalis muscle contraction with upgaze; and (5) Moaibus' sign, sympathetic overactivity-induced exophthalmos with resultant limited convergence.^[81] Although reports of a distal sensorimotor polyneuropathy in thyrotoxic patients are rare, improvement of the neuropathic features with attainment of the euthyroid state indicates that these features are manifestations of hyperthyroidism.^[91] Myasthenia gravis (MG) can be associated with hyperthyroidism, although some of the reported cases may have been secondary to coincident MG.^[78] Also, when bulbar weakness responds to treatment of the hyperthyroid state, it is more likely related to hyperthyroidism.^[92] When MG co-exists with thyrotoxic myopathy, the clinical findings do not differ from those in euthyroid patients, although the patients may be weaker due to the co-existence of two motor disorders. Thyrotoxic myopathy is characterized by the gradual onset of proximal limb weakness, which may be accompanied by myalgias, easy fatigability, and prominent atrophy. Although the muscular atrophy may be severe, most patients remain ambulatory. Shoulder girdle muscles can be more severely affected than the hip girdle muscles, with prominent atrophy and scapular winging.^{[76], [77]} Distal limb muscles are also affected, the facial muscles may be affected, and, rarely, bulbar and ocular muscles are involved.^{[77], [89]} Thyroid-associated ophthalmopathy refers to the exophthalmos and ocular muscle dysfunction associated with thyroid disease. It is seen in most patients with Graves' disease but is also seen in 5 percent of patients with Hashimoto's thyroiditis. It is not correlated with the onset of Graves' disease,^[93] having been reported to precede (rarely), occur concomitantly with, or develop after its treatment. It also does not correlate with the level of circulating thyroid hormone and may occur in euthyroid patients or in patients with hypothyroid Graves' disease.^[81] When it is prominent, thyroid-associated ophthalmopathy may cause exposure keratopathy (due to marked proptosis), as well as optic nerve compression. Thyrotoxic periodic paralysis refers to recurrent attacks of flaccid paralysis of the limbs and trunk (the oculobulbar muscles are usually spared or involved to a lesser degree) due to secondary hypokalemia.

Differential Diagnosis. The differential diagnosis of thyrotoxicosis includes other hypermetabolic disorders, euthyroid hyperthyroxinemia, and nonthyroidal causes. Occasionally, recognition that myopathic features are due to thyrotoxicosis can be difficult, especially if the myopathy is the presenting feature (rare), when exophthalmos is minimal, or when an apathetic state is present.^[94] When it is present, the observation of hyperreflexia is helpful, because this feature is not observed

in other metabolic myopathies. Thyrotoxic myopathy with pronounced muscular atrophy should be differentiated from progressive muscular atrophy by the presence of fasciculations and more profound weakness in the latter. When thyrotoxic myopathy involves the ocular and bulbar musculature, it must be differentiated from MG. In thyrotoxic myopathy, rapid muscle fatigue

and recovery with rest is not appreciated, a response to anticholinesterases is not observed, and decrement is not apparent on EMG; in MG, ocular and bulbar muscle involvement is more pronounced and atrophy is not present.^[89] Polymyositis should also be considered and is differentiated by EMG and muscle biopsy.

Evaluation. TFTs can confirm thyrotoxicosis, typically demonstrating an elevated free T_4 , total T_4 , T_3 RU, free thyroxine index (FTI), free T_3 , total T_3 , and a suppressed (usually undetectable) TSH. A normal or elevated TSH in the face of unequivocal clinical thyrotoxicosis should raise suspicion for a TSH-secreting pituitary adenoma. Other laboratory features may include anemia, hypokalemia, hypercalcemia, and an elevated erythrocyte sedimentation rate. Roughly half of hyperthyroid patients demonstrate EEG changes, most commonly generalized slowing or excessive fast activity, both of which resolve with attainment of the euthyroid state.^[78] Magnetic resonance imaging (MRI) with gadolinium may demonstrate the characteristic features of thyroid ophthalmopathy including multiple extraocular muscle (EOM) involvement, smooth margins gradually tapering into the tendon insertions, and uniform enhancement when contrast is administered. These features are readily displayed with fat saturation techniques that de-emphasize intraocular fat. Optic nerve impingement may also be visualized with a similar approach. MRI may also be useful in ruling out orbital pseudotumor, Tolosa-Hunt syndrome, orbital lymphoma, Wegener's granulomatosis, and orbital aspergillosis.^[95]

When co-existent MG is considered, acetylcholine receptor antibodies in response to edrophonium (Tensilon) may be helpful in its evaluation. Although the Tensilon test may be normal in MG (false-negative result) and may lead to improvement of dysthyroid orbitopathy (false-positive result),^[81] patients with thyrotoxic bulbar features typically do not have immunological, electrophysiological, or pharmacological evidence of MG.^[77]

Management. Almost all of the clinical features of thyroid dysfunction, with the exception of thyroid-associated ophthalmopathy, resolve once the euthyroid state is achieved.^[89] Medical treatment of thyrotoxicosis includes the use of beta blockers; antithyroid, anti-inflammatory, and immunosuppressive drugs; radioactive iodine-131; and iodine-containing compounds. Beta blockers, in addition to decreasing the beta adrenergic-mediated features of thyrotoxicosis, may decrease the peripheral conversion of T_4 to T_3 . Beta blockers are also useful in the prophylactic treatment of TPP while attainment of the euthyroid state is awaited. A typical dosage regimen is propranolol, 40 mg four times daily.^[77] In hyperthyroid patients with co-existent MG, beta blockers should be used cautiously because of their neuromuscular blocking properties.^[77] Higher grade orbital features typically require either systemic corticosteroids (with or without cyclosporine), irradiation, or orbital decompression,^[97] yet some believe surgery is rarely indicated because the dysthyroid orbitopathy usually spontaneously arrests before a serious degree of ophthalmopathy has been reached.^[98] One of the most frequent complications of thyroid surgery is recurrent laryngeal nerve paralysis.^[99] A more limited surgery involving partial lid suturing may be required to protect the cornea.

Parathyroid Disorders

See the sections on hypocalcemia and hypercalcemia.

Adrenal Disorders

HYPOADRENALISM

Pathogenesis and Pathophysiology. The adrenal gland is the effector organ of the hypothalamic-pituitary-adrenal (HPA) axis and secretes cortisol in response to stimulation by pituitary-derived corticotropin (adrenocorticotrophic hormone [ACTH]). Pituitary function, in turn, is under the control of corticotropin-releasing hormone from the hypothalamus. Dysfunction anywhere in the HPA axis may result in adrenal insufficiency. Primary adrenal insufficiency (PAI), is due to bilateral adrenal gland destruction and secondary adrenal insufficiency (SAI) results from hypothalamic or pituitary dysfunction. The most frequent cause of adrenal insufficiency is iatrogenic SAI following the withdrawal of exogenously administered steroids.

The fatigue and weakness associated with hypoadrenalism reflect the associated hypotension as well as the water and electrolyte disturbances. The role of glucocorticoids in catabolic energy mobilization likely also contributes.

Epidemiology and Risk Factors. PAI is relatively rare, may occur at any age, and affects both sexes equally.^[100] Acquired immunodeficiency syndrome and active tuberculosis are significant risk factors for PAI. Major risk factors for SAI include prior administration of exogenous corticosteroids, especially prolonged, high-dose courses, and any destructive lesion of the pituitary or hypothalamus.

Clinical Features and Associated Disorders. The clinical features of adrenal insufficiency are influenced by the site of dysfunction, because PAI affects all of the adrenocortical hormones, whereas SAI only affects glucocorticoids. Thus, hyperpigmentation, salt craving, and hyperkalemia are unique to patients with PAI. Patients with adrenal insufficiency may present acutely or as a chronic condition. Acute adrenal insufficiency is a medical emergency (so-called Addisonian crisis) characterized by mental status changes, fever, hypotension, volume depletion, arthralgias, myalgias, and abdominal pain that may mimic an acute abdomen.^[101] Chronic adrenal insufficiency may present more insidiously with fatigue, weakness, GI symptoms, amenorrhea, decreased libido, salt craving, arthralgias, and hypoglycemic symptoms. Neurological manifestations can include confusion, apathy, depression, psychosis, paranoia, and myalgias, as well as hypoglycemic symptoms.^[102] In addition, a past medical history of cancer, recent tuberculosis exposure or steroid usage, immunosuppression, a history of treated Cushing's syndrome, features of hypothalamic/ pituitary disease, or other endocrine deficiencies, as well as a family history of a sex-linked recessive disorder, should be sought.

Differential Diagnosis. In the industrialized world, approximately 70 percent of cases of PAI are autoimmune in etiology (due to the polyendocrine deficiency syndrome), 20 percent are related to tuberculosis (most common cause

worldwide), and the remaining 10 percent are due to other causes ([Table 38-9](#)).^[101] SAI commonly follows exogenous steroid withdrawal and the surgical treatment of Cushing's syndrome; it is uncommonly related to hypothalamic or pituitary lesions.^[101] The neurological differential diagnosis relates to the rapidity of onset of the hypoadrenalism. In the setting of acute adrenal insufficiency (i.e., Addisonian crisis), the differential diagnosis of acute onset encephalopathy must be entertained in addition to those disorders that produce septic shock. With a more chronic presentation, the differential diagnosis varies with the clinical manifestations and includes those disorders associated with encephalopathy, fatigue, weakness, or myalgias.

Evaluation. The evaluation of patients with suspected adrenal insufficiency serves to determine the adequacy of cortisol production and to localize the process within the HPA axis (i.e., PAI versus SAI). Tests to assess cortisol production include the serum cortisol level, ACTH (Cortrosyn) stimulation test, insulin tolerance test, and the metyrapone test. The plasma ACTH level is the principal localizing test,^[103] and in severely stressed patients with normal adrenal function, serum cortisol levels range from 20 to 120 $\mu\text{g}/\text{dL}$.^[101] In unstressed patients, the normal cortisol level overlaps with that observed in patients with adrenal insufficiency, making random cortisol testing less useful in this group.

Management. In patients receiving exogenous glucocorticoids, the prevention of HPA axis suppression is aided by using the lowest possible dosage, shortest duration, and an every-other-day dosing schedule, when possible. The treatment of adrenal insufficiency is hormone replacement. In general, in acute adrenal insufficiency, IV hydrocortisone is administered and fluid, Na, and glucose are replaced. In chronic adrenal insufficiency, the preferred replacement glucocorticoid is also hydrocortisone, because it has a short half-life, and is therefore less likely to produce Cushing's syndrome or osteoporosis.^[102] A typical regimen is hydrocortisone, 20 mg in the morning and 10 mg in the evening. Mineralocorticoid replacement may be required in PAI and is usually provided by fludrocortisone (Florinef), 0.05 to 0.1 mg/day, along with the recommendation for a high Na diet.

