Chapter 39 - Exogenous Acquired Metabolic Disorders of the Nervous System: Toxins and Illicit Drugs

Karen I. Bolla
Jean Lud Cadet

History and Overview

Metal Intoxication

Arsenic

Inorganic Lead

Organic Lead

Manganese

Inorganic Mercury

Organic Mercury

Aluminum, Thallium, and Other Metals

Organic Solvents

Mixed Solvents

Methyl Alcohol

Ethylene Glycol

N-Hexane and Methyl-*N*-Butyl Ketone

Toluene (methyl benzene)

Trichlorethylene

Acetone, Benzene, Carbon Disulfide, Carbon Tetrachloride

Gases

Carbon Monoxide

Cyanide, Ethylene Oxide, Nitrous Oxide

Pesticides

Organophosphate Insecticides

Organochlorine Insecticides

Other Pesticides: Methyl Bromide, Picrotoxin, and Strychnine

Animal Toxins

Snake and Spider Venoms

Tick Paralysis

Plant Toxins

Chickpea (Lathyrism)

Mushrooms

Bacterial Toxins

Diphtheria

Tetanus

Botulism

Illicit Drugs

Cocaine

Amphetamine Analogs

Methylenedioxymethamphetamine

Opioid Agonists

Hallucinogens

Methyl-phenyl-tetrahydropyridine

Phencyclidine

Cannabinol (Marijuana)

Reviews and Selected Updates

HISTORY AND OVERVIEW

Individual cases of lead poisoning were reported as early as 200 BC. However, it was not until the twentieth century that industrialization and modernization resulted in a need for medical evaluation and treatment of health effects caused by exposure to harmful chemicals. To meet this need, a new medical specialty was developed called occupational and environmental medicine. Unfortunately, the number of physicians in this specialty is too few to treat the number of patients requiring evaluation and treatment. Even in academic and workplace settings that offer this expertise, neurological input is paramount because many of the health effects due to chemical exposure are related to the central and peripheral nervous systems. Whereas some health effects such as pulmonary distress and gastrointestinal symptoms are noticed easily by the affected individual, some nervous system effects may be unrecognized. Acute, high-level exposure to a toxicant often results in clearly identifiable signs (e.g., delirium, seizures, or unconsciousness), but the residual effects, involving cognition, mood, and personality, are usually quite subtle. The most common clinical presentation is one of poor concentration, short-term memory loss, depressed mood, anxiety, restlessness, loss of interest in work and hobbies, decreased libido, irritability, headaches, weakness, and sleep disturbances ranging from insomnia to somnambulism. [1](#), [2](#) Patients may also report symptoms consistent with peripheral neuropathy.

The diagnosis of neurotoxicant-related damage is one of exclusion. Therefore, other causes of central and peripheral nervous system dysfunction must be ruled out, and a history of significant exposure must be substantiated. The neurological examination, electroencephalogram (EEG), computed tomography (CT) scan, and magnetic resonance imaging (MRI) scans are generally not helpful in making a specific diagnosis of toxic encephalopathy but are helpful in ruling out other causes of the patient's symptoms. In contrast, nerve conduction studies are useful in detecting peripheral neuropathies that are often associated with exposure to specific chemicals. Central nervous system effects

are best discovered with neuropsychological assessment. However, interpretation of decrements in performance on these tests is often erroneous if made by individuals who lack specific expertise in neurobehavioral toxicology. The reader is referred to Bolla [3](#) for an in-depth discussion of the use and limitations of neuropsychological methods for the detection of alterations in the central nervous system (CNS) following chemical exposure.

Once health effects have been detected, it can be problematic to relate these in a causal fashion to a specific chemical exposure. Since biomarkers for many chemicals are either difficult to obtain or do not exist, it is difficult to determine the intensity of current and past exposure, or even if an individual has been exposed to a toxic chemical. In instances of mass poisonings, this association can be made more readily. Also, for the evaluating clinician, a knowledge of the patient's baseline neurological function prior to exposure is important to ascertain whether there has been a change in neurological status, but it is rarely available.

Evaluation of the direct toxic effects on the CNS must also be considered in the context of the emotional state and personality characteristics of the patient. Psychological disturbance may be a primary or secondary sequela of chemical exposure. Emotional reactions to exposure may be as important as the direct physiological effects of the chemicals, especially when one is considering the cause and persistence of symptoms. In addition, specific inherent personality characteristics may predispose an individual to the development of physical, cognitive, and psychological symptoms even in the absence of any direct toxic effects on the nervous system. Certain individuals' expectations about the adverse health effects of suspected chemical exposure may result in an enhanced awareness of normal bodily sensations. The degree to which an individual is hypersensitive to endogenous stimuli (normal bodily sensations) may determine the duration and intensity of the symptoms.

This chapter focuses on the clinical manifestations subsequent to exposure to specific chemicals. The reader should be aware that the clinical symptoms reported in this chapter have been described in some studies, whereas other studies have failed to find significant symptoms associated with specific chemicals. In addition, not all symptoms listed for a given chemical are observed in one individual. Therefore, the association between symptoms and exposure to a given chemical is still controversial. In this chapter, the chemicals are organized by class (e.g., metals, organic solvents). [Table 39-1](#) lists the occupations and job-related sources associated with a number of different chemicals. As with any diagnostic process, the ability to make a differential diagnosis between neurotoxicant exposure, neurological disease, psychiatric disturbance, or malingering is based on the combined evidence taken from the occupational, medical, social, and academic histories, the physical and neurological examinations, biological monitoring, nerve conduction studies, EEG, CT/MRI, and the neuropsychological evaluation.

TABLE 39-2 -- SYMPTOMS ASSOCIATED WITH HEAVY METAL EXPOSURE

Metal	Proposed Toxic Mechanism	Tissue Assessed and Toxic Levels*	Associated Symptoms	Clinical Findings	Specific Treatments	Pathology
ALUMINUM	Decrease in glucose utilization; reduction of acetylcholine	Blood 6 µg/Lt (NC) Urine (24 hr) 20 µg/L (NC)	Respiratory dysfunction	Cognitive decline; halting speech; ataxia	Deferoxamine (DFO)	
ARSENIC	Prevents thiamine transformation into acetylcholine; affects pathways involved in oxidative metabolism	Blood, unreliable Urine (24 hr) 50 µg/g creatine (B, D, NC)	GI distress; respiratory distress; cardiac distress; elevated temperature; Mees lines	Headache; nervousness; vertigo; paralysis, seizures; myelopathy; hyperreflexia; neuropathy	Chelation; gastric lavage with electrolyte replacement; morphine for abdominal pain; IV fluids for dehydration	Cerebral congestion; white matter hemorrhagic lesions; demyelination of peripheral nerves; reduction in number of axons
Acute						
Chronic	Prevents thiamine transformation into acetylcholine; effects pathways involved in oxidative metabolism	Blood, unreliable Urine (24 hr) 50 µg/g creatine (B, D, NC)	Abdominal pain; dermatitis; increased risk of cancer	Headaches; fatigue; restlessness; vertigo; cognitive decline; visual changes or optic neuropathy; seizures; painful sensorimotor peripheral neuropathy		Cerebral congestion; white matter hemorrhagic lesions; demyelination of peripheral nerves; reduction in number of axons
LEAD	Changes in neurotransmitters; inhibits NMDA receptor complex	Blood 10 µg/dl (B, CW)	Respiratory distress	Lethargy; cognitive decline; gait disorder; ataxia; seizures	Removal from exposure; chelation with IV calcium disodium-EDTA, succimer (DMSA), or oral penicillamine	Unclear
Acute						
Children						
Adults	Changes in neurotransmitters; inhibits NMDA receptor complex	Blood 30 µg/dl Urine (24 hr) 150 µg/g creatine (B, CW); Zinc protoporphyrin in blood: 250 µg/dl erythrocytes or 100 µg/dl blood	GI distress; miscarriages; joint pain	Fatigue; delirium; seizures	Removal from exposure; chelation with IV calcium disodium-EDTA, succimer (DMSA), or oral penicillamine	Unclear
Chronic	Changes in neurotransmitters; inhibits NMDA receptor complex	Blood 10 µg/dl (B, CW)	Changes in auditory threshold; behavioral problems; cognitive decline; learning disabilities; attention disorder	Learning disorders	Removal from exposure; chelation	Unclear
Children						
Adults	Changes in neurotransmitters; inhibits NMDA receptor complex	Blood 30 µg/dl Urine (24 hr) 150 µg/g creatine (B, CW); Zinc protoporphyrin in blood 250 µg/dl erythrocytes or 100 µg/dl blood	Miscarriage/stillbirth; arthralgia; anemia; hypertension; gout; renal effects; decreased sperm count	Scotopic visual effects; depression; irritability; sleep disturbance; decline in libido; decreased cognition (learning and memory); fasciculations; parathesias; sensorimotor polyneuropathy; changes in auditory threshold	Removal from exposure; chelation	Punctate hemorrhages dilation of vessels and ventricles, involvement of ganglion cells; histologic changes in hippocampus
MANGANESE	Promotes formation of cytotoxic free radicals; oxidative stress; mitochondrial toxin	24 hour urine 3 µg/L (NC) Blood 2 µg/dl (NC)	Anorexia; manganese pneumonia	Headaches; apathy; fatigue; depression; hyperexcitability; dysarthria; psychotic; behavior; tremor; gait disorders; micrographia; parkinsonism	Removal from exposure; for chronic movement disorders; levodopa; 5-hydroxytryptophan	Histological changes of ganglion cells; damage to substantia nigra and globus pallidus; nerve cell changes in basal nuclei, frontal and parietal cortex, cerebellum, hypothalamus

MERCURY	Alters cell membranes; causes combination of: metabolic disturbance, disturbance of Ca ⁺ homeostasis, oxidative injury; aberrant protein phosphorylation	Blood 15 µg/L	Bronchial irritation; chills; gingivitis; GI distress; bloody diarrhea; brownish mouth lesions; metallic breath; respiratory distress; renal failure	Weakness; irritability; delirium; psychosis	Removal from exposure	Lesions in cerebral gray matter, cerebellum, brain stem nuclei
Inorganic Acute		Urine 35 µg/g creatinine (<i>B, NC</i>)				
Chronic	Alters cell membranes causes combination of: metabolic disturbance, disturbance of Ca ⁺ homeostasis, oxidative injury; aberrant protein phosphorylation	Blood 15 µg/L	Salivary gland swelling; excessive salivation; gingivitis; renal dysfunction	Shyness; fatigue; weakness; personality changes; hyperirritability; insomnia; depression; cognitive decline; visual disturbances; intentional tremor; parkinsonism; seizures; painful paresthesias; peripheral neuropathy (sensorimotor axonopathy)	Removal from exposure; chelation	Neuronal loss and gliosis of the calcarine cortex; atrophy of cerebellum, especially inferior vermis
Organic		Urine 35 µg/g creatine (<i>B, NC</i>)				
	Alters cell membranes; causes combination of metabolic disturbance, disturbance of Ca ⁺ homeostasis, oxidative injury, aberrant protein phosphorylation	Blood 15 µg/L (<i>D, NC</i>)	Primarily affects the nervous system	Cognitive decline; neurasthenia; paresthesias; ataxia; restricted visual fields; cortical blindness; peripheral polyneuropathy; intention tremor, motor neuron disease (ALS-like)	Chelation with D-penicillamine, BAL, or DMSA; selenium; vitamin E	Damages primary visual cortex, cerebellar cortex, pre and postcentral gyri, transverse gyrus, and putamen
		Urine (24 hr) unreliable				
		Hair 50 µg/g				
THALLIUM	Affects Na ⁺ /K ⁺ ATPase, porphyrin metabolism and SH groups	Urine (24 hr) 1 µg/g creatine(<i>NC</i>)	GI distress; alopecia	Irritability; fatigue; depression; confusion; movement disorder; optic abnormalities; sensory neuropathy; ascending weakness (Guillain Barre, polioliike)	BAL; Prussian blue (potassium ferrihexacyanoferrate); combined hemoperfusion and hemodialysis	Ganglion cell changes in cortex; demyelination; axonal degeneration; segmental myelin degeneration in peripheral nerves

* Biological exposure indices (BEIs). American Conference of Governmental Industrial Hygienists (ACGIH) values from ACGIH: Threshold Limit Values and Biological Exposure Indices for 1994-1995. Cincinnati, ACGIH, 1994.

Serum.

Whole blood.

NC, Level correlates poorly clinical symptoms; *D*, diet significantly influences the measurement; *B*, present in significant amounts in individuals not occupationally exposed; *CW*, correlates well with clinical symptoms. GI distress: nausea, vomiting, stomach cramps; BAL, British antilewisite; DMSA, dimercaptosuccinic acid.

(see [Table 39-1](#)). In lead-related industries, workers not only inhale lead dust and lead oxide fumes but may eat, drink, and smoke in or near contaminated areas, increasing the probability of lead ingestion. If the worker does not properly "clean up" before leaving work, he can bring lead dust home on his skin, shoes, and clothing, thus exposing family members. Sources of lead exposure for nonoccupational populations include air, food, water, certain consumer products, surface dust, and oils. Automobile emissions had been an important source of lead exposure, especially for urban residents. However, the de-lead of gasoline has significantly altered environmental levels of lead. Periodic assessment of national blood lead levels support this inference. From 1976 to 1978, median blood levels for adults in the United States were approximately 13 µg/dl¹⁴; in 1991 lead levels were estimated at 6 µg/ dl (Environmental Protection Agency, National Advisory Council for Environmental Policy and Technology [NACEPT] committee, 1993). The current major sources of lead in the environment appear to be lead paint in homes built prior to 1950 and lead used in plumbing (which was not restricted until 1986).

Children are especially vulnerable to the effects of lead, especially before the age of 5. Elevated lead levels in children are due to pica (compulsive eating of nonfood items) or to the mouthing of items contaminated with lead from paint dust. In addition, children absorb and retain more lead in proportion to their weight than adults. Young children also have a greater prevalence of iron deficiency, a condition that can increase gastrointestinal absorption of lead. Lead absorption from the gastrointestinal tract appears to differ with age. For example, in adults, approximately 10 percent of ingested lead is absorbed. However, in children, it is estimated that 40 to 50 percent of ingested lead is absorbed. Fetuses are at risk, since lead readily crosses the placenta. Exposure in utero can cause adverse neurological effects in the developing child.

Clinical Features and Associated Findings. Acute signs of lead toxicity in children include listlessness, drowsiness with clumsiness, and possibly ataxia. With very high levels of lead, convulsions, coma, and respiratory arrest may occur. Therefore, a diagnosis of lead toxicity in a child should be considered when a child presents with a change in mental status, gait disorder, or a history of seizures. Chronic low-level lead exposure in children may result in behavioral disturbances, learning disabilities, attention deficit hyperactivity disorder (ADHD), or cognitive decline.

Currently, acute lead encephalopathy due to industrial lead exposure is rare. Symptoms generally include delirium, combative irrational behavior, and seizures. Early signs of lead exposure include sleep disturbances, decreased libido, increased distractibility, increased irritability, and mental status changes marked by psychomotor slowing and memory dysfunction.

Both sensory and motor peripheral nerve involvement is seen in adults with chronic lead intoxication. Sensory complaints include paresthesias and spontaneous pain. Motor signs include local weakness, atrophy, and fasciculations. In severe cases of lead toxicity, wrist drop and foot drop have been well documented. Extensive bilateral neuropathy involving the hands, fingers, deltoids, biceps, and triceps may also occur. In individuals with predominantly motor findings, nerve conduction velocity may not be altered even after significant occupational exposure. However, in other cases mild slowing in nerve conduction velocity has been reported even in asymptomatic lead workers.

Anemia may be seen in patients with chronically elevated lead levels. Long-term lead exposure may have a direct effect on kidney function and may be associated with hypertension and gout. Increased frequencies of miscarriage and stillborn births have been documented in women working in the lead trades. Low prenatal lead exposure may produce low birth weight and premature birth. Lead affects the male reproductive system by reducing sperm counts and sperm motility.

In one series of studies an association was found between the body burden of lead, corresponding to blood lead levels of 25 to 55 µg/dl, and a drop in mean verbal IQ score of 4.5 points in exposed children.^{14, 15} In another study of total body burden, primary school children with high lead levels in teeth but no known history of lead poisoning had larger deficits in psychometric intelligence scores, speech and language processing, attention, and classroom performance than children with lower levels of lead. In a 1990 follow-up report of children who 11 years previously had been found to have elevated lead levels in their teeth, a sevenfold increase was noted in the odds of failure to graduate from high school, lower class standing, greater absenteeism, reading disabilities, and deficits in vocabulary, fine motor skills, reaction time, and eye-hand coordination.

Differential Diagnosis and Evaluation. The laboratory pattern typical of patients with lead intoxication includes elevations in whole blood lead levels, free

erythrocyte protoporphyrins (FEP), and urinary coproporphyrins. The blood lead level reflects more recent exposure to lead, while the free erythrocyte protoporphyrin level tends to reflect more chronic levels of exposure. Blood lead levels greater than 10 µg/dl in children and 30 µg/dl in adults are considered elevated. FEP levels begin to rise in adults once blood lead levels reach 30 to 40 µg/dl. The threshold blood zinc protoporphyrin level is 100 µg/dl. At present, the gold standard for measuring the body burden of lead is diagnostic chelation. Urinary lead excretion is measured after infusion of 1 g calcium ethylenediaminetetra-acetic acid (EDTA). Urinary excretion of more than 600 µg of lead over a period of 72 hours is considered elevated. A new noninvasive method of measuring the body burden of lead in bone is x-ray fluorescence (XRF).^[11] XRF promises in the future to become the noninvasive gold standard for estimating the total body burden of lead. Except for patients with acute high exposure, an EEG is not generally useful. In addition, neither CT nor MRI reveal any abnormalities. The neuropsychological evaluation may prove useful in assessing specific cognitive deficits in individuals exposed to lead. In some studies, workers with lead blood levels of below 30 µg/dl have demonstrated decreased muscle strain and affective complaints as well as decrements in visuomotor integration and psychomotor speed, short-term visual and verbal memory, attention or concentration, and problem-solving skills.^[12]^[13]^[14] Nevertheless, it should be noted that a recent comprehensive review of the published literature on the neurobehavioral performance of individuals exposed to inorganic lead failed to find enough

evidence to draw definitive conclusions on the negative influence of lead on human performance on neurobehavioral tests.^[15]

Management. In both children and adults with substantial lead levels, immediate removal from the sources of exposure to lead and administration of chelating agents presently comprise the treatment of choice. Specific chelating agents for lead include intravenous calcium disodium-EDTA and a new oral agent called succimer (dimercaptosuccinic acid, DMSA). Chelation with oral penicillamine may be used (up to 2 g/day). Multiple chelation cycles may be necessary, and at least 24 hours of rest between cycles is suggested. Adequate hydration should be maintained because chelating agents have been associated with renal toxicity and may dramatically increase circulating levels of lead owing to their ability to unbind lead from the bones. DMSA is a relatively new oral chelating agent that is reported to be safer than EDTA and penicillamine. Common side effects are renal sequelae and hypertension. The latest guidelines for treating children suggest starting chelation therapy for children with blood lead levels above 45 µg/dl. While chelation therapy may reduce symptoms of acute lead poisoning, amelioration of the neurological and renal sequelae of both acute and chronic lead intoxication is less likely. Prevention of lead toxicity in children includes removal of young children from contaminated environments, such as houses with peeling paints. Individuals who work in occupations where they might be exposed to lead should use mandatory personal protective equipment. Routine monitoring for lead levels is also advised.

Prognosis and Future Perspectives. As the work of Needleman and colleagues suggests,^[10] complete recovery of higher cognitive functions may not occur in children with early childhood exposure to lead. Likewise, it is unclear how much central nervous system function is recovered in adults, since research in this area is limited.

Organic Lead

Organic lead (tetraethyl lead, TEL) is used as an antiknock agent in gasoline and jet fuels. Tetraethyl lead is absorbed rapidly from the skin as well as the lungs and gastrointestinal tract and is converted to triethyl lead in the body. This form of lead may be responsible for its toxic effects. Due to its highly lipophilic nature, TEL passes the blood-brain barrier readily. It is soluble in CNS structures, especially the limbic forebrain, frontal cortex, and hippocampus. Symptoms of acute high-level exposure include delirium, nightmares, irritability, and hallucinations. Chronic effects of TEL include subtle cognitive and neuropsychiatric difficulties.^[16] Treatment is mainly supportive, but chelation may be helpful.

Manganese

Pathogenesis and Pathophysiology. Inhalation is the primary source of exposure. Neuropathologically, ganglion cells including cells of the pallidum show histological changes. Damage to the substantia nigra has also been seen, as have nerve cell alterations in the basal nuclei, frontal and parietal cortex, cerebellum, and hypothalamus.

Epidemiology and Risk Factors. The neurological syndrome manganism was first described in 1837. Since that time, hundreds of cases have been reported in the medical literature. Mining dust and industry are the primary sources of manganese (see [Table 39-1](#)). Like organic lead, manganese is also an antiknock additive in gasoline (MMT).

Outside the occupational setting, hospitalized patients receiving total parenteral nutrition (TPN) therapy that includes manganese can develop distinctive T1-weighted hyperintense patterns in the region of the globus pallidum. These apparent lesions disappear after cessation of TPN, but in some patients their presence correlates with clinical signs of parkinsonism and high blood levels of manganese.

Clinical Features and Associated Findings. The onset of symptoms is extremely variable from individual to individual and depends on the intensity of exposure, individual susceptibility, and possibly the type of ore involved. Symptoms may appear after only 1 or 2 months or after 20 years of exposure. The earliest signs of manganism include anorexia, asthenia, apathy, somnolence, headaches, and social withdrawal. Personality changes are common and consist of irritability, emotional lability, and periods of hyperexcitability (manganese psychosis). With continued exposure, moderate to high-level exposure symptoms characteristic of parkinsonism develop, including "masked facies" and bradykinesia. Speech is affected, becoming faint, monotonous, disjointed, occasionally unintelligible, and even mute. Other symptoms include weakness and fatigue, which increase until the worker is unable to go to work. Symptoms are generally confined to the extrapyramidal system, and gait difficulties are observed as retropulsion on rising and propulsion on walking, awkwardness and fine or coarse tremor of the hands, and gross rhythmical movements of the trunk and head. Micrographia in writing samples may also be evident. Whereas individuals with classic cases of severe manganism have more diffuse signs than those typical of Parkinson's disease, there are some concerns that chronic low or moderate exposure during occupations like welding could be a risk factor for typical Parkinson's disease.

Differential Diagnosis and Evaluation. Diagnosis requires a history of exposure to manganese in combination with physical findings. About 43 percent of the body burden of manganese is in the bone. Excretion is biphasic, consisting of a rapid phase with a half-life of 4 days and a second slower phase that has a half-life of 39 days. Methods of biological monitoring are poor, and individual manganese levels in blood and urine do not correlate with either present or past exposure. Diagnostic chelation with EDTA is not useful.

Management. Management involves removal of the patient from exposure. The chronic movement disorder may respond to the use of levodopa and 5-hydroxytryptophan. Patients studied by Mena and colleagues^[17] responded well to levodopa doses of more than 3 g/day, showing a marked reduction in rigidity and all other symptoms except speech disorders. Traditional chelation therapy has not proved helpful.

Prognosis and Future Perspectives. Manganism is

usually progressive once the syndrome develops. In the very early stages, symptoms may improve over a period of many months after the patient has been removed from exposure. This improvement is not thought to be correlated with a reduction in the concentration of manganese.^[18]

Inorganic Mercury

Pathogenesis and Pathophysiology. Elemental mercury is transported in blood plasma, proteins, and hemoglobin. In the appropriate conditions, mercury may be incorporated rapidly into the brain. Once incorporated into the body, mercury can be found in the urine as long as 6 years after exposure has ceased. Inorganic mercury has the greatest affinity for the kidney. Although concentrations are lower in the CNS, they may still be significant. In the brain, animal studies have shown that the highest concentrations of mercury occur in the brain stem, followed by the cerebellum, cerebral cortex, and hippocampus.

Inorganic mercury exerts its neurotoxic effects by altering membranes. A paucity of information is available on the pathological events resulting from inorganic mercury intoxication. Very few postmortem studies have been published, and results vary from normal to slight neuronal damage with evidence of intracellular

mercury.

Epidemiology and Risk Factors. Historically, inorganic mercury compounds have been used as antiseptics, disinfectants, purgatives, and components in the industrial manufacture of felt. Mercury was also used formerly in the form of cinnabar, a red pigment used for painting and coloring. Works of art containing cinnabar can be found in ancient Egyptian and Pakistanian ruins.

By current NIOSH estimates, 65,000 workers are potentially exposed to mercury. The occupations significantly at risk for mercury intoxication are listed in [Table 39-1](#). Mercury is also one of the most serious environmental pollutants in air and water. Between 1953 and 1956, an epidemic of methyl mercury poisoning occurred in Japan when a large number of villagers developed chronic mercurialism (Minamata disease) from ingesting fish contaminated with methyl mercury from industrial waste. There appears to be a wide range of individual susceptibility to the toxic effects of mercury; these may depend on the form of mercury involved, hygiene, diet (including vitamin deficiency), and some intrinsic differences in mercury metabolism. Metallic mercury becomes volatile at room temperature and thus generally enters the body through the inhalation of mercury vapors.

Clinical Features and Associated Findings. Acute mercury poisoning usually results from accidental ingestion of an antiseptic in the medicine cabinet. Symptoms of acute inorganic mercury poisoning consist of massive gastrointestinal vomiting and colitis with renal failure. The breath has a metallic odor. A brownish mercurial linear streak may be visible along the margin of the teeth. Symptoms of irritability, rapid onset of weakness in the lower limbs, psychotic episodes with delirium, hallucinations, and motor hyperactivity have been reported. The major threat to these patients is gastrointestinal hemorrhage, but after 24 hours renal failure becomes the predominant cause of morbidity.

Chronic mercury toxicity can result in tremor and weakness of the limbs or progressive personality changes. Mercury-induced tremors, also known as "hatter's shakes" or "Danbury shakes," consist of fine and regular tremors interrupted by much coarser myoclonic jerks. These tremors can be seen at rest and often diminish with activity. In the later stages of intoxication, gait and balance may be altered because of the continuous trembling. In addition, dyskinetic movements, pareses, and convulsions have been reported. At times, these patients present a typical picture of parkinsonism. Mercury can also cause peripheral polyneuropathy (sensorimotor axonopathy), which affects the lower extremities more than the upper ones. Paresthesias with extreme pain or peripheral neuropathy with muscle atrophy may also occur. Cognitive decline, vertigo, nystagmus, blurred vision, narrowing of the visual fields, optic neuritis, optic atrophy, sensory ataxia with a positive Romberg's sign, seizures, and vegetative disturbances have also been observed.

Personality changes can develop before neurological signs appear. So-called "mercurial neurasthenia" may develop for weeks or months before the patient seeks treatment. This syndrome consists of extreme fatigue, hyperirritability, insomnia, pathological shyness, and depression. The hyperirritability may become so severe that extremely violent behavior develops, possibly including homicidal acts.

Acrodynia, chronic mercury toxicity in children, is a syndrome consisting of painful neuropathy that involves significant autonomic changes. This syndrome includes redness and coldness in the hands and feet, pain in the limbs, profuse sweating of the trunk, severe constipation, and weakness. Tremors similar to those found in adults and personality changes may also occur.

Differential Diagnosis and Evaluation. Serum concentrations of mercury are unreliable indicators of inorganic and organic mercury toxicity because blood levels vary greatly between individuals and in the same individual. The threshold biological exposure index (BEI) for blood is 15 µg/L, and for urine it is 35 µg/g creatinine. However, urinary excretion is not a good measure of toxicity, since there seems to be little correlation between symptomatology and the amount of mercury excreted in the urine. Although the early differential diagnosis might include Parkinson's disease, the tremor seen with mercurial intoxication is not solely a resting tremor and is usually coarser than that found in patients with Parkinson's disease. Because the signs of mercury intoxication may mimic those of some common neurological syndromes, the correct diagnosis is dependent on a good occupational history, clinical symptomatology, and documentation of mercury in the patient's blood, urine, or hair.

Management and Prognosis. Removal of the patient from the sources of exposure and chelation with *N*-acetyl-D-penicillamine is recommended.

Prognosis and Future Perspectives. Follow-up of the survivors with Minamata disease years after poisoning occurred revealed decreased bilateral attenuation on CT scans in the visual cortex and diffuse atrophy of the cerebellum, especially the vermis.

Organic Mercury

Pathogenesis and Pathophysiology. Organic mercury readily crosses the blood-brain barrier, and its turnover in

the brain is slow. In cases of chronic exposure, approximately 10 percent of the body burden localizes in the brain. Less than 3 percent is degraded into inorganic mercury. In a single case study, histological changes and high mercurial content were noted in the corpus callosum. Excretion occurs primarily through the gastrointestinal tract, mostly through biliary secretion, and the mercury then undergoes almost immediate gastrointestinal reabsorption into the bloodstream. Neuropathological changes noted in 10 cases included damage to peripheral neurons in the myelin sheath accompanied by glial proliferation and mobilization of phagocytes.^[19] Anatomically, the most severe damage was found in the primary visual cortex, followed by the cerebellar cortex, the pre- and postcentral gyri, the transverse gyrus, and the putamen.

Epidemiology and Risk Factors. Sources of organic mercury include contaminated seafood or exposure to alkyl mercury (used in antifungal treatment of seed grains). There have been reports of massive intoxications resulting from ingestion of fish containing methyl mercury or from eating homemade bread prepared from seed treated with methyl mercury fungicide. Ingestion of livestock that have been fed grain treated with mercury-containing fungicides is an additional source.

Routes of absorption of organic mercury are primarily dermal and gastrointestinal. Organic mercury is slowly excreted through the kidneys, and its half-life varies from 40 to 105 days. Organic mercury readily crosses the placenta, resulting in blood concentrations in the fetus that are equal to or greater than those in the maternal blood. There have been several reports of fetal methyl mercury poisoning in asymptomatic mothers. Methyl mercury is also secreted in breast milk.

Clinical Features and Associated Findings. The clinical triad of organic mercury toxicity consists of peripheral neuropathy, ataxia, and cortical blindness. There may be a delay of 2 weeks to several months before symptoms appear after mercury exposure. The earliest symptoms may be paresthesias of the extremities, beginning distally and extending in a glove-stocking distribution. Touch and pain sensations are most impaired. Constriction of the visual fields is generally seen.^[20]

In infants born of intoxicated mothers, severe brain damage may develop including retardation and cerebral palsy. Motor neuron disease resembling amyotrophic lateral sclerosis (ALS) is another notable and prominent clinical pattern. In these patients, gradual weakness develops with features of both upper motor neuron disease (increased reflexes and prominent jaw jerk) and lower motor neuron disease (fasciculations and atrophy).

Differential Diagnosis and Evaluation. It is difficult to diagnose mercury toxicity from laboratory data because the blood and urine measurements vary widely. While measurements in blood and hair are less variable than those in urine, these do not necessarily reflect the degree of mercury toxicity. Hair samples must be collected according to specific protocols. For example, samples must be taken close to the scalp and then washed to remove contaminants such as hair dyes or hair treatments. The advantage of hair samples is that they provide exposure information for the past year. Hair sample levels are usually 300 to 500 times those seen in blood.

Management. Management of mercury toxicity depends first on eliminating the exposure. Other remedies include the use of mercury-binding chelators such as D-penicillamine, BAL, or DMSA, which may accelerate the excretion of mercury. However, because chelation mobilizes mercury from bones, it may cause the clinical symptoms to become worse and allow further deposits of mercury into the brain (especially BAL). Penicillamine may be more effective in improving the CNS effects of mercury. However, the side effects of penicillamine treatment may include hematopoietic suppression, alterations in cognitive and renal function, symptoms of myasthenia gravis, occasional hepatitis, and allergic reactions such as pruritus and swelling. With chelation, blood concentrations usually begin to decline after approximately 3 days. In asymptomatic individuals with increased blood concentrations of mercury, administration of selenium and vitamin E may prevent the development of symptoms. In patients with mild contractures, physical therapy can be helpful.

Prognosis and Future Perspectives. Most patients with severe mercury poisoning die within a few weeks of symptom onset. Some may survive with major

neurological disability. In those with mild or moderate neurological symptoms, improvement may occur within the first 6 months, mostly in children and young adults. Isolated cases have been reported in which bedridden individuals regained the ability to walk, and some children who were totally blind regained vision.

Follow-up of the survivors with Minamata disease years after poisoning revealed decreased bilateral attenuation on CT scans in the visual cortex and diffuse atrophy of the cerebellum, especially the vermis.