Lippincott, 1995, pp 682-686; and Rone JK: Adrenal insufficiency In Rakel RE (ed): Saunders Manual of Medical Practice, Philadelphia, WB. Saunders. 1996i, pp 653-656

HYPERADRENALISM

Hyperadrenalism refers to hypersecretory disorders of the adrenal medulla (e.g., pheochromocytoma) and cortex (e.g., aldosteronism and Cushing's syndrome). *Pheochromocytomas* are catecholamine-secreting tumors of neural crest (neuroectoderm) origin that may be sporadic or familial. In adults, approximately 10 percent of these tumors are malignant, 10 percent are extra-adrenal (i.e., 90 percent occur within the adrenal glands), and 10 percent are bilateral.^[104]

The major clinical features of pheochromocytoma are headaches, palpitations, diaphoresis, hypertension, hypotension, pallor, weight loss, chest pain, and abdominal pain.^[104] Other features include dizziness, anxiety, nausea, vomiting, diarrhea, mydriasis, tachycardia, pulmonary edema, and CHF.^[98] A more serious neurological feature is intracranial hemorrhage. *Pheochromocytoma multisystem crisis* is a serious and rare presentation that is characterized by encephalopathic features, multiple organ failure, fever, and labile blood pressure.^[105] Pheochromocytoma can be associated with multiple endocrine neoplasia (MEN) type II, neurofibromatosis, and von Hippel-Lindau disease.^[98]

The differential diagnosis of hypertension associated with hyperadrenergic symptoms is extensive and includes thyrotoxicosis, anxiety and panic disorders, hypoglycemia, diencephalic epilepsy, acute myocardial infarction, abrupt clonidine withdrawal, and drug usage (e.g., monoamine oxidase inhibitors, cocaine, decongestants). Although pheochromocytoma is rare, its life-threatening status requires consideration and exclusion whenever hypertension is associated with suggestive symptoms, especially the triad of headache, palpitations, and diaphoresis.

A total plasma catecholamine (epinephrine plus norepinephrine) level, drawn 30 minutes after supine rest, can be diagnostic. Values above 2000 pg/ml are pathognomonic for pheochromocytoma, whereas those below 1000 pg/ml exclude pheochromocytoma. Twenty-four-hour urine studies (metanephrines, normetanephrines, and vanillylmandelic acid) and clonidine suppression testing are required when values between these levels are obtained.^[104] Twenty-four-hour urine studies are diagnostic in up to 90 percent of patients with pheochromocytoma.^[98] Once the diagnosis of pheochromocytoma is confirmed, tumor localization becomes the priority and is best evaluated by abdominal CT.

For neurologists, it is important to consider pheochromocytomas in patients with headaches and other suggestive symptoms. Serious morbidity and mortality may occur when these patients present with headache and beta-blocker therapy is begun, which allows unopposed alpha adrenergic stimulation. This may result in CHF, myocardial or cerebral infarction, malignant hypertension, or death. When pheochromocytoma is considered to be a diagnostic possibility, referral to an endocrinologist for further evaluation and treatment is appropriate. With the widespread availability of imaging (CT, MRI) and biochemical assays, the incidence of undiagnosed pheochromocytoma has dropped significantly.^[104] With surgery, most pheochromocytomas are cured. However, 10 percent are malignant and current treatments for widespread metastases are unsatisfactory.

Aldosteronism results from the overproduction of aldosterone

by the adrenal cortex and can be primary or secondary. Primary aldosteronism refers to aldosteronism related to adrenal gland disorders such as aldosterone-secreting adrenal adenomas (Conn's syndrome) and functional overactivity of both adrenal glands (idiopathic hyperaldosteronism). Secondary aldosteronism refers to stimulation of aldosterone production by extra-adrenal influences, such as occurs in CHF, cirrhosis, volume depletion (or other conditions of decreased effective renal perfusion), and Bartter's syndrome, a rare disorder characterized by hyperreninemia, hypokalemia, and normal blood pressure. Aldosteronism, both primary and secondary, results in hypokalemia and metabolic alkalosis, which, in turn, may cause neurological symptoms. Primary aldosteronism is approximately twice as common in women, occurs between the ages of 30 and 50 years, and is found in approximately 1 percent of hypertensive patients.^[100] It is the most common endocrine cause of secondary hypertension.

Aldosteronism-induced hypokalemia may trigger episodic attacks of severe muscular weakness (similar to periodic paralysis), tetany, paresthesias, polyuria, and hypertension.^[106] The episodic attacks of weakness are similar to both the familial and thyrotoxic forms of periodic paralysis, although respiratory paralysis is more common.^[77] Unlike the familial form, hypokalemia and alkalosis may be present between attacks.^[77] In addition to episodic weakness, a subacute or chronic myopathy may develop. In this setting, serum creatinine kinase may be moderately elevated and EMG examination discloses myopathic features that are often accompanied by fibrillation potentials.^[77] Rarely, rhabdomyolysis and myoglobinuria occur. Laboratory features include an inability to concentrate the urine, hypernatremia, hypokalemia, metabolic alkalosis, and hypokalemic-induced EKG changes. The plasma renin activity should be measured, because this factor allows the differentiation between primary (suppressed) and secondary (elevated) aldosteronism.

The etiology dictates the treatment. In idiopathic hyperaldosteronism, medical therapy is primary, whereas hyperaldosteronism due to an adenoma is typically treated by surgical excision, although medical treatment with spironolactone (an aldosterone antagonist) and dietary Na restriction may be effective (antihypertensives may also be required).

Cushing's syndrome is the clinical expression of chronic excess adrenal corticosteroids (i.e., hypercortisolism) and can be classified into ACTH-dependent and ACTH-independent etiologies.^[107] Disorders belonging to the ACTH-dependent category overproduce cortisol in response to excessive ACTH release, whereas those in the ACTH-independent category produce cortisol without ACTH stimulation. ACTH-dependent causes account for 80 percent of the cases of endogenous Cushing's syndrome, and include ACTH-producing pituitary tumors (Cushing's disease; 65 percent), as well as both ACTH-producing (15 percent) and corticotropin-releasing hormone-producing (rare) ectopic tissue.^[108] ACTH-independent etiologies account for 20 percent of the cases of Cushing's syndrome, and include adenoma and carcinoma of the adrenal gland, nodular hyperplasia, and cortisol-secreting tumors.^[108] In addition to these endogenous etiologies, prolonged administration of exogenous glucocorticoids can cause a nearly identical syndrome.

The clinical features of Cushing's syndrome vary with the underlying etiology and are dependent on the amount of ACTH, cortisol, and other adrenocortical steroids secreted ([Table 38-10](#)). Neuropsychiatric manifestations can include irritability, emotional lability, depression, and psychotic episodes.^[78],^[99] Approximately 50 percent of the patients with Cushing's disease have muscle weakness.^[77] Other possible neurological signs are mental status changes and visual field defects as well as optic neuropathy when pituitary adenomas extend beyond the confines of the sella turcica. Rarely, the accumulation of fat epidurally can result in the development of a myelopathy. An association with idiopathic intracranial hypertension has also been reported (see [Chapter 53](#)).

Cushing's syndrome must be differentiated from disorders producing secondary hypercortisolism (e.g., obesity, major depression, alcoholism). Initial evaluation usually includes an overnight dexamethasone suppression test and a 24-hour urine collection for free cortisol. Free cortisol typically exceeds 90 µg/day in Cushing's

syndrome. The overnight dexamethasone suppression test assesses the patient's ability to suppress cortisol production in response to a low dose of dexamethasone. Typically, 1 mg of dexamethasone is administered at 11 PM, and a blood sample for serum cortisol is drawn at 8 AM. Serum cortisol is suppressed to below 5 µg/dl in normal individuals, whereas it is above 10 µg/dl in patients with Cushing's syndrome. False-positive results may be noted with physiological stress, estrogen or antiepileptic drug use, RF, and endogenous depression. ^[108]

Basic laboratory studies may identify glucose intolerance, leukocytosis with lymphopenia, polycythemia, and hypokalemia. Hypokalemia is unusual in Cushing's disease (10 percent) but is much more common in the ectopic ACTH syndrome (60 percent). ^[108] An MRI scan of the pituitary is the procedure of choice for the identification of pituitary adenomas. Abdominal CT scanning for the presence of an adrenal tumor is indicated in ACTH-independent syndromes.

TABLE 38-10 -- THE CLINICAL FEATURES OF CUSHING'S SYNDROME AND DISEASE

Cushing's Syndrome	Cushing's Disease
Hypertension, diabetes, hyperphagia, central obesity moon facies, dorsocervical fat deposition (buffalo hump; may cause myelopathy), hirsutism, acne, menstrual disorders evidence of protein catabolism (eg, easy bruising myopathy osteopenia), cutaneous lesions (hyperpigmentation; wide, purple striae), psychiatric manifestations	Mental status changes, idiopathic intracranial hypertension, visual field defects, optic neuropathy
Data from Lazer RB: Neuromuscular manifestations of endocrine disease. In Becker KL, Bilezikian JP Bremner WJ et al (eds): Principles and Practice of Endocrinology and Metabolism, 2nd ed Philadelphia, J.B. Lippincott, 1995, pp 1762-1770; and Schteingart DE: Cushing syndrome. In Becker KL, Bilezikian JP, Bremner WJ, et al (eds): Principles and Practice of Endocrinology and Metabolism 2nd ed. Philadelphia, J.B. Lippincott, 1995, pp 667-682	

The treatment of endogenous Cushing's syndrome depends on the underlying etiology.

Growth Hormone Disorders

Growth hormone (GH; somatotropin) is secreted by the anterior pituitary in response to hypothalamic GH-releasing hormone (GHRH). GH promotes linear growth and has both anabolic and catabolic effects. Hypersecretion of GH causes gigantism when it occurs before epiphyseal closure and acromegaly when it begins afterward. Hyposecretion causes short stature in childhood and possibly a chronic fatigue-like syndrome in adults. GH acts indirectly through insulin-like growth factors (IGFs, somatomedins), with IGF-1 (formerly somatomedin C) being the most important for growth. Prolonged exposure to elevated levels of GH and IGF-1 results in the insidious onset of skeletal and soft tissue overgrowth, the latter of which is most pronounced in tissues containing large amounts of cartilage proteoglycans. ^[109] Cortical bone density is increased and trabecular bone (e.g., vertebral) density is decreased, probably because of coexistent hypogonadism. ^[109] Soft tissue hypertrophy may result in compression neuropathies, radiculopathies, and rarely, myelopathy. ^[76]

More than 98 percent of cases of acromegaly are due to GH hypersecretion by a pituitary adenoma. ^[110] Rare etiologies include increased hypothalamic production of GHRH, ectopic pharyngeal pituitary tissue, and ectopic hormone (GH, GHRH)-secreting tumors (e.g., hypothalamic gangliocytoma; breast, stomach, and lung tumors). ^[109] GH-secreting pituitary adenomas are relatively rare, with an incidence of 3 to 4 per million and a prevalence of 50 to 70 per million. ^[110] There is no sexual predilection, and the majority of patients are diagnosed in their fourth or fifth decade, after a mean delay of 8.7 years. ^[111]

If it is present, an enlarging pituitary adenoma may produce headaches, visual changes (e.g., bitemporal hemianopia due to optic chiasm compression), and hypopituitarism (e.g., decreased ACTH or TSH levels due to anterior pituitary destruction), as well as DI (posterior pituitary involvement) and diplopia (due to cavernous sinus invasion). The lack of correlation between headache and tumor size reported in some series ^[111] suggests that headache may also be a feature of GH hypersecretion.

The hypersecretion of GH produces various forms of disfigurement and other physical changes ([Table 38-11](#)). Central sleep apnea has been reported in one third of acromegalic patients with sleep apnea. ^[112] Importantly, the presence of sleep apnea increases the risk for hypertension, myocardial infarction, and stroke, as well as accident susceptibility due to daytime sleepiness. ^[110] Mononeuropathies, especially compression neuropathies such as carpal tunnel syndrome (CTS), may be noted. CTS occurs in 50 percent of patients and is noted in 75 percent when EMG testing is performed. ^[77] Objective weakness, in a myopathic pattern, is observed in about 40 percent of acromegalic patients. ^[77] The weakness typically has an insidious onset and is a late manifestation, correlating best with the duration of acromegaly. ^[76] Polyneuropathies, nerve root and spinal cord compression, headaches, and visual changes have also been described. ^[76]

TABLE 38-11 -- GENERAL FEATURES OF GROWTH HORMONE HYPERSECRETION

Growth Hormone Hypersecretion
Musculoskeletal: Increased hat, glove, or shoe sizes; prognathism; prominent supraorbital ridges; coarsening of facial features (e.g, large bulbous nose, thick lips, separated teeth)
Endocrine: Hyperhidrosis, fatigue, exercise intolerance, hoarseness, sleep apnea (peripheral and central)
Cardiopulmonary: Hypertension, hyperlipidemia, cholelithiasis, carbohydrate intolerance, overt diabetes, heart disease (e.g., arrhythmias, congestive heart failure, coronary artery disease)
Other: Arthralgias, slight kyphosis, visceromegaly, reproductive problems (women: amenorrhea, galactorrhea, anovulatory problems; men: decreased libido, hypogonadism), hyperprolactinemia, adenomatous polyps and colon cancer, esophageal and gastric cancer, parathyroid and pancreatic islet cell adenomas (MEN-I syndrome)
Pituitary Gland Enlargement Headaches, visual changes (e.g., bitemporal hemianopsia due to optic chiasm involvement), hypopituitarism, diabetes insipidus, diplopia
MEN-I, Multiple endocrine neoplasia, type I Data from Kissel IT Endocrine myopathies, In Update on Neuromuscular Disease course 423 of the AAN annual meeting, Washington, D.C., May, 1994, pp 34-35 Murgans TA, Coates ML Diagnosis and treatment of acromegaly Am Fam Phys 1995 52:207-213; Molitch ME Clinical manifestations of acromegaly. Endocrinol Metab Clin North Am 1992;21:597-614; and Grunstein RR, Ho KY, Sullivan CE Sleep apnea in acromegaly Ann Intern Med 1991;115:527-532.

The most sensitive and specific screening test for acromegaly is the IGF-1 level. The pulsatile nature of GH secretion may result in a randomly high GH level being obtained in a normal person, as may physical stressors, making this a less useful test. All patients with elevated IGF-1 levels should have an oral glucose tolerance test, the gold standard for acromegaly. MRI can confirm the suspicion of a pituitary adenoma. When MRI is negative in an acromegalic patient, consideration should be given to the rarer etiologies of acromegaly.

The prevention of many of the sequelae of disorders associated with acromegaly (e.g., hypertension, cardiovascular disease, stroke, sleep apnea, diabetes, arthropathy) requires early identification and treatment. The management of acromegaly includes the identification of the source of the excess GH secretion and its excision, irradiation, or medical suppression. The somatostatin analog octreotide is a highly effective pharmacological means of controlling GH secretion, ^[88] but has the disadvantage of high cost and the need for multiple daily injections.

Glucose Metabolism Disorders

HYPOGLYCEMIA

Pathogenesis and Pathophysiology. Unlike other body tissues, the CNS relies almost exclusively on glucose as an energy substrate. CNS features that promote its vulnerability to hypoglycemia include its low glucose level (about 25 percent of the serum glucose value), its inability to store significant glucose as glycogen, and the high cerebral metabolic rate (5 mg/100 g brain tissue/min) for glucose. ^[113] Thus, for a 1400 g brain, the glucose requirement is 70 mg/min. The brain's dependence on glucose, coupled with its limited glycogen stores, results in rapid CNS dysfunction when hypoglycemia occurs and permanent neurological

sequelae if it is prolonged. The glucose level at which CNS dysfunction occurs depends on its rapidity of onset, the current level of CNS activity, the quantity of CNS glycogen, and the availability of alternative fuels. The immediate cause of CNS dysfunction is unknown. Although it was initially believed to be due to tissue energy depletion, high-energy organic phosphates are normal during the early stages of symptomatic hypoglycemia.^[53] Alternative explanations include accumulation of metabolic byproducts of nonglucose metabolism, impaired acetylcholine synthesis, and changes in neurotransmitter levels, such as those of glutamate, aspartate, and gamma-aminobutyric acid.^[53] When glucose slowly decreases, the CNS can use nonglucose substrates, especially ketoacids and glucose metabolism intermediaries,^[53] as well as several amino acids.^[53]

Epidemiology and Risk Factors. Hypoglycemia is a common problem without predilection for any age, gender, or ethnic group. Although excessive insulin administration is the most common cause of hypoglycemia,^[54] excessive use of oral hypoglycemic agents is another common cause. The major risk factor for the development of reactive hypoglycemia (infrequent) is GI surgery (e.g., vagotomy and pyloroplasty, gastrectomy, or gastrojejunostomy).

Clinical Features and Associated Disorders. Symptoms of hypoglycemia can be divided into adrenergic and neuroglycopenic (low CNS glucose). The adrenergic symptoms (e.g., diaphoresis, tachycardia, enhanced physiological tremor) are inversely correlated to the rate of development of hypoglycemia, being most pronounced with acute onsets. Hunger, visual disturbances, and altered temperature perceptions are other possible adrenergic features. The neuroglycopenic features include headache, malaise, impaired concentration, confusion, disorientation, irritability, lethargy, stupor, coma, generalized seizures, myoclonus, and psychiatric disturbance. Focal CNS dysfunction, including focal seizures, hemiplegia, paroxysmal choreoathetosis, and patchy brain stem and cerebellar involvement mimicking basilar artery thrombosis, have also been reported.^[114] With subacute onsets, drowsiness, lethargy, decreased psychomotor activity, and confusion may be observed,^[55] and when chronic, the insidious onset of memory, personality, and behavioral disturbances may suggest dementia.^[115] The medullary phase of hypoglycemia, characterized by deep coma, pupillary dilatation, shallow breathing, bradycardia, and hypotonicity, occurs at a blood glucose level of around 10 mg/dl.^[56]

Adrenergic features, when present, precede neurobehavioral features, thereby functioning as an early warning system. However, when sympathetic dysfunction (e.g., diabetic autonomic neuropathy) exists or when adrenergic blockers are being used, these features may be inapparent.

Differential Diagnosis and Evaluation. Hypoglycemia may be divided into fasting (the overwhelming majority), reactive (uncommon), and artificial ([Table 38-12](#)). Fasting hypoglycemia is usually the result of exogenous insulin or oral hypoglycemic administration by diabetic patients. Drug-induced hypoglycemia can be caused by pentamidine, nonsteroidal anti-inflammatory drugs, salicylates, sulfonamides, clofibrate, phenytoin, rifampin, thyroid hormone, anabolic steroids, and probenecid. Enzyme defects causing hypoglycemia are rare and typically begin in childhood. By prolonging the half-life of insulin and oral

TABLE 38-12 -- MAJOR CAUSES OF HYPOGLYCEMIA

Fasting
Inadequate glucose supply, excessive glucose demand
Reactive
Iatrogenic (abrupt discontinuation of total parenteral nutrition)
Fructose and leucine intolerance and galactosemia
Idiopathic
Artificial (lymphoproliferative disorders)
Data from Black TP Metabolic encephalopathies, In Weiner W J(ed) Emergent and Urgent Neurology Philadelphia, J B Lippincott, 1992, pp 27-57; Lockwood AH toxic and metabolic encephalopathies In Bradley WG, Daroff BB, et al (eds) Neurology in Clinical Practice, 2nd ed Boston, Butterworth-Heinemann 1996, pp 1335-1372; and Yealy DM, Wolfson AB Hypoglycemia. Emerg Med Clin North Am 1989;7 837-848

agents, RF may result in hypoglycemia. Liver disease may also cause hypoglycemia in this way while also impairing glucose production and glycogen storage. Disorders of fatty acid utilization increase the need for glucose and may rapidly result in hypoglycemia. Reactive hypoglycemia is most commonly caused by surgical procedures (iatrogenic) that result in rapid gastric emptying, which, in turn, stimulates excessive insulin release, thereby causing hypoglycemia.^[116]

The neurological symptoms associated with hypoglycemia primarily reflect CNS involvement (e.g., encephalopathy and seizures) and are related to the rapidity of onset. Diagnostic considerations of patients with hypoglycemia depend on the presenting manifestations (e.g., disorders known to produce seizures; when hypoglycemia is associated with such; or disorders known to produce encephalopathy, when hypoglycemia is associated with confusion).

Evaluation. Whipple's triad (hypoglycemic features, laboratory confirmation of a low serum glucose, and resolution of symptoms with glucose replacement) is diagnostic of hypoglycemia. To identify the underlying cause of hypoglycemia, other studies, including serum studies for C-peptide, proinsulin and insulin levels, antibodies to insulin or its receptor, and sulfonyleurea levels, may be required in addition to routine laboratories. Abdominal imaging (CT or MRI) and arteriography, for tumor localization, may be useful. In the evaluation of related neurological symptoms, the EEG reveals generalized slowing, unless the degree of hypoglycemia is mild. In this setting, hyperventilation-induced slowing may persist after hyperventilation is discontinued. In the setting of symptomatic hypoglycemia, the confusional state correlates with EEG slowing. Additionally, seizure activity may be observed. As the glucose level drops further, the comatose state supervenes and burst-suppression activity is demonstrated on the EEG. Intravenous administration of glucose can reverse hypoglycemic seizure activity and coma.

Regarding symptom resolution with glucose replacement, although catecholamine-mediated features usually respond within minutes, the CNS-related features may require longer for resolution.^[116] If the CNS features do not resolve within an hour, permanent CNS damage may have occurred. In addition, the possibility that the hypoglycemia is related to another disorder should be considered.

Management. Prevention of serious morbidity and mortality requires early recognition of hypoglycemia and

prompt glucose replacement, regardless of etiology. To avoid masking of the autonomic (warning) features of hypoglycemia, beta blockers should be avoided in patients taking hypoglycemic agents. To prevent the development of Wernicke-Korsakoff's syndrome in alcoholic and malnourished patients, thiamine supplementation (1 mg/kg) should also be administered before giving glucose. Malnourished patients should also receive niacin to prevent pellagra. Depending on the etiology, more specific therapies may be indicated (e.g., corticosteroid replacement for adrenal insufficiency).

Prognosis and Future Perspectives. Hypoglycemia is associated with a substantial morbidity, primarily related to accidents (e.g., vehicular) and seizures with resultant injuries.^[113] In the setting of hypoxic encephalopathy, premature prognostication should be avoided, given that slow improvement may continue for 1 to 2 years.^[59] When glucose is replaced before the medullary phase is reached, the features may be reversible. After this point, especially if treatment was delayed, recovery may be protracted or incomplete.^[59] The potential risk of glucose administration to euglycemic and hyperglycemic patients is small compared with the potentially substantial benefit. However, the possibility of cerebral ischemia must be considered, because hyperglycemia at the onset of brain ischemia worsens the postischemic outcome, whereas hyperglycemia occurring *after* experimental cerebral infarction does not.^{[54], [117]}

HYPERGLYCEMIA

Diabetic ketoacidosis (DKA) and NKHH, two hyperglycemic syndromes occurring among patients with diabetes, can both present with encephalopathy. In addition, patients with NKHH frequently present in coma or with new-onset seizures. Thus, because neurologists are often summoned early, they must be familiar with these disorders.