Aluminum, Thallium, and Other Metals

ORGANIC SOLVENTS (Table 39-3)

Mixed Solvents

Pathogenesis and Pathophysiology. Organic solvents are lipophilic and very volatile. Lipophilicity influences the anatomical distribution of the solvents to organs rich in lipids (brain and adrenals). Lipophilic compounds are eliminated through the kidneys after several osmotic conversions have occurred to make them more water soluble. The resulting metabolites can be more toxic than the original compounds. Reports of synergistic effects between organic solvents and alcohol are found in the literature. Paint "huffers" show signs of acute denervation in the peripheral nervous system and show evidence of frontal lobe atrophy on MRI. ^[21] At high dose levels, depending on the specific chemical, solvents may act as anesthetics (e.g., trichloroethylene [TCE]), convulsants (e.g., fluorothyl), anticonvulsants (e.g., toluene), anxiolytics (e.g., toluene), antidepressants (e.g., benzyl chloride), and narcotics (e.g., TCE). However, the mechanisms involved in solvent neurotoxicity are generally unknown. For many solvents it is not known which are neurotoxins, whether or not they require bioactivation to become toxic to the nervous system, and what targets within the nervous system are critical. It is also unknown how the toxic metabolites produce cellular changes that

TABLE 39-3 -- SYMPTOMS ASSOCIATED WITH ORGANIC SOLVENT EXPOSURE

Organic Solvents	Proposed Toxic Mechanisms	Tissue Assessed and Toxic Levels*	Associated Symptoms	Clinical Findings	Specific Treatments	Pathology
MIXTURES	Generally unknown, acts on neurotransmission	Not available	Irritant effects; contact dermatitis	Headaches; fatigue; irritability; depression; sleep difficulties; cognitive decline; decreased olfaction; peripheral neuropathy; myopathy	Removal from exposure	Atrophy (paint huffers)
ACETONE	Unclear	Urine 100 µg/L	GI distress; irritant effects	Nausea; vomiting; headache; dysphoria; bad dreams; vertigo	Removal from exposure	Unclear
BENZENE	Increases levels of GABA in cerebellum and pons; increases levels of glutamic acid decarboxylase (GAD); affects porphyrin metabolism	Urine 50 µg/g creatine; Exhaled air: mixed 0.08 ppm	Increased risk of cancer; pancytopenia	Ataxia; inebriation; muscular twitching; paralysis; seizures; unconsciousness; peripheral neuropathy in cases with associated toluene exposure	Removal from exposure; lecithin, vitamin C, pentanucleotide, folic acid, pyridoxine	Denervation and clinical atrophy
CARBON DISULFIDE	Alkylation of proteins	Urine 5 µg/g creatine	Pulmonary and dermal irritants; cardiac effects; toxic threshold lowered in alcoholism, diabetes mellitus, renal and hepatic diseases	Headaches; irritability; cognitive decline; psychosis; delirium; hearing loss; loss of corneal reflex; parkinsonism; peripheral polyneuropathy	Removal from exposure	Chromatolysis and vacuolation in frontal lobe, globus pallidum, and putamen; peripheral nerve myelin swelling and fragmentation
CARBON TETRACHLORIDE	Unclear	Not available	GI distress; hiccups; liver and kidney damage; toxic threshold lowered in alcoholism, obesity, diabetes, liver and kidney disease	Intoxication; headaches; vertigo; delirium; seizures; parkinsonism; optic atrophy; visual difficulties	Calcium gluconate and hemodialysis	Purkinje cell damage; cerebellar venous thrombosis and hemorrhagic infarcts; brain edema; neuronal loss; astrocytosis
ETHYLENE GLYCOL	Metabolizes to aldehydes and oxalate	100 ml	Renal effects; cardiopulmonary effects	Restlessness; agitation; seizures; absent corneal reflexes; coma	Early dialysis to correct acidosis	Cerebral edema; vascular engorgement; hemorrhage
METHYL ALCOHOL (METHANOL)	Oxidation to formaldehyde and formic acid	Urine 15 µg/L (<i>B, NS</i>) Formic acid in urine 80 µg/g creatine (<i>B, NS</i>)	GI distress	Headache; weakness; incoordination; delirium; hallucinations; visual loss; stupor; seizures; parkinsonism; death	Administration of ethyl alcohol, folic acid, or bicarbonate; frequent measures of blood methanol; CO ₂ , bicarbonate, pH; monitor serum potassium; administer peritoneal or hemodialysis	Shrinkage and degeneration of neurons; primarily in parietal cortex
METHYL-N-BUTYL KETONE (MBK)	Metabolized to 2,5 hexanedione	No specific findings	Euphoria	Weight loss; sensorimotor polyneuropathy	Removal from exposure	Multifocal axonal degeneration; myelin thinning
N-HEXANE	Metabolized to 2,5 hexanedione; inhibits glycolytic enzymes	Urine 5 µg/g creatinine (<i>NS</i>)	Euphoria	Headaches; poor appetite; mild euphoria; mostly peripheral polyneuropathy	Removal from exposure	Degeneration of peripheral nerve axons
TOLUENE (METHYL BENZENE)	Toxic effects similar to benzene	Hippuric acid in urine 2.5 µg/g creatine (<i>B, NS</i>) Venous blood 1 µg/L	Pulmonary effects; cardiac effects	Euphoria; fatigue; ataxia; dizziness; tremor; cognitive decline; seizures; delirium; olfaction; optic atrophy; hearing loss; peripheral neuropathy (in cases w/associated N-hexane exposure); alcohol intolerance	Removal from exposure	Cortical and cerebral atrophy

TRICHLOROETHYLENE (TCE)	Unknown, Toxic effects potentiated by alcohol	Trichloroacetic acid in urine 100 µg/g creatine (NS) Trichloroacetic acid and trichloroethanol in urine 300 µg/g creatine (NS) Blood-free trichloroethanol in blood 4 µg/L (NS)	Cardiopulmonary effects; toxic threshold reduced with alcohol	Headaches; insomnia; fatigue; anxiety; trigeminal nerve damage; neuroophthalmological findings; alcohol intolerance; cognitive decline; hearing loss; peripheral neuropathy	Removal from exposure	Myelin and axonal degeneration

* Biological exposure indices (BEIs). American Conference of Governmental Industrial Hygienists (ACGIH) values from ACGIH: Threshold Limit Values and Biological Exposure Indices 1994-1995. Cincinnati, ACGIH, 1994. *B*, Present in significant amounts in individuals not occupationally exposed; *NS*, nonspecific; may be observed after exposure to some other chemicals; GABA, gamma-aminobutyric acid.

result in human health effects. A wide variety of mechanisms related to the effects of organic solvents have been proposed. Neurotoxicity may result from effects on neurotransmitters such as dopamine and gamma-aminobutyric acid (GABA), although it is not known whether this occurs at specific receptor sites, at the bilipid layer surrounding the receptors, or at ion channels.

Epidemiology and Risk Factors. Due to the proliferation of the plastic and chemical industries, large segments of the population have been exposed to organic solvents. NIOSH estimates that in 1970, 9.8 million workers were exposed to solvents in the United States. Since solvents are highly volatile, and volatility corresponds to the amount of solvent that becomes airborne, the respiratory system is the primary mode of solvent absorption. The amount of uptake is modified by work load, respiratory rate, use of respirators, and adequacy of workplace ventilation. Because most solvents that cause health problems are mixtures of solvents, we will first discuss the neurological sequelae of exposure to organic solvents in general. Then we will describe briefly some of the more highly toxic individual organic solvents. Occupational settings of potential exposure to organic solvents are numerous and are shown in [Table 39-1](#). At present, it appears that the number of workers suffering adverse effects from exposure to organic solvents has decreased. This is due to closer adherence by industry to appropriate levels of safe airborne concentrations as well as to the mandatory use of personal protective equipment by workers. Unfortunately, the abuse of solvents in the form of "huffing" remains a public health concern. In these cases, substances such as paint, airplane glue, and gasoline are placed in plastic bags, which are then placed over the face and inhaled to produce a "high."

Clinical Features and Associated Findings. The digestive, hepatic, renal, and nervous systems are all affected by organic solvents. All solvents have nasal mucosal irritant effects. Symptoms of acute high-level exposure include headache, dysphoria, dizziness, euphoria, excitation, and exhilaration. However, with discontinuation of exposure, symptoms of acute exposure abate within hours. With extremely high levels of exposure such as those obtained during paint huffing, the later stages of intoxication include somnolence and coma followed by death.

Chronic low-level exposure is generally seen in industrial settings. In these cases, development of symptoms is insidious. Headaches are the most commonly reported symptom. Characteristically, these begin shortly after arriving at work and disappear at night, on weekends, and during vacations when patients are not in the vicinity of the organic solvents. Other complaints include irritability, personality changes, depression, memory loss, poor attention or concentration, sleep difficulties, decreased libido, and pain and numbness starting in the feet and then progressing to the hands (peripheral neuropathy). Neurobehavioral findings are most notable in activities demanding manual dexterity, executive or motor functioning, and olfaction. ^[22]

Differential Diagnosis. Diagnosis of solvent encephalopathy is generally confirmed by the presence of a positive exposure history, objective findings on neurobehavioral tests, and negative findings on neurological examination with the exception of the possible presence of a polyneuropathy. There are few reliable or easily attainable biomarkers of solvent exposure. Therefore, this diagnosis is often one of exclusion. The differential diagnosis includes other neuropathological conditions (e.g., cerebrovascular disease, tumor), heavy alcohol use, and neuropsychiatric disorders (e.g., affective disorders, anxiety, somatoform disorders). Often, individuals who have been exposed to chemicals with strong odors misinterpret normal body sensations as pathological symptoms. Subsequently, these symptoms are misattributed to chemical exposure because of reports by the news media exaggerating the dangers of commonly encountered environmental chemicals.

Evaluation. In 1985 an attempt was made to develop a rating classification system for individuals who were exposed to organic solvents. The following categories were proposed: Type I--Subjective nonspecific symptoms only. Patients complain of fatigue, memory and concentration difficulties, and changes in mood and sleep patterns. However, there is no objective evidence of neurobehavioral dysfunction. After discontinuation of exposure, symptoms completely disappear within 6 months to 1 year. Type IIa--Sustained personality and mood change. Affective changes are noted. These include depression, aggressiveness, fatigue, poor impulse control, and anhedonia. Neurobehavioral findings are negative. It is unclear if these symptoms are reversible. Type IIb--Impairment of intellectual function documented by objective neurobehavioral test results with possible mild neurological signs. Difficulty in concentration, memory loss, and a decline in learning capacity may be objectively detectable. After removal from exposure, these symptoms may remain stable or improve but should not become worse. Type III--Dementia, with neurological signs and/or neuroradiological findings. Neurobehavioral test results are significantly affected. Type III is related to repeated severe exposure (e.g., paint huffers). It is poorly reversible but generally does not progress once exposure is stopped. ^[23]

Nerve conduction studies can be extremely useful because many organic solvents affect the peripheral nervous system (PNS) before the CNS. Sensory polyneuropathy, more pronounced in the feet than in the hands, is characteristic of exposure to chronic organic solvents.

Management. Management consists of removal from the source of exposure. In addition, the anxiety and depression typically seen in these individuals can be treated with psychotropic medications and supportive psychotherapy.

Prognosis and Future Perspectives. Once removed from the source of exposure, symptoms should remain stable or improve over time. However, deterioration in function is often seen and can be attributed to psychological disorders that develop secondary to the organic solvent exposure.

Methyl Alcohol

Methyl alcohol (methanol, wood alcohol) is used as a solvent, a component of antifreeze, and an adulterant of alcoholic beverages. While this chemical is only mildly toxic, it is oxidized to formaldehyde and formic acid, which produce severe acidosis and are responsible for the symptoms of methanol abuse. Neuropathological changes in the

form of shrinkages and degeneration of neurons, primarily in the parietal cortex, have been reported. ^[24] The oxidation and excretion of methyl alcohol is so slow that toxic symptoms do not develop for 12 to 48 hours, although they may last for several days. Once apparent, toxic symptoms involve the visual apparatus, CNS, and the gastrointestinal and respiratory tracts. Early symptoms include nausea, vomiting, weakness, abdominal pain, vertigo, and headache. Additional symptoms may include restlessness, incoordination, and, in severe cases, delirium and hallucinations. Confusion and memory deficits are also reported. In severe cases, stupor, coma, tonic muscle contractions, hyperactive reflexes, visual loss, parkinson-like extrapyramidal syndrome, and convulsions may also be seen. In the most severe cases, death occurs from respiratory failure.

Treatment involves frequent measurements of blood methanol, carbon dioxide, bicarbonate, and pH. Ethyl alcohol may be administered to retard the conversion of methanol into toxic formaldehyde and formic acid. Bicarbonate can be given to correct severe acidosis. Serum potassium levels should be monitored because

bicarbonate tends to decrease potassium. Administration of folic acid may accelerate the metabolism of formic acid to carbon dioxide. Either peritoneal dialysis or hemodialysis can be used in patients with methanol blood concentrations of over 50 mg.

Ethylene Glycol

Antifreeze is the most common source of ethylene glycol. Due to its inebriant properties, ingestion of ethylene glycol can be fatal and accounts for about 40 to 60 deaths per year. While ethylene glycol itself is not toxic, it metabolizes to aldehydes and oxalate. The toxic dose is approximately 100 ml, and death is due to renal or cardiopulmonary mechanisms. After ingestion, symptoms may appear rapidly or may take hours to develop. Initial symptoms include restlessness and agitation, followed by somnolence, stupor, coma, and convulsions. The patient becomes cyanotic, pupils are nonreactive, and corneal reflexes are absent. In milder cases, fatigue, personality change, and depression are present. Ethylene glycol poisoning should be suspected when an apparently inebriated patient has no alcohol on the breath. Neuropathological changes have been reported and include cerebral edema, vascular engorgement, and hemorrhage. Treatment consists of correcting the acidosis and using early dialysis to remove the ethylene glycol, oxalate, and aldehyde and also treat the associated uremia.

N-Hexane and Methyl-N-Butyl Ketone

N-hexane is a component of a number of glues. Therefore, exposure is likely to come from inhalant abuse. With acute exposure, N-hexane causes euphoric effects. Pronounced peripheral polyneuropathy may occur after chronic intoxication. Hexane is metabolized to 2,5-hexanedione (2,5-HD), which is responsible for much of the neurotoxicity related to this compound.

Unlike toluene, hexane does not produce significant central neurological symptoms. Lightheadedness, headache, decreased appetite, and mild euphoria as well as occasional hallucinations may occur acutely, but seizures and delirium are not associated with N-hexane exposure. The predominant neurological feature of N-hexane exposure appears to be peripheral neuropathy. Symmetrical sensory dysfunction in the hands and feet is the usual presenting complaint. Decreased response to pin, vibration, and thermal stimulation is found on examination. Glue huffers may develop proximal weakness. The most prominent electrophysiological feature is slowing of motor and nerve conduction velocities, which occurs in proportion to the intensity of clinical disease. ^[25]

Methyl-N-butyl ketone (MBK) is used as a paint thinner, cleaning agent, and solvent for dye printing. Exposure to MBK is associated with sensorimotor polyneuropathy, which may begin several months after continued chronic exposure. In the later stages, axonal degeneration occurs distally.

There is no specific treatment for N-hexane and MBK neuropathy other than removal from the source of exposure. After removal, recovery (regeneration of peripheral nerve axons) may occur over a period of weeks.

Toluene (Methyl Benzene)

Toluene is a widely used solvent and is employed as a paint and lacquer thinner and as a cleaning and dyeing agent. It is also a constituent of motor and aviation fuels. Toluene is a major constituent of the glue used by paint huffers and has thus been implicated as the chemical responsible for the neurotoxic syndrome seen in this group of solvent abusers. Toluene's toxic effects are similar to those of benzene, although more mental status changes are seen.

With acute exposure, clinical signs include early exhilaration followed by fatigue, mild confusion, ataxia, and dizziness. With chronic use, exhilaration, euphoria, disinhibition, and tremor are common. Neurobehavioral effects include declines in performance IQ, decreased memory, poor motor control, decreased visuospatial functioning, and dementia. ^[26] Toluene appears to affect the CNS more readily than the PNS. Treatment primarily involves removal from exposure.

Trichlorethylene

Trichlorethylene (TCE) is used extensively in dry cleaning and for degreasing metal parts and extracting oils and fats from vegetable products. It is also used as an adhesive in the leather industry and occasionally in medicine as an anesthetic. A number of workers have become addicted to the fumes, since deliberate inhalation produces rapid euphoria. Fatalities resulting from bronchial constriction, pulmonary edema, and myocardial irritation have been reported.

TCE toxicity is associated with cranial and peripheral neuropathies. Mixed sensory and motor involvement of the trigeminal and facial nerves is characteristic of high-level TCE exposure. Neuro-ophthalmological findings include

retrobulbar neuropathy, optic atrophy, and oculomotor disturbances. Peripheral neuropathy is common, usually mixed and predominantly distal. Neuropathological examination has revealed extensive myelin and axonal degeneration. TCE may act as a demyelinating agent because of its lipid solvent qualities. The effects of TCE appear to be potentiated by alcohol.

Clinically, a history of possible TCE exposure should be investigated in any patient with trigeminal neuralgia or trigeminal dysfunction. Long-term exposure or acute high-level exposure also produces disturbances in memory. When a human volunteer was exposed to 2, 3, and 500 ppm for more than 2 hours, his major complaint was drowsiness. ^[27] At 500 ppm, however, a pronounced decrease in neuropsychological functioning was observed. General CNS symptoms include headaches, dizziness, fatigue, alcohol intolerance, neurasthenia, anxiety, and insomnia. Neurobehavioral effects include poor concentration and memory, decreased manual dexterity and visuospatial accuracy, and a slowed reaction time. As with the other organic solvents, treatment primarily involves removal from exposure.

Acetone, Benzene, Carbon Disulfide, Carbon Tetrachloride

See [Table 39-3](#) .

GASES ([Table 39-4](#))

Carbon Monoxide

Pathogenesis and Pathophysiology. Carbon monoxide enters the bloodstream through pulmonary absorption and binds reversibly to hemoglobin. The affinity of hemoglobin for carbon monoxide is about 225 times greater than that for oxygen. Thus, exposure to carbon monoxide resulting in increased carboxyhemoglobin decreases the amount of oxygen carried by the red blood cell. This results in pronounced tissue oxygen deprivation. Pathoclinical correlates generally show globus pallidus lucency and atrophy on CT scan ([Fig. 39-3](#)).^[28]

Epidemiology and Risk Factors. Carbon monoxide is an odorless, nonirritating gas, acute exposure to which accounts for over 3000 accidental or suicidal deaths each year and 10,000 episodes of illness. Industrial sources include portable kerosene heaters, hot water heaters, and furnaces. At home, inadequately vented fireplaces are a common source. However, the major source of carbon monoxide is automobile exhaust fumes, which have concentrations of approximately 50,000 ppm. While cigarette smoke may be a major source of carbon monoxide, it is diluted with air, making it significantly less toxic. The threshold limit value (TLV) of carbon monoxide is 50 ppm, which causes a carboxyhemoglobin saturation of 8 to 10 percent after an 8-hour exposure. Carboxyhemoglobin levels of more than 50 percent are considered threatening, and levels of 70 to 75 percent are usually fatal. Saturation

Figure 39-3 CT scan from a patient with carbon monoxide intoxication showing cystic lucencies in both globus pallidus (From Klawans HL, Stein RW, Tanner CM, Goetz CG: Pure parkinsonian syndrome following acute carbon monoxide intoxication. Arch Neurol 1982;39:302.)

may be obtained by either very high acute exposure or prolonged exposure to lower concentrations.

Clinical Features. Neurological signs of mild carbon monoxide poisoning include dizziness, headache, and impaired vision. As poisoning becomes more severe, symptoms develop into severe throbbing headaches, convulsions, and coma. Persistent chronic exposure, as occurs, for example, with inadequately vented heaters in the home, leads to blindness, deafness, pyramidal signs, extrapyramidal signs, and convulsive disorders.

Mild neurological effects may be transient to persistent and may appear immediately or days to weeks following exposure.^[28] Behavioral and psychiatric changes include irritability, violent behavior, personality disturbances, euphoria, confusion, and impaired judgment. Neurobehavioral sequelae include difficulties with visual and verbal memory, spatial deficits, and declines in cognitive efficiency and flexibility.^[29] Parkinsonism has also been reported after acute and chronic exposure.

Differential Diagnosis and Evaluation. Both clinical symptoms and a history of exposure to carbon monoxide are necessary for a diagnosis. In suspected cases of carbon monoxide exposure, blood levels of carboxyhemoglobin can be determined. However, the current level of carbon monoxide in the blood is not indicative of the severity of poisoning because carboxyhemoglobin may rapidly decline after exposure ceases. If a patient dies of carbon monoxide poisoning, however, the level of carboxyhemoglobin determined at postmortem represents the actual level of carbon monoxide at the moment of death, since carbon monoxide cannot be excreted without active respiration.

Management. Treatment involves removal of the patient from the contaminated environment as well as administration

of 100 percent oxygen. Hyperbaric oxygen reduces the half-life of carboxyhemoglobin to less than 25 minutes and is considered the treatment of choice for all patients with severe carbon monoxide intoxication. However, CNS oxygen toxicity is a potential risk of hyperbaric oxygen therapy. Additionally, hypothermia has been advocated to decrease the tissue demands of oxygen. Patients may be covered in ice for 8 to 12 hours at a temperature of 30 to 32° C.

Prognosis and Future Perspectives. The prognosis for patients with significant carbon monoxide poisoning varies. However, follow-up has shown the presence of neurological sequelae, consisting of cortical blindness, seizures, cognitive impairment with amnesia, polyneuropathy, and a parkinsonian syndrome. In a follow-up study performed 3 years after carbon monoxide poisoning, 43 percent of patients had impaired memory, 33 percent showed a deterioration of personality, and 13 percent showed neuropsychiatric damage.

Cyanide, Ethylene Oxide, Nitrous Oxide

See [Table 39-4](#) .

PESTICIDES (Table 39-5)

Organophosphate Insecticides

Pathogenesis and Pathophysiology. Organophosphates inhibit acetylcholinesterase and pseudocholinesterase. Insecticides that are cholinesterase inhibitors include chlorpyrifos (Dursban), diazinon, malathion, ethyl and methyl parathion, and trichlorofon. [30] The neurotoxicity of these compounds is related to their ability to inhibit acetylcholinesterase, which occurs in the brain, spinal cord, myoneural junctions, pre- and postganglionic parasympathetic synapses, and preganglionic and some postganglionic sympathetic nerve endings. The resulting increase in acetylcholine overstimulates the postsynaptic receptors in the cholinergic system, thus differentially stimulating nicotinic receptors (skeletal muscle and autonomic ganglia) and muscarinic receptors (secretory glands and postganglionic fibers in the parasympathetic nervous system).

Epidemiology and Risk Factors. Organophosphate insecticides are highly toxic to insects but are relatively less so to man and domestic animals. Although specific organophosphates such as triorthocresyl phosphate, nipafox, and trichlorofon compounds are obviously neurotoxic, the situation is less clear for other organophosphate pesticides. At risk are factory workers involved in the production of these compounds and agricultural workers who use them to spray crops. The occurrence of organophosphate poisoning in the United States is low, although epidemics have been reported in some Third World countries. It should be noted, however, that 1754 pesticide related cases were reported in California in 1987. California accounts for about one third of the agricultural workforce in the United States. Organophosphates are absorbed through the skin and respiratory tracts. In addition, small amounts may be ingested by eating foods that have been sprayed with organophosphates.

Clinical Features and Associated Findings. Clinically, patients with acute mild symptoms complain of vague fatigue, headache, dizziness, increased salivation, nausea and vomiting, diaphoresis, and abdominal cramps. Symptoms always develop within 24 hours after exposure. Difficulty with speaking or swallowing, shortness of breath, and muscular fasciculations have been reported in patients with more moderate poisoning. With increased severity of poisoning, more intense signs and symptoms can appear. These may include depressed levels of consciousness and marked myosis with no pupillary response. After initial recovery from acute severe intoxication, an organophosphate-induced delayed polyneuropathy (OPIDP) may develop. OPIDP is a distal dying back axonopathy characterized by cramping muscle pain in the legs, paresthesias, and motor weakness beginning 10 days to 3 weeks after the initial exposure. OPIDP-associated signs include foot drop, weakness of the intrinsic hand muscles, absent ankle jerk, and weakness of the hip and knee flexors. [31] Chronic low-level exposure has been associated with weakness, malaise, headache, and lightheadedness. Anxiety, irritability, altered sleep, tremor, numbness and tingling of the extremities, and small pupils may also be observed. [32] Neurobehavioral findings include decreased capacity for information processing, decreased memory and learning abilities, and poor visuoconstructional skills.

Differential Diagnosis and Evaluation. Diagnosis depends on exposure history, clinical symptoms, and abnormally low cholinesterase activity in the blood (BEI, 70 percent of baseline level). Serial cholinesterase levels that show a rise after removal from exposure are diagnostic of exposure. Fasciculations with miosis, although not always present, are also diagnostic of organophosphate poisoning. Also, improvement of acute symptoms can be expected after administration of atropine sulfate.

Management. At the time of ingestion, vomiting should be induced. The primary treatment for mild to moderate organophosphate poisoning is the administration of atropine sulfate (1 mg intravenously or intramuscularly) and pralidoxime (Protopam, 2-PAM, 1 g intravenously). However, potential complications of atropine toxicity include flushed, hot, and dry skin, fever, and delirium. Also, 2-PAM may cause dangerous increases in blood pressure. [30] In patients with very severe organophosphate poisoning, intravenous administration of pralidoxime will restore consciousness within 40 minutes.

Prognosis and Future Perspectives. Prolonged high exposure and the appearance of CNS and PNS symptoms may be associated with an incomplete recovery. However, recovery is complete within weeks to months after lower levels of exposure.

Organochlorine Insecticides

Pathogenesis and Pathophysiology. The neurotoxic mechanisms for dichlorodiphenyltrichloroethane (DDT) and other organochlorine insecticides is not well defined but may involve the excessive and spontaneous release of

acetylcholine. This is in contrast to the acute actions of organophosphates, which block the metabolism of acetylcholine extracellularly. Interestingly, because exposure to both organochlorines and organophosphates produces cholinergic overactivation, these chemicals can cause similar symptomatology.

Epidemiology and Risk Factors. Chlorinated hydrocarbon insecticides are highly soluble in fats and oils. In addition, they last an extremely long time in the environment, thus contributing to chronic toxicity. Commonly used organochlorine insecticides include aldrin, chlordane, DDT, endrin, heptachlor, chlordecone (kepone), and lindane. Most of these insecticides have been banned or restricted in the United States because of their persistence in the food chain, which leads to deleterious effects on wildlife. DDT was banned in the United States in 1973 but is still used in the Third World. Absorption may occur through respiration or through the oral or skin route.

Clinical Features and Associated Findings. Clinical manifestations of organochlorine neurotoxicity have been associated with an oral dose of 10 mg/kg. With acute DDT toxicity, patients report a metallic taste in the mouth. Within 1 hour they complain of dryness of the mouth and extreme thirst. Drowsiness or extreme insomnia, burning eyes, and a gritty sensation in the eyelid are also reported. Other symptoms may include aching of the limbs, muscular spasms, tremors, stiffness and pain in the jaw, difficulty with concentration, and night blindness. Chronic exposure to these compounds can cause tremor and convulsions. Upper extremity weakness, which progresses to wrist drop, may also occur. Mononeuropathy, optic neuropathy, and polyneuropathy have all been described in patients with chronic exposure. In workers in industrial settings that produce DDT and other chlorinated hydrocarbon insecticides, abnormal EEGs marked by bitemporal, sharp wave activity and shifting lateralization have been reported. [33]

Differential Diagnosis and Evaluation. The diagnosis is made by the history. Although organochlorines and their metabolites can be found in the blood, this test is generally unavailable.

Management. Treatment is supportive. For patients with intractable seizures, diazepam and pentobarbital may be useful. Pentobarbital may also accelerate the metabolism of organochlorines. Atropine and adrenergic amines are contraindicated because they may potentiate myocardial irritability.

Prognosis. With the exception of anticonvulsants in patients in whom seizures are prominent features, there are no specific antidotes for DDT.

Other Pesticides: Methyl Bromide, PicROTOXIN, and Strychnine

See [Table 39-5](#).

ANIMAL TOXINS

Snake, Scorpion, and Spider Venoms

Pathogenesis and Pathophysiology. Most animal neurotoxins affect the cholinergic system through either enhancement or blockade. Snake venoms are extremely toxic to cardiac muscle, coagulant pathways, and the nervous system.^[34] Snake venom acts either presynaptically as a toxin that inhibits the release of acetylcholine from presynaptic cells in the neuromuscular junction or postsynaptically as an agent that produces a nondepolarizing neuromuscular block. The resulting effect is a depression of cholinergic function at the neuromuscular junction. There is little evidence that snake bites act directly on the nervous system. Spider venom causes a release of acetylcholine, producing tetanic spasms followed by paralysis.

Epidemiology and Risk Factors. Poisonous snakes include vipers, rattlesnakes, cobras, kraits, mambas, and the American coral snake. Spiders such as the black widow probably account for most of the neurotoxic syndromes that occur after spider bites. Fatalities associated with spider bites occur in approximately 2.5 to 6 percent of cases.^[35] Tarantula bites are probably similar to those of the black widow spider.

Clinical Features and Associated Findings. The clinical presentation of persons with a snake bite include localized pain and swelling, headache, vomiting, loss of consciousness, paresthesias, ptosis, loss of vision secondary to coagulation disturbances, and hemorrhage into the retina. Symptoms after snake bite may develop in from 1 to 10 hours. Beginning signs of paralysis include difficulty with swallowing and opening the mouth. Depending on the species, scorpion stings may include both local and systemic complications. Early symptoms include pain, swelling, excessive salivation, sweating, and abdominal pain. Death may result from hypertension, peripheral circulatory collapse, and cardiac failure. Neurological sequelae are more common in children than in adults and include overexcitement, muscle rigidity, convulsions, and alteration of mental status, which is probably secondary to hypoxia. In those with spider bites, neurological sequelae include paresthesias, fasciculations, tremor, and hyperreflexia during the excitatory phase.

Differential Diagnosis and Evaluation. In patients with snake bites it is especially important to attempt to identify the specific snake involved, since a number of antivenins have been developed against specific poisons.

Management. Treatment of snake bites involves administration of anticholinesterases and specific antivenin as early as possible after the bite. If these are administered prior to the development of major weakness, both pre- and postsynaptic toxic effects can be aborted. Mechanical respiration may also be warranted. During the acute stages after a spider bite, atropine can be administered to control the cardiac muscle effort; gradual recovery will occur over approximately 2 days. Treatment for scorpion bites focuses primarily on supportive respiratory and cardiac measures and attention to coagulation.^[37]

Prognosis and Future Perspectives. Survival depends heavily on the control of cardiac and coagulation defects. The development of effective antitoxins and more rapid access to supportive care centers may improve the prognosis.

Tick Paralysis

Tick paralysis is a flaccid ascending paralysis caused by the bite of certain female ticks, specifically in North

America, *Dermacentor andersoni*, *D. variabilis*, *D. occidentalis*, *Amblyomma americanum*, and *A. maculatum*, which are found commonly in areas west of the Rocky Mountains. The toxin producing the disease is presumably excreted in the saliva of the mature female tick during engorgement. Although persons of any age may be affected, small children are particularly likely to become paralyzed. The head and neck are the most common sites of tick attachment, although any part of the body may be involved. There is some indication of an association between the proximity to the brain of the site of attachment and the severity of the disease. The toxin acts either by causing a failure to liberate acetylcholine at the neuromuscular junction or by causing a generalized depression of all excitable tissues, including the neurons of the spinal cord and brain stem. The course of tick paralysis depends on how soon the tick is found and removed. If it is removed before bulbar symptoms begin, improvement occurs within hours and is complete by 1 week. If bulbar symptoms have begun, death often occurs despite intensive therapy.^[38]

PLANT TOXINS ([Table 39-6](#))

Chickpea (Lathyrism)

Lathyrism is related to a neurotoxin acting through the glutaminergic system. Spastic paraplegia has been observed in Europe and India following consumption of different varieties of chickpea.^[38] Development of human lathyrism is associated with two potent neurotoxins found in the peas: alpha-amino beta oxalylaminopropionic acid and alpha-amino gamma oxalylaminobutyric acid.^[39]

Toxic neurological signs are seen when 30 percent or more of the diet consists of chickpeas. Men tend to be affected more than women. The onset is subtle, with pain in the lumbar region and stiffness and weakness of the lower extremities on awakening in the morning. A slight fever may be present. Paresthesias and weakness may develop during the next several days. The legs become spastic and exhibit clonic tremor. The upper extremities may also be involved in patients with severe disease. Within 1 to 2 weeks the pain and paresthesias usually disappear, although relapses sometimes occur. In addition to the more common spastic paraplegia, polyneuropathy and peripheral mononeuropathy may be present.

Mushrooms

Amanita mushrooms have strong anticholinergic effects due to their concentration of ibotenic acid, muscazone, and muscimol. Clinically, intoxication takes the form of agitation, muscle spasms, ataxia, mydriasis, and even convulsions. Additional indole compounds may account for the hallucinosis that is often seen with intoxication. The genera *Inocybe* and *Clitocybe* contain muscarine and cause cholinergic excitation at all parasympathetic nerve endings except those of the neuromuscular junctions and nicotinic sites. *Coprius atramentarius*, or Inky Cap, is a common mushroom that is generally considered edible. Its consumption in combination with alcohol, however, results in a severe toxic reaction similar to that seen with disulfiram. The syndrome includes facial flushing, paresthesias, and severe nausea and vomiting. The responsible toxin is coprine, which acts to increase acetaldehyde blood levels.

[PreviousNext](#)

BACTERIAL TOXINS

Diphtheria

Pathogenesis and Pathophysiology. Diphtheria is an acute infectious disease caused by the bacteria *Corynebacterium diphtheria*. Diphtheria is transmitted by respiratory droplets from infected persons or asymptomatic carriers. There are two forms, oropharyngeal and cutaneous, and the incubation period is from 1 to 4 days. The bacteria affects the respiratory tract and often the heart, kidneys, and nervous system as well. In the immediate area of the infection, usually the nose and throat, the bacteria produce

TABLE 39-6 -- BOTANICAL TOXINS

Plant	Chemical	Mechanism of Toxicity	Physiological Changes
<i>Amanita muscaria</i> mushroom (flyagarue)	Ibotenic acid	Activates NMDA receptors	Marked depolarization with excitation and excitotoxicity
<i>Clitocybe strombelga</i> mushroom	Acromelic acid	Activates kainic acid receptors	Spasms, excitation, seizures
Cycad	Muscane	Activates cholinergic parasympathetic endings	Severe sweating, salivation, and hypertension
	Beta-N-Methyl-amino-l-alanine (BMAA)	Activates NMDA receptors	Associated with ALS-Guamanian PD-dementia complex
Chickpea Lathyrus	Beta-N-Oxalyl-amino-l-alanine (BOAA)	Acts as an agonist of AMPA receptors in spinal neurons	Induces spastic paralysis of lower limbs termed neurolathyrism
Betel nut	Arecoline	Stimulates parasympathetic receptors and causes CNS arousal	Excitation, salivation, slowed heart rate
Henbane	Scopolamine	Antagonizes muscarinic cholinergic receptors	Rapid heart rate, sedation and confusion, dilated pupils
Deadly nightshade, Jimson weed	Atropine	Antagonizes muscarinic cholinergic receptors	Rapid heart rate, sedation and confusion, dilated pupils

NMDA, N-methyl D-aspartate; ALI, amyotrophic lateral sclerosis PD, Parkinson's disease AMPA, alpha-amino-3 hydroxy-5-methyl-4-isoxazolepropionic acid

a toxin that causes tissue damage and can spread via the bloodstream to other organs. Muscle and myelin are preferentially affected by this powerful exotoxin. Neurological symptoms result from either direct damage to muscle and peripheral nerve or from indirect damage caused by hypoxia and airway obstruction. Fortunately, the exotoxin does not penetrate the blood-brain barrier, and therefore the CNS is not directly affected. Pathological signs include demyelination of the ganglia of the peripheral nerves, especially the node of Ranvier, and the cranial and somatic nerves.

Epidemiology and Risk Factors. Diphtheria is now rare in many parts of the world owing to immunization. Potential risk factors for this disease are lack of immunization, crowding, and poor hygiene. In the United States, only five cases of diphtheria were reported in 1991. However, because of a drop in routine child immunizations in the U.S.S.R., a diphtheria epidemic that included more than 50,000 cases was reported in 1993 and 1994.

Clinical Features and Associated Findings. The clinical course follows a predictable pattern. Between the fifth and twelfth days of the illness the initial symptoms are sore throat, fever, a gray to black throat membrane, nasal voice, regurgitation, and dysphagia. At about this time the trigeminal, facial, vagus, and hypoglossal cranial nerves may be affected. In approximately half the patients who have postdiphtheria neurological dysfunction, ocular involvement and paralysis of accommodation were noted in the second or third week. Mononeuropathies can also occur within 2 weeks of onset, and further peripheral neuropathy, predominantly sensory polyneuropathy, or proximal motor neuropathy extending distally is characteristic in the sixth and seventh weeks of the illness. Sometimes toxic encephalopathy, consisting of a change in mental status, drowsiness, and possibly convulsions, is seen.