Pathogenesis and Pathophysiology. Although the brain tolerates hyperglycemia better than hypoglycemia, encephalopathic features still develop, usually as a

reflection of cerebral dehydration (e.g., intravascular hyperosmolality) or cerebral edema (e.g., too-rapid correction of the hyperglycemia). A correlation between the degree of encephalopathy and the serum osmolality exists, the pathophysiology of which has been discussed (see Hyponatremia). In addition to osmotic effects, intravascular coagulation related to hyperviscosity may occur.^[56]

The primary problem in DKA is insulin deficiency. This results in an increased ratio of glucagon to insulin, accelerated gluconeogenesis, enhanced glycogenolysis, and reduced glucose clearance, thereby producing hyperglycemia.^[118] In addition, insulin deficiency leads to increased fatty acid mobilization and the increased glucagon-to-insulin ratio induces fatty acid oxidation.^[118] Therefore lipolysis and ketone body formation occur. Once the renal threshold is exceeded, glucosuria occurs,^[113] which promotes polyuria, due to osmotic diuresis, and polydipsia. In the setting of NKHH, insulin production is usually sufficient to inhibit lipolysis (i.e., nonketotic) but insufficient to prevent hyperglycemia. As the serum osmolality slowly rises, cerebral idiogenic osmole formation occurs (to prevent dehydration), thereby making the patient susceptible to cerebral edema during rehydration.

Epidemiology and Risk Factors. The major risk factor for the development of hyperglycemia is diabetes mellitus, with a prevalence of about 1 percent in the United States. NKHH accounts for 10 to 20 percent of all cases of severe hyperglycemia,^[119] a value that is decreasing due to earlier detection of uncontrolled hyperglycemia.^[120] Because of the high glucose content of total parenteral nutrition, patients receiving this type of therapy are also at risk of developing hyperglycemia. The incidence of gestational diabetes (carbohydrate intolerance that is present only during pregnancy) ranges from 1 percent in predominantly rural areas to 12 percent in racially mixed urban areas.^[121]

Clinical Features and Associated Disorders. The general medical features of hyperglycemia include polyuria, polydipsia, and anorexia. Patients with DKA tend to be younger, type I diabetics, with a symptom onset measured in days. At onset, the mental status varies from normal (20 percent) to comatose (10 percent) and correlates most to the level of hyperosmolality.^[118] DKA is frequently precipitated by infection or noncompliance with insulin therapy. Patients with NKHH tend to be older, type II diabetics with more pronounced dehydration. Unlike patients with DKA, focal neurological abnormalities, seizures (both focal and generalized), and coma are commonly observed. The most common precipitants of NKHH are infection, chronic renal insufficiency, GI bleeding, pancreatitis, stroke, burns, and certain medications.^[120]

Differential Diagnosis. Although patients who present with encephalopathy may easily be diagnosed with hyperglycemia as the cause, diagnostic difficulty arises when encephalopathic patients present without a history of diabetes. Blood glucose determinations must be performed on all encephalopathic patients, and when they are shown to be hyperglycemic, DKA and NKHH, in addition to uremia, hepatic failure, toxin ingestion, starvation ketosis, alcoholic ketoacidosis, lactic acidosis and other causes of encephalopathy, must be excluded. A history of ethanol abuse and, typically, a lack of hyperglycemia helps differentiate alcoholic ketoacidosis. Evidence of renal dysfunction and the absence of ketones helps differentiate uremia, and starvation ketosis is not associated with hyperglycemia.

Evaluation. In evaluating patients with hyperglycemic-induced encephalopathy, precipitating factors and secondary disturbances should be sought, including electrolyte disturbances (hypokalemia, hypophosphatemia, hypomagnesemia), infection (leukocytosis, urinalysis, chest x-ray study, blood and urine cultures), and hypokalemic-induced EKG changes. In addition, ABGs and serum osmolality, as well as renal and hepatic function, should be assessed. Hyperamylasemia, seen in nearly 80 percent of patients with DKA, may result in an incorrect diagnosis of pancreatitis.^[118] Typical laboratory features in patients with DKA include blood glucose above 400 mg/dl, arterial blood pH below 7.2, bicarbonate below 10 mEq/L, and an elevated serum osmolality (usually below 350 mOsm/L). Ketone bodies and beta-hydroxybutyrate are elevated in the blood and urine, and there is a marked glycosuria.^[113] In patients with NKHH, the blood glucose level is usually above 800 mg/dl and the osmolality above 350 mOsm/L.^[56]

Management. If encephalopathic features are noted in a known diabetic, 25 g of dextrose should be administered intravenously because hypoglycemia is the most common

cause of mental status changes and this dosage will not cause harm in the setting of DKA.^[122] The primary treatment of DKA is insulin replacement, which facilitates glucose uptake and glycogen formation, and reduces the rate of ketone body formation. Volume repletion initially requires NS, because most patients have TBW deficits of roughly 5 L.^[118] This also lessens the degree of cerebral edema. Half-normal saline can be substituted once the orthostasis resolves, and 5-percent dextrose can be added after the glucose drops to 250 mg/dl or below. Although cerebral edema is a concomitant of treatment, a malignant increase in cerebral edema may occur, with resultant increased ICP, rapid deterioration, and death.^[113] In this setting, aggressive treatment of cerebral edema must be undertaken, typically with hyperventilation, mannitol administration, and ICP monitoring. Because the major problem in patients with NKHH is dehydration, the primary treatment is rehydration, followed by insulin therapy and correction of underlying illnesses. Normal saline is the fluid of choice, and once blood glucose levels reach 250 mg/dl, 5-percent dextrose is provided to avoid hypoglycemia.

Seizure control requires normalization of serum osmolality and glucose. Standard antiepileptic drugs are ineffective, and furthermore, some antiepileptic drugs, such as phenytoin, can inhibit the release of endogenous insulin.^[119] In DKA, the rate of patient mortality remains significant (6 to 9 percent), with most deaths related to cardiovascular or cerebral complications, or the precipitating factor.^[113] Mortality rates as high as 40 to 70 percent are reported for NKHH.

Diabetes

The neurological complications of diabetes were first recognized in 1798, and until 1864, diabetes was considered an effect of neuropathy.^[123] For discussion purposes, the neurological complications of diabetes can be divided into CNS, cranial nerve, and PNS disturbances, of which PNS disturbances predominate. These disorders involve different parts of the nervous system, and therefore, produce different clinical manifestations.

CENTRAL NERVOUS SYSTEM COMPLICATIONS OF DIABETES

The brain, although not frequently discussed as a target of the complications of chronic diabetes, is nonetheless affected by this disorder. In addition to the neurological complications of glycemic extremes previously discussed (see Hypoglycemia and Hyperglycemia), patients with diabetes have an increased stroke incidence, increased stroke severity, and possibly, a chronic encephalopathy.^[124] Regarding stroke, diabetes increases the risk of large, medium, and small vessel atheroma, as well as arteriolar and capillary microangiopathy, even after other concomitant risk factors (e.g., hypertension) are excluded.^[125] In addition, studies have shown that the presence of hyperglycemia at the time of stroke results in more severe brain injury and, hence, a poorer stroke outcome (see Hyperglycemia). CNS abnormalities reported in patients with diabetes include increased P-300 latency, abnormal psychometric tests, and among children with diabetes, lower school achievement test scores.^[125] Potential causes for encephalopathy in patients with diabetes include vascular (e.g., stroke, altered BBB function, and cerebrovascular reactivity), metabolic (e.g., altered glycemia, ketosis, hypoxia, electrolyte changes, and neurotransmitter changes), and the co-existence of other disorders (e.g., hypertension, RF).^[124]

Spinal cord abnormalities include infarction and pseudotabes diabetica. Pseudotabes diabetica reflects dorsal root ganglia disease, which, in turn, causes posterior column degeneration. Thus, this actually represents a disorder with a PNS onset resulting in secondary distal axon degeneration (i.e., the dying back phenomenon) causing posterior column degeneration.

CRANIAL NERVE COMPLICATIONS OF DIABETES

The cranial mononeuropathies complicating diabetes primarily involve the oculomotor nerves (i.e., oculomotor [cranial nerve (CN) III], trochlear [CN IV], and abducens [CN VI]). Facial neuropathy and anterior ischemic optic neuropathy are briefly discussed, because these items are reviewed elsewhere in this text. Although peripheral nerve infarction has been the presumed mechanism of cranial mononeuropathies among diabetic patients, microinfarction-induced fascicular disruption within the brain stem parenchyma has been identified in many of these patients.^[126] Diabetic oculomotor cranial mononeuropathies primarily involve CN III, followed by CN VI; CN IV is uncommonly affected alone. Clinically, patients notice the onset of eye pain or headache, followed by diplopia. The ophthalmoplegia reflects muscle weakness in the distribution of a single oculomotor nerve. Typically, in the setting of CN III involvement, pupillary sparing is noted. This likely reflects the peripheral location of the pupillomotor fibers, which are therefore supplied by external larger vessels, rather than internal small vessels. However, this is not always the case. Pupillary involvement is found in 10 to 20 percent of patients with vasculopathic (e.g., diabetes) cranial mononeuropathies and pupillary sparing is found in 8 to 15 percent of patients with aneurysms.^[127] Concerning the latter, pupillary involvement usually appears within 3 to 5 days.^[128] Even patients with complete paralysis tend to recover without residual weakness, usually within 3 months.^[123] Among patients with diabetes, facial mononeuropathies occur with increased frequency and a poor outcome may be observed.^[123] Thus, the facial mononeuropathy associated with diabetes may be secondary rather than idiopathic. Differences noted in diabetic

patients with facial mononeuropathies support this statement and include (1) normal taste (argues for a different lesion site), (2) more frequent recurrent or bilateral facial nerve involvement, and (3) more frequent axon loss as the underlying pathophysiology rather than demyelinating conduction block,^[129] which explains the poorer outcome. Clinically, patients with CN II involvement and an anterior ischemic optic neuropathy suffer acute visual loss, visual field defects (usually inferior altitudinal), or both. Ophthalmologically, a pale and swollen optic disk (usually superiorly), accompanied by flame-shaped hemorrhages within the optic disk or

the peripapillary retina, is observed. In addition, most of these patients have a small optic disk, no central cup, and anomalous branching patterns of the optic disk vessels, a triad referred to as the *disk at risk*.^[127] Importantly, there is a 40-percent chance of a similar episode in the contralateral eye and a 2- to 4-percent chance of a recurrent episode in the same eye.^[127] Among this patient population, the occurrence of diabetes mellitus is increased (20 percent).^[127] However, this may reflect the increased prevalence of hypertension among the diabetic population.

PERIPHERAL NERVOUS SYSTEM COMPLICATIONS OF DIABETES

A great variety of PNS disorders are observed among patients with diabetes, and these disorders can be divided into focal, segmental, and generalized.

Focal Peripheral Nervous System Disorders. The focal PNS disorders include focal myopathies and mononeuropathies. The etiologies of focal myopathies include traumatic (associated with insulin injection injury) and vascular (related to thigh muscle infarction). Mononeuropathies may be divided into those affecting the cranial nerves (discussed earlier) and those affecting the somatic nerves. Somatic mononeuropathies result from entrapment or compression and nerve infarction. Entrapment and compression tend to occur in the same nerves and at the same sites as among the nondiabetic population--median mononeuropathies at the wrist (i.e., CTS), ulnar mononeuropathies at the elbow, and common peroneal mononeuropathies at the fibular head. The prevalence of CTS among diabetics, as among the nondiabetic population, increases in the presence of polyneuropathy.^[130] An increased incidence of ulnar neuropathy also exists, whereas the occurrence of a common peroneal mononeuropathy at the fibular head is likely coincident.^[130] Concerning the lower extremity, although femoral mononeuropathies are the most frequently reported lower extremity mononeuropathies among diabetic patients, they are extremely rare. The initial publications on diabetic femoral neuropathies likely represent mislabeled diabetic amyotrophy (discussed later), and in subsequent publications, these authors noted that the lesions were located more proximally.^[129] Thus, common peroneal mononeuropathies are the most common lower extremity mononeuropathy. These lesions occur unilaterally or bilaterally and can be caused by either compression or nerve infarction.^[129] Regarding patients with nerve infarction, the onset is acute and painful, the pathophysiology reflects axon loss, and recovery is often slow and suboptimal. The poor outcome reflects several features, including (1) the lesions tend to be complete, and robust collateral sprouting cannot occur; (2) the lesions tend to involve the nerve trunks proximally or in their midportion, and the distance required for proximodistal regeneration is greater; and (3) the lesions tend to occur in elderly patients.^[129] Unlike nerve infarction, which produces solely axon loss, compressive lesions may produce demyelinating conduction block, axon loss, or a combination of the two, and therefore, it is not unexpected that, in general, patients with compressive lesions tend to have a better outcome. Except for an attempt to control the serum glucose concentration better, the mononeuropathies occurring among diabetic patients are treated in the same manner as those occurring among nondiabetic patients.

Segmental Peripheral Nervous System Disorders. The diabetic polyradiculopathy syndromes belong to this category. The term diabetic myelopathy was introduced by Bruns in 1890 and was displaced by Garland in 1955 when it became clinically and pathologically apparent that the disease process was not a myelopathy.^[123] Garland suggested the intentionally nonlocalizing term diabetic amyotrophy. Several years later, Sullivan suggested the term asymmetrical (motor) proximal neuropathy, variations of which appear in most current discussions.^[131] Historically, at least 20 synonyms for this entity have been used, which is a reflection of its varied presentations.^[129] The term diabetic thoracoabdominal neuropathy (discussed later) has at least 10 synonyms.^[129] In 1981, Bastron and Thomas proposed the more general term *diabetic polyradiculopathy* for all of the diabetic neuropathies other than distal symmetrical polyneuropathy,^[132] thereby incorporating several of the various diabetic polyradiculopathy syndromes into a single entity (e.g., diabetic amyotrophy and diabetic thoracoabdominal neuropathy). In addition, they coined the term *territorial extension* to describe the cephalad, caudal, or contralateral progression of this process from the root region to another. Based on this framework, Wilbourn drew several important conclusions, including (1) the root level is primarily attacked; (2) single or contiguous roots are attacked most severely; (3) territorial extension occurs in approximately two thirds of patients; (4) some root regions are more likely to be affected than others; (5) when uncommon root regions are involved, they generally follow involvement of the more typical root region; (6) the predominant pathophysiology is axon loss; and (7) the majority of patients have co-existing diabetic distal symmetrical polyneuropathy (DDSPN).^[129] Thus, the commonly observed diabetic amyotrophy reflects isolated root involvement of the L2-L4 root levels, whereas diabetic thoracoabdominal neuropathy reflects isolated root involvement of the mid- to lower thoracic root levels. Also, when patients with diabetic amyotrophy develop foot drop, it most likely reflects territorial extension into the L5 level, and should it progress more caudally, global leg muscle involvement will develop. Bilateral shoulder girdle weakness is occasionally observed.^[129]

Generalized Peripheral Nervous System Disorders. Disorders included in this category are DDSPN and diabetic autonomic neuropathy. DDSPN is the most common form of diabetic neuropathy and resembles the polyneuropathies caused by numerous other disorders. Different diagnostic criteria and methods of detection, applied to patients with diabetes of varying duration (i.e., patient selection bias), have lead to a wide variation in its reported incidence and prevalence. Typically, paresthesias and numbness begin in the toes and ascend proximally in a stocking-like distribution. When the ascent reaches the upper tibia, the hands begin to become involved. Once involved, the upper extremity disturbance also progresses proximally, in a glove-like distribution. This distribution pattern, in which the longest nerves are first affected, is often referred to as a dying-back neuropathy. At this time, diminished or absent ankle reflexes and foot intrinsic muscle weakness are evident. Even anhidrosis follows this pattern, which typically begins in the foot and predisposes patients to foot ulcers.

The electrodiagnostic abnormalities also show a distal to proximal gradient. The most sensitive NCS are the plantar mixed NCS, followed by the superficial peroneal and sural sensory NCS, followed by the upper extremity sensory NCS. The motor NCS abnormalities and needle electrode examination abnormalities follow this same pattern. When one considers that a nerve is made of sensory, motor, and autonomic axons ranging in size from small to large, it is easy to envision the range of clinical symptoms this disorder produces. Small fiber sensory disruption causes loss of pain and temperature perception, as well as more prevalent features of dysautonomia. Large fiber sensory involvement impairs proprioception, vibratory perception, gait (sensory ataxia), and reflexes. Motor axon dysfunction produces weakness, and autonomic axon involvement produces various dysautonomic features. Occasionally, patients present with disproportionate small fiber or large fiber sensory involvement or autonomic involvement. As pointed out by Dyck and colleagues, a continuum of fiber involvement is most common, with the disproportionate cases representing the extremes of a normal distribution.^{[123], [130]} Thus, diabetic autonomic neuropathy can present in isolation, although uncommonly; and the symptoms reflect the wide distribution of autonomic fibers: pupillary (miotic pupils with sluggish light reflex), cardiovascular (resting tachycardia, orthostatic hypotension), GI (constipation), genitourinary (impotence, reduced vaginal lubrication), and sudomotor (distal anhidrosis) systems.^[125] The symptoms, evaluation, and management of diabetic autonomic neuropathy have been reviewed.^[133] Hyperglycemic polyneuropathy refers to transient, distal paresthesias or dysesthesias occurring just before the diagnosis of diabetes or following ketoacidotic coma. The treatment of painful diabetic neuropathy is often the major management problem and can be challenging. For mild cases, simple analgesics may suffice, as may cold water soaks and the use of support stockings for evening pain. The potential for nephrotoxicity limits the usefulness of chronic nonsteroidal anti-inflammatory drugs, and the potential for addiction (as well as the occurrence of tolerance) limits the utility of narcotics. Tricyclic antidepressants, such as amitriptyline and nortriptyline, desipramine, carbamazepine (perhaps the drug of choice if the pain is lancinating or paroxysmal), and mexiletine have been shown to be of value. The anticholinergic side effects associated with the tricyclic antidepressants limit their utility for patients with accompanying autonomic dysfunction. These agents, as well as others, have been reviewed.^[125]

ORGAN FAILURE

Hepatic Failure

Because of the complexity of liver metabolism, patients with liver disease may develop many complications, including neurological dysfunction. This problem can be expected, considering the important role the liver plays in both nutrient metabolism (glycolysis, nutrient biosynthesis) and detoxification. The term HE refers to diffuse cerebral dysfunction occurring secondary to liver disease. When HE develops acutely in patients with liver disease of less than 8 weeks' duration, the term fulminant hepatic failure (FHF) is used, whereas the term portal-systemic encephalopathy (PSE) is used when HE develops in patients with chronic liver disease. This differentiation has therapeutic implications because a number of treatments exist for patients with PSE, whereas no specific form of treatment has been proved beneficial in FHF, except urgent liver transplantation.

Pathogenesis and Pathophysiology. Although neither the responsible toxin nor the pathogenesis of HE is known, it is believed to result from impaired hepatic degradation of neurotoxic substances arising from the GI metabolism of nitrogenous compounds. Normally, these GI products are delivered to the liver by the portal vein. There are two mechanisms by which hepatic impairment may result in the systemic accumulation of these gut-derived substances: (1) direct entry of portal vein-derived blood into the systemic circulation (shunting) secondary to the formation of portal systemic collaterals (e.g., PSE) and (2) impaired detoxification secondary to hepatocyte dysfunction (e.g., FHF). HE results in increased BBB permeability, which, in turn, enhances the entry of these substances into the CNS, facilitating the development of HE. This may explain the reason patients with liver disease can become symptomatic with only minimal hyperammonemia and their sensitivity to precipitation by ammonia-producing processes.^[134] Normally, the brain removes ammonia by converting it to glutamine. If glutamine accumulates rapidly, the increased intracellular osmolality of the brain can cause cerebral edema.^[135]

A variety of substances have been implicated in the pathogenesis of HE, including ammonia, endogenous benzodiazepines, Na/K ATPase inhibitors (e.g., glutamine, short-chain fatty acids, aromatic amino acids, and mercaptans), false neurotransmitters (e.g., octopamine), and gamma-aminobutyric acid.^[136] The leading hypothesis relates to the effects of ammonia and states that HE results from its systemic accumulation. Findings supporting this hypothesis include (1) patients with HE usually have elevated arterial ammonia levels, (2) the degree of hyperammonemia correlates with the depth of coma, (3) ammonia metabolites (alpha-ketoglutarate and glutamine) are elevated in the brains and CSF of patients with HE, (4) the BBB permeability increases for ammonia, (5) the cerebral metabolic rate increases for ammonia, (6) experimental administration of ammonium salts results in reversible HE, (7) ammonia-forming compounds in the GI tract (e.g., protein meals, blood) reproducibly precipitate coma, (8) all proven treatments reduce blood ammonia levels, and (9) patients with urea cycle enzyme defects develop hyperammonemia and encephalopathy in the setting of normal liver function.^[134], ^[135], ^[137] A second hypothesis is the false neurotransmitter theory. This theory suggests that the increased ratio of aromatic to branched-chain amino acids occurring in liver failure causes an increased entry of aromatic amino acids into the brain (i.e., less competition). The enhanced entry of aromatic amino acids, in turn, increases the synthesis of serotonin and false neurotransmitters (e.g., octopamine). The increased quantities of false neurotransmitters could theoretically competitively inhibit the normal function of true neurotransmitters. However,

although false neurotransmitters do accumulate in PSE, there is no evidence that they are responsible for the encephalopathy. Because the pathogenesis of HE is probably not due to the accumulation of any single cerebral toxin, a multifactorial process is more likely, with the accumulation of multiple substances synergistically contributing to its development.

Epidemiology and Risk Factors. FHF is rare, with an incidence of approximately 2000 cases per year in the United States.^[138] Viral hepatitis, usually hepatitis B or hepatitis C, is the most common cause of FHF in the United States and accounts for approximately 75% of cases.^[138] Among patients with hepatitis B, approximately 1 percent develop FHF. Drug-induced liver dysfunction is second in frequency.^[135] Abnormalities associated with liver disease, such as hypoxia, acid-base disturbances, and electrolyte abnormalities, predispose patients to the development of encephalopathy. Retrospective epidemiological studies have shown a correlation between intracranial hemorrhage and hepatic disease, with the relative risk for intracranial hemorrhage increased roughly five-fold among patients with liver disease.