Differential Diagnosis and Evaluation. The diagnosis must be based on the clinical history and clinical presentation. Physical examination may show a characteristic gray membrane in the throat, enlarged lymph glands, and swelling of the neck and larynx. In patients with a clinical picture of Guillain-Barre syndrome with visual blurring and palatal involvement, a diagnosis of diphtheria should be questioned. Diphtheric polyneuropathy can be distinguished from all other polyneuropathies by the early bulbar symptoms, unique ciliary paralysis, and subacute evolution of a delayed symmetrical sensorimotor peripheral polyneuropathy. Diagnostic testing should include Gram's stain of the infected membrane, a throat culture, and an electrocardiogram (ECG), which will show evidence of myocarditis.

Management. There is no specific treatment for the neurological symptoms of diphtheria. Treatment generally involves administration of antitoxin within 48 hours of the earliest signs of infection, rest, and maintenance of proper airway and cardiac function. All contacts of the infected person should be immunized, since protective immunity is not present longer than 10 years after the last vaccination. Diphtheria is preventable through immunization at the age of 3 months. Booster doses at 1 year and before the child enters school are suggested.

Prognosis. The death rate is 10 percent. If the patient does not expire because of respiratory distress or cardiac failure, he or she stabilizes and slowly recovers completely. Therefore, activities should be slowly resumed.

Tetanus

Pathogenesis and Pathophysiology. Tetanus is caused by a powerful exotoxin, *Clostridium tetani*, which produces spores. The spores can remain dormant in the soil or in animal excrement for many years until they enter the body and produce a toxin. In patients with tetanus toxicity, both the CNS and the PNS as well as the musculature are involved. The major CNS effect occurs through disinhibition on gray matter gangliosides and through presynaptic antagonism of GABA. At high concentrations, tetanus toxin acts like botulism toxin in that it inhibits the release of acetylcholine at cholinergic synapses. The nervous system is infected by tetanus through retrograde axonal transport from the site of infection. The incubation period may range from 5 to 25 days but can be only a few hours. Early in the illness, pathological changes include changes in the nerve cells of the cortex and brain stem. If the illness lasts for more than 5 days, demyelination and gliosis may occur, and in the most severe cases, hemorrhages can occur.

Epidemiology and Risk Factors. In Third World countries, tetanus is still an important cause of morbidity and mortality. The bacteria can be transmitted in the anaerobic conditions of wounds, through soil-contaminated injuries, and, less commonly, by unclean needles used by drug abusers. Tetanus is seen only in adults who have not been immunized. About 50 to 100 cases are reported in the United States each year, and 60 percent of those cases occur in adults over the age of 60.

Clinical Features and Associated Findings. The clinical course consists of early symptoms of chills, headache, restlessness, and pain at the site of injury. Tightness in the jaw and mild stiffness and soreness in the neck are usually noticed within a few hours. As symptoms develop, the jaw becomes stiff and tight (lockjaw). Muscular involvement then progresses to the throat and facial muscles. Muscular rigidity may then become generalized and may include the trunk and extremities. Rigidity in the abdominal muscles can result in a forward arching at the back. The tetanic contractions occur periodically and can cause severe pain. In the most severe cases, convulsions and marked dyspnea with cyanosis can occur, terminating in asphyxia and sudden death. Mental status remains intact. However, the patient suffers from anxiety and mental and physical agony.

Differential Diagnosis and Evaluation. A diagnosis of tetanus can be made by a positive history of a prior wound, a high titer of serum antibody to tetanus, a history of partial immunization, and clinical symptoms as just outlined. Tetanus must be differentiated from the stiff-person syndrome and the Moersch-Woltman syndrome. Trismus is not typical of stiff-person syndrome.

Management. Patients should be hospitalized and external stimuli kept to a minimum. The infected wound should be debrided. Muscle relaxation can be initiated by

the use of barbiturates or diazepam. Although antiserum does not neutralize the toxins fixed in the nervous system, human tetanus immunoglobulin (TIG) should be given.

One dose of 3000 to 6000 units given intramuscularly into three sites simultaneously is recommended. If human antitoxin is unavailable, equine antiserum can be given. Tetanus is prevented by immunization. Children should be immunized at 2 months to 6 years of age. In adults, tetanus boosters last approximately 10 years.

Prognosis and Future Perspectives. The prognosis is poor. The fatality rate is approximately 65 percent. Death generally occurs rapidly between the third and fifth day of illness and is due to exhaustion, medullary failure, asphyxia resulting from spasm, or circulatory failure resulting from exertion on the heart. Occasionally, tetanus antitoxin produces an adverse reaction involving primarily the PNS. After 6 months, recovery is usually complete.

Botulism

Pathogenesis and Pathophysiology. Botulism is the most potent poison known to man. It is produced by the spores of *Clostridium botulinum*. Three distinct varieties of the disease exist. Foodborne botulism results primarily from the ingestion of contaminated home-canned fruits and vegetables. Since this type of botulinum toxin is produced by spores that are already formed and ingested, toxic signs appear rapidly, usually between 8 and 36 hours after ingestion, and an incubation period is not required. After ingestion of the botulinum toxin, neurological signs appear within hours or at most 1 week. Wound botulism is both an infection and an intoxication. The organism enters through the wound site, and the spores may germinate locally in the tissues, producing a potent exotoxin. The third form of botulism is infantile botulism, which occurs in the first 6 months of life. It is related to the absorption of *C. botulinum* from the gastrointestinal tract. The basic pathophysiological mechanism of botulism neurotoxicity is inhibition of acetylcholine release.

Epidemiology and Risk Factors. Each year, approximately 20 cases of foodborne botulism in adults and 250 cases of infantile botulism are reported. Infantile botulism produces a very different clinical syndrome from that outlined below. This disease has been reported only within the last decade. Interestingly, botulinum toxicity has been offered as a possible explanation for the sudden infant death syndrome (SIDS). The age distribution is the same, and 10 infants with SIDS in California in 1977 also had evidence of intestinal infection with *C. botulinum*. Botulism may cause sudden infant death by producing flaccidity of the upper airway or tongue muscles, leading to airway obstruction during sleep. ^[42]

Clinical Features and Associated Findings. Early signs of toxicity include nausea and vomiting with abdominal pain, and diarrhea. Other symptoms include ptosis, extraocular paresis, and progressive weakness suggestive of myasthenia gravis. Cranial nerve symptoms most commonly involve the eyes. Additional symptoms include dryness of the mucous membranes, vertigo, deafness, dysphasia, swallowing difficulties, breathing difficulty that may lead to respiratory failure, speech impairment, absent or decreased gag reflex, and absent or decreased deep tendon reflexes. By the second to fourth day of the illness, muscular weakness develops. Often muscular involvement is limited to the neck muscles, resulting in an inability of the patient to raise the head. ^[43]

In infants symptoms consist of constipation, weakness with loss of muscle tone, and an alert but weak appearance.

Differential Diagnosis. Weakness can be differentiated from Guillain-Barre syndrome because the weakness associated with botulism toxicity is descending, so the proximal muscles are affected before the distal extremities. The progressive weakness is suggestive of myasthenia gravis; however, the pupillary dilation seen in botulism is not characteristic of myasthenia.

Evaluation. Confirmation of the diagnosis depends on detection of the toxin either in the patient (blood) or in the implicated food. A stool culture is often useful.

Management. Once the patient has been admitted to the hospital, respiration should be monitored. Trivalent ABE antitoxin is recommended.

Prognosis and Future Perspectives. In severe cases, a downward course is rapid and terminates in death. Death occurs in 70 percent of untreated cases. If the patient survives, recovery begins within a few weeks.

ILLICIT DRUGS ([Table 39-7](#))

Cocaine

Pathogenesis and Pathophysiology. Blockade of the uptake of monoamines into the presynaptic terminals is probably responsible for the acute effects produced by cocaine. Depending on the synapse affected, this blockade leads to increased levels of dopamine (DA), norepinephrine, or serotonin. The increase in neurotransmitters can

TABLE 39-7 -- SUMMARY OF NEUROLOGIC SIGNS AND SYMPTOMS OF DRUG ABUSE

SEIZURES	Opiates, stimulants, over-the-counter drugs

then lead to overstimulation of postsynaptic receptors and increased neurotransmission.

Cocaine can cause strokes when taken either intranasally, intravenously, or intramuscularly.^{[44], [45]} The effects of cocaine on the cerebral circulation are due primarily to direct vasoconstriction, probably related to stimulation of noradrenergic receptors by increased levels of norepinephrine. In addition, cocaine can enhance platelet response to arachidonic acid, thus promoting aggregation.

Cocaine-induced strokes may be ischemic or hemorrhagic. Cocaine-ischemic strokes can present as transient ischemic attacks. Infarctions in the distribution of all major arteries have been described. Cocaine-induced strokes in young patients have increased remarkably.^[46] Although cerebral infarction has been attributed to vasculitis and vasospasm, there are few documented examples of vasculitis in autopsied cases.^{[47], [48]}

Intracerebral or subarachnoid hemorrhages may also be associated with cocaine use. The majority of these cases occur in the presence of saccular aneurysm or vascular malformations. Infarctions and hemorrhages have occurred in newborns whose mothers had used cocaine prior to delivery.

The mechanisms of cocaine-related stroke are unclear. However, it has been reported that cocaine hydrochloride is more often associated with hemorrhagic stroke than with occlusive stroke, whereas hemorrhagic and occlusive strokes occur with roughly equal frequency in patients who use cocaine alkaloid ("crack"). The effects of crack on the regulation of calcium fluxes may be related to the rising prevalence of stroke. Acute hypertension can lead to intracranial hemorrhage, especially in subjects with underlying aneurysms or vascular malformations. Myocardial infarction, cardiac arrhythmia, and cardiomyopathy carry a very high risk of embolic stroke.

Cerebral vasoconstriction may be a cause of occlusive stroke. It may be significant that cocaine metabolites also cause cerebral vasospasm. These metabolites may be detectable in the chronic user's urine for weeks. In addition, transcranial Doppler ultrasound examination has revealed increased distal arteriolar resistance in volunteers who use cocaine intranasally.

The neuropsychological effects of cocaine are thought to be due to decreased dopamine levels in the brain. This hypothesized dopamine decrease may be secondary to long-term depletion of DA, which occurs with repeated drug administration. However, there is very little evidence to support this view. Preliminary human studies using controls suggest that chronic cocaine use produces subtle impairment in short-term auditory recall, concentration, and reaction time. A CT study has shown that habitual cocaine users (those who use the drug at least twice weekly for 2 years or more) have significant degrees of cerebral atrophy (enlargement of the lateral ventricles and widening of the sylvian fissures) compared with first-time users and non-users. Studies examining the consequences of chronic cocaine abuse in abstinent cocaine abusers have shown that cerebral metabolism in the medial orbitofrontal cortex and basal ganglia during the first week of abstinence from cocaine is higher than that in normal subjects but then falls below normal levels and remains so for at least 3 months.^[49] In another positron emission tomography study, glucose metabolism in the entire cerebral cortex, thalamus, and midbrain was reduced following acute administration of cocaine.^[50]

Epidemiology and Risk Factors. Cocaine was first used by South American Indians between 2000 and 1500 BC. From the 1920s to the 1960s, recreational use of cocaine in the United States was limited to jazz musicians and the "cultural avant garde." Subsequently, the use of cocaine has been steadily increasing. The number of Americans estimated to have tried cocaine at least once rose from 5.4 million in 1974 to 21.6 million in 1982. Annual revenue from the cocaine industry is estimated to be at least \$27 billion. In the mid-1980s, the development of crack cocaine caused a marked increase in the number of new cocaine users, to an estimated 5000 new users a day, 6 million regular users, and 1 million compulsive users. In 1991 it was estimated that at least 1.75 to 1.9 million Americans used cocaine weekly. This epidemic of cocaine use with its associated medical and neurological sequelae has turned cocaine into a major public health catastrophe.

Clinical Features and Associated Findings. Cocaine produces a brief rush, which peaks at 1½ to 2 minutes. This rush is followed by euphoria, excitability, and hypervigilance. The acute administration of cocaine causes both psychiatric and neurological symptoms. Acute psychiatric symptoms include anxiety, insomnia, paranoia, agitation, and psychosis. Neurological symptoms include stereotypy, bruxism, chorea, dystonia, myoclonus, seizures, lethargy, strokes, and coma. In addition, high doses of cocaine cause tachycardia, tachypnea, and hypertension. Parenteral cocaine users are also at risk for stroke related to infection, such as endocarditis and the acquired immune deficiency syndrome (AIDS).

Differential Diagnosis and Evaluation. The clinical presentation of a cocaine-induced neurological disorder can mimic a number of other neurological abnormalities. However, a cocaine-related stroke or other neurological disorder can be diagnosed if a urine toxicology screen is positive for cocaine. It is important to perform the toxicology screen within the first 24 hours of presentation because of the short half-life of cocaine in the urine. However, urinary cocaine metabolites such as norcocaine and benzoylecgonine may remain positive for several days. Urine toxicology screening is indicated in all patients who present to the emergency room with

an acute neurological syndrome because a very high prevalence of cocaine use exists in many communities, including suburban areas.

Management. Treatment of cocaine-induced neurological abnormalities depends on the clinical presentation. In patients with acute paranoia or psychosis, neuroleptics are indicated. However, it is important to note that cocaine abusers may be at increased risk for acute dystonic reaction secondary to antipsychotic drugs. In these cases, anxiolytics can be very helpful. Other complications, including strokes, are treated according to the clinical presentation.

Amphetamine Analogs

Pathogenesis and Pathophysiology. The pathophysiological basis for the complications associated with amphetamine

use are not well understood. Amphetamine-induced cerebral vasculitides cause occlusive as well as hemorrhagic strokes. Methamphetamine use can cause necrotizing angiitis. Also, cerebral arteritis with multiple occlusions of arterioles was reported in young abusers of intravenous methamphetamine who were hospitalized because of coma or stroke.^[51] Angiographic studies in such patients have shown occlusions or beading of vessels in the internal carotid, distal middle cerebral, and lenticulostriate arteries.^[52]

To test the role of methamphetamine in the etiology of vasculitis, monkeys were given methamphetamine intravenously and then underwent serial angiograms.^[53] Some of the animals showed beading of small and large vessels that persisted or progressed over a 2-week period. Hypertension and behavioral changes were also seen. At autopsy, subarachnoid hemorrhages were found in some animals as well as brain petechiae, infarcts, microaneurysms, and perivascular white cell cuffing. More severe vasculitides were reported in another study of monkeys that received intravenous methamphetamine three times weekly for up to a year.^[54] Angiographic and histological changes have also been reported in monkeys given intravenous methylphenidate.^[54] Sural nerve biopsy showed hypersensitivity angiitis of medium and small arteries and veins in an adolescent amphetamine abuser who presented with mononeuritis multiplex.^[55]

Epidemiology and Risk Factors. Amphetamines have been used for several decades to promote weight loss. They are also used in the treatment of attention deficit disorder and narcolepsy and as an adjunctive treatment in patients with treatment-resistant depression. During the 1960s and early 1970s, amphetamines were widely abused by people involved in the so-called counterculture movements. During the 1980s and 1990s, most of these drugs were replaced by cocaine. Nevertheless, prescribed amphetamines remained a significant source of abusable drugs. More recently, drugs such as methamphetamine (METH, Ice) and methylenedioxymethamphetamine (MDMA, Ecstasy) have undergone a major resurgence among adolescents and young people in their early twenties. MDMA is used frequently at "raves" and has become a major public health issue in some communities. METH is also widely used in California and in some midwestern states, where it is synthesized in basement laboratories. It has been predicted that these drugs will replace cocaine as the major drugs of abuse in the 1990s. In Japan, METH abuse has been rampant since the end of World War II.

Clinical Features and Associated Findings. The amphetamine analogs tend to produce very similar signs and symptoms. These include hyperalertness, euphoria, hyperactivity, and greater physical endurance. Higher doses of these drugs can cause dysphoria, headaches, and confusion.^[56] Unlike cocaine, these drugs can produce a prolonged rush when taken intravenously, and inhalation of METH can sometimes cause a more rapid rush. These responses are due to their longer half-lives; also, the psychological response to amphetamine analogs usually lasts longer than that of cocaine. In fact, METH can induce psychotic symptomatology that is often indistinguishable from that of an acute schizophrenic break. METH-induced psychosis is very common in Japan.

Tourette's syndrome can be exacerbated and precipitated by amphetamine, methylphenidate, and pemoline; it sometimes clears with discontinuation of the drug but occasionally persists.^[57],^[58] The bruxism and choreiform movements that develop with chronic amphetamine use may also persist after the drug has been discontinued.

Strokes are also frequent complications of amphetamine abuse. Intracerebral hemorrhages have been reported after either nasal or intravenous use of these drugs. Often, strokes are preceded by complaints of severe headaches. Blood pressure is elevated in more than half the subjects who come to medical attention, in whom the diastolic pressure may be as high as 120 mm Hg. CT scans have shown intracerebral, intraventricular, or subarachnoid hemorrhage. Cerebral angiography shows irregular narrowing of the distal cerebral vessels, which is consistent with the presence of vasculitis.

Management. In patients who present with acute psychotic symptomatology, antipsychotic drugs may be indicated. It is very important to pay close attention to the patient's vital signs because amphetamines can cause a marked increase in body temperature. These patients may be more prone to develop the neuroleptic malignant syndrome. In such cases, it might be more beneficial to use a quiet, cool room for treatment rather than pharmacological agents. If this is not possible, anxiolytic agents are recommended. The clinical presentation of the patient should determine the exact method of management.

Prognosis and Future Perspectives. Whether the amphetamines can cause permanent psychiatric or cognitive disturbances is uncertain. Ten users of amphetamines reported decreased memory or poor concentration ability after they achieved abstinence. There are also reports of lasting psychosis or dementia. Formal studies of cognitive performance in chronic amphetamine abusers have not been systematically performed.

Methylenedioxymethamphetamine

Methylenedioxymethamphetamine (MDMA; Ecstasy) is a derivative of methamphetamine. It is reported to cause severe damage to the serotonergic neurons in nonhuman primates and decreases in the serotonin metabolite 5-hydroxyindoleacetic acid (5-HIAA) in the cerebrospinal fluid of humans who have abused the drug.^[59] MDMA acts as a stimulant and a hallucinogen. It is abused by individuals who wish to intensify their emotional and sensory experiences. MDMA and a close congener, methylenedioxyamphetamine (MDA), are reported to cause changes in the strength of the emotions. Psychiatrists have experimented with these drugs to facilitate psychotherapy, especially in patients who have difficulty in expressing their emotions.

MDMA and MDA can cause increases in blood pressure and heart rate, anxiety, and hyperactivity. Neurological side effects include pupillary dilatation and tremors. Seizures, strokes, and coma have also been reported with the use of MDMA.

Opioid Agonists

Pathogenesis and Pathophysiology. Opioid drugs can cause respiratory suppression because of the high density

of opioid receptors in the brain stem nuclei. These receptors subserve respiration. CT studies have revealed cerebral and cerebellar white matter lucencies in patients who present with pseudobulbar palsy and quadriplegia. Postmortem studies have also shown edema and spongiform-type changes in the white matter of heroin abusers.^[60] It is possible that these pathological changes may be secondary to the adulterants used with these drugs, such as chloroquine. This adulterant is often used in conjunction with heroin.

A large number of heroin abusers develop AIDS. At autopsy, neuropathological abnormalities consistent with AIDS are found. Almost all had neurological symptoms and signs prior to death. Retrospective surveys of AIDS cases suggest that parenteral drug abusers are more likely than other high-risk groups to have cryptococcal meningitis and CNS toxoplasmosis. No differences were found between parenteral drug abusers and nondrug-abusing homosexuals in the prevalence of these infections or of neurological symptoms including dementia, seizures, or peripheral neuropathy. On the other hand, Kaposi's sarcoma is rare in drug abusers. Neuropsychological studies of asymptomatic HIV-seropositive parenteral drug abusers found no evidence of significant cognitive impairment, a finding that needs to be evaluated further.

Epidemiology and Risk Factors. The poppy has been used for its opioid content for more than a few thousand years. Opium has been available in Europe since the middle of the sixteenth century. By the nineteenth century, opium was popular in many countries as a euphoriant. After the Civil War, opioid use became widespread in the United States, and opium was present in a number of over-the-counter remedies, including Dover's powder, Godfrey's cordial, and Darby's carminative. The number of Americans reportedly addicted to opioids at the beginning of the twentieth century ranges from 200,000 to more than 1 million. Most were white

middle-aged women who took opium in medicines. More recently, opioid agonists are used for their acute euphoric effects. Three milligrams of heroin are equivalent to about 10 mg of morphine. Until the advent of crack cocaine, heroin was probably the most common illicit drug used in many metropolitan areas. In the late 1960s, heroin-related fatalities were a very common cause of death in New York City men aged 15 to 35. In 1985, there was a striking rise in the number of fatal heroin overdoses in New Mexico; this was attributed to the availability of Mexican "black tar" heroin. Heroin (diacetylmorphine) is metabolized to 6-acetylmorphine and morphine.

Clinical Features and Associated Findings. The acute effects of opiates include euphoria and drowsiness.^[61] Parenteral heroin produces a "hit" that lasts for about a minute. It is often compared to orgasm. The user then experiences a dreamlike and pleasant drowsiness. Visual hallucinations have been reported after morphine or heroin administration. Nausea and vomiting can also occur. Drug abusers often experience dryness of the mouth, pruritus, suppression of the cough reflex, respiratory depression, hypothermia, postural hypotension, and constipation.

Pentazocine (Talwin) and tripeleminamine (Pyribenzamine) were widely abused in some American cities in the 1970s.^[62] Cerebral hemorrhages resulted from the injection of crushed oral tablets that were suspended in water and passed through a cigarette filter. Pulverized meperidine tablets have caused seizures and fundal hemorrhages. Cerebral vasculitides have also been reported in users of these drugs.

The chronic use of heroin can result in myelopathy, which is probably of vascular origin.^[63] Acute paraparesis, sensory loss, and urinary retention usually occur shortly after administration of the drug. Possible causes of spinal lesions include hypotension, embolism of foreign objects, and direct toxic effects of the drugs. Vasculitis affecting mainly the small arteries and arterioles has been reported. Also noted is an anterior spinal artery syndrome with quadriplegia that follows supraclavicular heroin injection.

A number of other neurological complications affect heroin users. Peripheral neuropathy can present as a Guillain-Barre syndrome.^[64] The peripheral nerves may also be damaged secondary to direct injection or to pressure palsies. Ulnar and femoral neuropathies have also been observed. Painful brachial and lumbosacral plexopathies are also common; these can result from a septic aneurysm affecting the subclavian or axillary arteries. Vocal cord paralysis can follow repeated jugular vein injections.

Adulteration of heroin with chloroquine can cause headache, confusion, and visual disturbances. Spongiform encephalopathy has also been reported. In these patients, there were symptoms of apathy, bradyphrenia, dysarthria, and ataxia. There are also signs of spastic hemiparesis or quadriparesis, tremor, chorea, myoclonus, pseudobulbar palsy, fever, and blindness. Heroin use is also a risk factor for new-onset seizures independent of head injury, infection, stroke, or alcohol. Infections are a common cause of morbidity in heroin users. Osteomyelitis is associated with back or neck pain, radiculopathy, and sometimes even cord compression. Cervical infection is especially common among addicts who inject into the jugular vein. Symptoms frequently precede diagnosis by several weeks. *Staphylococcus aureus* and *Pseudomonas* are common etiological factors in these infections. Bacterial endocarditis can lead to intraparenchymal or extraparenchymal abscess of the brain or spinal cord, meningitis, cerebral infarction, diffuse vasculitis, and subarachnoid hemorrhage from rupture of septic mycotic aneurysms. Progressive neurological symptoms, including headache, fever, syncope, hemiparesis, and aphasia, are a common presentation of mycotic aneurysms.

Tetanus has been reported in skin poppers who suffer from multiple skin abscesses.^[65] Among drug users, curarization is frequently necessary to control symptoms. Botulism with dysphagia, blurred vision, dysphonia, and descending paralysis has also occurred in parenteral heroin abusers.

Coma is a common presentation of opioid overdose. In some comatose patients, pulmonary edema is frequently present. These patients do not respond to naloxone. In milder cases, overdose of heroin can be associated with spastic quadriparesis, deafness, seizures, and dystonia. Postanoxic encephalopathy has also been reported. Death can follow very small amounts of heroin or methadone. Some of these complications may be due to adulterants. For example, quinine causes cardiac conduction abnormalities and ventricular fibrillation. The combination of heroin, ethanol, and quinine might synergize to cause sudden death.

78

Management. The treatment of opioid-related complications is based on the clinical presentation. Naloxone (2 mg) is initially administered for patients with respiratory depression. Increments of 2 to 4 mg can be repeated up to a total dose of 20 mg, depending on the clinical status of the patient. Higher doses are often used for those with propoxyphene, pentazocine, diphenoxylate, nalbuphine, or butorphanol toxicity. It is often necessary to administer naloxone intramuscularly or subcutaneously because of the bad veins of these patients. The clinician must be aware of the potential for precipitating withdrawal symptoms with overdosage of an antagonist. Based on the clinical status of the subject, it may be necessary to titrate a naloxone infusion because methadone and propoxyphene have long half-lives.

If heroin is taken in combination with cocaine or amphetamine, paranoid psychosis can be unmasked through the use of naloxone. Opioids taken in combination with barbiturates or ethanol can produce a coma that does not respond to naloxone.

Hallucinogens

Hallucinogens (psychedelics) have been used and abused since time immemorial. Many of these compounds, including mescaline (peyote cactus) and psilocybin (mushrooms), are used in religious ceremonies by Native Americans. These drugs were used actively during the 1960s and early 1970s. In the 1980s they were displaced by cocaine, but there has been a resurgence in their use, especially among teenagers.

The most commonly abused hallucinogen in the United States is lysergic acid diethylamide (LSD). LSD is made from lysergic acid found in the fungus, ergot, which can grow on grains. Many of the hallucinogens are structurally similar to serotonin, which suggests that this class of drugs exerts its effects by altering this neurotransmitter. LSD also alters adrenergic mechanisms in the periphery and acts as a partial dopaminergic agonist. It is the most powerful hallucinogen and produces symptoms at doses varying from 25 to 50 µg. LSD is sold in a variety of forms, including small sticky pieces of paper that contain as much as 300 µg of the drug. LSD is readily absorbable after oral administration. Its effects peak after 2 to 4 hours and may last for several hours.

Symptoms consist of euphoria, intensive arousal, panic, or even depression. Perceptual distortions are very common, as are hallucinations. Neurological abnormalities include papillary dilatation, lacrimation, and hyperreflexia. Patients report visual changes consisting of increased intensity of colors and alterations in shapes. No toxic fatalities have been reported with LSD use. A number of LSD users have recurring episodic visual disturbances, which include flashes of color, geometric pseudohallucinations, and fleeting perceptions in the peripheral visual fields. Formerly known as "flashbacks," these have been renamed the hallucinogen persisting perception disorder (HPPD). Some chronic heavy users of LSD have been reported to suffer from impaired memory, poor attention span, and confusion.

Users of LSD may require treatment because they experience severe anxiety, intense depression, or suicidal ideation. Therapy consists of "talking the patient down," which is a highly effective approach. If medication is required, diazepam given orally is the drug of choice.

Methyl-phenyl-tetrahydropyridine

The first case of methyl-phenyl-tetrahydropyridine (MPTP)-induced parkinsonism was reported in 1979.^[66] The subject later died of a drug overdose. At autopsy, destruction of the substantia nigra zona compacta was evident; other areas usually involved in Parkinson's disease such as the locus coeruleus were not affected. This article lay dormant until parkinsonism began appearing in the San Francisco Bay area among users of MPTP sold as "synthetic heroin." The responsible chemical was identified as a byproduct of meperidine synthesis, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP).^[67]

The cerebrospinal fluid (CSF) of affected patients contains decreased homovanillic acid levels similar to those observed in patients with Parkinson's disease.^[68] Positron-emission tomography (PET) using 18F-dopa of asymptomatic drug users exposed to MPTP showed decreased dopa uptake, which suggests that the numbers of DA terminals and, by extension, the nigral cell bodies were decreased. The MPTP model of dopamine depletion has been helpful in mechanistic studies of the degenerative and regenerative potential of the nigrostriatal DA system. MPTP is metabolized to 1-methyl-4-phenylpyridinium (MPP+) by monoamine oxidase B. MPP+ is then taken up into DA terminals, where it blocks complex I of the mitochondrial respiratory chain. This blockage may lead to adenosine triphosphate (ATP) depletion with secondary cellular demise due to energy crisis. The possibility that abnormalities in the respiratory chain could also lead to cytotoxic oxygen-based free radicals has also been put forward.^[69]

MPTP has also caused parkinsonism in laboratory workers who were accidentally contaminated through inhalation or skin contact. Bradykinesia and rigidity can be

very severe, with muteness and inability to swallow. As in idiopathic Parkinson's disease, levodopa/carbidopa and bromocriptine can provide dramatic relief in these patients. Patients develop typical side effects of these drugs, including dyskinesia, on-off phenomenon, and psychiatric symptoms.

Phencyclidine

Phencyclidine (PCP) was developed initially as an anesthetic. However, a large number of patients developed postoperative psychosis after its administration. These occurrences stopped its use for this purpose in humans. Significantly, PCP affects all neurotransmitter systems. During the 1970s PCP was sold as "angel dust," and its use was rampant. At present, PCP is mainly used by lower middle class white men in a very few localities. It can be injected, snorted, smoked, or eaten, and has been found in samples of LSD, amphetamines, and marijuana. PCP has been sold as mescaline or as one of the hallucinogens.

PCP can cause a mixed euphoric-dysphoric syndrome with increasing doses of the drug. Users have reported sensations of time slowing, of relaxation, and of numbness. High doses of PCP can cause a psychotic picture similar to that of schizophrenia, with increasing agitation, hallucinations, and bizarre and violent behaviors. Catatonia has also been reported. Patients with PCP-induced psychosis may show increased body temperature, hypertension, and increased sweating. Neurological abnormalities include miosis, horizontal and vertical nystagmus, and ataxia. Increased muscle tone, hyperreflexia, and tremors have also been reported. Very high doses of the drug have been reported to cause seizures and even coma. Delirium lasting for several days is common in patients recovering from PCP-induced coma.

Treatment of an intoxicated PCP user involves putting the subject in a very calm environment. Neuroleptic drugs are relatively contraindicated because they have the potential to cause development of the neuroleptic malignant syndrome or to precipitate seizures. Benzodiazepines are the drugs of choice in treatment of PCP-induced intoxication. Enhancement of PCP clearance by acidification of the urine is recommended in comatose patients.

Cannabinol (Marijuana)

Marijuana is one of the most commonly abused drugs. It was used as early as 3000 BC in cultures as diverse as those found in the Middle East and Asia. The drug is known by a number of names, including hashish, ganja, and bhang. Low to moderate doses of the drug cause very few psychological and physiological symptoms. The pharmacologic actions and the long-term effects of chronic use are still unclear.

Delta-tetrahydrocannabinol (THC) is derived from the marijuana plant, *Cannabis sativa*. The drug can be smoked, eaten, or taken intravenously. Its potency varies greatly. When smoked, the peak plasma level of the drug is reached within 10 minutes, although psychological effects do not develop until 20 to 30 minutes. The effects can last up to 3 hours. However, THC is absorbed and accumulates in tissues such as the testes and the brain.

THC causes euphoria, feelings of relaxation, and heightened sexual arousal. Some individuals experience increased hunger; others report increased suspiciousness, paranoia, and aggressiveness, and still others become quite withdrawn socially.

Neurological signs and symptoms include confusion, disorientation, and an organic delusional syndrome. Some recurrent users develop short-term memory deficits. Nystagmus, ataxia, and tremors have also been reported. The drug can precipitate seizures in patients with known seizure disorders. Life-threatening neurological abnormalities are very rare.

Treatment of patients with acute toxic reactions involves reassurance that the problems will clear up within a few hours. Because of the possible high concentration of the drug in various tissues, the neurological effects of the drug may take up to 8 hours to clear. No specific drug is necessary, although a benzodiazapine may be useful. In patients in acute psychotic states, haloperidol 5 to 20 mg/ day in divided doses is recommended.

ACKNOWLEDGMENT

The authors would like to thank Regina Galanti for her assistance in the preparation of this chapter.

HISTORY AND DEFINITIONS

The study of nutritional disorders of the nervous system is complex for several reasons. First, multiple deficiencies may co-exist in the same patient in certain settings, such as malnutrition and malabsorption states. Second, nutritional disorders can occur with the ingestion of potentially toxic agents as in alcohol, making it difficult to separate the neurotoxic effects from a specific dietary deficiency. Third, in several disorders a single so-called biochemical lesion has not been identified, such as in Marchiafava-Bignami disease, central pontine myelinolysis, Strachan's syndrome, and deficiency amblyopia. Fourth, the rapidity of onset of some syndromes may not be interpreted as nutritional. Instead of evolving in a slowly progressive fashion, some deficiency states may become acutely symptomatic when triggered by an environmental stressor or sudden increase in metabolic demands for the deficient nutrient. The administration of intravenous glucose to a thiamine-depleted alcoholic patient may precipitate acute Wernicke-Korsakoff syndrome (WKS) owing to the sudden increase in thiamine-dependent carbohydrate catabolism. Intractable vomiting due to hyperemesis gravidarum may also cause WKS. Similarly, nitrous oxide administration to patients with asymptomatic cobalamin deficiency may cause an acute myeloneuropathy. Additionally, sudden changes in tissue osmolarity, such as the rapid correction of hyponatremia, may lead to central pontine myelinolysis ([Table 40-1](#)).

Fifth, at times, the same deficient nutrient may not affect patients uniformly. Thiamine deficiency leads to capillary proliferation, petechiae, and microglial degeneration of midline central nervous system (CNS) nuclei in some patients, and in others, it leads to peripheral nerve axonal degeneration. Neurological symptoms and signs of individual deficiency states often overlap, making clinical distinction difficult. For example, encephalopathy may be seen in deficiencies of thiamine, cobalamin, and niacin; myeloneuropathy

TABLE 40-1 -- ACUTE AND SUBACUTE PRESENTATION OF NUTRITIONAL DEFICIENCY SYNDROMES

Syndrome	Clinical Setting
Wernicke-Korsakoff syndrome	Administration of intravenous glucose to a thiamine-deficient alcoholic patient
Wernicke-Korsakoff syndrome	Intractable vomiting due to hyperemesis gravidarum or gastroplasty
Postgastroplasty neuropathy	Intractable vomiting and severe weight loss in patients following weight reduction surgical procedures
Vitamin B12 myeloneuropathy	Nitrous oxide administration in cobalamin-deficient patients
Central pontine myelinolysis	Sudden change in tissue osmolarity in critically ill patients or alcoholics

may be present in deficiencies of cobalamin and vitamin E; neuropathy can result from deficiency of B complex vitamins (thiamine, pyridoxine, and cobalamin) and pyridoxine excess; and optic neuropathy may be seen in cobalamin deficiency, vitamin A excess, or a combined deficiency of B complex vitamins, such as in deficiency amblyopia.