Clinical Features and Associated Disorders. The neurological manifestations of HE range from subtle psychomotor abnormalities to coma and death. The exact clinical picture depends on the rapidity of onset, the degree of liver dysfunction, and the degree of portal-systemic shunting. PSE, the much more commonly encountered form, is mostly observed among patients with chronic liver disorders (e.g., cirrhosis). In addition to the neurological features, these patients may have numerous other clinical findings (Table 38-13). PSE is typically precipitated by ammonia-producing processes, such as GI bleeding, increased dietary protein, constipation, and azotemia. Other known precipitants include infection, hypokalemia, hypoglycemia, hypoxia, and medications (e.g., sedative-hypnotics, analgesics).^[137] Usually, the onset of encephalopathy is slow and insidious, often beginning with anxiety, altered sleep patterns and mood, agitated delirium, or a decreased attention span. Eventually, lethargy progresses to stupor and coma.^[137] Asterixis is almost always present, and as the encephalopathy progresses, increased muscle tone, hyperreflexia, and extensor plantar responses are commonly noted. As part of the coma, decorticate and decerebrate posturing may also be observed. Unless a superimposed acute event occurs, cerebral edema is uncommon in these patients.^[136] Unlike UE, seizures are infrequent and suggest the presence of a coexistent disorder.

TABLE 38-13 -- CLINICAL FEATURES OF CHRONIC LIVER DISEASE

Subjective	Objective
Anorexia, fatigue	Jaundice, scleral icterus, Kayser-Fleischer rings (Wilson's disease, primary biliary cirrhosis), fetor hepaticus (musty, sweet breath odor), spider nevi, gynecomastia, caput medusa (dilation of the umbilical vessels), splenomegaly, ascites, xanthomas, palmar erythema, Dupuytren's contractures of the hands and feet

The onset of FHF is much more rapid and is typically associated with severe liver disease. Mental status changes, such as agitation, inappropriate behavior, and impaired judgment, appear early and may quickly progress to stupor and coma. Unlike PSE, cerebral edema with increased ICP is common and may result in cerebral herniation and death. Seizures and focal neurological signs are uncommon and suggest a co-existent process (e.g., subdural hematoma [SDH]).

In addition to developing encephalopathy, some patients with chronic liver disease develop hepatocerebral degeneration, a slowly progressive and irreversible neurodegenerative syndrome associated with extensive portosystemic shunting. It is characterized by tremor, rigidity, bradykinesia, ataxia, dysarthria, choreoathetosis, and dementia. Studies have shown a selective loss of dopaminergic D2 (postsynaptic) receptors in the globus pallidus of patients with PSE, suggesting that these extrapyramidal signs may reflect dopaminergic neuronal dysfunction.^[137] Rarely, spinal cord degeneration (hepatic myelopathy), characterized by spastic paraparesis, hyperreflexia, and extensor plantar responses, is observed.^[139] The presence of polyneuropathy has been variably reported. When they are present, these signs are typically mild or asymptomatic. It is not known whether these neuropathic changes are directly related to hepatic dysfunction or to the disease process causing the liver impairment (e.g., alcohol abuse, hemochromatosis).

Differential Diagnosis and Evaluation. Any disorder resulting in liver failure may cause HE. Viral hepatitis is the most common cause of FHF in the United States, followed by drug-induced liver dysfunction (e.g., acetaminophen, isoniazid, rifampin, methylodopa [Aldomet], halothane), fatty infiltration, Reye's syndrome, infiltrative diseases, and less common causes.^[131], ^[138]

The diagnosis of HE is clinical and depends on the identification of precipitating factors and the observation of a good response to empirical treatment.^[140] Unfortunately, there are no pathognomonic features of HE, and all of its typical features may be noted with encephalopathies of other etiologies. Patients suspected of having HE require a thorough neurological examination. Laboratory studies help exclude alternative etiologies of encephalopathy and identify other complications related to hepatic disease. Potentially helpful laboratory studies include a CBC, electrolytes, BUN, Cr, glucose, Ca, drug screen, B₁₂ level, ABGs, and liver function tests. There is no correlation between the degree of HE and the degree of liver function test abnormality. In fact, liver function tests may be normal in the setting of severe, chronic liver disease. An arterial blood ammonia level should be drawn, placed on ice, and immediately assayed. Venous samples are unacceptable because tourniquet-induced muscle ischemia can result in the release of ammonia from muscle (possible false-positive result), and muscle itself can take up variable amounts of ammonia producing false-negative results.^[134] Although it is infrequent, a normal value does not exclude HE, especially in the fasted state.^[136], ^[140] Although its absolute value does not correlate with the degree of HE, the ammonia level is useful in following the individual patient's course and response to therapy.

The EEG typically reveals generalized slowing, and triphasic waves may also be seen. Triphasic waves, although

characteristic of HE, are not specific for this disorder and can be observed in a wide variety of encephalopathic states and structural processes ([Fig. 38-3](#)). Because the degree of slowing is proportional to the severity of encephalopathy, serial EEGs allow for the assessment of the subsequent clinical course and response to treatment. If the patient is febrile or if meningismus is observed, CSF analysis should be cautiously performed, because increased ICP or a coagulopathy may also be present in this patient population. The opening pressure should be recorded and routine CSF studies obtained. In HE, the CSF protein may be mildly elevated, and glutamine levels are usually elevated. The glutamine level has been cited as the biochemical parameter most closely correlated to the degree of HE. ^[135], ^[141]

Once HE is diagnosed, the degree of impairment should be clinically graded and used as a baseline for future comparisons. Daily handwriting samples, number connection tests (e.g., trailmaking), and mental status examinations are helpful in the daily assessment of patients with HE. ^[136] The most widely used grading system categorizes patients into one of four stages, based primarily on alterations in mentation and the EEG. ^[135] Stage I is characterized by subtle changes in thought processes and personality, such as dyscalculia, poor handwriting, impaired construction of simple figures, difficulty connecting a series of numbers, and sloppiness. At this stage, any abnormalities on the EEG are subtle. In stage II, more obvious changes in thought processes, such as confusion, inappropriate behavior, decreased attention, drowsiness, and abnormal sleep patterns, are noted. Asterixis and hyperreflexia are usually present, and clonus as well as extensor plantar responses may also be observed. The EEG shows generalized slowing. In stage III, further worsening of thought processes occurs, with confusion and an even shorter attention span. The patient is unable to perform fine motor movements and remains asleep most of the time. Asterixis is present, and the EEG shows more pronounced slowing; in addition, triphasic waves may be observed. In stage IV, the patient is comatose. Brain stem reflexes persist until the deepest stages of coma are reached. The EEG shows generalized delta frequency slowing. ICP monitoring can be helpful in the management of patients in stages III and IV by guiding therapy, facilitating the early detection of rising ICP, and identifying patients with sustained ICP elevations, so that they may be excluded from emergency liver transplantation procedures. ^[135] When ICP monitoring cannot be performed, the patient must be followed closely for evidence of cerebral herniation so that treatment can be provided at a time when the process may be reversible.

In HE, focal neurological features are unexpected and suggest a co-existent structural abnormality (e.g., SDH) or focal metabolic abnormality (e.g., postictal state). In these cases, CT or MRI studies of the head are warranted. In patients with hepatocerebral degeneration, reversible MRI abnormalities, which are most pronounced in the globus pallidus, may be seen. A recent expedited publication reported that proton magnetic resonance spectroscopy can be used to detect specific metabolic abnormalities in this region of the brain, thereby constituting an early marker of metabolic alteration. ^[142]

Management. Prevention is an important aspect of treatment among patients with chronic liver disease. Known precipitants of HE should be avoided and, if they are identified, reversed. Because the onset of PSE is slow, insidious, and often subclinical, patients with chronic liver disease should undergo periodic psychometric testing. ^[143] As many as 70 percent of patients with cirrhosis and without evidence of an overt encephalopathy have significant impairment when tested. ^[134] Because the visuospatial sphere is the most frequently affected, the Reitan Trials A and B,

Figure 38-3 A 58-year-old patient with hepatic encephalopathy. The patient's EEG demonstrates classic triphasic waves that are more prominent ante. (From Luders HO, Koechler S: *Atlas und Klassifikation der Elektroenzephalographie*, Verlag, CIBA-Geigy 1994, p 118.)

Block Design, and Symbol-Digit subtests of the Wechsler Adult Intelligence Scale-Revised (WAIS-R), as well as the Purd Pegboard test are frequently employed and commonly found to yield abnormal results. ^[134]

In the patient with HE, empiric therapy should be initiated, whereas other causes of encephalopathy are being excluded and precipitating factors are being sought. Thiamine hydrochloride, 100 mg IV, is administered and should be followed by a daily dosage of 50 mg PO to prevent Wernicke-Korsakoff syndrome.

General measures in the treatment of HE include maintaining adequate nutrition, good renal function, and acid-base status, as well as reducing colonic ammonia production. Because normal brain pH is 6.95 and blood pH is 7.4, there is a tendency for ammonia to enter the brain. By minimizing the interaction between enteric bacterial flora and nitrogenous substances, colonic ammonia production is reduced. Dietary protein restriction, avoidance of constipation, and GI tract evacuation are helpful in this respect. The GI tract is evacuated through the use of cathartics (e.g., lactulose) and enemas. Lactulose is a synthetic disaccharide capable of reducing arterial ammonia levels. In the colon, it is converted into acidic metabolites, which create a pH gradient across the intestinal wall. Colon acidification was thought to select for bacteria that did not contain urease. Instead, colon acidification decreases blood ammonia by trapping it in the acidified feces, thereby making it unavailable for absorption. ^[144] In addition, the pH gradient causes movement of ammonia into the colon. The dosage is usually titrated to yield 2 to 3 soft bowel movements per day, typically requiring 30 to 40 g four times daily. If the patient is comatose, hourly doses of 20 to 30 g are provided until a catharsis is produced, after which the dosage can be reduced. ^[134] Some patients do not tolerate lactulose, presumably because of the associated contaminants, such as lactose, galactose, and other carbohydrates. Lactitol, another synthetic disaccharide, is better tolerated. It is purer than commercial lactulose and, therefore, has less adverse effects, such as nausea, diarrhea, and intestinal cramping. Unfortunately, it is more expensive and not available in the United States. Neomycin, a nonabsorbable antibiotic, kills colonic bacteria, and thereby decreases both the bacterial nitrogen content and the synthesis of urea. Compared with lactulose, it has more side effects without increased efficacy. In addition, there is some evidence that aminoglycosides contribute to the development of hepatorenal syndrome, and for that reason, they are rarely used today. In the setting of neomycin resistance, metronidazole is an alternative. Dietary protein restriction (less than 1 g/kg dry weight of high biological value protein) and the administration of multivitamins, folate and thiamine supplements, vitamin K, and at least 2000 calories per day should be provided. ^[138], ^[143] Therapies considered to be nonbeneficial include branched-chain amino acid solutions, serotonin reuptake inhibitors, L-dopa, and bromocriptine. ^[137] Sodium benzoate was also shown to reduce blood ammonia levels in a double-blinded and randomized trial of 38 patients with PSE. ^[145] Improvement within 1 to 3 days of starting empirical therapy is expected. Failure to respond suggests the wrong diagnosis, a missed precipitant, multiple causes of the encephalopathy, or the most common cause, a missed nosocomial infection. ^[140] In addition to the general measures listed earlier, more specific treatments may be required. Orthotopic liver transplantation (OLT) represents an alternative for patients with little chance of recovery. A review of the patients undergoing OLT reported a number of neurological sequelae, including severe quadriplegia, perioperative mononeuropathies, and herpes zoster-related radiculopathies. ^[146] A recent review of the causes and outcome of seizures in the post-OLT patient population revealed that the majority of new-onset seizures after OLT were related to immunosuppressive treatment, did not require antiepileptic drug (AED) therapy for favorable long-term outcome, and were not as ominous as previously thought. ^[147]