Sixth, the underrecognition of nutritional disorders in industrialized countries has led to difficulties in diagnosis, and these deficiencies may be more common than has been clinically appreciated. Although the incidence of WKS has traditionally ranged from 1 to 3 percent, autopsy data suggest a higher incidence, ¹³ and others report thiamine deficiency in up to 17 percent of elderly patients hospitalized for non-neurological reasons. ¹⁴ One study of thiamine deficient alcoholics showed that over 50 percent of patients were also riboflavin deficient, and 2 percent had a concomitant deficiency of pyridoxine. ¹⁵ Cobalamin deficiency occurs in 5 to 14 percent of ambulatory elderly, ¹⁶ and up to 27 percent of hospitalized elderly develop protein-energy malnutrition (PEM) during their hospital stay. ¹⁷

Finally, several inherited enzyme deficiency disorders, although not accompanied by a vitamin deficiency may nonetheless be vitamin responsive ([Table 40-2](#)). Homocysteinemia responds to pharmacological doses of folate, cobalamin, and pyridoxine, whereas methylmalonicacidemia responds to cobalamin. Maple syrup urine disease, a branched-chain aminoaciduria, may be responsive to high-dose thiamine which induces the enzyme alpha-ketoacid decarboxylase, promoting metabolism of branched-chain amino acids. Beta-methylcrotonylglycinuria and propionic-acidemia may be responsive to biotin replacement; Hartnup's disease, a disorder of tryptophan metabolism, is also responsive to niacin.

VITAMIN DEFICIENCIES

Thiamine

The discovery and isolation of vitamins began with the study of beriberi in the 19th century. Although beriberi has been recognized for centuries, it was not until the Industrial Revolution that the disease reached epidemic proportions. Grain mills began producing polished rice, which was mechanically stripped of the nutrient-rich husk. Epidemics of painful polyneuropathy and heart failure rapidly developed in regions where rice was the major source of carbohydrate, particularly in Asia. In 1897, Eijkman demonstrated the disease in pigeons after feeding the birds polished rice; he then cured the disease by feeding the same birds crude, unpolished rice. A search then began for the antineuritic factor within the rice husks. Funk thought he had identified the antiberiberi factor in 1911 as an amine within rice bran extracts and coined the term vitamin. Elvehjem later identified Funk's substance as the anti-pellagra factor nicotinic acid amide (niacin). The antiberiberi factor was synthesized in 1936, and the name was changed to thiamine to reflect the molecule's sulfur content.^[9]

Pathogenesis and Pathophysiology. The metabolically active form of thiamine, called thiamine pyrophosphate (TPP), is critical in the intermediary metabolism of carbohydrate. TPP is involved in three enzyme systems: (1) pyruvate dehydrogenase, which converts pyruvate to acetyl coenzyme A; (2) alpha-ketoglutarate dehydrogenase, which catalyzes the conversion of alpha-ketoglutarate to succinate in the Krebs cycle; and (3) transketolase, which catalyzes the pentose monophosphate shunt (Fig. 40-1 (Figure Not Available)). A deficiency of TPP leads to elevated levels of serum pyruvate and occasionally lactate, reduced red blood cell (RBC) transketolase activity, and a corresponding increase in transketolase activity in response to added TPP (TPP effect). It is not understood how TPP deficiency leads to the hallmark pathology.

Pathologically, patients with WKS show capillary proliferation and petechiae; spongy degeneration of astrocytes with neuronal preservation occurs in midline structures of the brain, such as the medial thalamic nuclei, mammillary bodies, periaqueductal gray area of the mesencephalon, and pontine tegmentum (Fig. 40-2). Degeneration of the superior cerebellar vermis is usually present. The lesions in the thalami and mammillary bodies probably account for the confusion, memory loss, and confabulation. The pontine tegmental lesions may cause the oculomotor palsies, and the truncal ataxia may result from the midline cerebellar degeneration. Cellular injury in these regions

TABLE 40-2 -- CHARACTERISTICS OF DISORDERS RESPONDING TO LARGE DOSES OF VITAMINS AND CO-FACTORS

Vitamin	Disorder	Affected Enzyme	Therapeutic Dose
Thiamine (vitamin B1)	Branched-chain ketoaciduria (maple syrup urine disease)	Branched-chain ketoacid decarboxylase	5 to 20 mg
	Lactic acidosis	Pyruvate carboxylase	5 to 20 mg
	Pyruvic acidemia	Pyruvate dehydrogenase	5 to 20 mg
Cobalamin (vitamin B12)	Methylmalonicaciduria	Methylmalonyl CoA mutase apoenzyme	2000 µg
	Homocystinuria	Defects in adenosyl-cobalamin and methyl-cobalamin synthesis	500 to 1000 µg
Pyridoxine (B6)	Homocystinuria	Cystathionine synthase	200 to 1200 µg
	Pyridoxine-responsive infantile seizures	Glutamic acid decarboxylase	10 to 50 mg
Niacin	Hartnup's disease	Intestinal malabsorption of tryptophan	<400 mg
Folic acid	Homocystinuria	Methylenetetrahydrofolate reductase	<10 mg
Biotin	Beta-methylcrotonylglycinuria	Beta-methylcrotonyl CoA carboxylase	5 to 10 mg
	Propionicacidemia	Propionyl CoA carboxylase	5 to 10 mg

Figure 40-1 (Figure Not Available) Major metabolic pathways involving coenzymes formed from water-soluble vitamins (Modified from Marcus R, Coulston AM: Water soluble vitamins. In Gilman AG, Goodman LS, et al [eds]: The Pharmacologic Basis of Therapeutics, 7th ed. New York, McGraw-Hill, p 1556.)

may be due to the inhibition of ATP synthesis and the induction of abnormal carbohydrate metabolism. With thiamine deficiency polyneuropathy, the nerve shows axonal degeneration with secondary demyelination. Because of the frequency of this neuropathy in alcoholics, there is debate as to whether the cause is alcohol toxicity or thiamine deficiency. It has been theorized that the neuropathy of dry beriberi may be related to TPP deficiency-induced impairment of nerve excitability and conduction.^[9]

Epidemiology and Risk Factors. Thiamine is most abundant in yeast, pork, legumes, cereal grains, and rice, and the recommended daily allowance of this vitamin is 0.5 mg/1000 kcal.^[10] The total body store is 30 to 100 mg, and it is present in heart, skeletal muscle, liver, kidneys, and brain. Because there is a limited quantity stored, the supply must be constantly replenished. The half-life of thiamine is approximately 2 weeks, and patients may suffer severe neurological complications and even death after 6 weeks of total thiamine depletion. Patients at high risk for deficiency include adults who derive most of their carbohydrate from milled rice, alcoholics, and infants breast fed by malnourished mothers. Other potentially thiamine-deficient states include prolonged total parenteral nutrition,^[11] hyperemesis gravidarum,^[12] anorexia nervosa, gastric or jejunoileal bypass,^[13] intractable vomiting following gastric stapling for morbid obesity,^[14] and severe malabsorption. Thiamine deficiency is also found in those who are prisoners of war^[12] or those who engage in a hunger strike. Thiamine deficiency has also been reported after longstanding peritoneal and hemodialysis.^{[15], [16]}

Clinical Features and Associated Disorders. WKS and polyneuropathy (dry beriberi) are the two neurological disorders resulting from thiamine deficiency. Wernicke's disease and Korsakoff's psychosis often overlap, with Wernicke's disease having acute features of confusion, ataxia, and oculomotor palsies and nystagmus and Korsakoff's psychosis having delayed and often irreversible anterograde and retrograde memory impairment. Korsakoff's dementia may follow one or more episodes of Wernicke's encephalopathy. Although prospective clinical studies, including those of Victor,^[9] suggest a high incidence of the classic triad in WKS, other autopsy series have found pathological evidence for the disorder in many patients with only one or two symptoms during life.^[2]

The frequency of WKS from autopsy series ranges from 0.8 to 2.8 percent. The disorder is probably underdiagnosed during life. WKS is most common in alcoholics because patients are particularly susceptible to thiamine deficiency due to a combination of poor diet, inadequate intake and impaired absorption of vitamins, and overdependence on alcohol as a source of calories. Certain individuals may also have a genetic predisposition toward the development

Figure 40-2 Wernicke's encephalopathy. Gross appearance characterized by petechial hemorrhages in the typical locati (Reprinted with permission from Okazaki H. Fundamentals of Neuropathology, 2nd ed. New York, Igaku Shoin, 1989, p 192.)

of WKS owing to an abnormality of thiamine-dependent enzymes.^{[17], [18]}

Patients with thiamine deficiency may become acutely symptomatic when challenged with large doses of carbohydrate. An example is the alcoholic patient receiving intravenous glucose who then becomes agitated, confused, and ataxic. Acute attacks may also be produced by excessive vomiting, such as that associated with hyperemesis gravidarum, presumably due to markedly increased metabolic demands in the setting of decreased consumption.^[9]

Mental status changes may include a global confusional state, memory loss, and agitation. Rarely, patients develop stupor and coma. Ocular abnormalities include nystagmus, lateral rectus palsies, conjugate gaze palsy, ptosis, retinal hemorrhages, pupillary abnormalities, and scotomas. Ataxia may be severe, preventing an affected patient from standing without assistance. Finger-to-nose and heel-to-shin tests are often normal when the patient is tested in the bed. Truncal ataxia often becomes obvious only on standing or sitting, reflecting the midline degeneration of the superior division of the vermis.

Polyneuropathy is present in over 80 percent of patients with WKS. It presents with slowly progressive muscular weakness and sensory and reflex loss, accompanied by burning feet and lancinating pains. Calf tenderness is a prominent feature. Bilateral foot drop and even wrist drop may be present (Fig. 40-3 (Figure Not Available)). Patients may also develop an autonomic neuropathy with orthostatic hypotension.

Differential Diagnosis. The presence of mild peripheral edema with a peripheral neuropathy may be a helpful physical sign to suggest thiamine deficiency with co-existing cardiac failure (wet beriberi). Thiamine deficiency should be considered in the differential diagnosis of an axonal polyneuropathy and be distinguished from diabetes, uremia, autoimmune and inflammatory conditions, and hereditary neuropathies. Other considerations in patients presenting with confusion, ataxia, and oculomotor disturbances should include hypoxic-ischemic encephalopathy, Leigh's encephalomyelopathy, adrenoleukodystrophy, metachromatic leukodystrophy, brain stem encephalitis, and certain infectious disorders (syphilis and human immunodeficiency virus). Other nutrients deficient among alcoholics may include folic acid, pyridoxine, and niacin.^[10]

Evaluation. The evaluation of patients with thiamine deficiency begins with a high index of suspicion, and the clinician must recognize that the disorder is not restricted to alcoholics. Several tests, including RBC transketolase activity assay, TPP stimulation of RBC transketolase (the TPP effect), and 24-hour urinary excretion of thiamine are used to assess thiamine status. Serum thiamine levels lack

Figure 40-3 (Figure Not Available) Bilateral wristdrop and footdrop in a 40-year-old woman with Wernicke-Korsakoff syndrome and polyneuropathy (From Victor M, Adams RD, Collins GH: *The Wernicke-Korsakoff Syndrome*. Philadelphia, FA Davis, 1971.)

Figure 40-4 (Figure Not Available) T2-Weighted magnetic resonance imaging of a patient with Wernicke-Korsakoff syndrome, demonstrating symmetrically increased signal intensity in the periaqueductal gray and midline structures (From Yamashita M, Yamamoto T: *Wernicke encephalopathy with symmetric pericentral involvement: MR findings*. *J Comput Assist Tomogr* 1995;19:307.)

sufficient sensitivity and specificity to be used alone. RBC transketolase activity, with or without TPP challenge, is the most accurate assessment tool.^[20] Magnetic resonance imaging (MRI) may show abnormal signal in the midline nuclei corresponding to the pathological lesions described (Fig. 40-4 (Figure Not Available)).^[11],^[21]

Management. Treatment of suspected WKS begins with the immediate administration of at least 100 mg intravenous thiamine, followed by 100 mg IM daily for 3 to 5 days. Patients should then be maintained on 50 mg oral thiamine and daily multivitamins.

Prognosis and Future Perspectives. Whereas early recognition and treatment may reverse all symptoms, in practice, WKS often goes unrecognized until late in the disease, and therapy rarely reverses all of its manifestations. The oculomotor disturbances respond best to treatment and may show improvement within hours. Confusion and ataxia are more resistant. The peripheral neuropathy is often resistant to therapy unless it is treated early. Despite treatment, the mental changes of WKS may progress to permanent and disabling dementia.^[22] Recent work by Gold and colleagues has found abnormalities of thiamine metabolism in patients with Alzheimer's disease.^[23] Molecular genetics may help identify patients and families with a hereditary predisposition toward the development of WKS. Further characterization of the role of thiamine in the sodium-potassium ATPase pump may further our understanding of its role in nerve excitability and conduction, increasing our understanding of the pathogenesis of the neuropathy.^[4] Some countries have experimented with fortification of food substances with thiamine to reduce the incidence of WKS, and fortification of alcoholic beverages has been advocated.

Niacin and Nicotinic Acid

Nicotinic acid deficiency was found to be the causative agent of pellagra in 1937, yet the name was changed to niacin in order to prevent confusion with the tobacco derivative, nicotine. Niacin includes both nicotinic acid and nicotinamide, which form the metabolically active nicotinamide adenine dinucleotide (NAD) and NAD phosphate (NADP), an end product of tryptophan metabolism. More than 200 enzymes are dependent on NAD and NADP to carry out oxidation and reduction reactions, and these enzymes are involved in the synthesis and breakdown of all carbohydrates, lipids, and amino acids. Although niacin is endogenously produced in humans, exogenous intake is required to prevent deficiency. Niacin is found in meats, liver, fish, legumes, peanuts, enriched bread, coffee, and tea.

Pellagra continues to occur in portions of Africa and Asia, especially in populations dependent on corn as the principle source of carbohydrate. When corn is first soaked in lime water, as is done in Mexico when tortillas are prepared, niacin is liberated and deficiency occurs less commonly. In the United States, niacin deficiency is seen in alcoholics and in those taking isoniazid. There is a single case report of a patient developing nicotinic acid deficiency after valproic acid therapy.^[24] Pregnant women are protected from niacin deficiency owing to their enhanced ability to convert tryptophan to niacin endogenously, particularly in the third trimester.

Pellagra, or rough skin, affects the skin, the gastrointestinal system, and the CNS. Hence, the classic triad of the three Ds--dermatitis, diarrhea, and dementia. In industrialized countries, particularly among alcoholics, niacin deficiency may present only with encephalopathy.^[25]^[26]^[27] Patients may have altered sensorium, diffuse rigidity of the limbs, and grasping and sucking reflexes. Dementia and confusion are the most constant findings, followed by diarrhea (50 percent), and dermatitis (30 percent).^[27] Spinal cord and peripheral nerve defects have also been reported, particularly in prisoners of war.^[12] Co-existing deficiencies of thiamine and pyridoxine are common, especially in alcoholics. Hartnup's disease, an autosomal recessive defect in tryptophan absorption by the gut and kidney, can give a clinical

picture identical to pellagra that is responsive to niacin administration. Carcinoid syndrome can also produce niacin deficiency. Because all tryptophan is diverted to the production of serotonin in this disorder, none is available for the production of nicotinic acid, thereby predisposing to deficiency in the absence of supplementation.

Superphysiological doses of niacin (1.5 to 3 g daily) have been used successfully in the treatment of hypercholesterolemia, and this practice diminishes mortality by reducing a coronary artery disease risk factor. Side effects of high-dose niacin include flushing, hyperuricemia, hyperglycemia, and elevations in liver enzymes.

In the evaluation of potential niacin deficiency, nicotinic acid metabolites can be detected in the urine; however, clinical suspicion and ease of treatment make this measurement impractical and unnecessary. The administration of 40 to 250 mg of niacin daily is adequate to reverse most of the signs and symptoms of niacin deficiency. With proper therapy, the prognosis for the resolution of neurological symptoms is good.

Cobalamin (Vitamin B₁₂)

Pathogenesis and Pathophysiology. Vitamin B₁₂ deficiency produces neurological and hematological effects by impairing the function of two enzyme systems (Fig. 40-5 (Figure Not Available)).^[4],^[28] Methylcobalamin is a co-factor of methionine synthase, a cytosolic enzyme that catalyzes the conversion of homocysteine and methyltetrahydrofolate to produce methionine and tetrahydrofolate. Methionine is further metabolized to S-adenosylmethionine, which is necessary for methylation of myelin sheath phospholipids and proteins. Tetrahydrofolate is the required precursor for purine and pyrimidine synthesis. In the mitochondria, adenosylcobalamin catalyzes the conversion of L-methylmalonyl CoA to succinyl CoA.

In deficiency states, serum levels of homocysteine and methylmalonic acid rise. Although the mechanism of megaloblastic changes in both folate and cobalamin deficiency is reasonably well understood, the biochemical basis of the neurological damage that occurs in cobalamin deficiency remains uncertain. Of the two reactions that require cobalamin, the methionine synthase reaction is considered more likely to play a critical role in nervous system function. Rarely, neurological complications have also been reported in folate deficiency, because methionine synthase also requires this co-substrate.^[29] It has been proposed that the accumulation of methylmalonate and propionate provide abnormal substrates for fatty acid synthesis, resulting in abnormal odd-carbon and branched-chain fatty

acids, which may be incorporated into the myelin sheath and interfere with impulse conduction.

Vitamin B₁₂ deficiency results in demyelination of the posterior columns, corticospinal tracts, and white matter of the cerebral hemispheres (Fig. 40-6).^[30] Less commonly, a sensorimotor and autonomic neuropathy that is axonal and demyelinating in nature may also be present.^[31] These lesions lead to a constellation of symptoms, including cognitive and affective disorders, ataxia, spasticity, and paresthesias.

Epidemiology and Risk Factors. The total body store of cobalamin is 2000 to 5000 µg, half of which is stored in the liver. The recommended daily allowance is 6 µg/day, and the average diet provides 20 µg/day. Because the vitamin is tightly conserved through enterohepatic circulation, 2 to 5 years elapse before a subject develops cobalamin deficiency from malabsorption, and as long as 10 to 20 years are needed to induce a dietary deficiency from a strict vegetarian diet.

The most common cause of vitamin B₁₂ deficiency is pernicious anemia or autoimmune parietal cell dysfunction (Table 40-3).^[32] The mean age of diagnosis is 60 years, and the female-to-male ratio is approximately 1.5:1. In white populations, the incidence of the disease increases with increasing age, peaking after age 65. In Hispanic and African populations, there is an overall younger age distribution, especially among women. When using radioassay-derived serum cobalamin levels below 200 pg/ml or elevated levels of homocysteine and methylmalonic acid as diagnostic criteria, the prevalence of B₁₂ deficiency from all causes ranges from 7 to 16 percent.^[3]

See the text for description. ¹² indicates vitamin B₁₂ (cyanocobalamin); MF₁₂, methylcobalamin; DF₁₂, deoxyadenosylcobalamin; TcII, transcobalamin II; ¹²TcII, transcobalamin II-bound cobalamin; MTHF, methyltetrahydrofolate; THF, tetrahydrofolate; and CoA, coenzyme (From Flippo TS, Holder WD Jr: Neurologic degeneration associated with nitrous oxide anesthesia in patients with vitamin B₁₂ deficiency. Arch Surg 1993;128:1391-1395.)

Figure 40-6 Subacute combined degeneration of the spinal cord. A thoracic cord segment showing spongy degeneration of the white matter in a typical distribution (Weill's (From Okazaki H: Fundamentals of Neuropathology, 2nd ed. New York, Igaku Shoin, 1989, p 195.)

Other causes of B₁₂ deficiency include ileal resection, parasitic infestations from *Diphyllobothrium latum*, Crohn's disease and other malabsorption states, short gut syndrome, veganism, chronic alcoholism with poor diet, and rare congenital enzyme deficiencies.

Clinical Features and Associated Disorders. Subacute combined degeneration of the spinal cord, peripheral nerve dysfunction, and cerebral dysfunction are classic features of the disorder. Many patients present without accompanying anemia or macrocytosis. Heaton and associates reviewed 143 patients who had 153 episodes of cobalamin deficiency.^[33] Seventy-four percent of the episodes presented with neurological symptoms, including paresthesias, numbness, gait ataxia, fecal incontinence, leg weakness, impaired manual dexterity, impaired memory, and impotence. Rarely, patients had orthostatic lightheadedness, anosmia, diminished taste, paranoid psychosis, and diminished visual acuity. The remaining 26 percent presented

with non-neurological symptoms classically associated with pernicious anemia, including tiredness, syncope, palpitations, sore tongue, diarrhea, and other bowel disturbances. On examination, patients demonstrated a neuropathy alone (25 percent), isolated myelopathy (12 percent), and a combined neuropathy and myelopathy in 41 percent. Memory dysfunction and affective and behavioral changes were seen in 8 percent, whereas 14 percent had a normal examination.

There have been several reports of patients developing a myeloneuropathy after exposure to nitrous oxide.^[28],^[34],^[35] This occurs in two populations: Those with normal cobalamin levels, but who chronically abuse the anesthetic gas for recreational purposes, and those with a subclinical B₁₂ deficiency who, after a short exposure to nitrous oxide for a dental or surgical procedure, develop paresthesias, burning feet, and ataxia. Nitrous oxide is a potent oxidizing agent, which irreversibly oxidizes the cobalt core of cobalamin from a 1+ valence state to 3+ valence state, rendering methylcobalamin inactive. This effectively inhibits the conversion of homocysteine to methionine, thus interdicting the supply of S-adenosylmethionine.

Low cobalamin levels have also been found in occasional patients with multiple sclerosis^[36] and HIV infection^[37]; however, no pathogenic relationship or treatment response has been established in either disorder.

Differential Diagnosis. Vitamin B₁₂ deficiency must be differentiated from other causes of myelopathy and neuropathy. Myelopathy and mental decline may also be seen in multiple sclerosis, but the other neuropathic signs of vitamin B₁₂ deficiency should clarify the likely diagnosis. Other disorders that may have both central and peripheral manifestations include syphilis, amyotrophic lateral sclerosis, Friedreich's ataxia, vitamin E deficiency, metachromatic leukodystrophy, adrenomyeloneuropathy, mitochondrial cytopathy, and ceroid lipofuscinosis. These diagnoses should be considered in patients with the paradoxical findings of absent ankle reflexes and extensor plantar responses.

Evaluation. An algorithm for the diagnosis and treatment of cobalamin deficiency has been established (Fig. 40-7 (Figure Not Available)).

Figure 40-7 (Figure Not Available) Algorithm for cobalamin deficiency diagnosis and treatment. A higher normal reference range should be applied if chemiluminescence or other nonradioisotopic ligand-binding assays are used. If the clinical picture is suggestive of possible cobalamin deficiency, patients with serum¹² greater than 300 pg/ml should be investigated similarly. IM, intramuscular (From Green R, Kinsella LJ: Current concepts in the diagnosis of cobalamin deficiency. Neurology 1995; 45:1435-1440.)

It is based on two assumptions: (1) a normal cobalamin assay does not fully exclude cobalamin deficiency; and (2) the normal range may vary depending on the assay type. Many laboratories are switching from radioassay to chemiluminescence assay, which may have a higher normal reference range (250 to 1100 pg/ml).

In a patient with signs and symptoms of cobalamin deficiency, a cobalamin assay should be ordered initially. If the assay result is less than the lower limit of normal, intrinsic factor antibodies should be measured. In pernicious anemia, additional laboratory evidence of an autoimmune process is often found. Serum antibodies are present against parietal cells in 90 percent and against intrinsic factor in 60 percent of patients with pernicious anemia. Unfortunately, false-positive results for the gastric parietal cell test are common (found in 10 percent of people older

than 70 years of age), and although the test for intrinsic factor antibodies lacks sensitivity, it is much more specific. If this test is positive, confirmation of the diagnosis of pernicious anemia with a Schilling test (see later) is not necessary.

In patients with serum cobalamin levels in the lower normal range, but in whom one still suspects cobalamin deficiency, the measurement of metabolite levels is appropriate. If either is elevated, then serum intrinsic factor antibodies should be measured. If the test for intrinsic factor antibodies is negative, then measurement of the serum gastrin level may be useful for establishing the presence of achlorhydria, which is almost invariably associated with pernicious anemia. The presence of hypersegmentation may be a sensitive marker for cobalamin deficiency, even in the absence of anemia or macrocytosis.

If metabolites or the serum gastrin levels are elevated, a Schilling test should be performed to evaluate for the presence of cobalamin malabsorption. Technically, patients with classic pernicious anemia have an abnormal test result when radioactive cobalamin alone is given by mouth (Part I of the Schilling test). This abnormality is corrected when the test is repeated with intrinsic factor (Part II of the Schilling test). Abnormally low secretion of cobalamin in Part II of the Schilling test indicates an intestinal cause for the cobalamin malabsorption, such as inflammatory bowel disease. Part II of the Schilling test may be repeated, after giving antibiotics or vermicides to exclude bacterial overgrowth (so-called blind loop syndrome) or fish tapeworm infestation due to *Diphyllobothrium latum*. Normal results on Part I of the test in a patient with cobalamin deficiency may be observed in total vegetarians. It may also occur in patients with food-cobalamin malabsorption who show normal absorption of crystalline cobalamin but are unable to digest and absorb cobalamin present in food due to achlorhydria. This defect can be identified using a modified Schilling test in which radioactive cobalamin is administered with food.

Management. Treatment may begin with intramuscular (IM) injections of 1000 µg of cobalamin per day for 5 days, then 500 to 1000 µg IM every month. Oral replacement is an alternative for patients who cannot tolerate intramuscular injections or for whom they are impractical. Because 1 percent of all ingested cobalamin may be absorbed by passive diffusion, cobalamin requirements can be satisfied with oral therapy, even in patients with pernicious anemia, as long as the dose is sufficient. A daily dose of 1000 µg/day will yield 10 µg of absorbed cobalamin, which exceeds the recommended daily allowance. It may be practical to replenish cobalamin stores first using injections of cyanocobalamin for 1 week and then to maintain patients using a 1000 µg daily oral supplement.

Prognosis and Future Perspectives. The earlier intervention begins, the more likely the patient is to have a complete recovery.^{[33], [37A]} Paresthesias often improve within several weeks, whereas spinal cord dysfunction may require several months. About 2 percent of patients experience an acute worsening of paresthesias immediately following vitamin B₁₂ supplementation, but this addition does not impair the long-term response to therapy. Folate supplementation may reverse the hematological abnormalities but will not prevent neurological deterioration. With early recognition, patients may resume a normal lifestyle with limited impairment of gait or cognition. Spasticity due to spinal cord dysfunction, when it is established, is often difficult to reverse but may continue to improve over many months to years. Ten to twenty percent of patients may relapse owing to noncompliance with long-term supplementation. These patients often develop identical symptoms that respond equally well to repeat treatment.^[37A]

Hyperhomocysteinemia has been directly linked to an increasing incidence of coronary and cerebrovascular disease. It is present in cobalamin, pyridoxine, and folate deficiencies; renal failure; and heterozygous homocysteinemia. Therefore, vitamin B₁₂ deficiency, as well as folate and pyridoxine deficiencies, may be independent risk factors for the development of carotid and coronary disease. This association awaits further study. Approximately 40 percent of patients with biochemical cobalamin deficiency may be asymptomatic. A high index of suspicion for B₁₂ deficiency is warranted in view of its high prevalence in the elderly.

Pyridoxine (Vitamin B₆)

Pyridoxal phosphate is the active biochemical form of pyridoxine. It is a coenzyme of amino acid metabolism, particularly tryptophan and methionine. By inhibiting methionine metabolism, excessive S-adenosylmethionine accumulates, which inhibits nerve lipid and myelin synthesis.^[10] Because tryptophan is required in the production of niacin, pyridoxine deficiency can produce a secondary niacin deficiency indistinguishable from primary pellagra. Pyridoxine is also involved in lipid and neurotransmitter synthesis. Dopamine, serotonin, epinephrine, norepinephrine, and gamma aminobutyric acid (GABA) all require pyridoxine for their production. Lott and associates have documented reduced pyridoxal phosphate and GABA concentrations in the brain of a child dying with pyridoxine-responsive seizures.^[38]

The recommended daily allowance of pyridoxine is 2 mg. It is found most abundantly in enriched breads, cereals and grains, chicken, orange and tomato juice, bananas, and avocados. Patients at risk for pyridoxine deficiency include those with general malnutrition, prisoners of war, refugees, alcoholics, infants of vitamin B₆-deficient mothers, and patients using isoniazid and hydralazine. Surveys of hospitalized elderly patients have shown up to 5 percent may have a vitamin B₆ deficiency.^[4] A rare autosomal recessive disorder of pyridoxine-responsive or pyridoxine-dependent neonatal seizures also exists.

Pyridoxine is unique in that both the deficiency and toxic states result in a peripheral neuropathy. Deficiency affects the blood, skin, and nervous system. The skin changes are indistinguishable from pellagra, probably due to the close interaction of niacin and pyridoxine. Pyridoxine improves the microcytic anemia of alcoholics as well as the anemia associated with pyridoxine-responsive seizures in infants. Pyridoxine-deficient peripheral neuropathy is seen primarily in patients on isoniazid or hydralazine, and it is characterized by sensory loss in distal limbs, weakness, and reflex changes. Patients describe burning feet and painful paresthesias.

Figure 40-8 (Figure Not Available) Vitamin E deficiency myelopathy. Cross section of cervical spinal cord. The triple arrowheads denote light-staining symmetrical areas of degeneration involving the posterior columns. The two single arrowheads indicate involvement of the dorsal and ventral spinocerebellar tracts. In the posterior columns, the fasciculus cuneatus is affected to a greater extent than the gracilis. Microscopically, numerous swollen and dystrophic axons (spheroids) and astrocytosis are present in the posterior columns, and nerve cell loss is seen in the dorsal root ganglia (luxol-fast blue-periodic acid-Schiff) (From Rosenblum JL, Keating JP, Premsky AL, Nelson JS: A progressive neurologic syndrome in children with chronic liver disease. *N Engl J Med* 1981;304:506.)

CNS manifestations include depression, irritability, and confusion.^[39] Infants born to pyridoxine-deficient mothers may develop neonatal seizures^[40] as part of their vitamin deficiency state, a condition distinct from hereditary pyridoxine-responsive seizures. Up to 10 percent of patients who are on isoniazid and have tuberculosis may develop a peripheral sensory neuropathy. Isoniazid promotes increased pyridoxine excretion in the urine, resulting in a deficiency state. Similar changes are seen in patients on hydralazine.

Excess pyridoxine also results in a peripheral neuropathy. Megadoses of pyridoxine produce a sensory neuropathy, generally in excess of 2 g/day but has been reported with longstanding use of as little as 200 mg/day.^{[41], [42]} Symptoms of paresthesias, ataxia, and burning feet occur 1 month to 3 years after starting pyridoxine. Sural nerve biopsies show reduced myelin fiber density and myelin debris, suggesting axonal degeneration. After stopping pyridoxine, all patients improve, but the condition resolves entirely in only a few. Contrary to claims in the lay press, such cases demonstrate that not all B vitamins, even though they are water soluble and are excreted in the urine, are benign when taken in megadoses.

Urinary assays for xanthurenic acid and other pyridoxine metabolites may be performed following tryptophan loading in patients suspected of having pyridoxine deficiency. In the serum, cystathionine levels may also be elevated in this condition.

Daily intake of vitamin B₆ (150 to 450 mg) prevents the neuropathy of isoniazid and should be used by patients on this drug. Once it is established, the neuropathy does not entirely resolve but may improve with replacement vitamin B₆.

Vitamin E

Alpha-tocopherol is the most active form of vitamin E present in humans. Tocopherol is absorbed and incorporated into chylomicrons in the small intestine. It is carried in portal blood to the liver and alpha-tocopherol transfer protein (alpha-TTP) binds and recycles vitamin E in the liver for incorporation into low-density lipoproteins and very low density lipoproteins.^[43] Once it is delivered to the cells, alpha-tocopherol serves as an antioxidant, preventing free radical peroxidation and injury to cell

membranes. It is stored in adipose tissue, liver, and muscle. Deficiency can occur at any stage of tocopherol metabolism: reduced intake, fat malabsorption, inhibition of enterohepatic circulation, mutation of alpha-TTP, and abetalipoproteinemia. Vitamin E deficiency leads to axonal membrane injury, with resultant axonal degeneration of peripheral nerve, dorsal root ganglia, and posterior columns (Figs. 40-8 (Figure Not Available) and 40-9 (Figure Not Available)). ^[44] Superficially, the spinal cord abnormalities bear a striking resemblance to those found with subacute combined degeneration

Figure 40-9 (Figure Not Available) Teased nerve preparation in a patient with vitamin E deficiency, demonstrating axonal degeneration (sural nerve, osmium impregnation) (From Rosenblum JL, Keating JP, Prensley AL, Nelson JS: A progressive neurologic syndrome in children with chronic liver disease. *N Engl J Med* 1981;304:507.)

of vitamin B₁₂ deficiency. However, the lesions of vitamin B₁₂ deficiency are due to spongy demyelination of the posterior columns and lateral tracts, whereas those of Vitamin E deficiency are the result of swollen and dystrophic axons, or spheroids, and astrocytosis in the posterior columns, dorsal root ganglia, and Clarke's column.

Vitamin E is fat soluble and found in abundance in vegetable oils and wheat germ. The recommended daily allowance is 10 mg (10 IU) for men, and 8 mg (10 IU) for women. Patients at risk for the development of vitamin E deficiency include those who have the following clinical conditions: hypobetalipoproteinemia or abetalipoproteinemia (Bassen-Kornzweig syndrome); other disorders of the pancreas and liver, such as cystic fibrosis and primary biliary atresia; PEM; familial vitamin E deficiency due to a defect in alpha-TTP; and other malabsorptive states that result in cholestasis (Crohn's disease, ulcerative colitis, and celiac disease) ([Table 40-4](#)). Pregnancy increases vitamin E serum concentrations, but premature infants often have low levels of vitamin E due to a lack of adipose tissue as well as difficulty in transplacental migration of the vitamin. The majority of patients who have vitamin E deficiency are those with severe malabsorptive states present since birth, or rare familial vitamin E deficiency due to transfer protein abnormalities.

Patients develop areflexia, cerebellar ataxia, cutaneous sensory impairment, position and vibratory sense abnormalities, and less commonly, ophthalmoplegia, muscle weakness, nystagmus, extensor plantar responses, ptosis, and dysarthria ([Table 40-5](#)). ^[45] Acanthocytosis and pigmentary retinopathy is seen primarily in patients with abetalipoproteinemia. Patients with abetalipoproteinemia and congenital malabsorption develop symptoms in childhood and adolescence. Occasionally, adults with acquired malabsorption present with progressive ataxia. The familial vitamin E deficiency phenotype is indistinguishable from Friedreich's ataxia (Fig. 40-10 (Figure Not Available)). Autosomal recessive familial vitamin E deficiency has been studied extensively and found to be due to a frame shift mutation within the alpha-TTP gene on chromosome 8. Defective alpha-TTP prevents incorporation of vitamin E into very low density lipoproteins. ^[46], ^[47]

TABLE 40-4 -- VITAMIN E DEFICIENCY-ASSOCIATED DISORDERS

Abetalipoproteinemia (Bassen-Kornzweig disease)
Celiac disease
Chronic pancreatitis
Chronic cholestatic liver disease
Cystic fibrosis
Familial vitamin E deficiency (alpha-tocopherol transfer protein mutation)
Homozygous hypobetalipoproteinemia
Inflammatory bowel disease
Intestinal lymphangiectasia
Malnutrition
Postgastrectomy
Short bowel syndromes
Total parenteral nutrition
Tropical sprue
Whipple's disease

TABLE 40-5 -- NEUROLOGICAL FINDINGS IN VITAMIN E DEFICIENCY

Truncal and appendicular ataxia
Areflexia
Abnormal vibration sense and proprioception
Ophthalmoplegia
Retinitis pigmentosa and acanthocytosis (in patients with abetalipoproteinemia)
Dysarthria
Generalized weakness
Extensor plantar responses

Friedreich's ataxia, Machado-Joseph disease, and other familial spinocerebellar ataxias ^[48] should be considered in the differential diagnosis of patients presenting with this constellation of signs and symptoms.

Serum alpha-tocopherol is a reliable indicator of body vitamin E content. Tocopherol isomers can also be assessed using thin layer chromatography. Approximately 90 percent or more of vitamin E is alpha-tocopherol, which can be directly measured in the serum. Occasional patients with hyperlipidemia may have a falsely low alpha-tocopherol level. Vitamin E deficiency may result in electrophysiological abnormalities, including low amplitude sensory nerve action potentials, slowed conduction, and abnormal somatosensory evoked potentials. ^[49]

Administration of alpha-tocopherol (400 mg bid) may reverse or prevent the progression of the effects of a deficiency state. Doses of up to 100 mg/kg/day may be

Figure 40-10 (Figure Not Available) Patient with isolated vitamin E deficiency demonstrating gait characterized by pseudodystonic extension of the knees, as well as prominent lordosis, and genu recurvatum (From Jackson CE, Amatao AA, Barohn RJ: Isolated vitamin E deficiency. *Muscle Nerve* 1996;19:1163. Reprinted by John Wiley & Sons, Inc.)

required in those with abetalipoproteinemia and the familial vitamin E deficiency syndrome. Whereas oral doses of alpha-tocopherol correlate well with plasma levels, comparable increases in the ventricular cerebrospinal fluid do not occur, suggesting that CNS penetration may be exceedingly low. ^[50] An injectable vitamin E preparation is available for those who cannot absorb oral medication. The prognosis for recovery depends on the duration of symptoms before the initiation of treatment.

Pantothenic Acid, Vitamin A, and Vitamin D

Pantothenic acid is part of coenzyme A, an essential element of carbohydrate and fatty acid synthesis and degradation. Because of its ubiquity, no single neurological syndrome is known to be caused by pantothenate deficiency, with the exception of generalized malaise. ^[51]

Vitamin A, derived from beta-carotene, is necessary for normal vision and reproduction. Deficiency leads to night blindness and corneal ulceration. ^[52] Hypervitaminosis of 25,000 IU daily for 1 to 2 years may cause symptoms of pseudotumor cerebri, including raised intracranial pressure and visual disturbances. ^[53] , ^[54] Hypervitaminosis in pregnant mothers may lead to birth defects and learning disabilities.

Vitamin D is necessary for calcium absorption in the gut. Deficiency leads to osteomalacia, hypocalcemia, and hypophosphatemia. ^[55] The reason why muscle weakness occurs in such patients is unclear, and the phenomenon is explained only in part by low serum calcium. ^[56] , ^[57]

[Previous](#)[Next](#)

PROTEIN-ENERGY MALNUTRITION

In acute starvation, the nervous system sustains itself first on glucose derived from alanine, then on ketone bodies from the breakdown of fats. This process continues until fat is depleted, and then catabolism returns to visceral proteins. Death results from cardiac muscle resorption and eventual cardiac failure. In chronic PEM, the nervous system adapts poorly, and a retarded rate of brain growth, hypomyelination, and slowed conduction velocities of peripheral nerves results.

Chronic PEM has traditionally been a disease of the Third World, particularly Africa and Asia. In industrialized countries, it is seen in young children in poverty, the elderly, alcoholics, or in children born to malnourished mothers. PEM also occurs in hospitalized elderly, particularly those suffering from sepsis, burns, or other serious illnesses that preclude a normal diet. Up to 27 percent of hospitalized elderly develop PEM during their hospital stay, with an associated increased risk of mental status changes, depression, and prolonged length of stay.^[1] In patients with third-degree burns, up to 500 g of muscle may be lost in a day, and death from malnutrition may occur in 2 to 3 weeks.

Traditionally, PEM has been viewed as either a primary protein deficiency (kwashiorkor), or an energy deficiency (marasmus). Kwashiorkor occurs in children older than 18 months and is often associated with diarrheal illnesses or other infectious diseases. Owing to the severe protein deficiency, circulating serum proteins are inadequate to maintain normal oncotic pressure, leading to marked peripheral edema. Marasmus occurs in children younger than 1 year of age and is not accompanied by edema. PEM may cause mental changes, including apathy and irritability, muscle wasting, generalized weakness, hypotonia, hyporeflexia, and gait impairment. Following a return to a normal diet, an acute encephalopathy has been described in some patients with PEM marked by rigidity, tremors, asterixis, and mental confusion.^[58], ^[59] Infectious diseases may precipitate kwashiorkor in a patient with borderline malnutrition. PEM needs to be distinguished from other wasting conditions and edematous states such as thiamine deficiency, HIV infection, and the cachexia of malignancy.

The patient's nutritional status should be assessed by a careful dietary history. Energy malnutrition is defined as a 10 percent loss of ideal body weight.^[1] Protein malnutrition requires assessment of serum proteins, including albumin, prealbumin, and total lymphocyte count. Because asterixis may be seen in some patients recovering from kwashiorkor and mistaken for hepatic encephalopathy, measurement of serum ammonia is often helpful to exclude this diagnosis.

Nutritious food and vitamin supplements generally lead to a complete recovery. Whether PEM results in long-term growth retardation and delayed intellectual development is controversial.^[60] This condition is best prevented by education of affected family members on proper nutrition. In the United States, hospitalized elderly are perhaps at the greatest risk for PEM, and nutritional assessments of all patients at risk should be undertaken at admission to prevent serious malnutrition and to reduce the incidence of morbidity and mortality.

OTHER NUTRITIONAL DEFICIENCIES

Strachan's Syndrome

In 1888, Henry Strachan, a British medical officer stationed in Jamaica, described a syndrome of painful peripheral neuropathy, ataxia, optic neuropathy, and stomatitis among sugar cane workers.^[61] Denny-Brown and others found similar ailments among allied troops liberated from prisoner-of-war camps after World War II.^[12] In these patients, other symptoms included sensorineural deafness, dizziness, confusion, spastic leg weakness, foot drop, Wernicke's encephalopathy, and rare cases of neck extensor weakness and myasthenic bulbar weakness. Poor nutrition, hard physical labor, and concurrent infection were thought to be exacerbating factors. In Fisher's autopsy series of Canadian prisoners of war, the most prominent pathological finding was demyelination of the posterior columns of the thoracic and cervical spinal cord.^[62] This demyelination accounted for the loss of vibratory and position sense and sensory ataxia. Pathologically, the optic and auditory nerves showed moderate to severe demyelination.

More recently, an outbreak of optic and peripheral neuropathy closely resembling Strachan's syndrome occurred in Cuba in 1992 to 1993, following the loss of food and fuel exports.^[63] Fifty thousand people developed isolated or combinations of optic neuropathy, painful sensory neuropathy,

dorsolateral myelopathy, sensorineural deafness, spastic paraparesis, dysphonia, and dysautonomia. Almost half (45 percent) developed centrocecal scotoma and optic neuropathy only, often following a period of weight loss. Optic neuropathy and myeloneuropathy were seen in 24 percent, optic neuropathy and sensorineural hearing loss in 14 percent, and peripheral and optic neuropathies with hearing loss in 7 percent.^[63] Proposed mechanisms included vitamin B complex and thiamine deficiency, cyanide intoxication, viral infection, and mitochondrial deletion. Infections appeared to precipitate or exacerbate symptoms. Almost all patients responded to early supplementation with B complex vitamins. Evidence for peripheral nerve involvement has been mixed. Clinical evidence of neuropathy is often lacking despite severe symptoms. Fisher examined the peripheral nerves in 2 of 11 patients at postmortem and found no abnormalities; however, nerve teasing and modern histopathological techniques were not used. Osuntokun documented peroneal nerve conduction slowing and normal conduction of the median and ulnar nerves,^[64] whereas Borraero found abnormal sural nerve action potentials only in the most severely affected individuals.^[65] Sural nerve biopsies showed axonal degeneration of large myelinated fibers.

Extensive study of the epidemiology of the Cuban outbreak revealed smoking, weight loss, sugar consumption, and excessive alcohol intake as risk factors. Urban men 25 to 64 years of age were most affected. Pregnant women, children, and the elderly were minimally affected; however, these groups were targeted for supplementation before the outbreak. Women were more likely to develop paresthesias in the feet, whereas men were more likely to develop optic neuropathy.^[66] In Africa, pregnant women are most vulnerable,^[64] and smoking and weight loss were the strongest risk factors for the optic neuropathy variant.

This clinical syndrome should be distinguished from beriberi, vitamin B₁₂ deficiency, pellagra, tropical spastic paraparesis (human T-cell lymphotropic virus-1 [HTLV-1]), tropical ataxic neuropathy of Africa, subacute myelo-optic neuropathy, clioquinol ingestion in Japan, Leber's optic neuropathy, and nutritional amblyopia. In order to do so, dietary and family histories; vitamin B₁₂, folate, and transketolase levels; medication history; and an HTLV-I assay should be obtained.

Treatment consists of re-establishing a balanced diet with B complex vitamin and vitamin A supplementation. In the Cuban experience, long-term sequelae were rare, because most had early treatment with nutritional supplements, including B complex and vitamin A. In prisoners of war with longstanding symptoms, persistent ataxia, burning feet, and visual defects often persisted despite adequate supplementation.

Postgastroplasty Polyneuropathy

Some patients undergoing bariatric, or weight reduction, surgery develop a syndrome of acute or subacute sensory loss, weakness, and areflexia in the limbs, usually following a period of dramatic weight loss and repeated bouts of protracted vomiting.^[67] A few patients have also developed a type of encephalopathy that is clinically and pathologically identical to WKS, with or without an associated polyneuropathy.^[14] Indeed, Wernicke and Korsakoff each described young women with intractable vomiting in their original reports: One woman had attempted suicide by drinking sulfuric acid, whereas the other had hyperemesis gravidarum.^[8]

Of 37 cases of postgastroplasty polyneuropathy reviewed, 26 developed neuropathy alone, 2 had encephalopathy, and 9 had features of both.^{[13], [14], [67], [68], [69], [70], [71]} One patient developed blindness and optic neuropathy. Intractable vomiting is a constant feature. The syndrome may present suddenly several months after surgical procedures that include gastrojejunostomy, gastric stapling, vertical banding gastroplasty, and gastrectomy with Roux-en-Y anastomosis.^[13] Following a period of recurrent vomiting and precipitous weight loss, patients develop numbness and tingling in the soles of the feet, calves, and thighs. Distal or proximal weakness may develop, and the patient may have difficulty arising from a chair or climbing stairs. Pain is not a dominant feature, unlike nutritional neuropathy, in which the calves are often exquisitely tender. Examination shows symmetrical sensory loss in the legs more than the arms, muscle weakness, and areflexia. Patients may develop quadriparesis and prolonged or permanent disability. When the condition is accompanied by encephalopathy, patients may demonstrate confusion, memory loss, and affective disturbances. Many patients have been mistakenly diagnosed early in their course as having a conversion disorder.

In this setting, Guillain-Barre syndrome, cobalamin myeloneuropathy, critical illness polyneuropathy, compressive radiculopathy, WKS, beriberi, Strachan's syndrome, hypocalcemia, and hypomagnesemia should be considered in the differential diagnosis.

Nerve conduction studies show severe reduction of sensory and motor action potentials, variable slowing, and absent or prolonged late responses in this disorder. Needle examination shows diffuse denervation with fibrillations, consistent with an axonal and demyelinating sensorimotor polyneuropathy. The polyneuropathy is axonal and demyelinating in type, acute in onset, and slow to resolve. Pathological studies have shown lipid-laden neurons and Schwann cells surrounding demyelinating and degenerating axons.^[67]

Although thiamine deficiency has been suggested as the cause, reports documenting low thiamine activity are lacking. Furthermore, the pathology of the peripheral nerve is unlike any known nutritional neuropathy, and some patients have developed the neuropathy despite adequate nutritional supplementation.^[72] The pathophysiology of this disorder is unknown, but may be related to the rapid mobilization of lipid in the surgically starved. Controversy exists whether vitamin and nutritional supplementation alone or reversal of the surgical procedure is most helpful in resolving the neuropathy. All patients following bariatric surgery should adhere to a strict dietary regimen with additional vitamins. If vomiting develops, patients should receive parenteral nutrition, vitamins, and thiamine. Most patients recover fully, but some have residual weakness and sensory loss. The degree of disability appears to depend on the duration and severity of symptoms before diagnosis and treatment.

ALCOHOL AND THE NERVOUS SYSTEM

Overview and Pharmacology

Alcohol is one of the most widely used psychoactive drugs, and alcoholism is characterized by the chronic, repetitive, excessive use of alcohol such that it interferes with the health, personal relationships, and livelihood of the drinker. In pharmacological terms, alcoholism is the addiction to alcohol. Although the cause of alcoholism is unknown, there clearly are genetic, environmental, and cultural factors involved. In the United States, the incidence of alcoholism cannot be determined specifically, but it is estimated that 10 percent of adult Americans are affected by alcohol abuse and dependence.

The active ingredient in most common alcoholic beverages is ethanol or ethyl alcohol, yet other impurities, including enanthic ethers, amyl alcohol, and acetaldehyde, may be contained in some liquors. Alcohol is absorbed from the stomach as well as the duodenum and jejunum, and can be detected in the blood within 5 minutes of ingestion. Absorption rates are faster in patients with gastrectomies and in those individuals who are habituated to alcohol. Once it is in the bloodstream, alcohol enters other organs and can be detected in the cerebrospinal fluid, urine, and alveolar air. Alcohol is metabolized mainly in the liver, where it is oxidized to acetaldehyde via multiple enzymes but most importantly through the actions of alcohol dehydrogenase. Oxidation may also occur through peroxisomal and mitochondrial catalases, as well as by the microsomal ethanol-oxidizing system. Acetaldehyde itself may have effects independent from those of alcohol in the development of intoxication and addiction, although this remains speculative. As an end product, acetaldehyde is probably converted to acetate through the action of aldehyde dehydrogenase, but the exact degradation product of acetaldehyde is unknown. Once alcohol absorption ceases and equilibration within tissue has occurred, alcohol is metabolized at a constant rate without correlation to its blood concentration. This contrasts with acetaldehyde metabolism, which does depend on the tissue concentration of this metabolite. The rate of metabolism of alcohol can be enhanced by the administration of insulin, amino acids, and fructose, whereas starvation has the opposite effect.

The mechanism of action of alcohol on the nervous system has been debated for decades, and since the turn of the century, some investigators have speculated that alcohol acts as a nonspecific drug, producing its actions via perturbation of neuronal membrane lipids. More recently, it has been suggested that ethanol acts at the interface between membrane lipids and integral membrane proteins.^[72] Neurotransmitter-gated ion channels have also been the focus of attention regarding the potential sites of alcohol action, including nicotinic acetylcholine, GABA_A, and *N*-methyl-D-aspartate (NMDA) receptor-ion channels. Alcohol affects the function of these receptor-ion channels mostly via direct interactions, yet the molecular structure of the alcohol-binding site has yet to be determined.

Tolerance to alcohol is defined as an acquired resistance to the effects of the drug, which can be related to pharmacokinetic, pharmacodynamic, environmental, and behavioral factors. It has been hypothesized that tolerance represents an adaptive change in the CNS with mechanistic similarities to learning or memory function. Recently, Szabo and Hoffman demonstrated that daily intracerebral injections of human recombinant brain-derived neurotrophic factor, neurotrophin-3, and neurotrophin-4/5, following ethanol withdrawal, maintained ethanol tolerance as compared with controls.^[73] The authors suggest that some neurotrophins may modulate neuroadaptation to ethanol through their actions as either growth factors or the modulation of the function of post-mitotic neurons. These actions could ultimately result in alterations in gene expression, producing the observed behavioral consequences. Tolerance to alcohol may also involve adaptive changes in neuronal membrane lipids, neurotransmitter receptors, ion channels, or intracellular secondary messengers that serve to counteract the short-term effects of alcohol.

Acute Intoxication

In the nervous system, alcohol acts as a depressant, and small doses may lead to disinhibition or a slight euphoria. The toxic effects of alcohol become more prominent with rising blood levels, yet through repeated consumption, humans can become habituated rapidly. Although blood levels of 100 mg/dl typically cause drunkenness in occasional imbibers, chronic alcohol abusers can tolerate levels up to 500 mg/dl without any apparent effects. The toxic effects of alcohol can be produced in any individual who ingests sufficient quantities of the substance. The state of drunkenness or acute intoxication is recognized by slurred speech, an erratic gait, and disinhibited verbosity and behavior. The phenomenon of acute intoxication depends on the blood alcohol concentration, the rate at which it has been attained, and the time during which it has been maintained.^[74] Pathological intoxication refers to an episode of uncharacteristic behavior during a drinking bout. This behavior may include violence and is mainly attributable to the disinhibiting effect of a heavy consumption of alcohol. This behavior typically abates as the blood alcohol level falls, but at times, the use of restraints and sedation may be necessary. Parenteral sedatives, including phenobarbital and benzodiazepines, may be used.

An alcoholic blackout refers to a period of time during acute alcoholic intoxication that a person subsequently does not recall. It is a blank space in the continuum of a person's memory and objectivity, and there are no outward signs other than those of typical drunkenness. The blackouts may be complete for the period or fragmentary, and memory may be restored during a later drinking bout. These blackout periods correlate poorly with withdrawal symptoms and are not associated with chronic memory disturbances, or the alcoholic dementia seen in some individuals. Blackout periods are associated with a high blood alcohol level and may occur in both the social and dependent drinker. Management includes supportive therapy and education.

The syndrome of drunkenness is so well recognized, even among lay people, that the main challenge for physicians is not to overlook concomitant intoxication with other drugs or other causes for ataxic gait, stupor, and coma. A blood alcohol level is the most important laboratory test to

support a diagnosis of alcohol intoxication. However, because habituated alcoholics can tolerate several times the levels of nonhabituated individuals, the test result must be interpreted in light of the person's status in this regard.

The most important therapeutic problem in the setting of acute intoxication is respiratory depression. With higher blood alcohol levels, stupor and coma can occur, yet there are no distinctive clinical characteristics of alcoholic coma. The diagnosis should be suggested by the clinical setting. Respiratory depression is an early feature, so the diagnosis must be made promptly and should be treated in an intensive care unit. Mechanical ventilatory support should be instituted when necessary, and hypovolemia, acid-base balance, electrolyte, and temperature abnormalities must be corrected. Glucose (50 ml of 5 percent solution) with 100 mg intravenous and 100 mg intramuscular should be given if hypoglycemia is suspected. Because alcohol is absorbed rapidly, gastric lavage with activated charcoal is not likely to be of value in preventing a deeper intoxication. Death has occurred with blood alcohol levels of 4000 mg/L, and a level of 5000 mg/L is lethal in 50 percent of patients.^[75] Recovery from alcohol-induced coma with high blood alcohol levels can be hastened with hemodialysis, but this measure is rarely indicated.^[76] Unless the patient develops fatal coma or suffers trauma as a result of incoordination, virtually all episodes of acute alcohol intoxication resolve without sequelae.

Withdrawal Syndromes

The manifestations of alcohol withdrawal occur when a person decreases or stops a high level of alcohol intake, either after a binge lasting a matter of days or after the regular ingestion of alcohol sustained over many months. Although the exact mechanisms are not known, most symptoms appear related to overactivity of various portions of the nervous system resembling a "rebound" phenomenon after profound suppression, and its basis may relate to alterations in the function of GABA or NMDA receptor systems. The earliest findings of alcohol withdrawal typically occur within 6 to 8 hours of alcohol cessation.^[77] Tremulousness is the earliest and most common complaint, and many alcoholics view their so-called shakes as an indication that it is time to resume drinking in order to avoid more severe complications of withdrawal. Tremor appears within hours of cessation of alcohol ingestion and gradually increases to a peak within 1 or 2 days.^[78] The tremor is postural and appears to be irregular due to its variable but large amplitude. The amplitude may increase at the end points of an action, and the typical frequency varies from 6 to 11 Hz.^[79] This movement abnormality mainly involves the hands yet can cause titubation. The tremor remits during relaxation and sleep but often persists for weeks after discontinuation of alcohol consumption. The pathophysiological mechanisms of the tremor are not known, but it probably represents an exaggerated physiological tremor.^[80] The tremulousness is associated with hyperacuity of all sensory modalities, hyperreflexia, hypervigilance, anxiety, tachycardia, hypertension, and insomnia. The severity of these signs and symptoms vary with the intensity and duration of the previous alcohol exposure. In mild forms of withdrawal, the signs and symptoms usually resolve after 48 hours.

In severe reactions, patients may experience additional symptoms including auditory hallucinations, which usually take the form of identifiable voices saying critical or threatening things to the patient. When they occur, hallucinations generally appear within 24 hours of withdrawal. At first, patients tend to accept the voices as real and react accordingly, but as the intensity of the hallucinations wanes, they recognize their true origin. The hallucinosis may be accompanied by global confusion, and

the autonomic hyperactivity continues and may become more pronounced.

Between 6 and 48 hours following alcohol discontinuation, seizures occur in approximately 3 to 4 percent of untreated patients.^{[81], [82]} Although the seizures are almost always multiple with short interictal intervals over a few hours, there may be only a single seizure.^[81] The seizures are generalized tonic-clonic, and focal seizures should suggest the presence of a focal lesion in addition to the effects of the alcohol. Alcoholics may also develop seizure disorders as a result of acute head trauma, the presence of a subdural hematoma, or other causes seen in nonalcoholics. Alcohol withdrawal itself may also potentially aggravate any pre-existing seizure disorder unrelated to the alcohol abuse. Thirty to forty percent of patients with seizures progress to delirium tremens if they are left untreated.^{[77], [83]} One quarter of these individuals do so without an interceding lucid period. The remaining individuals have a period of improvement ranging between 12 hours and 5 days.^{[77], [83], [84]}

Delirium tremens comprises a combination of psychic and autonomic hyperactivity, occurring usually after 3 to 5 days of alcohol abstinence but may be seen as late as 14 days. Only 5 to 6 percent of untreated patients withdrawing from alcohol develop this syndrome.^[84] Patients with delirium tremens are agitated, hallucinating, and confused. The hallucinations are frequently of a visual nature, but other types occur. In addition, fever, tachycardia, diaphoresis, hypertension and confusion are typical. Seizures are uncommon during this phase of withdrawal. Once it is present, the delirium typically lasts for 3 days.

Often by the time patients reach the hospital, alcohol is no longer detectable in the blood. Therefore the diagnosis depends on the history and documentation of other clinical signs that are suggestive of chronic alcoholism (e.g., liver disease). Those patients with seizures or delirium tremens require laboratory screening for superimposed metabolic disorders which may contribute to the clinical picture. Additionally, individuals with clinically uncharacteristic seizures should undergo CT of the brain to rule out focal trauma, stroke, or hemorrhage. The electroencephalogram (EEG) may also be helpful in this setting because it may demonstrate focal slowing or epileptiform activity. Generally, the EEG shows a sequence of changes induced by alcohol beginning with a decrease in the frequency during chronic intoxication, followed by a return to normal with alcohol cessation. During the awake EEG, withdrawal seizures may be precipitated by photic stimulation.

Febrile, delirious patients should have close monitoring of their vital signs, preferably in an intensive care unit, while a search is conducted for possible sources of infection

that may cause or contribute to the clinical presentation. Volume repletion is often necessary due to excessive perspiration. Owing to possible nutritional deficiencies, 100 mg IV and 100 mg of intramuscular thiamine should be provided before the administration of glucose in order to prevent the acute precipitation of WKS. Intravenous fluids should also be supplemented by daily B-complex vitamins. Benzodiazepines are helpful in reducing anxiety and tremulousness, and may be useful in the prevention of seizure activity during withdrawal.^[85] Chlordiazepoxide and diazepam are long-acting drugs with pharmacologically active metabolites and repeated daily dosages can result in accumulation of these agents. Oxazepam, in contrast, is rapidly converted to an inactive compound and does not accumulate and contribute to excessive CNS depression.

Beta blockers or clonidine can be used to treat the associated tachycardia and hypertension.^{[86], [87]} Because withdrawal seizures are typically self-limited, treatment is generally not required. Furthermore, the value of phenytoin in uncomplicated withdrawal seizures has not been demonstrated, and the long-term administration of anticonvulsants is usually ineffective in preventing recurrences. Some studies have reported better control of seizures in patients with a previous history of seizures when phenytoin is added to benzodiazepine administration. Evidence from other reports has conflicted with this finding. Status epilepticus is rare in alcohol withdrawal but should be treated in a manner similar to the one used when it is found in other clinical settings.

As a group, the alcohol withdrawal syndromes represent self-limited episodes that resolve with no residual effects. However, delirium tremens carries a measurable mortality rate (perhaps 10 to 20 percent) due to autonomic dysfunction. The obvious means of preventing these disorders is drinking alcohol only in moderation. For those who are abusing alcohol already, the only sure way to prevent withdrawal syndromes is to continue the alcohol, which is rarely practical in a hospital setting.

Alcoholic Dementia and Cerebral Atrophy

Some authorities have contended that chronic excess ingestion of alcohol leads to cerebral atrophy and alcoholic dementia. However, the notion that alcohol has a direct toxic effect on cerebral tissue is greatly disputed. Most cases of dementia in alcoholics can be explained on the basis of Korsakoff's disease, other nutritional deficiencies, or medical causes. This syndrome has been described only in longstanding alcohol abusers, and the essential clinical features of this putative syndrome are the combination of cognitive and behavioral deficits including impaired memory and judgment, loss of social refinements, and paranoid ideation. Symptoms and signs develop gradually and continue to progress as long as alcohol abuse continues. Patients often show other stigmata of longstanding alcohol abuse. The major diagnostic distinction is with a slowly evolving form of Korsakoff's psychosis. Other considerations when encountering an impaired intellect in alcoholics include hepatic encephalopathy, subdural hematoma, hydrocephalus (from prior trauma or meningitis), or anoxic encephalopathy. Other dementing illnesses unrelated to alcoholism, such as Alzheimer's disease, should be considered. Brain imaging may reveal shrinkage of cerebral volume, especially in the frontal lobes. This finding is potentially reversible if patients can cease alcohol intake. To the extent that some cases represent a slowly evolving form of Korsakoff's disease, regular ingestion of thiamine supplements should help prevent the development of dementia. Once it is established, the dementia tends to remain static if alcohol consumption decreases, whereas it may progress if there is no change in lifestyle.

Deficiency Amblyopia

This disorder is most likely related to the depletion of one or more B vitamins, although none has been specifically implicated. Deficiency amblyopia occurs only after severe and prolonged nutritional deprivation. The strict dietary deficiencies required to produce amblyopia are known to occur mainly in mistreated prisoners of war and alcoholics. Smoking tobacco was once considered another risk factor (hence, the alias tobacco-alcohol amblyopia), but this is no longer believed to be true.

Patients with this disorder experience the subacute onset (over days to weeks) of symmetrical loss of visual acuity, and colors perceived appear to be washed out. On examination, the central portion of vision is especially impaired, and occasionally patients exhibit pallor of the optic discs. Patients often have evidence of other syndromes of nutritional deficiency, including a predominantly sensory polyneuropathy. The possible causes of optic neuropathy are legion, and most are much more common than deficiency amblyopia. The diagnosis should be suggested by the clinical setting.

The most valuable test in the evaluation of these patients is perimetry, which allows for the confirmation of the central or centrocecal distribution of the visual field defect. The diagnosis can be solidified, retrospectively, by a positive response to treatment. Because this disorder results from extreme nutritional deprivation, prevention is relatively easy. Any reasonably balanced diet should provide sufficient vitamin intake for this purpose. Substantial recovery is possible in most cases by eating a nutritious diet supplemented by multivitamins. The majority of patients recover if proper treatment is instituted and the degree of recovery is inversely proportional to the duration of nutritional deprivation.

Cerebellar Degeneration

Although a definite association between cerebellar degeneration and nutritional deficiency is not established in alcoholism, thiamine deficiency is suggested by the clinical and pathological resemblance to the cerebellar involvement in Wernicke's disease. Alcoholism is the chief risk factor for the development of this disorder, and males are affected more often than females. The main clinical manifestation is a disorder of gait characterized by instability and a widened base. Patients are unable to walk with one foot

placed in front of the other and occasionally there is frank ataxia of the lower extremities, which is best appreciated on a heel-to-shin test. The gait disorder develops gradually, or occasionally in a stepwise fashion. The upper limbs are only rarely involved.

Because this disorder is associated with alcoholism, many patients have evidence of other complications of nutritional deficiency, particularly a polyneuropathy. In alcoholics, alternate causes of gait ataxia include Wernicke's disease, acquired hepatocerebral degeneration, and the effects of head trauma. Cerebellar syndromes

featuring prominent speech or oculomotor deficits should suggest another cause for the ataxia, even in alcoholics.

MRI may demonstrate atrophy of the anterosuperior vermis, which is best seen on a midline sagittal image. With the uncertain pathogenesis, the only known effective preventive measure is the treatment of alcoholism. However, it is likely that avoiding nutritional deficiency would eliminate the risk of alcoholic cerebellar degeneration. The utility of vitamin supplementation after the cerebellar degeneration has occurred is unproven. In most cases, the gait disorder progresses over weeks to months, and then persists indefinitely. A small number of patients show only brief manifestations with spontaneous resolution.

Marchiafava-Bignami Disease

The majority of the pathological changes in this disease occur in the middle lamina of the corpus callosum. The mechanism responsible for the white matter damage and the reason for the particular vulnerability of the corpus callosum are unknown. Longstanding alcohol abuse is clearly a risk factor, but Marchiafava-Bignami disease has also been described in nonalcoholics. The rarity of this disorder when measured against the prevalence of alcoholism also suggests that other factors are involved. Originally thought to selectively affect Italians, Marchiafava-Bignami has been found in other populations as well.

There is no consistent or typical clinical presentation, but manifestations usually encompass both cognitive and behavioral aspects. Many patients appear to become progressively demented, disinhibited, or aggressive. Transient neurological deficits, often focal in nature, may form part of the clinical picture. Seizures and impaired consciousness may be terminal events. Because chronic alcoholism is present in most cases, other typical findings in this population include polyneuropathy or ataxia. Hospital admissions, however, are usually precipitated by complications of alcohol withdrawal. Korsakoff's psychosis, alcoholic dementia, hepatic encephalopathy, and subdural hematoma form a partial list of conditions causing dementia or behavioral disorders in alcoholics and should be considered in the differential diagnosis. Brain MRI scans may show lesions in the corpus callosum. In most cases, the disorder progresses slowly, sometimes taking years to lead to stupor, coma, and death.

Alcoholic Myopathy

There are two forms of alcoholic muscle disease: (1) an acute, painful myopathy associated with weakness, cramps, swollen and tender muscles, high creatine kinase, and rhabdomyolysis with or without myoglobinuria; and (2) a chronic myopathy that is painless and often unnoticed by the patient, causing proximal weakness and type II fiber atrophy on nerve biopsy. In addition to skeletal muscle involvement, patients may have an associated cardiomyopathy.^[88]

Proposed mechanisms of alcoholic injury have included mitochondrial dysfunction, phosphorus and potassium depletion, and rhabdomyolysis induced by either alcohol-related seizures or limb compression from alcoholic stupor. Alcohol may also act synergistically with nutritional deficiencies to disrupt energy metabolism, although a mitochondrial defect has not been demonstrated.^[89] The acute myopathy may require an additional insult, such as hypokalemia, fasting, seizures, delirium tremens, or prolonged limb compression. In chronic myopathy, type IIb fiber atrophy and fiber size variability are present.^[90] In acute myopathy, necrosis with or without inflammation, regenerating fibers, and type I atrophy are seen pathologically. Women are more susceptible than men to develop this complication due to a 40% lower dose of alcohol required to produce cardiac and skeletal myopathy.^[88] Women may metabolize alcohol more slowly, leading to higher blood levels, possibly due to decreased gastric alcohol dehydrogenase and liver metabolism.

Acute necrotizing myopathy and rhabdomyolysis cause severe painful swelling of one or more muscles with induration of the skin and soft tissues. Creatine kinase levels may be elevated, and myoglobinuria may result in acute renal failure. Acute attacks resolve in days to weeks after abstaining and long-term disability is uncommon unless the patient has repeated attacks.^[91] Chronic myopathy is painless weakness of proximal muscles. A cardiomyopathy, peripheral and autonomic neuropathies, and other complications of alcohol abuse may be concomitantly present in these patients. Other myopathic processes including inflammatory (polymyositis/dermatomyositis), endocrine (thyroid, cortisol), electrolyte disorders (low potassium, phosphorus, calcium, and magnesium), toxins (colchicine), and infectious agents (legionella, mycoplasma, viral) should be considered in this clinical setting.

Martin and colleagues performed muscle biopsies in 151 consecutive inpatient alcoholics. Only half had weakness, and 15 percent had an elevated CK level. A chronic myopathy was observed in 60 percent, and 5 percent had necrosis, suggesting an acute myopathy on muscle biopsy. Clinical evidence of a peripheral neuropathy was suggested in 65 percent, yet half were asymptomatic.^[92]

In the evaluation of these patients, laboratory studies should include CK, aldolase, electrocardiograph, and echocardiogram. In one series of patients, the aldolase level was more commonly elevated than CPK and may be more helpful in the diagnosis.^[89] Rarely, when the diagnosis is in question, a muscle biopsy is warranted. Management includes strict abstinence from alcohol, intravenous saline diuresis to prevent renal failure from myoglobinuria, and thiamine and multivitamin supplementation.

Alcoholic Neuropathy

Alcoholic neuropathy is difficult to separate from nutritional, specifically thiamine-deficient, neuropathy.^[92] The

clinical pattern and pathology of axonal degeneration is virtually identical to beriberi. The incidence ranges from 9 to 30 percent among hospitalized alcoholics,^[93]^[94] and up to 93 percent of ambulatory alcoholics may have electrophysiological evidence of neuropathy.^[95] Victor and associates found signs of polyneuropathy in 82 percent of 230 patients with WKS,^[9] and 84 percent of patients, who were able to give a dietary history, reported at least a 20-pound weight loss in the previous year. Alcoholic neuropathy occurs in those patients consuming at least 100 g of alcohol daily for several years. It is potentiated by nutritional deficiency. Men outnumber women, but women may be more susceptible at lower doses than men.^[96] Although it is not known how alcohol injures peripheral nerves, theories include altered membrane lipid permeability^[97] and oxidation injury from free radical formation.^[98] How nutritional deficiency may potentiate the toxicity of alcohol awaits further study.