Prognosis and Future Perspectives. The mortality rate for patients with FHF, despite aggressive therapy, is approximately 85 percent. ^[134] Age, etiology, and degree of encephalopathy influence survival in FHF. Younger patients have a more favorable outcome, with the discriminatory age lying between 30 and 50 years. ^[148] Recovery from FHF is expected when the condition is due to hepatitis A and acetaminophen hepatotoxicity, yet the rate is only 40 percent when it is associated with hepatitis B and 20 percent when it is associated with hepatitis C or drug-induced hepatitis. When FHF is associated with Wilson's disease, recovery almost never occurs. ^[135], ^[149] The recovery rate approaches 75 percent for patients who do not progress beyond stage II, whereas less than 20 percent of those patients reaching stage IV survive. ^[135] In patients with FHF, death is commonly caused by complications involving other organ systems, two thirds of which are neurological. ^[138] OLT has increased the survival rate significantly (50 to 90 percent) and, in the case of patients with cirrhosis, can normalize their neuropsychiatric status. Ultimately, the prognosis is related to the ability of the liver to regenerate or the availability of livers for transplantation.

Typically, patients with PSE have a good prognosis for full recovery, especially if a precipitating factor can be identified and reversed. When the cause cannot be reversed, continuous therapy is required (e.g., surgical portacaval shunts). Still, the underlying etiology, the occurrence of secondary complications, and the degree of encephalopathy affect survival. Favorable prognosticators include an identifiable and treatable precipitant, mild encephalopathy, and lack of secondary complications. ^[134]

Renal Failure

The kidney is one of the principle homeostatic organs of the body and is involved in the regulation of water, electrolyte, and acid-base balance; the excretion of metabolic waste products; and the synthesis of erythropoietin, renin, and 1,25-DHCC. This section focuses on the neurological manifestations of RF, both acute (ARF) and chronic (CRF), and the neurological complications of its treatment.

Pathogenesis and Pathophysiology. UE regularly occurs when the glomerular filtration rate falls below 10 percent of normal, regardless of whether it occurs with

ARF or CRF.^[150] The fact that dialysis can rapidly clear UE suggests that the responsible molecules causing UE are water soluble and small to moderate in size. However,

because renal insufficiency causes a spectrum of biochemical abnormalities, the individual significance of any single abnormality is indeterminable.

Although water, osmolality, acid-base, and electrolyte abnormalities are commonly observed in patients with RF, they do not appear to contribute substantially to the development of UE. The brain water content in uremic patients is normal,^[151]^[152]^[153] and an absence of brain edema in animals with acute uremia^[152] further argues against water toxicity as the cause of UE. Although the increase in brain osmolality (from 310 to 350 mOsmol/kg water) noted in ARF patients is due to urea, this compound is nontoxic, even at high concentrations.^[53] Among CRF patients, urea constitutes only half of the osmotically active particles, with the unidentified remainder referred to as idiogenic osmoles.^[154] The lack of a significant gradient between the blood, CSF, and brain urea concentrations^[155] also argues against osmolality variability as the primary cause of UE.

The accumulation of toxic organic acids in the CNS has been proposed as a possible mechanism of UE.^[60] However, studies of CSF acidity in uremic patients^[156] and of acid-base balance in the CSF, blood, brain, and skeletal muscle of uremic dogs^[157] have been normal. Although the permeability of the BBB is increased toward insulin and sucrose, its permeability toward weak acids is decreased.^[53]

Cooper and associates^[153] studied the brains of 10 patients who had died of uremia and noted the brain content to be normal for K, Cl, and Mg; slightly decreased for Na; and approximately doubled for Ca. In experimental uremia, increased brain Ca levels have been associated with an increase in the PTH level.^[153] In addition, the increase coincided with the onset of EEG abnormalities, with both appearing about 2 days after onset of the RF. In a study of 20 dialysis patients with EEG slowing, a direct correlation was noted between the plasma concentration of the N-terminal fragment of PTH and the degree of EEG slowing.^[158]^[159] Administration of PTH to normal dogs produces EEG changes similar to those seen in uremic animals. The EEG abnormalities, as well as the increased brain Ca, can be prevented by performing a parathyroidectomy before the induction of RF.^[53] PTH accumulation probably affects the Ca pump,^[160] suggesting that this hormone is a uremic toxin.^[161] Although more recent studies have corroborated the relationship between PTH and brain Ca content abnormalities,^[162] the fact that this hormone is not dialyzable argues against it as the uremic toxin responsible for UE. Ca content may be affected by other system abnormalities.

Uremic neuropathy (UN) is the most common neurological manifestation observed among CRF patients. It is pathologically characterized by axon loss. Its pathogenesis is unknown but, like UE, improvement occurs following dialysis, suggesting that the responsible substances are dialyzable. Because some patients experience neuropathic improvement only when their dialysis time is increased, it is postulated that the responsible substances are larger than urea (because larger molecules require more time to cross dialysis membranes). Hypotheses concerning the role of PTH and Ca metabolism in UN have been advanced and are supported by the following features: (1) PTH increases the Ca content of nerve; (2) increased nerve Ca content slows its conduction velocity; (3) the observed slowing is prevented by performing parathyroidectomy before the administration of PTH; and (4) the PTH level is inversely related to the nerve conduction velocity in uremic patients. Like UE, the strongest argument against PTH as the mediator of UN is its nondialyzability. Also, hyperparathyroidism is not typically associated with a neuropathy.

Epidemiology and Risk Factors. In the United States, although the frequency of ARF is low (roughly 30 patients/ million/year),^[163] the prevalence of end-stage renal disease increased from 45,000 in 1977 to greater than 165,000 in 1990.^[164] In the United States, hypertension and diabetes are the leading causes of CRF.^[164] The most important risk factors for the development of UN are the duration and severity of the RF.^[158] In recent years, the appearance of neuropathy in chronic hemodialysis patients has become rare,^[165] which is the result of earlier treatment, more intensive dialysis, and technical improvements in dialysis membranes (thinner, with greater clearance properties).^[166]

Clinical Features and Associated Disorders. The clinical features of UE are similar to those of other metabolic encephalopathies. The typical progression of clinical features begins with inattentiveness, impaired concentration, fatigue, apathy, and irritability, which is usually accompanied by motor manifestations (e.g., tremor, asterixis, and myoclonus). Tetany, seizures (focal and generalized), focal neurological signs, and meningeal features are also common.^[113]^[167] One or more of these features may predominate, and symptom fluctuation is typical. Without treatment, coma develops and Kussmaul breathing may be followed by Cheyne-Stokes breathing. Simultaneous evidence of CNS depression (lethargy, obtundation, coma) and excitation (agitation, myoclonus, seizures) are important features of UE.^[158] In CRF patients, personality changes and features of polyneuropathy may be the earliest features, because the encephalopathic manifestations may not appear until the process is advanced.^[54]^[168]

Asterixis, first described by Adams and Foley^[169] in patients with PSE and later noted by Tyler in uremic patients,^[170] is a nonspecific feature of metabolic encephalopathies typically present once higher cortical function is affected.^[167]^[171] In patients incapable of voluntarily maintaining a posture (e.g., comatose patients), the examiner can position the ankles of a supine patient near the buttocks and observe for abduction-adduction movements at the hip joints.^[172] Myoclonus is often multifocal and is more common in the deeper stages of encephalopathy.^[166]^[167] Uremic twitching (severe asterixis with myoclonus) can be continuous and evident during both wakefulness and sleep,^[59] and may simulate a multifocal seizure disorder,^[167] chorea, or ballismus.^[173] Other motor system abnormalities include muscle cramping and tetany, which may be overt or latent.^[158]^[167]

Seizures, which are relatively uncommon in other metabolic encephalopathies,^[166] occur in approximately 25 percent of patients with UE. The seizures are usually generalized,^[166] although focal motor seizures may also be seen.^[158]^[173] Seizures occur earlier and more frequently (40 percent) among ARF patients than among CRF patients (10 percent).^[166] In addition, seizures may occur due to dialysis disequilibrium syndrome (see later), hypertensive encephalopathy, water intoxication, or other metabolic encephalopathies.

Unlike the flaccidity characterizing some metabolic encephalopathies,

limb tone is usually increased in UE and may even be asymmetrical.^[166]^[167] As the disorder progresses, opisthotonic or decorticate posturing may be observed.^[174] Cranial nerve reflexes (e.g., corneal, oculocephalic, and pupillary) are normal, unless the patient is deeply comatose.^[158] Sensory examination abnormalities in a stocking-glove distribution and hyporeflexia suggest the presence of UN. Wernicke's encephalopathy has been reported in hemodialysis patients, which is a reflection of the water-soluble, and hence dialyzable, nature of thiamine.

UN is a symmetrical, sensorimotor, axon loss, dying-back (i.e., it has a distal-proximal gradient) polyneuropathy that is clinically indistinguishable from other polyneuropathies that have a stocking-glove distribution. Although lower extremity vibratory sensation impairment^[175] and loss of deep tendon reflexes^[170] have been reported as early features, suggesting early large-fiber involvement, a wide spectrum of clinical patterns has been observed. The sensory aspects of UN were recently studied, and paradoxical heat sensation (i.e., the perception of heat in response to low temperature stimulation), was identified in 15 of 36 (42 percent) patients,^[176] more than four-fold greater than the normal population.^[177] Although burning dysesthesias have been frequently cited as a characteristic feature of UN, Asbury has reported them to be rare, a likely reflection of routine supplementation with thiamine and other water-soluble vitamins. Autonomic symptoms, such as orthostasis, impotence, diarrhea, and hyperhidrosis, are commonly reported.^[178] An acute, flaccid quadriplegia has also been reported.^[179] The restless legs syndrome (see [Chapter 54](#)) occurs in over 40 percent of uremic patients^[180]^[181]^[182] and may be a harbinger of polyneuropathy. Although distal lower extremity cramping has also been suggested to herald polyneuropathy, cramps occur in patients without neuropathic features and are more frequent among patients with ARF.^[166] Other features reported in uremic patients include myopathy,^[60]^[183] optic neuropathy, isolated mononeuropathies, flaccid quadriparesis (due to hyperkalemia), and vestibulocochlear and neuromuscular junction disturbances (due to aminoglycoside antibiotics). CTS is another manifestation of uremia that may result from the deposition of amyloid fibrils. The amyloid fibrils are composed of beta-2 microglobulin, a substance that is poorly dialyzed and builds up over time in chronically hemodialyzed patients. The shoulder joints and carpal bones are frequently involved and abnormalities may be seen on plain films of these areas.