Attempts to control for the influences of alcohol and nutrition have yielded conflicting results. Alcoholics with neuropathy were allowed to continue drinking while receiving a nutritious diet with vitamin supplementation, and all noted improvement in symptoms.^[99] Hallet and co-workers were unable to produce neuropathy in monkeys after 3 to 5 years of a high alcohol diet.^[100] However, Behse and Buchthal reported 37 cases of alcoholic neuropathy in patients drinking about 3 L of thiamine and pyridoxine-fortified beer daily, the equivalent of 100 ml of ethanol.^[96] Fourteen of 37 (37 percent) had marked weight loss. All patients had normal serum vitamin levels, except for one with thiamine deficiency and three with folate deficiency. The pattern and severity of the neuropathy did not differ between those with and without adequate nutrition. Similarly, Monforte and colleagues found no relationship between the nutritional status and the incidence of autonomic and peripheral neuropathies in alcoholics.^[101] Pathologically, the peripheral nerve undergoes axonal degeneration with loss of large and small myelinated fibers in autonomic,^[102] sensory, and motor nerves.^[96]

The neuropathy is often asymptomatic until it is pointed out to the patient. The symptoms begin with paresthesias and burning feet, and later, painful calves, numbness, cramps, weakness, and sensory ataxia may develop. On examination, patients may have sensory loss (vibratory and deep sensation) in the distal legs, motor weakness, areflexia, calf tenderness, and orthostatic hypotension.^[102] The skin of the legs becomes shiny, swollen, and subject to trauma and ulceration. Neuropathic joint degeneration may occur with bony resorption and deep tissue infection.^[93] Other neurological processes including beriberi, inflammation, or metabolic disturbances should be ruled out. Blood studies and neurophysiological studies are useful in evaluating these patients and establishing the diagnosis.

These individuals are best managed by recommending abstinence from alcohol intake and enhancing their diet with vitamin supplements. Supplemental thiamine and pain control may be warranted in selected individuals. The prognosis depends on the severity and duration of symptoms. Behse and Buchthal found no evidence of clinical improvement or regeneration on nerve biopsy in 17 patients studied 2 years later.^[96] The earlier patients abstain and establish regular diets, the more likely they are to recover from the neuropathy. Alcoholics with autonomic neuropathy have a reduced life expectancy.^[103]

Alcoholism and Movement Disorders

In addition to the classic postural tremor associated with alcohol withdrawal, other movement disorders can occur in the setting of alcohol abuse and withdrawal.^[104] A rare, slow tremor of the lower extremities can also occur in alcoholics and is produced by the synchronous flexion-extension of the muscles of the hip girdle.^[105] This 3-Hz tremor is associated with alcoholic cerebellar degeneration affecting the anterior superior vermis and cerebellar hemispheres.^[106] When they are supine, patients with this form of tremor may reveal a kicking movement when the legs are elevated and the knee and hip joints are flexed 90 degrees. It can be best observed when

the patient stands with the feet together and the knees partially bent. This results in a slow up and down movement of the body.

Transient parkinsonism may rarely appear in the setting of alcohol abuse or withdrawal in patients with no liver dysfunction. ^[107], ^[108] This typically occurs a few days after alcohol cessation and is characterized by bradykinesia, stooped posture, and a coarse resting tremor in the hands. Cogwheel rigidity of the limbs can also be appreciated. These episodes may occur during alcohol withdrawal. These signs may last for a few weeks or months, yet they do not persist. Transient dyskinesias with lingual-oral, neck, or limb movements have been reported in some alcoholics. ^[109], ^[110]

With chronic abuse of alcohol, hepatic inflammation and fibrosis can occur and may be associated with encephalopathy. In this setting, patients have an altered level of consciousness with diffuse slowing and at times triphasic waves on an EEG. Asterixis, or so-called negative myoclonus, is a classic finding in these patients and is characterized by clusters of brief irregular lapses of sustained posture. ^[111], ^[112] On examination, this may be best demonstrated by asking the patient to hold out his or her upper extremities and extend the hands at the wrist. The involuntary lapses in posture are associated with 50- to 200-msec periods of electrical silence in muscles that are tonically active. The mechanisms of this movement are unknown. Chronic or persistent choreiform movements may also occur with alcoholic liver disease. ^[37A]

Fetal Alcohol Syndrome

The mechanism by which the abnormalities of the fetal alcohol syndrome are produced is unknown, but it is thought to be due to a direct teratogenic effect. There is no general agreement regarding the limits of vulnerability of the fetus in terms of gestational age. To date, this syndrome has been described only in children of mothers who drank alcohol frequently during their pregnancy. Fetal alcohol syndrome results in low birth weight and small head circumference. Cranial and joint deformities are common, and the children feed poorly and are "colicky" and tremulous. The infant mortality rate associated with this

condition is high, and survivors suffer an increased risk of mental retardation. Many, but not all, of the mothers of affected babies suffered from withdrawal seizures, delirium tremens, or hepatic encephalopathy during the pregnancy. Infants with fetal alcohol syndrome have a higher incidence of various congenital brain malformations.

Because addicts often abuse several drugs, it is important to consider that an irritable, tremulous, small baby may also result from use during pregnancy of crack cocaine or other agents. There are no laboratory tests of value to support or refute the diagnosis of fetal alcohol syndrome. Maternal education regarding the toxic effects of alcohol is of paramount importance in preventing the fetal alcohol syndrome. There is no safe minimum amount of alcohol consumption that can be guaranteed not to be toxic to a fetus, so mothers-to-be are urged to abstain entirely from alcohol throughout their pregnancy. There is no direct treatment for the effects of the fetal alcohol syndrome, although proper postnatal nutrition and care will help affected babies as they do unaffected ones. Approximately one in six babies born with this syndrome die. Of the remainder, about half suffer permanent physical or mental handicaps.

ACKNOWLEDGMENT

We thank Monroe Cole, MD, for his thoughtful review of the manuscript.

The diagnosis and therapy of central nervous system (CNS) viral infections is one of the most rapidly evolving and exciting areas in neurology. Viruses gain access to the CNS either through the bloodstream or through an intraneuronal route from the peripheral nerves. Viruses may cause acute CNS disease such as meningitis or encephalitis, a delayed complication of an acute infection such as postinfectious polyneuritis or autoimmune encephalomyelitis, latent infections with recurrence of disease from time to time, or slowly progressive neurological disorders. The important human nervous system viruses are listed in [Table 41-1](#). The most common acute CNS viral infections are meningitis and encephalitis. The classic clinical presentation of viral meningitis includes fever, headache, photophobia, myalgias, and nausea and vomiting. There is no alteration in the level of consciousness. The viral etiological agents of meningitis are listed in [Table 41-2](#), and [Table 41-3](#) lists a differential diagnosis of aseptic meningitis. Viral encephalitis is characterized by fever, an altered level of consciousness, headache, and seizure activity. The etiological agents of viral encephalitis are listed in [Table 41-4](#). In addition, viral encephalitis may present as a focal encephalitis with focal neurological deficits and focal seizure activity. The etiological agents of focal encephalitis are listed in [Table 41-4](#).

In addition to meningitis and encephalitis, CNS enteroviral infections may present as an acute transverse myelitis (characterized by abrupt onset of weakness of the limbs progressing to flaccid paralysis in association with a sensory level), single or multiple limb paralysis (polio), cerebellar ataxia (a common presentation of enteroviral CNS infection in children), a chronic meningoencephalitis ([Table 41-5](#)), or a postinfectious polyneuritis. Measles and rubella viruses can cause a slowly progressive neurological disease that presents several years after the acute viral illness has occurred. Other viruses such as the human T-cell lymphotropic virus type 1 (HTLV-1) can cause a slowly progressive neuromyelopathy in adulthood with no prior history of apparent infection. Human herpesviruses, herpes simplex virus and varicella-zoster virus, are the prototypical viruses that establish lifelong latent infections in human peripheral and CNS sensory ganglia that may episodically reactivate, resulting in acute infection. This chapter reviews the epidemiology, pathogenesis, clinical features, diagnosis, and management of the human nervous system viruses listed in [Table 41-1](#).

RNA VIRUSES

Enteroviruses (Echoviruses and Coxsackieviruses)

Epidemiology and Risk Factors. Enteroviral infections occur primarily in the summer and autumn months in temperate climates; infants, young children, and immunocompromised patients are at greatest risk of infection. The enteroviruses comprise a total of 68 distinct serotypes of human pathogens, but the most common enteroviruses that cause aseptic meningitis are the coxsackieviruses B5, B3, B4, and A9; the echoviruses 30, 11, 7, 9, 6, 4, and 18; and enteroviruses 70 and 71. ^{[1], [2]}
The clinical signs and symptoms observed during enterovirus CNS infection depends to some extent not only on the patient's age but also on the state of the individual's immune system. Neonates are at greatest risk for severe infection, either meningitis or meningoencephalitis. Enteroviral infection in agammaglobulinemic individuals may cause a chronic meningitis or meningoencephalitis. Enteroviral CNS infection in infants older than 2 weeks of age and in children and adults is rarely associated with severe disease and is most often an aseptic meningitis.

may also enter through the conjunctiva of the eye, initially producing a conjunctivitis before they spread to the CNS. When enteroviruses enter the host through the nasopharynx, the initial spread and replication of virus may take place in the upper respiratory tract lymphatics, but more often the viral inoculum is swallowed. Once in the alimentary tract, the virus may infect the intestinal lining cells and remain limited to the gastrointestinal tract, causing symptoms of gastroenteritis and diarrhea, or it may traverse the intestinal lining cells, replicate in Peyer's patches in the mucosa of the lamina propria, and then disseminate to other organs, including the CNS. Most enteroviruses spread to the CNS via the bloodstream, but a small percentage may reach the CNS by direct neural spread from nerves terminating in the intestinal tissue. Virus traverses the blood-brain barrier either at the choroid plexus, where it may infect endothelial cells and spread into the cerebrospinal fluid causing a meningitis, or at the endothelium of the cerebral capillary cells in the brain parenchyma causing an encephalitis.

Although viremia typically occurs 2 to 3 days after the enterovirus has infected the alimentary tract, signs and symptoms of CNS disease typically develop 5 to 16 days after the initial infection and may be biphasic, with minor illness preceding the onset of neurological disease. Unlike most viral infections, in which cell-mediated immunity is the primary host defense against infection, clearance of enteroviral infection by the host is antibody mediated. For this reason, infants and young children and individuals with antibody deficiencies, particularly patients with X-linked

agammaglobulinemia, are prone to severe or chronic enteroviral meningitis or meningoencephalitis. [1]

Clinical Features and Associated Findings. Enteroviral CNS infection may be an aseptic meningitis, an encephalitis, a focal encephalitis (group A coxsackieviruses), an acute transverse myelitis, single or multiple limb paralysis (poliomyelitis syndrome), Guillain-Barre syndrome, cerebellar ataxia, or a chronic meningoencephalitis. [2], [3], [4], [5]

Aseptic Meningitis. Enteroviruses are presently the most common cause of aseptic meningitis, accounting for 80 to 92 percent of all cases of aseptic meningitis for which an etiologic agent is identified. [2] Certain serotypes (group B coxsackieviruses and the echoviruses) are associated with a greater frequency of meningitis than other serotypes. [2], [3] In a review of aseptic meningitis in 274 children less than 2 years of age, the group B coxsackieviruses and the echoviruses were the etiologic agents in 156 (92 percent) of the 169 laboratory-diagnosed cases. [10] The clinical presentation of aseptic meningitis includes fever (38° to 40° C), severe headache, nausea and vomiting, photophobia,

TABLE 41-5 -- CAUSES OF CHRONIC/RELAPSING MENINGOENCEPHALITIS

Enteroviruses (agammaglobulinemic patients)
Measles (SSPE)
Rubella virus (progressive rubella panencephalitis)

and nuchal rigidity. Neurological abnormalities are rare, and enteroviral meningitis in otherwise healthy children and adults is rarely associated with severe disease or poor outcome. [2]

Encephalitis. Enteroviral CNS infection may be severe, fatal, or protracted in infants and in individuals with agammaglobulinemia. In neonates, the illness begins with fever and nonspecific signs such as vomiting, anorexia, rash, or upper respiratory findings. Signs of meningeal inflammation may or may not be present at this stage. As the disease progresses, hepatic necrosis, myocarditis, necrotizing enterocolitis, disseminated intravascular coagulation, and other signs of "sepsis" may develop. The onset of encephalitis is characterized by an altered level of consciousness, seizures, and focal neurological deficits. [2] Unlike enteroviral aseptic meningitis, neonatal enteroviral meningoencephalitis may be fatal or associated with long-term sequelae. The infected neonate appears to be at greatest risk for severe morbidity and death when signs and symptoms develop in the first days of life, an onset suggestive of intrauterine or parturient exposure caused by maternal infection. [2] Chronic enteroviral meningoencephalitis has been reported in patients with agammaglobulinemia. The disease is most frequently caused by echoviruses, and the typical clinical presentation is that of a slowly progressive neurologic disease with ataxia, headache, seizures, paresthesias, and loss of cognitive skills. This change in cognitive skills may be marked by loss of developmental milestones, episodic confusional states, and personality changes. Some patients also have non-neurologic manifestations of chronic enteroviral infection, including fever, dermatomyositis-like syndrome, rashes, and hepatitis. [4] An enterovirus may also cause a focal encephalitis, but unlike patients with herpes simplex virus encephalitis, patients with enteroviral focal encephalitis typically improve spontaneously within 1 or 2 days of admission. The association of a macular or maculopapular rash with the clinical signs and symptoms as described earlier warrants the inclusion of enterovirus in the differential diagnosis of a focal encephalitis.

Paralysis. Coxsackieviruses and echoviruses have been implicated as the etiologic agents of acute transverse myelitis, which is characterized by the abrupt onset of weakness of the limbs that progresses to flaccid paralysis, and diminished and then absent deep tendon reflexes, in association with a sensory level. [4], [11] Nonpolio enteroviruses may also cause paralysis of a single limb or multiple limbs that may resemble poliomyelitis. [2] The clinical disease and pathology associated with coxsackie and echovirus paralytic disease are generally much less severe than those seen with poliovirus. Echovirus type 70, the cause of epidemics of acute hemorrhagic conjunctivitis, has been associated with acute paralytic disease in Asia, Africa, and Latin America. Echovirus type 71, the usual etiologic agent of hand-foot-mouth disease, has been responsible for epidemics of paralytic disease in Bulgaria, Hungary, and the United States. [12], [13] Infection of the anterior horn cells by a nonpolio enterovirus may contribute to disease in patients with postpolio syndrome, causing slowly progressive motor neuron damage. [12]

Differential Diagnosis. The diagnosis of enteroviral aseptic meningitis is based on examination of the cerebrospinal

fluid (CSF). The opening pressure should be normal or slightly increased, and there is a mild lymphocytic pleocytosis, a normal or slightly increased protein concentration, and a normal glucose concentration. The white blood cell count typically is less than 1000 cells/mm³. [14]

Because enteroviral meningitis is quite common in neonates, it is important to emphasize the normal values for the CSF total white blood cell (WBC) count, and protein concentration in neonates (0 to 4 weeks), older neonates (4 to 8 weeks), and children and adults. The upper limit of normal for the CSF total WBC count is 22/mm³ in infants 0 to 4 weeks old, 15/mm³ in infants 4 to 8 weeks old, and 5/mm³ in those older than 8 weeks of age. [15], [16] In normal uninfected CSF in newborns, about 60 percent of the cells are polymorphonuclear leukocytes and 40 percent are mononucleated cells. [16] In uninfected CSF in children and adults, the normal WBC count ranges from 0 to 5 mononuclear cells (lymphocytes and monocytes) per mm³. In normal uninfected CSF in children and adults there should be no polymorphonuclear leukocytes; however, with the use of the cytocentrifuge, an occasional polymorphonuclear leukocyte may be seen. If the total WBC count is less than 5/mm³, the presence of a single polymorphonuclear leukocyte may be considered normal. [16] The normal protein concentration in neonates and older neonates is greater than that in children and adults. A CSF protein concentration as high as 150 mg/dl is considered normal in the neonate. By 1 year of age, the normal value for the lumbar CSF protein concentration is 45 mg/dl. [16] The upper range of normal for the lumbar CSF protein concentration in the adult is 50 mg/dl. The CSF white blood cell count is often higher in those with coxsackievirus aseptic meningitis than in patients with echovirus aseptic meningitis, and counts as high as 2000/mm³ have been reported. A predominance of polymorphonuclear leukocytes may be seen early in the disease course with a transition to a lymphocytic pleocytosis as the disease progresses. In addition, hypoglycorrhachia has been reported in some patients with enteroviral aseptic meningitis. [17]

At the present time, isolation of an enterovirus by CSF viral culture is the gold standard for diagnosis of an enteroviral CNS infection. When an enterovirus is isolated from a non-CSF site (throat, stool, serum, urine) in conjunction with a CSF pleocytosis and an absence of bacteria by Gram's stain or the latex agglutination technique, enteroviral meningitis is the presumptive diagnosis. An enterovirus isolated from a non-CSF site may, however, be unrelated to the CNS infection. [16] The recent development of the reverse transcriptase polymerase chain reaction (rt-pcr) technique for the diagnosis of enteroviral meningitis will significantly improve

identification of the etiologic agent of aseptic meningitis. As a general rule, CSF viral culture is negative in approximately 25 to 33 percent of CSF specimens from patients with enteroviral meningitis. In these patients, approximately two-thirds of CSF specimens are found to be positive for enterovirus by rt-pcr. ^[1], ^[2]

An enterovirus is the likely etiologic agent in the patient with a clinical presentation of aseptic meningitis, CSF findings of a lymphocytic pleocytosis with a normal glucose concentration, and a fourfold or greater increase in antiviral IgG antibody between acute and convalescent sera or the first-time appearance of virus-specific IgM antibodies.

Management. Because the majority of enteroviral infections are spread by the fecal-oral route, enteroviral infections are best prevented by proper handwashing techniques. Infants and children are at particular risk for these infections, and good hygiene, including parental handwashing after urine and stool diaper changes and washing the hands of the infant or child before eating, can reduce the transmission of these infections. Children and adolescents should be discouraged from sharing water bottles and drinking cups during athletic events.

There is no specific antiviral therapy for enteroviral CNS infection. Intravenous immune globulin has been used to treat enterovirus infections in newborns and patients with agammaglobulinemia and other immunodeficiency states with good success, but it is not recommended in children and adults with uncomplicated enteroviral aseptic meningitis. ^[3], ^[19], ^[20]

Prognosis and Future Perspectives. With the exception of neonates and patients with agammaglobulinemia, the majority of patients with enteroviral aseptic meningitis have a benign self-limited course of disease and recover within a week. As discussed previously, neonates and patients with agammaglobulinemia may have a severe, fatal, or protracted course of enteroviral meningoencephalitis. The prognosis of patients with acute transverse myelitis due to an enteroviral infection is generally good. ^[4], ^[12] The prognosis of limb paralysis due to an enteroviral infection is generally much better than that due to poliovirus. ^[7]

Poliovirus

Epidemiology and Risk Factors. Poliomyelitis was the most frightening infectious disease during the first half of the twentieth century. Large epidemics led to extensive research in the epidemiology and pathogenesis of the disease. The poliovirus was first isolated in 1908 by inoculation of monkeys with a cell-free extract made from the spinal cord of a patient with fatal poliomyelitis. ^[21], ^[22] It was not, however, until 1937 that the virus was isolated from intestinal washings, and by 1941 it was clear that the gastrointestinal tract played a major role in the pathogenesis of this infection. ^[23] Shortly thereafter it was recognized that the majority of poliovirus infections are a form of acute gastroenteritis. Paralysis develops in less than 1 in 100 individuals infected with the poliovirus. ^[24] In 1949 Enders, Weller, and Robbins made the major discovery that the poliovirus could be grown in tissue cultures of human embryonic skin, muscle cells, and intestinal tissue. Prior to that the only source of the poliovirus was nervous tissue from infected monkeys, an unacceptable inoculum in humans. ^[21] The work of Enders and his colleagues, combined with the efforts of the National Foundation for Infantile Paralysis, led to the recognition that there were only three serotypes of poliovirus and laid the groundwork for the development of the killed virus vaccine by Jonas Salk in 1955, and the oral live attenuated virus vaccine by Albert Sabin in 1961. ^[21], ^[25] Poliomyelitis has been nearly eradicated from North America and Europe, but outbreaks of the disease continue to occur in Asia and Africa, where an estimated 250,000 cases and 25,000 deaths currently occur annually. ^[26]

Pathogenesis and Pathophysiology. Poliovirus is a member of the Picornaviridae. There are three immunologically defined serotypes of poliovirus, all of which are capable of causing paralytic disease. The poliovirus is a single-stranded RNA enterovirus. ^[22] Natural polio infection occurs through ingestion of the virus, which initially multiplies in the oropharyngeal and intestinal mucosa. Poliovirus either enters the CNS via the bloodstream or, alternatively, may be transmitted to the CNS through vagal autonomic nerve fibers in the intestinal lumen. ^[22] A temporal association corresponding to the incubation period of the disease was observed between tonsillectomy and the development of bulbar poliomyelitis, suggesting that the exposure of nerve endings via tonsillectomy could transmit poliovirus to the CNS. ^[27] A third hypothesis is that ingested poliovirus initially replicates in the gastrointestinal tract; then a viremia ensues, and disseminated virus replicates at an extraneural site (i.e., skeletal muscle cells). Virus is then transported from the muscle cells via the peripheral nerves to the CNS. The hypothesis that poliovirus replicates in muscle cells and then enters the CNS through the peripheral nerves has been supported by the clinical observations that vigorous exertion or injury of a limb was temporally associated with limb paralysis. ^[22] In the Cutter incident, children inoculated intramuscularly with incompletely inactivated polio vaccine developed focal limb paralysis. ^[28], ^[29] Poliovirus replicates in the muscles of monkeys after intramuscular injection and causes limb paralysis of the injected limb. ^[28] The poliovirus receptor (PVR), a member of the immunoglobulin superfamily of proteins, is present at the motor endplate. During acute infection, the poliovirus may bind to the PVR-expressing motor endplate and travel by way of endocytosis and retrograde transport to the anterior horn cells in the spinal cord and brain stem. ^[28] Acute paralytic poliomyelitis is then characterized pathologically by severe anterior horn inflammation with loss of spinal and bulbar motor neurons. ^[30]

In his classic work on acute polio infection, Bodian noted evidence of a marked scarcity of normal-appearing neurons, even in cases of very mild paralysis, suggesting that acute paralytic polio was a generalized neuronal disease. The earliest cellular change in the motor neurons was dissolution of the cytoplasmic Nissl substance (chromatolysis). Infected neurons that exhibited only a mild degree of diffuse chromatolysis survived and continued to support motor units; in contrast, neurons that had severe chromatolysis followed by nuclear invagination and perinuclear chromatin aggregation could not support motor units, and subsequently permanent loss of function occurred in these muscle groups. ^[30], ^[31]

Postpolio syndrome, defined as "the development of new muscle weakness and fatigue in skeletal or bulbar muscles, unrelated to any known cause, that begins 25 to 30 years after an acute attack of paralytic poliomyelitis," is most likely explained by the status of the motor neurons that survived the initial infection. The surviving motor neurons, in an attempt to reinnervate the muscle fibers orphaned by the death of their parent motor neurons, adopt in their motor unit territory additional muscle fibers, so that the number of muscle fibers innervated by a single motor neuron may be four to five times the normal number. This puts metabolic stress on the neuronal cell bodies that, after a number of years, leads to a slow deterioration of nerve terminals. As each terminal dies, muscle fibers drop out, and weakness slowly progresses. ^[31]

Clinical Features and Associated Findings

Nonparalytic or Preparalytic. As stated previously, the majority of poliovirus infections were asymptomatic or characterized by a nonspecific viral syndrome of malaise, myalgias, and low-grade fever.

Paralytic. Patients who developed paralytic poliomyelitis may initially have had clinical symptoms of fever, malaise, headache, and gastrointestinal or upper respiratory tract symptoms. These symptoms subsided, only to recur after several days in association with increasing signs of meningeal irritation, headache, and stiff neck. When the illness progressed to the paralytic form, muscle soreness was prominent, particularly in the back and neck. Patients who developed paralysis usually did so on the second to fifth day after meningeal signs and fever became evident. Once weakness began, it typically progressed for only the first few days after its onset. The fever persisted for several days but often subsided before the paralysis was complete. Patients complained of severe muscle pain and spasms with asymmetrical flaccid muscle weakness that usually affected a lower extremity. Severe bulbar weakness occurred in 10 to 15 percent of patients with paralysis. The disease was most common in infants and children between the ages of 6 months and 10 years, and was more common in the late summer and autumn months. Acute mortality usually resulted from respiratory or bulbar involvement. ^[24]

Postpolio Syndrome. The following criteria are necessary for a diagnosis of postpolio syndrome as the cause of progressive weakness: (1) a history of documented acute paralytic poliomyelitis in childhood or adolescence as evidenced by a well-documented acute febrile paralytic attack during a polio epidemic that resulted in residual lower motor neuron weakness; (2) partial recovery of motor function and functional stability or recovery for at least 15 years; (3) residual asymmetrical muscle atrophy with weakness, areflexia, and normal sensation in at least one limb; and (4) normal sphincteric function. ^[32]

Differential Diagnosis. Although the poliovirus now can be recovered from stool, throat washings, CSF, and blood, during the polio epidemic in this century virological confirmation was not available. The diagnosis was based on the clinical syndrome of fever with paralysis and residual lower motor neuron weakness. Examination of the CSF in the preparalytic stage showed an increase in the opening pressure and an increase in the white blood cell count that initially might be a predominance of polymorphonuclear leukocytes, but within a few days' time was characterized by a predominance of lymphocytes. White blood cell counts of 10 to 1000/mm³ were typically seen. The protein concentration in the CSF at the onset of illness might be normal or slightly increased. Patients who developed paralysis had a higher number of white blood cells in the CSF and a higher protein concentration than patients who did not develop paralysis. ^[24]

Needle examination shows a reduced number of voluntary motor unit potentials in the initial phase of paralysis, but in subsequent months, as the patient improves, the motor units become markedly enlarged, reflecting the reinnervation of the denervated muscle fibers.

Management. The management of patients with poliomyelitis and the postpolio syndrome is largely supportive. The treatment of bulbar poliomyelitis was significantly improved by the development of the "iron lung" in the 1930s. Patients with lower extremity weakness were initially treated with splints and plaster casts. Prolonged casting, often for months at a time, was typically employed. Eventually, the use of splinting and casting was replaced by physical therapy, braces, and other assistive ambulatory devices.^[24] Anticholinesterase therapy has been beneficial in the treatment of symptoms of weakness and fatigue in patients with postpolio syndrome.^[33]

The Advisory Committee on Immunization Practices (ACIP) of the United States Public Health Service has recommended that the United States adopt a sequential poliomyelitis immunization schedule—two doses of inactivated polio vaccine (IPV) followed by two doses of live oral polio vaccine (OPV).^[34],^[35] At the present time, the World Health Organization recommends only OPV for both routine immunization and to achieve polio eradication.^[35],^[36] Although OPV is among the safest of vaccines, one case of vaccine-associated polio occurs for every 2.5 million doses of OPV administered. The proposed sequential schedule recommended by the ACIP is a compromise that seeks to retain the advantages of OPV while preventing half of the 8 to 10 vaccine-related cases that occur every year in the United States.^[35]

Mumps

Epidemiology and Risk Factors. Mumps is a member of the Paramyxoviridae group and is an enveloped virus containing a single-stranded RNA genome.^[37] Prior to the widespread use of the trivalent measles-mumps-rubella (MMR) vaccine, mumps was an epidemic disease that occurred in the winter and spring months. Mumps was the most common cause of viral meningitis and encephalitis in many countries, the frequency of aseptic meningitis being estimated at 1 per 1000 cases of clinical mumps with much higher figures observed during epidemics.^[38] In some countries, mumps was the most common cause of meningoencephalitis in children under 15 years of age.^[39]

The live mumps vaccine has a 95 percent protection rate, and the MMR vaccine containing the Jeryl Lynn strain of mumps virus has nearly eliminated meningitis and meningoencephalitis due to mumps. In 1989 the Immunization Practices Advisory Committee in the United States estimated that the incidence of postvaccination encephalitis within 30 days of vaccination was 0.4 cases per 1 million doses administered.^[40],^[41]

The use of the Urabe Am 9 mumps vaccine was associated with a number of cases of aseptic meningitis in Canada and Japan, with an estimated rate of one case per several thousand vaccinations. The vaccine-associated cases of aseptic meningitis were mild and were rarely associated with sequelae, but the occurrence of aseptic meningitis with the vaccine containing the Urabe strain led to replacement of this strain of mumps virus with the Jeryl Lynn strain in many mass vaccination programs.^[37]

Pathogenesis and Pathophysiology. Mumps virus spreads by respiratory droplets. After local replication occurs in the respiratory mucosa, viremia ensues. Parotitis occurs because the virus has an affinity for parotid ductal epithelial cells.^[42] The mumps virus is neurotropic and meningo-tropic, and the CNS is infected in the course of the viremia.^[41] Virus infects the endothelial cells of the choroid plexus.

Clinical Features and Associated Findings. The mean incubation period for mumps is 16 to 18 days, and symptoms develop in 60 to 70 percent of those infected. Thirty to 40 percent of natural mumps infections are asymptomatic.^[41] When symptomatic, an initial febrile illness with parotitis occurs in 95 percent of patients, and orchitis occurs in 25 percent of males.^[42] Although many children with wild mumps meningitis have parotitis, clinical evidence of parotitis is not absolute.^[43] CNS infection occurs in the absence of parotitis in 36 to 50 percent of cases.^[42]

Mumps meningitis is characterized by fever, headache, vomiting, and signs of meningeal irritation. The clinical presentation of mumps encephalitis includes seizures, altered consciousness, behavioral abnormalities, sensory abnormalities, and difficulty with balance.^[42] Mumps is a well-recognized cause of acquired deafness due to sensorineural hearing loss, which is typically unilateral and has been attributed to a cochlear neuritis with or without labyrinthine inflammation.^[44] Mumps can cause an epididymo-orchitis, with subsequent infertility, pancreatitis, juvenile diabetes mellitus, fatal myocarditis, and abortions.^[38]

Differential Diagnosis. The diagnosis of mumps aseptic meningitis is suggested by the clinical appearance of parotitis and meningitis and is established by examination of the cerebrospinal fluid. The classic CSF abnormalities are a lymphocytic pleocytosis (300 to 600 cells/mm³) and either a normal or decreased glucose concentration.^[45] A positive CSF viral culture establishes the diagnosis. A fourfold rise in mumps antiviral antibody in convalescent sera compared to acute sera is also diagnostic, except in patients who have recently been immunized, in which case a fourfold rise in mumps-specific IgG may simply represent successful immunization. The diagnosis of mumps meningoencephalitis is made similarly by isolating the virus from the CSF and/or by noting a fourfold rise in mumps antiviral antibody between the acute and convalescent sera. The electroencephalogram (EEG) is reported to be abnormal in 100 percent of patients with mumps meningoencephalitis.^[42],^[46]

Management. No antiviral therapy is available for mumps meningitis or meningoencephalitis. Fortunately, these neurological complications have largely been eradicated through the widespread use of the MMR vaccine. As described earlier, there have been no cases of postvaccine meningitis with use of the Jeryl Lynn strain of mumps virus vaccine. The propensity of the vaccine to cause meningitis appears to have been associated with the Urabe strain, and a reported reduction in vaccine-associated aseptic meningitis in Canada following the change from the Urabe to the Jeryl Lynn mumps virus-containing MMR vaccine supports this observation.^[43]

Arthropod-borne Viruses

Epidemiology and Risk Factors. The arthropod-borne viruses (arboviruses) are transmitted to humans by the bite

of a mosquito or tick. The epidemiology of arthropod-borne viral encephalitis is influenced by the season, the geographic location, the regional climatic conditions, such as the amount of spring rainfall, and the patient's age. LaCrosse virus is the most important arboviral cause of pediatric encephalitis in the United States.^[46] The midwestern states of the United States report the highest incidence of LaCrosse virus infections. The LaCrosse virus belongs to the California group of encephalitis viruses. It is responsible for nearly all infections due to California group viruses in the United States. Most cases occur in late summer to early fall. The vector, *Aedes triseriatus*, is a forest-dwelling mosquito, and the risk of infection is associated with outdoor activities in woodland areas.^[47] St. Louis encephalitis (SLE) occurs as periodic focal outbreaks of encephalitis in the midwestern, western, and southeastern United States, followed by years of sporadic cases. St. Louis encephalitis virus has caused large urban epidemics of encephalitis.^[47],^[48] Western equine encephalitis virus is an alphavirus that infects horses and humans in western North America, with most cases occurring between April and September. Eastern equine encephalitis (EEE) virus is also an alphavirus that infects horses and humans, primarily along the eastern seaboard and the Gulf coast; its peak activity occurs in August and September. Eastern equine encephalitis virus has been isolated from species other than horses including pheasants, piglets, and litters of puppies.^[49] It causes a much more severe encephalitis than western equine encephalitis virus. Venezuelan equine encephalitis virus is endemic in South America and has caused rare cases of encephalitis in Central America and the southwestern United States, particularly in Texas.

Japanese B encephalitis virus is a member of the St. Louis complex of flaviviruses and is the most common cause of arthropod-borne human encephalitis worldwide. Epidemic disease occurs in China and the northern parts of southeast Asia, as well as in areas of India and Sri Lanka.^[50] The principal vector is a rice-field-breeding culicine mosquito. There is no seasonal pattern to Japanese B encephalitis except in some instances when outbreaks are associated with rainfall, irrigation, or floods.^[51] Dengue, a mosquito-borne flavivirus infection that is hyperendemic in Thailand, is a leading cause of hospitalization of children in southeast Asia.^[52] The principal vector is the mosquito *Aedes aegypti*, which breeds indoors in clean water, mainly in artificial water containers.^[51]

The most important tickborne causes of viral encephalitis in North America are Powassan (POW) virus and Colorado tick fever (CTF) virus. Powassan virus is a flavivirus most closely related to Russian spring-summer and Central European encephalitis viruses. The POW virus is widely distributed in the United States, but human infections with POW virus occur infrequently. In the years 1958 to 1994, a total of 24 confirmed POW cases among humans was reported in North America.