Differential Diagnosis and Evaluation. When patients with known RF present with encephalopathic features, concomitant medical problems, such as DKA, hypertensive encephalopathy, hypertensive intracranial hemorrhage, intracranial abscess, infectious meningitis, primary CNS lymphoma, and hepatic or pulmonary insufficiency, should be sought. Current medications should be reviewed for drugs that are metabolized or excreted by the kidney, especially those known to have neurological manifestations. For patients receiving dialysis treatments, determine (1) the temporal relationship between the last dialysis session and the onset of encephalopathic features, (2) the current dialysis regimen, (3) occurrence of neurological symptoms with previous dialysis sessions, and (4) the length of time the patient has been undergoing maintenance dialysis. Initial laboratory studies should include CBC with differential, prothrombin time (PT), partial thromboplastin time

(PTT), electrolytes, BUN and Cr, glucose, liver function tests, Ca, Mg, P, and urinalysis. Finally, if infection is suspected and a source is not immediately apparent, lumbar puncture for CSF analysis should be performed.

Patients with RF who have focal neurological findings or seizures require additional evaluation with head CT or MRI to evaluate for SDH, intracerebral hemorrhage, infarction, abscess, neoplasm, or other focal processes. An EEG is also helpful and typically shows diffuse slowing (indicative of an encephalopathy), may show triphasic waves (consistent with a metabolic process), and sometimes shows paroxysmal activity that includes spikes or sharp waves.^[56] Electrodiagnostic testing helps characterize an identified polyneuropathy and may be used to monitor the course of disease after dialysis has been initiated. Secondary hyperparathyroidism should be considered in those patients noted to have proximal extremity muscle weakness and the appropriate laboratories ordered.^[166]

Management. Because drugs requiring renal metabolism or excretion can accumulate to toxic levels in patients with RF, medication selection is important for the prevention of neurological side effects. In this population, aminoglycoside antibiotics are commonly used but may cause cochlear, vestibular, or neuromuscular junction disturbances. The use of B vitamin supplementation in those patients undergoing maintenance dialysis can help prevent UN.

UE requires definitive treatment and is directed toward correcting its cause (e.g., urinary tract obstruction), when possible. Otherwise, dialysis is required to manage fluid, electrolyte, and acid-base imbalances commonly seen in this setting. A nutritionist, to recommend dietary guidelines (e.g., salt, protein), can be very helpful. Because tremulousness, asterixis, and myoclonus tend to resolve as the UE improves, they usually do not require specific treatment. When they are severe, asterixis and myoclonus may respond to clonazepam or valproic acid.

The management of seizures in this patient population warrants separate discussion because changes in plasma protein binding and AED metabolism complicate its management. For highly protein-bound AEDs, such as phenytoin, decreased plasma protein binding increases the percentage of unbound (free, active) drug. Normally, phenytoin is about 90 percent protein bound and 10 percent unbound, yet in uremic patients, the percentage of unbound phenytoin may approach 25 to 75 percent.^[113], ^[184] Because the rate of AED diffusion into the brain is proportional to the unbound fraction,^[185] the CNS concentration increases^[186] and adjustments may be required. Because the therapeutic range of total phenytoin is 10 to 20 µg/ml and nonuremic patients have 10 percent in the unbound state, the therapeutic range of free phenytoin is 1 to 2 µg/ml. Therefore, when uremic patients require phenytoin, the required dosage is best determined by following the free phenytoin level. Because phenytoin is not dialyzable, supratherapeutic levels should be used only when necessary for seizure control. A potential for cross-reactivity between phenytoin and its metabolites exists whenever immunological methods are used to determine free phenytoin levels and can result in falsely elevated levels.^[187] For any given

phenytoin dose, the drug level is lower in patients with RF,^[188] a reflection of the increased volume of distribution^[189] and rate of metabolism.^[190], ^[191] The rate of metabolism reduces the half-life of phenytoin to 8.1 hours in uremics.^[190] The increased proportion of free phenytoin balances the greater volume of distribution and shorter half-life; thus, the same loading and maintenance doses used in nonuremic patients are used in this clinical situation. However, because the half-life is decreased, a dosage regimen of three times a day is favored over a twice-daily regimen.

Although phenobarbital is renally excreted, it is a useful AED for the treatment of epilepsy in this patient population, provided that sedation can be avoided. Because phenobarbital is only 40 to 60 percent protein bound, its level can be decreased by dialysis. When phenobarbital is used, a postdialysis serum phenobarbital level should be obtained and a supplemental dosage provided. Valproic acid is useful for myoclonus and generalized seizures. Seizures occurring during or up to 8 hours after a dialysis run can be a manifestation of the dialysis disequilibrium syndrome. In these patients, prophylactic AEDs are recommended until uremia is controlled.^[171] Also, decreasing the blood flow rate and duration of dialysis, increasing dialysis frequency, and the administration of hypertonic mannitol during dialysis can help with seizure control.

Treatment of the RF improves the UN, and patients with mild UN typically recover completely with maintenance dialysis. Conversely, patients with severe UN rarely recover, even after several years of treatment, and the slowed nerve conduction velocities are only mildly improved by dialysis.^[166] Renal transplantation is much more effective at relieving neuropathic symptoms than is maintenance dialysis.^[192], ^[193] NCS show improvement within days of transplantation^[194] and the improvement continues with complete recovery at times.^[192], ^[193] Neuropathic pain associated with RF can be treated as well with tricyclic antidepressants or Carbamazepine (see [Chapter 20](#)). Uremic optic neuropathy causes rapidly progressive visual loss that responds to hemodialysis and corticosteroid treatment.^[60]

NEUROLOGICAL COMPLICATIONS OF DIALYSIS

Complications associated with dialysis include dialysis disequilibrium syndrome (DDS), dialysis dementia, SDH, dialysis headaches, exacerbation of migraine headaches, muscle cramping, neurological vitamin deficiency syndromes, ischemic neuropathy due to the presence of an arteriovenous fistula, and CTS.

DDS refers to a transient form of encephalopathy related to dialysis. Although its pathogenesis is unknown, it most likely results from a shift of water into the brain (i.e., cerebral edema) in response to the rapid reduction of serum osmolality occurring with dialysis. The duration of symptoms reflects the time required for the brain to decrease its own osmolality. In the predialysis state, idiogenic osmoles allowed the brain to protect itself against dehydration (i.e., it countered the increased serum osmolality). Conversely, in the postdialysis state, this previously protective feature becomes detrimental. Arieff and colleagues^[158] compared different rates of hemodialysis in uremic dogs and showed that the amount of cerebral edema was greater in the more rapidly hemodialyzed group. This hypothesis is further supported by the appearance of DDS during the early phases of a hemodialysis program rather than after routine maintenance dialysis has begun. This likely reflects the greater net difference between the predialysis and postdialysis serum concentrations of dialyzable molecules occurring with the earlier dialysis treatments. The onset of DDS is usually around the third or fourth hour of a dialysis run (sometimes up to 24 hours after) and typically lasts several hours. Although DDS is seen in all age groups, it is more common at the extremes of age. Delirium, although infrequently precipitated, often lasts several days.^[195] Symptoms of DDS are usually self-limited and include headache, anorexia, nausea, emesis, hypertension, disorientation, tremors, twitching, blurred vision, fatigue, muscle cramps, restlessness, and dizziness.^[196] More serious neurological sequelae, such as seizures, coma, and death, were not uncommon before 1970, when aggressive dialysis was used. Uncommon features, including exophthalmos, increased intraocular pressure,^[197] papilledema,^[60] and increased ICP, have been reported.^[158] If muscle cramping occurs, it may respond to quinine sulfate, 320 mg PO, at the beginning of each dialysis.

The differential diagnosis of DDS includes malignant hypertension, Wernicke's encephalopathy, UE, dialysis dementia, SDH, hyponatremia, hypercalcemia, hypoglycemia, NKHH, hypoxic-ischemic processes, copper and nickel intoxication, and excessive ultrafiltration.^[150] DDS may respond to an extension of the dialysis period from 4 to 6 hours, or switching to peritoneal dialysis.

Dialysis dementia, also called dialysis encephalopathy, is a rare, subacutely progressive, irreversible, and fatal encephalopathy that was initially described in 1972 in chronic hemodialysis patients.^[198] The disorder usually begins with memory problems and dysarthric, stuttering, hesitant speech, progressing to mutism, asterixis, myoclonus, dementia, coma, and death.^[54] The speech disorder is initially intermittent, appearing during and just after dialysis, but eventually becomes permanent.^[59], ^[167] Other features include personality and behavioral changes, and occasionally apraxia of speech.^[59] Delusions, hallucinations, gait disturbances,^[60] and focal neurological abnormalities^[167] may also be seen. Seizures are common and usually multifocal.^[199]

It is now strongly suspected that dialysis dementia is caused by high brain aluminum content. In 1976, Alfrey and co-workers^[200] reported that the brain aluminum content was greater in patients with dialysis dementia than it was in normal controls. Although oral P-binding drugs were initially considered to be the source of exogenous aluminum, this did not explain the geographical variation in the incidence of the disorder. Researchers discovered a difference in dialysate aluminum content among various dialysis centers,^[201] and epidemiological studies linked dialysis dementia to municipal water supplies with high aluminum levels.^[202] Unexplained sporadic cases in centers with low aluminum dialysate content, however, have been reported.^[202] The high blood aluminum levels in these sporadic cases suggest that the GI absorption of aluminum (oral P-binding drugs) may occasionally cause this syndrome.

In evaluating these patients, it is important to remember

that dialysis dementia is rare and should always be a diagnosis of exclusion. The differential diagnosis includes DDS, hypertensive encephalopathy, structural lesions (e.g., SDH, stroke), and metabolic encephalopathies such as drug intoxications. Trace element intoxications, decreased glucose, electrolyte disorders (increased Ca, decreased Na or phosphorus), hyperosmolal states, hyperparathyroidism, and UE should also be considered.^[150] Changes in dialysis schedule, a change in baseline

metabolic status, infection (e.g., dialysis shunt, brain abscess, hepatitis), and treatable encephalopathies (B₁₂, folate, TFTs) can present similarly.^[201] Routine laboratory studies, urinalysis, chest x-ray study, and neuroimaging, when focal neurological abnormalities are identified, are also required. If an infectious cause is suspected, CSF examination may be required. The EEG is invariably abnormal, showing characteristic bursts of frontal slowing and epileptiform spikes.

Dialysis dementia does not respond to an increase in weekly dialysis time or renal transplantation. Because deferoxamine crosses the BBB, binds aluminum with greater affinity than do plasma proteins, and results in a dialyzable complex, it can be used to treat this disorder.^[203] The CSF aluminum content increases with deferoxamine treatment, a finding that correlates with deterioration,^[201] and it has been associated with visual and auditory disturbances.^[60] Several dosing protocols have been reported, and treatment duration has not yet been determined.^[201]^[204]^[205]^[193] Seizures are treated similarly to those in other patients with RF.

On average, dialysis dementia begins 37 months (range 9 to 84 months) after hemodialysis is initiated and has an average survival of 6 months (range 1 to 15 months).^[206] However, waxing and waning courses, several-year survivals, and transient symptoms have also been reported.^[207]^[208] Reports from Europe and the United States have suggested that dialysis dementia might be part of a larger syndrome, including anemia, bone disease, and a proximal myopathy.^[209]