The risk of infection is highest in wooded areas, where the potential for contact with infected ticks is highest. [49] Colorado tick fever virus is a member of the family Reoviridae. This virus has caused human infections in Colorado, Utah, Montana, California, Wyoming, Idaho, Oregon, South Dakota, Washington, New Mexico, Nevada, and southern Alberta and British Columbia, Canada. The primary risk of acquiring CTF is through exposure to infected *Dermacentor andersoni* ticks during outdoor recreational activities in mountain areas where the CTF virus is endemic in the months of April through June. [48]

Pathogenesis and Pathophysiology. Arboviral infections are transmitted to humans by a mosquito or tick bite. After local replication of the organism at a skin site, a viremia occurs with seeding of the reticuloendothelial system, including the liver, spleen, and lymph nodes. With continued viral replication at these sites, a secondary viremia occurs, seeding the CNS. [53] The probability of CNS infection depends on the efficiency of viral replication at the extraneural sites and the degree of the ensuing viremia. The arboviruses can invade the CNS through the cerebral capillary endothelial cells of the cerebral blood vessels or through the choroid plexus. [47]

Clinical Features and Associated Findings

California Group Virus Encephalitis. Virtually all cases of California group virus encephalitis in the United States are caused by the LaCrosse strain. This virus typically produces clinically recognizable disease only in children and adolescents (aged 4 to 11 years). The LaCrosse virus may produce an aseptic meningitis or a mild encephalitic illness. A distinct prodromal phase characterized by fever, chills, headache, nausea, vomiting, and abdominal pain lasting 1 to 4 days commonly precedes the onset of symptoms of encephalitis. [54] Encephalitis is characterized by fever, somnolence, and obtundation; seizures occur in approximately 50 percent of children and focal neurological signs in 20 percent, raising consideration of encephalitis due to herpes simplex virus type 1. [47] In adults, infection either is asymptomatic or causes a benign febrile illness or aseptic meningitis. [55]

St. Louis Encephalitis. St. Louis encephalitis virus may cause a mild febrile illness with headache, an aseptic meningitis, or an encephalitis. The onset of encephalitis may be abrupt or preceded by an influenza-like prodrome of malaise, myalgias, and fever. The onset of encephalitis is characterized by symptoms of headache, nausea, vomiting, confusion, disorientation, irritability, stupor, tremors, and occasionally convulsions. The severity of illness increases with increasing age, and almost 90 percent of elderly individuals develop encephalitis. [47] A unique clinical feature of this form of encephalitis is the syndrome of inappropriate antidiuretic hormone secretion with hyponatremia, which can complicate this infection. [55]

Western Equine Encephalitis. Western equine encephalitis tends to occur in children younger than 1 year old and in adults over age 50. [53] Inapparent infections with western equine encephalitis virus are more common than symptomatic cases. Like the other arthropod-borne encephalitides, western equine encephalitis begins with an influenza-like syndrome of fever, malaise, myalgias, pharyngitis, and vomiting. As the disease progresses, irritability, convulsions, or coma develops. [47]

Eastern Equine Encephalitis. Eastern equine encephalitis virus causes a much more severe form of encephalitis than western equine encephalitis virus. Encephalitis is more common in infants and children. There may be an influenza-like prodrome with fever, headache, vomiting, malaise, and lethargy, but more typically patients with eastern equine encephalitis have an abrupt onset of high fever

and convulsions and a rapid progression from stupor to coma. [47], [56] Eastern equine encephalitis may present with focal signs or focal seizure activity, thus mimicking herpes simplex virus encephalitis. [47] In the series by Deresiewicz and colleagues, the mortality rate was 36 percent, and 35 percent of survivors had moderate or severe residual disability. Distinctive radiographic features by computed tomography (CT) or magnetic resonance imaging (MRI) of early basal ganglion and thalamic involvement help distinguish this type of encephalitis from herpes simplex encephalitis.

Venezuelan Encephalitis. Infection with Venezuelan encephalitis virus is typically mild, and encephalitis occurs only rarely. Children and the elderly are at greatest risk for encephalitis. Pharyngitis is a unique clinical feature of this form of arthropod-borne encephalitis. [53]

Japanese Encephalitis. The incubation period of Japanese B encephalitis after a mosquito bite varies from 5 to 15 days. The onset of disease is characterized by a high fever with malaise, headache, nausea, and vomiting. These symptoms last from 1 to 6 days and may resolve or progress to a severe fulminant encephalitis with fever, vomiting, convulsions, and coma. Children most frequently have an encephalitis syndrome. [51]

Dengue Encephalitis. The neurological features of encephalitis due to the dengue viruses include headache, seizures, nuchal rigidity, altered level of consciousness, behavioral disorders, delirium, paralysis, and cranial nerve palsies. The neurological manifestations of CNS dengue virus infection were previously thought to be secondary to vasculitis with cerebral edema, hypoperfusion, hyponatremia, and multiorgan failure, but recently this theory has been challenged by evaluation of a number of cases in which encephalitis occurred early in the illness coinciding with the viremic phase, suggesting that encephalitis is due to direct involvement of the brain by the virus itself. [57]

Tickborne Encephalitis. The onset of encephalitis due to the Powassan virus is abrupt, with headache and fever to 40° C and convulsions. There may be a prodromal phase of sore throat, lethargy, and headache. The encephalitis may be associated with focal neurological signs and may thus mimic herpes simplex virus encephalitis. [48] Infection with the Colorado tick fever virus is typically a biphasic illness. The onset of illness is characterized by fever, chills, arthralgias, myalgias, severe headache, ocular pain, conjunctival injection, nausea, and occasionally vomiting. A petechial or maculopapular rash may be seen. Defervescence may then occur, only to be followed by the recurrence of fever in 2 to 3 days. Aseptic meningitis and encephalitis occur primarily in children and may be associated with a petechial or maculopapular rash or a more severe rash with purpura and petechiae. Disseminated intravascular coagulation and gastrointestinal bleeding may complicate the course of the illness. [48]

Differential Diagnosis. Based on criteria established by the Centers for Disease Control (CDC), a confirmed case of arboviral disease is defined as a febrile illness with mild neurologic symptoms, aseptic meningitis, or encephalitis with onset during a period when arbovirus transmission is likely to occur, plus at least one of the following: (1) fourfold or greater rise in viral antibody titer between acute and convalescent sera; (2) viral isolation from tissue, blood, or cerebrospinal fluid; or (3) specific immunoglobulin M (IgM) antibody in cerebrospinal fluid. A presumptive case is defined as a compatible illness plus either a stable elevated antibody titer to an arbovirus (mf320 by hemagglutination inhibition, mf128 by complement fixation, mf256 by immunofluorescent assay, or mf160 by plaque-reduction neutralization test) or specific IgM antibody in serum by enzyme immunoassay. [48] The differential diagnosis of arbo- viral encephalitis includes herpes simplex virus encephalitis, bacterial, tuberculous, and fungal meningoencephalitis, brain abscess, rickettsial infections, infective endocarditis, CNS vasculitis, and carcinomatous meningitis.

The characteristic abnormalities found on examination of the CSF in patients with arboviral meningitis or encephalitis are: (1) a normal or mildly elevated opening pressure; (2) an initial polymorphonuclear leukocytic pleocytosis early in infection with a shift to a lymphocytic or mononuclear pleocytosis later in the illness; (3) a normal glucose concentration; and (4) a normal or mildly elevated protein concentration. LaCrosse virus has not been isolated from CSF. St. Louis encephalitis virus, eastern equine encephalitis virus, and western equine encephalitis are rarely isolated from CSF. [48] A few distinguishing features of the laboratory diagnosis of arboviral meningitis or encephalitis deserve comment. Eastern equine virus encephalitis is the arboviral infection with the highest CSF white blood cell count. The CSF in patients with eastern equine virus encephalitis has 200 to 2000 cells/mm³, 60 to 90 percent of which are polymorphonuclear leukocytes. The typical cell count in the CSF of SLE infection is less than 200 cells/mm³; however, infection with this virus may be suggested by laboratory evidence of hyponatremia due to the inappropriate secretion of antidiuretic hormone.

Although the CDC criteria for arboviral infection is described above, for general clinical purposes the diagnosis is made by detecting a fourfold or greater increase in virus- specific IgG between the acute and convalescent sera, and/ or by identifying virus-specific IgM in the serum or CSF. [47] The CSF in Japanese B encephalitis usually has a pleocytosis with WBC counts of 10 to 1000/mm³, and viral- specific IgM antibodies can be demonstrated in CSF in 80 percent of patients at the time of admission. [51] Dengue viruses can be isolated from the CSF and detected by the polymerase chain reaction. [57] Neutralizing antibody is usually detectable at the time of onset of illness with Powassan virus. Virus has been isolated from the basal ganglia, cortex, and cerebellum of brain tissue in fatal cases. Colorado tick fever is characterized by leukopenia and in some instances thrombocytopenia. Early in the disease, Colorado tick fever virus can be isolated from serum, but later on it is more easily isolated from blood clots and from erythrocytes. Viremia may last for several months. [48]

Management and Prognosis. There is no antiviral therapy for the arboviral encephalitides. Treatment consists primarily of supportive care with management of the

neurological complications of seizures and increased intracranial pressure.

The majority of patients with California encephalitis recover completely, but 15 percent experience sequelae of behavioral abnormalities or recurrent seizures. Mortality is low, less than 1 percent. Sequelae occur in 20 percent of survivors of St. Louis encephalitis, consisting of irritability, memory loss, and occasionally seizures or motor deficits. The mortality rate is 2 to 20 percent, with the

higher figure occurring in the elderly. Western equine encephalitis has a mortality rate of 5 to 15 percent. Neurological sequelae are rare except in children who develop the disease when they are younger than 6 months of age. In young children, long-term sequelae consist of seizure disorders, paralysis, and developmental delay. Postencephalitic parkinsonism has been reported in some adult survivors of western equine encephalitis. The mortality rate from eastern equine encephalitis is 60 to 75 percent, and neurological sequelae, consisting of mental retardation, seizures, spastic paralysis, and behavioral abnormalities, are common in those that survive. Mortality is less than 1 percent from Venezuelan equine encephalitis, and neurological sequelae are rare. Vaccines for pre-exposure prophylaxis are available for western equine encephalitis, EEE, and Venezuelan equine encephalitis viruses, but not for SLE or LaCrosse virus.

High-dose dexamethasone therapy has been utilized in the treatment of acute encephalitis due to Japanese encephalitis virus, but it appears to have little effect on outcome. A clinical trial of interferon-alpha in Japanese encephalitis patients in Thailand has produced promising results. The intrathecal synthesis of IgM antibody appears to be an important determinant of survival. The majority of patients who have antibodies in their spinal fluid on the day of admission survive; a large proportion of those who do not, die. Japanese encephalitis is preventable through vaccination. For primary immunization, two doses of inactivated Japanese encephalitis virus vaccine are administered at intervals of 7 and 14 days. A third injection is given a few months after primary vaccination to ensure full protection. This vaccination protocol may be all that is necessary for people who live in endemic areas; however, those in nonendemic areas may need further periodic booster injections.

The management of dengue encephalitis is nearly always complicated by the systemic effects of this virus including vasculopathy, thrombocytopenia, and coagulopathy. The majority of patients require transfusion of whole blood, fresh frozen plasma, and platelets. When disseminated intravascular coagulopathy complicates this infection, the mortality rate is high. Full recovery is possible. Of the 24 total cases of Powassan virus encephalitis that occurred in North America from 1958 to 1994, four of the acute infections were fatal, and two patients died 1 and 3 years after onset because of sequelae that were reported to be directly related to the disease. Sequelae are common in patients who survive this infection, the most common of which is hemiplegia. Paralysis and atrophy of the shoulder muscles has also been reported. Few fatalities and minimal sequelae have been reported in cases of Colorado tick fever encephalitis.

Influenza Virus

Epidemiology and Risk Factors. The term influenza derives from a flu epidemic in the 15th century that was attributed to an influence of the stars. Influenza viruses are single-stranded RNA viruses that are members of the orthomyxovirus family. Influenza A virus is a major cause of respiratory disease in children and adults. Influenza B and varicella-zoster virus are the most common antecedent infections in patients with Reye's syndrome. Influenza-type illnesses have been reported to precede the development of acute ascending paralysis, the Guillain-Barre syndrome. In utero exposure to the influenza virus has been suggested as a contributing factor to the development of schizophrenia. The occurrence of influenza in mothers in the first trimester of pregnancy has been associated with an increased risk of neural tube defects. A reversible paralytic syndrome and the Guillain-Barre syndrome have been associated with influenza immunizations.

Pathogenesis and Pathophysiology. The influenza virus is transmitted from person to person by aerosolized or respiratory droplets. The virus attaches to and replicates in ciliated columnar epithelium of the upper and lower respiratory tracts, following which a viremia ensues. The major neurological complications of influenza are Reye's syndrome, postinfectious polyneuritis, and acute viral myositis.

Clinical Features and Associated Findings

Influenza. The symptoms of influenza begin rapidly with fever, usually 101° to 102° F, associated with myalgias, headache, lethargy, and respiratory tract symptoms of dry cough, rhinorrhea, and sore throat. Eye pain and photophobia may occur. Influenza rarely causes gastrointestinal symptoms in adults; however, up to 50 percent of children have nausea, vomiting, and abdominal pain. Systemic symptoms and fever usually last 2 to 3 days and rarely more than 5 days.

Reye's Syndrome. Reye's syndrome occurs primarily in children, most often in association with influenza B and varicella-zoster infections. Reye's syndrome is an acute, noninflammatory encephalopathy associated with hepatic dysfunction due to microvesicular fatty infiltration of the liver. Reye's syndrome usually begins with severe vomiting, and this is one of the cardinal features of this syndrome. Vomiting is followed by or associated with lethargy progressing to stupor and coma. The CDC's criteria for Reye's syndrome include (1) an alteration in the level of consciousness with the CSF containing less than 8 cells/mm³; or (2) an alteration in the level of consciousness and cerebral edema without perivascular or meningeal irritation; and, (3) either microvesicular fatty infiltration of the liver or a greater than threefold rise in serum glutamic-oxaloacetic transaminase (SGOT) level or ammonia.

Postinfectious Polyneuritis. The clinical picture of Guillain-Barre syndrome following an influenza virus infection is indistinguishable from Guillain-Barre syndrome of other causes.

Acute Viral Myositis. Influenza A and B have been associated with myositis. Benign acute myositis is characterized by transient severe pain and weakness affecting the calves; it primarily affects children and occurs during epidemics of influenza.

Differential Diagnosis. The influenza virus can be cultured from throat and nasopharyngeal swabs obtained within 3 days of onset of illness. Acute and convalescent sera should be sent to the laboratory to detect seroconversion or a fourfold or greater increase in virus-specific IgG between the serum samples. A fourfold rise in antibody titer indicates that the patient was recently infected with the influenza virus but is not definitive proof that the influenza virus is the etiological agent of the neurological syndrome.

Management and Prognosis. The majority of acute influenza infections are self-limited. The use of salicylates

(e.g., aspirin) should be avoided in children with flulike symptoms to decrease the risk of Reye's syndrome.

Inactivated and live attenuated influenza vaccines are available. Vaccination is presently recommended for individuals who are at risk for influenza-related complications (e.g., pneumonia, myocarditis, exacerbation of chronic medical conditions); these include individuals older than age 65, persons with chronic cardiopulmonary disease including children with asthma, and residents of chronic care facilities. In addition, persons with chronic illnesses such as diabetes or renal disease and those compromised by immunosuppression should be vaccinated. Individuals who can transmit influenza to high-risk persons such as health care workers, nursing home and chronic care facility employees, and household members of high-risk persons should also be vaccinated.

Measles

Epidemiology and Risk Factors. Measles is one of the three major infectious diseases worldwide and causes about 1.5 million childhood deaths per year. In the 1960s, prior to routine childhood immunization, more than 400,000 cases of measles were reported annually; in comparison, less than 4000 cases were reported annually in the early 1980s. From 1988 to 1990, the incidence of measles increased eightfold. Between 1987 and 1990, 52,846 cases of measles were reported to the CDC. This marked increase in the number of cases of measles was attributed to outbreaks among unvaccinated preschool-age children and to outbreaks among vaccinated school-age children who had received only a single dose of measles vaccine.

Encephalitis is a rare complication of measles infection. It occurs in one of three distinct types: (1) postinfectious or autoimmune encephalomyelitis, which presents as a sudden recurrence of fever with an altered level of consciousness, seizure activity, and multifocal neurological signs during convalescence from measles; (2) subacute sclerosing panencephalitis (SSPE), which presents after a latent period of 6 years or more from an acute measles infection and has an insidious onset of

neurological dysfunction associated with myoclonus and seizure activity; it progresses to coma and death within 1 to 2 years; and (3) subacute measles encephalitis (subacute inclusion body encephalopathy, progressive infectious measles encephalitis), which most commonly occurs in immunosuppressed individuals after a latent period of 1 to 10 months between the measles-like illness and the encephalitis.^[72]^[73]^[74] Encephalomyelitis occurs in 1 per 1000 individuals who develop measles (mostly in older persons), and between 5 and 10 children per million who contract measles develop subacute sclerosing panencephalitis.^[75]

Pathogenesis and Pathophysiology. Measles virus is spread by respiratory droplets, and only a small amount of virus is required to produce the infection. Virus replicates in the respiratory tract and then spreads to the local lymphatic tissues. Amplification of virus in the lymph nodes produces a primary viremia that results in the spread of virus to multiple lymphoid tissues and the skin, kidney, gastrointestinal tract, and liver. In these organs, the virus replicates in endothelial cells, epithelial cells, and monocytes and macrophages. Measles virus can be detected in peripheral blood leukocytes at the time of onset of prodromal symptoms and for several days after the onset of the rash. The fusion of the measles virus-infected cells leads to the formation of multinucleated giant cells, a pathological hallmark of this infection.^[74]

Postmeasles encephalomyelitis (postinfectious encephalomyelitis, autoimmune encephalomyelitis) is a perivenular demyelinating disease rather than an inclusion body encephalitis. Histologically, the lesions resemble those induced experimentally by injection of animals with myelin proteins with adjuvant, that is, experimental, autoimmune encephalomyelitis.^[69] There is little evidence of virus in the brain, as assessed either by virus isolation and antigen and RNA detection or by the appearance of measles virus-specific antibody in the cerebrospinal fluid.^[74]

The pathogenesis of subacute sclerosing panencephalitis and of subacute measles encephalitis has, however, been attributed to measles virus persistence in the central nervous system.^[73]^[76] The histological features of SSPE include inflammatory infiltrates, glial nodules, degeneration of neurons, hyperplasia of astrocytes and microglia, and intranuclear inclusion bodies of Cowdry type A with abundant measles virus antigen.^[72] The histological diagnostic features of subacute measles encephalitis include intranuclear eosinophilic, and sometimes intracytoplasmic, inclusion bodies in neurons and oligodendrocytes with abundant paramyxovirus nucleocapsids and measles virus antigen.^[72]^[73]

Clinical Features and Associated Findings

Measles. The onset of measles is characterized by fever, cough, coryza, and conjunctivitis associated with Koplik's spots, which are small, white punctate lesions on the buccal mucosa. A maculopapular rash appears 2 to 3 days later, first on the face and behind the ears and then spreading in a centrifugal fashion to the trunk and extremities.^[74] The cephalocaudal spread of the maculopapular rash is quite characteristic of measles.

Postinfectious Encephalomyelitis. Postmeasles encephalomyelitis usually occurs within 2 weeks after the onset of the rash. There is a sudden recurrence of fever associated with a decrease in consciousness, seizures, and multifocal neurological abnormalities. Mortality is approximately 20 percent, and sequelae are common in survivors.^[69]^[74]

Subacute Sclerosing Panencephalitis. SSPE is a progressive central nervous system disorder that begins several years after measles infection in early childhood and is characterized by behavioral abnormalities, intellectual deterioration, motor rigidity, and myoclonic jerks that progress to coma and death.

Subacute Measles Encephalitis. Neurological signs resulting from subacute measles encephalitis typically develop 1 to 9 months after exposure to measles or from the time of onset of clinical measles. The disease is characterized by seizure activity, an alteration in the level of consciousness, and focal neurological deficits including hemiparesis, ataxia, and disturbances of language and vision. Seizure activity may be focal or generalized, and epilepsy partialis continua is a prominent feature.^[73]^[75] The majority of patients who develop subacute measles encephalitis are immunosuppressed.

Differential Diagnosis. The differential diagnosis of measles includes illnesses associated with fever and an erythematous maculopapular rash such as scarlet fever, rubella, meningococcemia, Kawasaki's disease, toxic shock syndrome, and erythema multiforme due to a hypersensitivity to medications.^[77]^[78]

During the viremia of measles infection, measles virus can be isolated from peripheral blood mononuclear cells.^[79] The clinical diagnosis, however, is more typically based on the presence or a history of the characteristic findings of fever, an erythematous maculopapular rash demonstrating a cephalocaudal spread, coryza, cough, conjunctivitis, and Koplik's spots. Laboratory results that support a diagnosis of measles are the detection of measles IgM and a fourfold increase in measles IgG between acute and convalescent sera.^[77] The diagnosis of postmeasles encephalomyelitis is based on the occurrence of encephalitis within 2 weeks of the rash of measles associated with a recurrence of fever.

The diagnosis of SSPE is typically based on the characteristic clinical appearance as described earlier and the appearance of periodic complexes on the EEG, which in the presence of clinical myoclonic jerks have a one-to-one relationship with the periodic EEG complexes.^[80] Measles antibody titers in CSF are typically elevated in patients with SSPE.

The diagnosis of subacute measles encephalitis can be confirmed only by brain biopsy but is suggested by the following: (1) a history of measles or exposure to measles within 1 to 10 months of presentation; (2) an immunocompromised state; (3) refractory focal seizures (epilepsia partialis continua) as part of the neurological symptomatology; and (4) absence of fever.^[73] Examination of the CSF reveals a mild mononuclear pleocytosis and a mild elevation in the protein concentration, but in about a third of the patients the CSF is entirely normal. The electroencephalogram is slow with nonspecific abnormalities. Detection of measles virus RNA by polymerase chain reaction technology may make the diagnosis of subacute measles encephalitis considerably easier.

Management and Prognosis. The dramatic increase in measles from 1987 to 1990 led to two principal changes in the recommendations for measles vaccination made by both the Immunization Practices Advisory Committee (ACIP) and the American Academy of Pediatrics Committee on Infectious Diseases of the Centers for Disease Control and Prevention: (1) the age for the initial measles vaccination was changed from 15 months to 12 months, and (2) a second dose of measles vaccine was recommended at either 4 to 6 years or at the time of entry to middle or junior high school.^[71] The vaccine in use today is a live attenuated measles virus that was developed from the original Edmonston strain of measles virus isolated by Enders in 1954.^[74]

Measles during pregnancy has a more severe clinical course and is associated with an increased risk of premature labor or spontaneous abortion.^[70]^[81] Pregnancy is a significant risk factor for mortality during measles.^[70] Measles infection in pregnancy does not, however, appear to be associated with an increased risk of congenital anomalies, leading to the suggestion that although infection with measles increases the risk of premature termination of pregnancy within the first 2 weeks of onset of the rash, if pregnancy continues, the likelihood of a favorable outcome is high.^[81] It is recommended that susceptible pregnant women exposed to a person with active measles receive serum immune globulin (gamma globulin 16.5 percent) within 6 days of exposure to prevent or modify subsequent disease. All infants born to mothers with active measles in the 6 days before delivery should also receive intravenous immunoglobulin prophylaxis (500 mg/kg) immediately after birth and again 1 week later.^[70]^[81]^[82] Ribavirin has been shown to be effective against measles virus in vitro. It has been suggested that ribavirin might be useful as therapy for immunocompromised patients with measles, although anecdotal case reports in which intravenous ribavirin was used have not demonstrated a therapeutic effect. Ribavirin does cross the placenta and is present in amniotic fluid in potentially therapeutic levels. Teratogenic effects have been reported in rats (but not primates) given high doses of ribavirin during pregnancy; therefore, there is some concern about the possible teratogenicity of this drug.^[70]

Treatment of the encephalitis syndrome described earlier that may complicate measles infection is primarily supportive. There are a few favorable case reports of the use of ribavirin in patients with subacute measles encephalitis; however, firm recommendations cannot be made at this time.^[73]^[83] There are reports of clinical improvement in patients with SSPE who were treated with inosiplex and intrathecal interferon-alpha, as well as reports of patients who showed no improvement with this therapy. No firm recommendations can be made at this time.

Arenavirus (Lymphocytic Choriomeningitis Virus)

Epidemiology and Risk Factors. The natural reservoir for the lymphocytic choriomeningitis virus (LCMV) is the common house mouse. Hamsters and laboratory animals can also be infected with this virus. Most human infections result from contact with house mice.^[84]^[85] Four clinical syndromes due to infection with LCMV have been described: (1) subclinical asymptomatic infection, (2) nonmeningeal influenza-like illness, (3) aseptic meningitis, and (4) meningoencephalomyelitis.^[84] The

LCMV was the first specific etiological agent of the aseptic meningitis syndrome to be identified. [85]

Pathogenesis and Pathophysiology. The LCMV is a member of the arenavirus family and is maintained in nature primarily by vertical intrauterine infection in mice, hamsters, and rodents, producing a chronic asymptomatic infection in the offspring. These animals shed the virus in saliva, nasal secretions, semen, milk, urine, and feces. [87] The route of transmission to humans remains unknown but is presumed to occur through contamination of open cuts or aerosolized spread of virus. There is no evidence of person- to-person transmission of LCMV infection. [86] Local replication of LCMV is followed by dissemination to the reticuloendothelial system with a subsequent viremia. [87] The CNS is infected during the course of the viremia.

Clinical Features and Associated Findings. Clinical manifestations of acute LCMV infection in children and adults range from asymptomatic seroconversion to an in

fluenza-like illness to an aseptic meningitis, and rarely to a meningoencephalomyelitis. In patients with aseptic meningitis there is often a history of a biphasic illness. The first stage resembles an influenza-like illness. This is then followed by a symptom-free period of time varying from a few days to 3 weeks, which is followed in turn by the acute onset of high fever, headache, vomiting, and signs of meningeal irritation. [84] Although the clinical presentation of CNS infection with LCMV is most frequently an aseptic meningitis, it may also be a meningoencephalitis. Congenital LCMV infection can result in intrauterine or early neonatal death, hydrocephalus, chorioretinitis, and psychomotor retardation. [87]

Differential Diagnosis. The diagnosis of LCMV infection can be made by the appearance of IgM antibodies in a serum sample or by a fourfold or greater rise in antibody titer between the acute and convalescent serum samples. The classic cerebrospinal fluid abnormalities include the following: (1) a lymphocytic pleocytosis of 300 to 3000 cells/mm³, and (2) hypoglycorrhachia. [84] LCMV is one of the few etiological agents of an aseptic meningitis with hypoglycorrhachia. LCMV can be isolated from the CSF. The diagnosis of congenital LCMV infection is based on the clinical presentation and laboratory evidence of persistently high IgG immunofluorescent antibody (IFA) titers. [87]

Management. Prevention of LCMV infection is the priority. Laboratory animals acquired from areas where arenaviruses are indigenous should be tested for LCMV infection. Pregnant women should avoid contact with laboratory and household mice and hamsters. LCMV aseptic meningitis in children and adults is self-limited and complete recovery is the rule.

Rubella

Epidemiology and Risk Factors. Since the rubella vaccine became available in 1969, rubella and the neurological complications of rubella have been due primarily to periodic outbreaks of the disease. The neurological syndromes associated with rubella virus infection include (1) the congenital rubella syndrome, (2) acute encephalitis complicating rubella, (3) postrubella polyradiculoneuritis, and (4) progressive rubella panencephalitis. [88], [89] Acute encephalitis is a rare complication of rubella infection, with a reported incidence of 1 in 5000 to 1 in 24,000 cases. [90] Postrubella polyradiculoneuritis complicates rubella in an estimated 4 percent of patients. Only five cases of acute postrubella polyradiculoneuritis have been reported in the last 30 years. [89] The most common neurological complication of rubella infection is the congenital rubella syndrome. The gestational age at the time of infection determines the risk of fetal anomaly. [90] The risk of congenital rubella syndrome is greatest when infection occurs during the first trimester. Progressive rubella panencephalitis is a slow virus disease of the central nervous system that has many clinical similarities to subacute sclerosing panencephalitis caused by measles virus and is an uncommon late-onset manifestation of congenital rubella. [91]

Pathogenesis and Pathophysiology. The rubella virus is a single-stranded RNA virus. Infection is acquired by droplet inhalation; viral replication occurs in the nasopharynx with a subsequent viremia. The CNS is infected in the course of the viremia. Maternal viremia during the first trimester of pregnancy can infect the placenta and spread to the fetus. [92] Disease in the fetus exposed to this virus during the first trimester is severe. [93]

Clinical Features and Associated Findings

Rubella. Rubella is a generalized maculopapular exanthem associated with fever. Arthralgias, lymphadenopathy, and conjunctivitis may also be associated with the acute illness.

Acute Encephalitis. Acute encephalitis is a rare complication of rubella infection. Symptoms usually appear within 1 to 6 days after the typical maculopapular rash develops and are characterized by headache, dizziness, lethargy, behavioral abnormalities, coma, and generalized or focal seizures in as many as 50 percent of cases. The case fatality rate of acute rubella encephalitis is low, and most nonfatal cases recover rapidly with minimal or no sequelae. [94]

Postrubella Polyradiculoneuritis. Postrubella polyradiculoneuritis develops abruptly as the exanthem of rubella fades and has the clinical features of the Guillain-Barre syndrome. The duration of the illness is usually brief. [89]

Congenital Rubella Syndrome. Features of the congenital rubella syndrome include intrauterine growth retardation, sensorineural deafness, cataracts, congenital glaucoma, patent ductus arteriosus, pulmonic stenosis, microcephaly, mental retardation, meningoencephalitis, purpuric rash, hepatosplenomegaly, and radiolucent bone densities. [94] In addition to these clinical signs, which are present at birth, children with congenital rubella syndrome may develop delayed-onset progressive rubella panencephalitis, a slow virus disease of the CNS that has many clinical similarities to subacute sclerosing panencephalitis caused by measles virus. [91] This syndrome may also follow childhood rubella in rare instances. [95] Symptoms typically begin between the ages of 8 and 19 years with deterioration in school performance and behavior sometimes associated with seizures. The neurological deterioration progresses to a global dementia with ataxia, spasticity of gait, dysarthria, and dysphagia. Progressive pallor of the optic disks and a maculopathy occur. [96]

Differential Diagnosis. Examination of the CSF in patients with rubella encephalitis may be normal or may demonstrate a mild to moderate mononuclear cell pleocytosis and an elevated protein concentration. Virus is rarely isolated from the CSF in patients with rubella encephalitis. Electroencephalography may demonstrate diffuse or focal abnormalities. Diagnosis is made by detection of rubella-specific IgM antibodies in serum or by demonstration of a fourfold rise in rubella-specific IgG in the convalescent sera compared to the acute sera. [88] Similarly, the diagnosis of postrubella polyradiculoneuritis is based on the findings of a demyelinating peripheral neuropathy following an exanthematous illness. One of the characteristics of the rash of rubella is that the maculopapular rash almost invariably begins on the face before it becomes generalized, and it is often associated with posterior cervical adenopathy. [97] A description of this type of rash preceding the clinical syndrome of polyradiculoneuritis is suggestive of rubella. By the time the polyradiculoneuritis develops, serum for IgM antibodies to rubella virus may

be negative. A single elevated rubella IgG titer is suggestive but not diagnostic of a recent rubella infection, but when associated with a history of the rubella rash as described above it is quite compatible with the diagnosis.

In infants who have clinical evidence of the congenital rubella syndrome at birth, serum IgM antibody to rubella virus and viral cultures should be obtained. Other laboratory abnormalities supporting the diagnosis of congenital rubella syndrome include hyperbilirubinemia, thrombocytopenia, elevated serum transaminase levels, and long bone radiographs demonstrating metaphyseal lucencies. Neuro- imaging studies reveal intracranial calcifications, delayed myelination, or ventriculitis. [96] Several different methods have been used to make an intrauterine diagnosis of rubella infection including isolation of the rubella virus in the amniotic fluid obtained by amniocentesis, cordocentesis, use of the polymerase chain reaction method on extracts from chorionic villi and placenta, and ultrastructural examination of amniotic fluid cells using transmission and scanning electron microscopy. [97] Examination of the CSF in progressive rubella panencephalitis demonstrates a mild lymphocytic pleocytosis (0 to 37 cells/mm³), a moderate increase in the protein concentration (60 to 142 mg/ml), and intrathecal immunoglobulin synthesis. [98]

Management and Prognosis. The key to management of the neurological complications of rubella is prevention. The rubella vaccine licensed for use in the United States is a live attenuated RA 27/3 rubella virus. [92] The immunogenicity of the vaccine is reduced by whole blood transfusion; therefore, it is recommended that rubella vaccine not be given for 3 months after immunoglobulin or whole blood transfusion. [99] The incidence of arthritis after vaccination is low when the RA 27/3 strain of rubella vaccine is used. Breast feeding is not a contraindication to postpartum immunization. Infants infected with the rubella virus through breast milk may experience a mild rash, but the majority remain asymptomatic, and no serious adverse effects have been reported. [94] Currently, the first dose of rubella vaccine is given to

children as part of the measles- mumps-rubella (MMR) vaccine at 12 to 15 months of age. A second dose of the MMR vaccine is recommended when the child first enters school or later when he or she enters middle school. ^[92]

Human T-Cell Lymphotropic Virus Type 1

Epidemiology and Risk Factors. The human T-cell lymphotropic virus type 1 (HTLV-1) causes a rapidly progressive adult T-cell leukemia or lymphoma (ATLL), and a slowly progressive neuromyelopathy known as HTLV- 1-associated myelopathy-tropical spastic paraparesis (HAM-TSP). ^[98], ^[99] The distribution of HTLV-1 infection is worldwide with major foci of endemic infection in southwestern Japan, the Caribbean, Central and South America, sub-Saharan Africa, the Middle East, and Melanesia. It is estimated that between 10 and 20 million people are infected with HTLV-1. In the United States and Europe, HTLV-1 is found primarily in intravenous drug abusers. ^[98] Transmission of HTLV-1 can occur from mother to child primarily by breast milk, between intravenous drug addicts through the sharing of contaminated needles and syringes, by sexual contact, and by the transfusion of contaminated blood products. Vertical transmission of HTLV-1 from mother to child has been reported to occur in 15 to 20 percent of children born to HTLV-1 positive mothers. Breast milk appears to be the principal route because seroconversion rates are 14 to 20 percent for breast-fed infants compared to 3 to 5 percent for bottle-fed infants. ^[100] Sexual transmission of HTLV-1 is fairly inefficient compared to transmission of the human immunodeficiency virus (HIV). Blood transfusion is, however, a very efficient means of transmission of HTLV-1, and the greatest risk is incurred by recipients who receive seropositive blood stored for less than 1 week, who require multiple transfusions, or who receive immunosuppressive therapy at the time of the transfusion. ^[101]

Pathogenesis and Pathophysiology. There are presently two major theories of the pathogenesis of HAM- TSP, an autoimmune model and a cytotoxic model. In the autoimmune model, HTLV-1 activates autoreactive T cells, which then migrate to the central nervous system, penetrate the blood-brain barrier, and stimulate the production of inflammatory cytokines, leading to subsequent tissue destruction. ^[99], ^[102] In the cytotoxic model, tissue destruction is caused by a CD8-mediated cytolytic attack against HTLV-1-infected CNS cells or infected CD4 T cells in the CNS. An early event in HAM-TSP appears to be a breakdown of the blood-brain barrier, leading to perivascular influx of mononuclear cells. CD4 T cells are the predominant cell type early in disease, but CD8 T cells are found almost exclusively in the later stages of disease. As the duration of HAM-TSP progresses, an increasing number of CD8 cells infiltrate the CNS. This infiltration is associated with an upregulation of HLA class 1 and class 2 molecules and an increased expression of cytokines. The end result is demyelination with axonal involvement that is widespread in the spinal cord, and the corticospinal tracts tend to be more affected than the more heavily myelinated posterior columns. The thoracic spinal cord is the area of maximum involvement. ^[99], ^[103]

Clinical Features and Associated Findings. HTLV- 1-associated myelopathy-tropical spastic paraparesis is a slowly progressive spastic paraparesis marked by hyperreflexia, bladder dysfunction, constipation, and impotence in males. Sensory abnormalities due to demyelination of the posterior columns occur less frequently than motor abnormalities and present primarily as paresthesias of the lower extremities. ^[101]

Differential Diagnosis. The differential diagnosis includes myelopathy due to a compressive lesion of the cord from a disk, tumor, or infection, subacute combined degeneration resulting from vitamin B₁₂ deficiency, HIV-1 myelopathy, multiple sclerosis, and syphilis.

Serological testing should be performed to detect HTLV- 1 antibodies in serum. Magnetic resonance imaging (MRI) of the brain may demonstrate hyperintense lesions in the subcortical white matter on T2-weighted scans, resembling the lesions of multiple sclerosis. ^[104] Elevated antibody titers to HTLV-1 can be detected in blood and cerebrospinal fluid of patients with HAM-TSP.

Management and Prognosis. The presence of inflammatory cells including macrophages and T cells in

HAM-TSP spinal cord material, in addition to the upregulation of HLA and cytokine molecules, suggests that an increase in immunological activity in the CNS is the basis of the pathogenesis of HAM-TSP. ^[103] Immunosuppressive therapy is the only modality available at the present time to treat HAM-TSP. There is no specific antiviral therapy. The best means of treatment may be prevention through an HTLV-1 vaccine, and it has been suggested that the development of vaccination against the HTLV-1 retrovirus would serve as a pathfinder for the development of a vaccine against HIV. ^[98]

DNA VIRUSES

Herpes Simplex

Epidemiology and Risk Factors. Herpes simplex virus (HSV) infections of the central nervous system are of several types: (1) an acute encephalitis, (2) a benign recurrent lymphocytic meningitis, (3) an acute facial nerve paralysis, (4) recurrent ascending myelitis, and (5) a neuritis localized to a single sensory nerve. Neonatal HSV infections occur at a rate of approximately 1 in 3500 to 5000 deliveries per year in North America. Three forms of infection of the newborn are recognized: infection localized to the skin, eye, and mouth (SEM); encephalitis; and disseminated disease with involvement of the CNS. Neonatal HSV infections are usually caused by HSV type 2 (HSV-2).^[105]

In children aged 6 months or older and in adults, HSV type 1 (HSV-1) is the most common cause of sporadic fatal encephalitis. Herpes simplex encephalitis is estimated to occur in 1 in 250,000 to 500,000 persons per year.^[106] HSV-2 is increasingly recognized as the etiological agent of benign recurrent lymphocytic meningitis, and HSV-1 as the etiological agent of acute facial nerve paralysis, Bell's palsy.

Pathogenesis and Pathophysiology. The human herpesviruses are neurotropic viruses that are able to establish active and latent infections in the CNS and can cause tissue damage through viral replication in nervous tissue and reactivation from the latent state.^[107] The pathogenesis of neonatal HSV disease is different from that of HSV disease in older infants, children, and adults. Neonatal HSV infection is acquired most commonly when the fetus comes in contact with infected maternal genital secretions. The type of maternal infection, whether primary or recurrent, has a significant influence on the risk of infection to the fetus. Maternal primary infection at the time of delivery is associated with a fetal risk of infection of approximately 35 percent. Maternal recurrent infection at the time of delivery is associated with a significantly lower risk to the fetus of approximately 3 percent.^[105]

There are two forms of HSV encephalitis during the neonatal period. In babies with encephalitis alone, the illness begins, on average, within 2 weeks of birth. Infection of the CNS by HSV in these neonates is thought to occur by intraneuronal routes. The majority of these babies do not develop skin lesions, and brain disease is often localized to one or both temporal lobes, but it can progress to involve other areas of the brain. In contrast, in newborns with encephalitis resulting from disseminated disease, symptoms of brain involvement begin at the age of 7 to 9 days or earlier. The CNS becomes infected through bloodborne spread of the virus, and neuroimaging procedures reveal multiple areas of hemorrhagic necrosis throughout the cerebral cortex.^[105], ^[106]

In children and adults, HSV-1 encephalitis occurs as either an acute infection or as reactivation of latent infection in the trigeminal ganglion. Infection most commonly involves the temporal cortex, the orbital-frontal cortex, and the limbic structures. In most cases the initial infection begins in the oral cavity, and the virus spreads transneurally along a division of the trigeminal nerve to the trigeminal ganglion.^[107] In experimental animal models of HSV-1 encephalitis, intranasal inoculation leads to viral entry via the olfactory nerve with subsequent infection of the olfactory bulb. Infection then develops in the temporal cortex analogous to human disease; however, the olfactory bulb is rarely affected in humans, and therefore the olfactory nerve is less likely to be the site of viral entry in humans.^[108] The extent and severity of CNS disease is related to the neurovirulence of the virus, the degree of viral inoculum, the immunocompetence of the individual, and possibly genetic determinants of susceptibility to HSV infection.^[109]

The human herpesviruses have the ability to establish lifelong latent infection in the peripheral sensory ganglia (PSG), in the trigeminal ganglion, and in the motor neurons of the hypoglossal nucleus. During acute infection, cells that are infected with HSV-1 ultimately die. The pathogenesis of virus that establishes latency is fundamentally different. Following peripheral inoculation, HSV-1 DNA viral particles are carried by retrograde axonal flow to the PSG. Since HSV is a lytic virus and replication within a cell results in cell death, latency cannot be established in cells in which the virus has completed a full replication cycle. During attachment of HSV-1 to the axonal membrane of the peripheral nerve, the virus loses its envelope, and the contents of the tegument as well as the capsid are transported to the neuronal nucleus. Vmw65, an HSV-1 transactivating protein that is a component of the viral tegument, has a role in this process. The amount of Vmw65 that is carried with the virus to the cell nucleus eventually determines the fate of the infection. If sufficient amounts reach the neuronal cell body, a replication cycle ensues, and the cell dies; if, however, the amount of Vmw65 is insufficient, no replication cycle begins, and latent infection is established.^[107] No infectious viral particles are present during latent infection. During latent HSV-1 infection the linear DNA is present as a circular molecule that is not integrated into the host cell DNA.^[110] External stimuli triggering reactivation of HSV include injury to tissues innervated by the neurons harboring latent infection, and the systemic conditions of exposure to sun, fever, malignancy, and immunosuppression. Even after numerous repeated bouts of reactivation, most patients do not have permanent sensory loss or any other neurological deficit in the affected dermatome, presumably because reactivation is not associated with significant destruction of latently infected neurons.^[107]^[108]^[109]^[110] The nature of the latent state of the HSV virus in the trigeminal ganglion is not as well understood as HSV infection in the peripheral nervous system. CNS disease as

a result of HSV-1 infection, herpes encephalitis, in immunocompetent individuals is a very rare single event, whereas HSV infection in the peripheral nervous system may recur many times during an individual's lifetime. It is estimated that in approximately a third of patients, HSV-1 encephalitis occurs during the primary viral infection, and that in the other 70 percent, HSV-1 encephalitis is due to reactivation of latent infection in the trigeminal ganglion.^[107] The pathogenesis of herpes simplex virus infection as a cause of benign recurrent lymphocytic meningitis is postulated to be due to HSV-2 primary infection or to reactivation in a sacral dorsal root ganglion that seeds the CSF subarachnoid space and produces meningitis.^[111] The pathogenesis of herpes simplex viral infection in acute facial nerve paralysis is presumed to be reactivation of latent infection in the geniculate ganglion.^[112]

Clinical Features and Associated Findings

Acute Encephalitis. As discussed in the preceding section on pathogenesis, HSV encephalitis typically involves the temporal lobe or lobes, the orbital-frontal cortex, and the limbic structures. The clinical presentation is that of a focal encephalitis characterized by focal neurological deficits (hemiparesis in approximately a third of patients), focal seizure activity often involving the temporal lobe, headache, altered behavior, personality changes, fever, and altered levels of consciousness. The classic paper on diseases that mimic herpes simplex encephalitis appeared in JAMA in 1989.^[113] This study, which included a total of 432 patients who underwent brain biopsy for presumptive herpes simplex encephalitis, predated the routine use of MRI and the availability of CSF polymerase chain reaction (PCR). Today the differential diagnosis of acute focal encephalitis with fever, after neuroimaging and CSF analysis, is that of a focal viral encephalitic process. The causes of a focal viral encephalitic process are listed in [Table 41-4](#).

Recurrent Lymphocytic Meningitis. HSV-2 is an etiologic agent of benign recurrent lymphocytic meningitis (Mollaret's meningitis).^[111] This meningitis is characterized by recurrent attacks of fever, headache, and meningeal irritation that last from 2 to 5 days. There may also be symptoms of a sacral radiculitis.

Bell's Palsy. HSV is an etiological agent of acute facial nerve paralysis.^[112]

Differential Diagnosis. MRI is preferred over the CT scan for demonstration of the early lesions of herpes simplex virus encephalitis. On T2-weighted images high signal intensity lesions in the medial and inferior temporal lobes may be seen extending up into the insula. The cerebrospinal fluid is under increased pressure, the protein concentration is mildly to moderately elevated, and a lymphocytic pleocytosis is present, as are red blood cells and/or xanthochromia, which reflect the hemorrhagic necrotic nature of the encephalitis; the glucose concentration is normal or mildly decreased. CSF viral cultures for HSV-1 are almost always negative.

The PCR technique, a highly sensitive and specific test for herpes simplex virus encephalitis, may be negative initially in the first 24 to 48 hours of infection but then becomes positive and remains positive for up to 2 weeks, at which time it again becomes negative. HSV DNA was detected by PCR in the CSF of 53 (98 percent) of 54 patients with biopsy-proven HSV encephalitis. Positive results were found in three (6 percent) of 47 patients whose brain tissue was culture negative.^[114] False-positive PCR analysis for HSV DNA has been reported, and a laboratory with expertise in the PCR technique should be used.^[115] CSF and serum should also be sent for HSV antibody assay. The intrathecal synthesis of HSV-specific antibody can be detected, usually within 3 to 10 days or more after the onset of symptoms, and remains positive for several days after the PCR becomes negative. A serum-to-CSF ratio of less than 20:1 suggests intrathecal production of antibodies to HSV-1. The electroencephalogram may also contribute to the diagnosis by showing periodic focal or unilateral high-amplitude complexes consisting of a single wave or a group of waves that repeat at fairly regular intervals and are expressed maximally over the involved temporal lobe. For the diagnosis of benign recurrent lymphocytic meningitis, CSF should be analyzed by the PCR method for HSV-2 and/or HSV-1.^[111]

Establishing the etiological agent of a facial nerve paralysis is typically difficult except when the characteristic lesions of the Ramsay Hunt syndrome are present. The PCR technique has been used to detect HSV DNA in facial nerve endoneurial fluid and in patients with Bell's palsy, thus identifying HSV-1 as an etiological agent.^[116]

Management. Acyclovir is the drug of choice for neonates with HSV infections of the CNS and for patients with herpes simplex virus encephalitis. While the standard of care has been a dose of 10 mg/kg three times daily (for a total of 30 mg/kg/day) for 14 days, higher dosages and longer courses are being investigated. Approximately 5 to 10 percent of patients with herpes simplex encephalitis show a relapse clinically.^[106] It is recommended that the use of brain biopsy be reserved for patients in whom the diagnosis remains unclear despite the diagnostic studies described above and for those in whom progressive neurological deterioration occurs despite acyclovir therapy.^[106] Patients with HSV-related Mollaret's meningitis may benefit from prophylactic acyclovir because this treatment has been demonstrated to be effective in preventing recurrent genital herpes.^[117] A combination of oral acyclovir and prednisone has also been recommended for the treatment of acute idiopathic facial nerve palsy, but firm recommendations cannot be made at this time.

Varicella-Zoster Virus

Epidemiology and Risk Factors. Varicella-zoster virus (VZV) is the etiological agent of chickenpox. Von Bokay was the first to observe that susceptible children might develop varicella after exposure to the herpes zoster virus. Joseph Garland, a long-term editor of the *New England Journal of Medicine*, was the first to suggest that zoster reflected activation of a latent varicella virus.^[118] In 1954, Thomas Weller confirmed von Bokay's observation that children develop varicella following exposure to patients with herpes zoster by demonstrating, with tissue culture and antibody studies, that the two diseases were caused by the same virus.^[119] The likelihood of developing zoster increases with advancing age, a phenomenon attributed to immune senescence and a decline in the VZV-specific

T-lymphocyte population.^[120] Varicella, or chickenpox, results from the initial exposure to VZV, and approximately 1 in 1000 to 4000 patients with varicella develop neurological complications of encephalitis (which most often presents as an acute cerebellar ataxia), aseptic meningitis, polyneuritis, multiple cranial neuropathies, or Reye's syndrome.^[119] Postherpetic neuralgia is the most common neurological complication of zoster. Varicella-zoster virus is also the etiological agent of the Ramsay Hunt syndrome. J. Ramsay Hunt introduced the term herpes zoster oticus in 1907 to refer to a herpetic inflammation of the geniculate ganglion.^[121] Varicella-zoster virus encephalitis is increasingly recognized in immunosuppressed individuals, particularly those with the acquired immunodeficiency syndrome, and is characterized by multifocal ischemic and hemorrhagic infarctions associated with demyelination.^[122]

Pathogenesis and Pathophysiology. VZV is a double-stranded DNA virus. Initial infection occurs in the mucosa of the upper respiratory tract and/or in the conjunctivae. The initial site of replication of the virus is unknown but most likely includes adenoid-tonsillar tissues of the head and neck. A primary viremia occurs 4 to 6 days later. The virus then undergoes a second cycle of replication at multiple sites within the host. Thereafter, a second viremia occurs with infection of the capillaries of the skin and the appearance of the characteristic vesicular lesions of chickenpox.^[123]

The mechanism by which VZV establishes latency in the sensory ganglia is not as well understood as the mechanism by which HSV establishes latency. However, by analogy to HSV, it is presumed that viral multiplication in epithelial cells extends locally to involve the distal ramifications of sensory nerves. The virus then travels by axonal transport along the sensory nerves to the neuronal cell body in the sensory ganglia. The VZV virus may also arrive at the sensory ganglia via a hematogenous route during the viremic stage of chickenpox. Once in the ganglia, VZV establishes a lifelong latent infection. Non-neuronal cells are also involved in the pathogenesis of VZV latency. In contrast, in primary HSV infection few non-neuronal cells are infected. Zoster exhibits a predilection for the mid to lower thoracic (T3-T12), upper lumbar (L1-L2), and ophthalmic (V1) dermatomes. The propensity for zoster to occur in these dermatomes is attributed to the fact that chickenpox lesions are concentrated in these regions; thus, there is a greater proportion of cells in the corresponding sensory ganglia that become latently infected via neural transport.^[120] In an autopsy series of 14 adults in which the PCR technique was used to detect VZV DNA in the sensory ganglia, VZV DNA was detected in the trigeminal ganglia in 10 of 11 (91 percent) adults and in the thoracic ganglia in 12 of 14 (86 percent) adults.^[124] Reactivation of VZV from the sensory ganglia leads to centrifugal migration of the virus through the nerve to the epithelial surface of the corresponding dermatome, yielding the classic vesicular eruption.^[120] Pathological studies of sensory ganglia during herpes zoster show extensive necrosis and neuronal destruction, and it has been suggested that zoster-associated neuralgia may be a consequence of this extensive cytopathology.^{[110], [120]}

Clinical Features and Associated Findings. As described earlier, the neurological complications of varicella include encephalitis, aseptic meningitis, polyneuritis, multiple cranial neuropathies, and Reye's syndrome.

Encephalitis. Approximately 1 in 4000 children with varicella under the age of 15 develop acute cerebellar ataxia days to a week following the appearance of the varicella rash. There is a 5 percent mortality rate and a 17 percent morbidity rate, including mental retardation, seizures, and ataxia.^[119]

Varicella-zoster virus encephalitis in immunosuppressed patients occurs days to months following zoster or may develop without any history of a vesicular rash. The symptoms of encephalitis include fever, seizures, focal neurological deficits, and an alteration in consciousness. There is radiological evidence of multifocal ischemic and hemorrhagic infarctions that involve white matter more than gray matter and are often concentrated at the gray-white matter junction. Small demyelinating lesions with preservation of axons are also seen and are attributed to small vessel vasculopathy.^[122]

Facial Nerve Paralysis. Both herpes simplex virus and VZV are etiological agents of Bell's palsy. VZV is more likely than HSV to cause a complete seventh nerve paralysis with concomitant severe pain and sensorineural hearing loss. Complete recovery of facial function may not occur.^[121]

Reye's Syndrome. Reye's syndrome is discussed in the earlier section on influenza virus in this chapter.

Neuralgia. Pain is the most common symptom of zoster and may precede the eruption by days to weeks. It may occasionally be the only manifestation--the so-called zoster sine herpate.^[125] The pain of zoster tends to resolve with time, or it may be associated with or followed by postherpetic neuralgia. The latter is defined as the presence of pain for more than a month after the onset of the zoster eruption.^[125] Postherpetic neuralgia is the most common neurological complication of VZV.

Thrombotic Cerebrovasculopathy. The neurological syndrome of thrombotic cerebrovasculopathy associated with herpes zoster infection presents as a herpes ophthalmicus eruption followed by headache and the apoplectic onset of hemiplegia. On neuroimaging there is evidence of infarction in the distribution of the anterior or middle cerebral arteries, which on angiography is seen to be due to multifocal thrombosis. The pathogenesis of this syndrome appears to be direct viral invasion of the arterial walls via viral spread along the intracranial branches of the trigeminal cranial nerve. This syndrome is extremely rare.^[119]

Differential Diagnosis. The diagnosis of VZV encephalitis is suggested by the clinical presentation, supported by the neuroimaging abnormalities described above, and associated with a CSF lymphocytic pleocytosis. Varicella-zoster antibody measured by indirect immunofluorescence is present in a titer of 1:2 or more in the CSF in 94 percent of patients.^[119] Detection of VZV DNA in CSF by PCR can confirm the diagnosis.^[122] The diagnosis of Bell's palsy due to VZV is suggested by the classic vesicular eruption on the pinna, or the ear may be reddish and have a hyperemic concha or helix.^[121] The diagnosis of postherpetic neuralgia is made on clinical grounds.

Management and Prognosis. VZV encephalitis is treated with intravenous acyclovir ([Table 41-6](#)). Early treatment with prednisone and acyclovir appears to improve the outcome in patients with Bell's palsy due to VZV.^[121]

TABLE 41-6 -- ANTIVIRAL AGENTS

Antiviral Agent	Dosage	Indications	Adverse Effects
Acyclovir	1. 10 mg/kg intravenously every 8 hours 2. 800 mg orally 5 times/day	1. Herpes simplex virus encephalitis 2. Zoster	Renal toxicity, nausea, confusion Headache, nausea, diarrhea
Valaciclovir	1.0 g orally 3 times/day	Zoster	
Famciclovir	750 mg orally 3 times/day	Zoster	

Ganciclovir	Induction therapy: 5 mg/kg twice daily intravenously Maintenance therapy: 6 mg/kg once daily intravenously	CMV	Neutropenia, thrombocytopenia, confusion, convulsions, dizziness, headaches, nausea
Foscarnet	Induction therapy: 60 mg/kg intravenously every 8 hours Maintenance therapy: 100-120 mg/kg intravenously daily	CMV	Renal toxicity, anemia, hypocalcemia, hypophosphatemia, seizures

Prednisone also appears to be beneficial in the treatment of neuritis due to zoster but does not appear to have any effect on the development of postherpetic neuralgia. Similarly, oral acyclovir (800 mg five times daily) appears to reduce the pain associated with a zoster rash but does not have an effect on the development of postherpetic neuralgia.^[125] Valaciclovir (1.0 g orally three times per day) and acyclovir (800 mg orally five times per day) were approximately equal in their ability to decrease virus shedding and accelerate the time to cutaneous healing of zoster.^[126] Valaciclovir is a prodrug of acyclovir, and achieves by oral administration plasma acyclovir concentrations similar to those achieved only with intravenous acyclovir.^[125] Famciclovir is a prodrug of penciclovir, an acyclic guanine derivative that is similar to acyclovir in terms of structure, spectrum of activity, and mechanism of action.^[126] A trial comparing famciclovir (at doses of 250 mg, 500 mg, or 750 mg three times daily) with acyclovir (800 mg five times per day) in 544 immunocompetent adults with herpes zoster demonstrated that famciclovir was equivalent to acyclovir in terms of acceleration of cutaneous healing, loss of acute pain, safety, and tolerance.^[126] If begun within 72 hours after the appearance of the rash, famciclovir, valaciclovir, or acyclovir reduces the acute pain in patients with zoster. At this point in time, no single drug can be recommended over another except to say that famciclovir and valaciclovir can be given less often than acyclovir. Corticosteroids appear to improve the quality of life after zoster even though they do not alter the course of postherpetic neuralgia; therefore, their administration in combination with an antiviral agent is recommended in individuals in whom they are not contraindicated.^[125] Postherpetic neuralgia can be treated with topical lidocaine-prilocaine cream or 5 percent lidocaine gel. Topical capsaicin cream is not recommended because of the burning that occurs with its application. A tricyclic antidepressant agent such as amitriptyline or desipramine can be started at a low dose (12.5 to 25 mg) at bedtime. Patients should be advised that it takes several weeks to achieve maximum benefit from an antidepressant drug. Anticonvulsant drugs, specifically carbamazepine, can reduce the lancinating component of the neuropathic pain.^[125]

Cytomegalovirus

Epidemiology and Risk Factors. Cytomegalovirus (CMV) is the most common life- and sight-threatening opportunistic viral infection in patients with AIDS.^[127] Central nervous system infection by CMV in patients with AIDS may take the form of one or more of five distinct neurological syndromes: retinitis, polyradiculomyelitis, encephalitis with dementia, ventriculoencephalitis, and mononeuritis multiplex.^[128] Organ transplant recipients are also at risk for encephalitis due to CMV. Newborns with congenital CMV infection may have seizures, spasticity, microcephaly, chorioretinitis or optic atrophy, and neuroradiographic evidence of intracerebral calcifications and cerebral atrophy.^[129]

Cytomegalovirus is a DNA virus and a member of the herpesvirus group, which includes VZV, herpes simplex virus types 1 and 2, and Epstein-Barr virus. All of these viruses have a propensity to assume a latent state in humans and to undergo reactivation.^[129] Primary infection with CMV is usually benign; approximately 80 percent of adults in the United States have complement fixation (CF) antibodies to CMV by the age of 40, but under conditions of immune suppression, latent virus may be reactivated, producing a variety of systemic and neurological syndromes.

Pathogenesis and Pathophysiology. CMV is acquired by close personal contact through saliva, cervical secretions, and semen, and through blood transfusion. In congenital CMV infections, the fetus acquires the infection transplacentally. Symptomatic congenital CMV infection is a complication only of primary maternal infection; infants born to immune mothers may be infected but appear to be asymptomatic in the newborn period. Perinatal infection in infants occurs either through contact with CMV-infected uterine cervical secretions or through transmission of CMV in breast milk. Infection of the CNS results from viremia, and CMV has a predilection to infect the ependymal cells lining the ventricles and the gray matter in the cortex, basal ganglia, brain stem, and cerebellum.^[128],^[129] The CNS symptoms and neuropathological abnormalities observed in CMV-infected fetuses have been attributed to chronic intrauterine CMV encephalitis.^[129]

Clinical Features and Associated Findings. As stated earlier, CMV may cause congenital disease, retinitis, lumbosacral polyradiculopathy and myelitis, encephalitis with dementia, ventriculoencephalitis, mononeuritis multiplex, and infectious polyneuritis--the Guillian-Barre syndrome.

Congenital CMV Infection. The clinical spectrum of congenital CMV infection varies from an asymptomatic

infant to one who has the signs and symptoms of disseminated disease. In the most severe form of congenital CMV infection, the virus affects multiple organs, and the infant has hepatitis, splenomegaly, pneumonitis, jaundice, thrombocytopenia, chorioretinitis, hemolytic anemia, petechial or purpuric rash, seizures, spasticity, microcephaly, optic atrophy, and neuroimaging evidence of intracerebral calcifications and cerebral atrophy.^[129]

Retinitis. The presenting complaint of CMV retinitis is usually unilateral "floaters" or decreased visual acuity. Ophthalmological examination demonstrates large white-colored areas with perivascular exudates and hemorrhages. Initially these abnormalities are found at the periphery of the fundus, but if left untreated, lesions progress to involve the macula and the optic disk.^[130]

Lumbosacral Polyradiculopathy and Myelitis. The presentation of this syndrome is characterized by a subacute onset of weakness, areflexia, and sensory loss in the legs in association with bladder- or anal-sphincter dysfunction. The disease evolves as an ascending paraparesis.^[128] Clinical evidence of lower extremity weakness, areflexia, and bilateral Babinski's signs (if the spinal cord is involved) suggests this syndrome.

Encephalitis. Patients with AIDS and encephalitis due to CMV present with forgetfulness, memory impairment, apathy, and withdrawal like patients with HIV encephalitis, except that patients with CMV encephalitis have had AIDS longer and have lower mean CD4 lymphocyte counts at presentation. Patients with CMV encephalitis also have rapidly progressive cognitive impairment, and their survival is markedly shorter than that of patients with HIV dementia. CMV encephalitis is characterized by multifocal, diffusely scattered, small microglial nodules and inclusion-bearing cytomegalic cells that are concentrated in the gray matter in the cortex, basal ganglia, brain stem, and cerebellum. There is a strikingly high incidence of hyponatremia, hyperkalemia consistent with an Addisonian state, dilutional hyponatremia with hypo-osmolality, or hypernatremia due to dehydration in patients with CMV encephalitis.^[128]

Ventriculoencephalitis. A distinction is made between CMV encephalitis, described earlier, and CMV ventriculoencephalitis, which is characterized by necrosis of the cranial nerves and of the periventricular parenchyma.^[128] This syndrome presents as a rapidly fatal delirium with oculomotor palsies and nystagmus, and a linear homogeneous increased signal on T2-weighted MRI scans around the ventricles with ventriculomegaly.

Mononeuritis Multiplex. CMV mononeuritis results from focal necrotizing vasculitis of the epineural arteries and presents as a multifocal or asymmetrical sensory or motor deficit in the distribution of a peripheral or cranial nerve.^[128]

Differential Diagnosis. The diagnosis of congenital CMV infection is made by recovery of infectious virus from urine, saliva, buffy coat leukocytes, or CSF. Demonstration of seroconversion or a fourfold increase in CMV antibody titers between the acute and convalescent sera strongly supports recent CMV infection. CT scan demonstrates intracerebral calcifications and cerebral atrophy in newborns with CNS symptoms.^[129] The diagnosis of CMV retinitis is made clinically because it is impractical to obtain fluid or tissue from the eye for culture or microscopic examination. Blood, urine, or semen can be cultured to document active CMV infection in the patient, but the relevance of these cultures is questionable because patients without retinitis have positive cultures.^[130] In patients with CMV lumbosacral polyradiculopathy, the cerebrospinal fluid often demonstrates a pleocytosis with a neutrophilic predominance, the protein concentration is elevated, and the glucose concentration may be low or normal. Culture of CSF for CMV is the gold standard, but this test is insensitive (positive in 60 percent of patients), and CSF should also be analyzed by the PCR technique.^[131],^[132] Magnetic resonance imaging may reveal enlargement of the conus medullaris, clumping of lumbosacral rootlets, or enhancement (with gadolinium) of the leptomeninges of the lower spinal cord.^[128] In patients with CMV encephalitis there may be a mild mononuclear pleocytosis and an elevated protein concentration. CSF should be analyzed for CMV DNA by PCR. In patients with CMV ventriculoencephalitis, magnetic resonance imaging (as described above) may demonstrate increased periventricular signal intensity on T2-weighted images. In all patients in whom a CMV neurological syndrome is

suspected, culture of the CSF and analysis of CSF by PCR to detect CMV DNA should be performed.

Management. Ganciclovir and foscarnet are the two antiviral agents that have been proved effective in the treatment of CMV retinitis. CMV polyradiculopathy, encephalitis, and ventriculoencephalitis have been treated with dosing regimens that are identical to those used for CMV retinitis, although their clinical efficacy has not been established (see [Table 41-6](#)). Ganciclovir 5 mg/kg intravenously is given twice daily during "induction" therapy for a minimum of 2 to 3 weeks. This is followed by maintenance therapy at a dose of 6 mg/kg intravenously qd. Foscarnet is given in a dose of 60 mg/kg administered intravenously every 8 hours for induction therapy for a minimum of 2 to 3 weeks, followed by maintenance therapy of 100 to 120 mg/kg given intravenously qd. The doses of ganciclovir and foscarnet must be reduced when renal function is impaired or renal toxicity develops. A reversible leukopenia is an adverse effect of ganciclovir, as is a thrombocytopenia. Adverse effects of foscarnet include renal toxicity, anemia, hypocalcemia, hypophosphatemia, and seizures.^[130] Both CMV encephalitis and ventriculoencephalitis have been reported in patients receiving maintenance therapy for CMV retinitis even when the retinitis remains under control.^{[127], [128]}

Human Herpesvirus-6

Epidemiology and Risk Factors. Human herpesvirus-6 (HHV-6) is the causative agent of the common childhood infection roseola infantum (exanthem subitum).^[133] The virus was first isolated in 1986 from the peripheral blood lymphocytes of patients with AIDS and those with lymphoproliferative disorders. It is a member of the human herpesvirus family and shares some DNA sequence homology with the cytomegalovirus.^[134] Saliva may be the major mode of transmission of HHV-6. Primary infection may be symptomatic or asymptomatic; the virus is then able to become

latent in the host and reactivates in the presence of immunosuppression. The majority of the population is exposed to HHV-6 in infancy, and by the age of 2 years, most children are seropositive.^[134]

Pathogenesis and Pathophysiology. HHV-6 DNA has been detected by PCR in six of nine (66 percent) normal brain tissue specimens in one study, and in the CSF of nine of ten patients with exanthem subitum and neurological symptoms.^{[135], [136]} Human T-lymphocytes are the primary cell type infected by HHV-6, but HHV-6 has also been shown to infect cells of neuronal and glial origin in vitro.^[135] The detection of HHV-6 DNA by PCR in children with exanthem subitum and neurological symptoms suggests that HHV-6 invades the brain during acute infection.^[136] The presence of HHV-6 DNA in normal brain tissue specimens is evidence of the persistence or latency of HHV-6 in the central nervous system.^[135] Reactivation of latent HHV-6 infection has been demonstrated in children and in immunocompromised adults.^{[137], [138]}

Clinical Features and Associated Findings. As previously stated, HHV-6 is the etiological agent of childhood exanthem subitum. The most common CNS complications of primary HHV-6 infection are seizures, meningoencephalitis, and encephalopathy.^[137] HHV-6 has been reported as the etiological agent of focal encephalitis in a bone marrow transplant recipient and in immunocompetent adults with focal encephalitis in whom the clinical presentation suggested herpes simplex virus encephalitis.^{[134], [138]} CNS infection with HHV-6 has also been associated with diffuse or multifocal demyelination and a clinical picture of fulminant multiple sclerosis.^[139] Disseminated HHV-6 infection has been reported in children and adults with AIDS.^{[140], [141]}

Exanthem Subitum. Roseola infantum or exanthem subitum is a common disease of infancy characterized by high fever for a few days followed by the appearance of a generalized maculopapular rash when the fever subsides. Febrile convulsions in this disease have a reported incidence of 13 to 30 percent, children 12 to 15 months of age being at highest risk.^{[133], [136]}

Encephalitis and Focal Encephalitis. HHV-6 DNA has been recovered from the brain of a patient at autopsy who died of encephalitis 5 months after undergoing allogeneic bone marrow transplantation.^[138] Three of 37 patients with a clinical presentation suggestive of herpes simplex encephalitis and 6 of 101 patients with clinical and laboratory evidence of herpes simplex encephalitis were found to have HHV-6 DNA in their CSF when samples of CSF were sent to the University of Alabama for the purpose of undergoing diagnostic PCR analysis for possible herpes simplex encephalitis. The spectrum of disease ranged from mild encephalitis with complete resolution to severe neurological dysfunction and death.^[134] A dense and disseminated active HHV-6 infection was found in the brain tissue of a young woman with a fulminant demyelinating disease that was clinically and histopathologically diagnosed as acute multiple sclerosis.^[139]

Differential Diagnosis. Primary HHV-6 infection is diagnosed by culture of peripheral blood mononuclear cells and a concomitant fourfold or greater rise in IgG titer between the acute and convalescent sera. CSF can be analyzed by PCR to detect HHV-6 DNA. IgM antibody may be present during reactivation, and therefore its presence does not differentiate a primary infection from reactivation.^[137]

Management. Limited information is available on the susceptibility of HHV-6 to antiviral agents. The pattern of antiviral inhibition of HHV-6, however, resembles that of the human cytomegalovirus, suggesting that ganciclovir and foscarnet may be effective for the treatment of HHV-6 infections.^[142]

Epstein-Barr Virus

Epidemiology and Risk Factors. Epstein-Barr virus (EBV) is a human B-lymphotropic virus, the causative agent of infectious mononucleosis. The major route of transmission of EBV is through saliva, and EBV infects the epithelial cells of the oropharynx and adjacent structures as well as those of the uterine cervix. Epithelial cells may play a major role in the persistence of EBV by allowing chronic viral replication and release of infectious particles throughout the lifetime of a virus-infected host. Eighty to 90 percent of children in developing countries are seropositive for EBV between 2 and 3 years of age. By the third decade, nearly 100 percent of adults have EBV serum antibodies.^[143]

Pathogenesis and Pathophysiology. EBV is a lymphtropic virus that selectively infects B lymphocytes. B lymphocytes are infected by EBV during their passage through the chronically EBV-infected oropharyngeal epithelium. EBV has the unique biological property of being able to induce dysregulated activation and growth of a subpopulation of the infected B cells that then grow continuously as lymphoblastoid cell lines that secrete immunoglobulins.^{[143], [144]} Central nervous system invasion by infected B lymphocytes appears to be important in the pathogenesis of central nervous system disease.^[145]

Clinical Features and Associated Findings. Infectious mononucleosis is the only known disease caused by acute EBV infection. The neurological complications of infectious mononucleosis include meningoencephalitis, Guillain-Barre syndrome, cerebellitis, transverse myelitis, cranial nerve palsies of which the most common is a seventh nerve palsy, and a variety of optic nerve abnormalities (papilledema, optic neuritis, retrobulbar neuritis).^[146] EBV infection is almost universally associated with primary central nervous system lymphomas in patients with AIDS.^[147] Persistent viral activity or reactivation of EBV has been studied in the etiology of chronic fatigue syndrome.

Infectious Mononucleosis. The term infectious mononucleosis was first used in 1920 to describe the clinical findings of medical students attending Johns Hopkins University who had the typical clinical picture of this disease associated with atypical mononuclear cells.^[146] The clinical course of infectious mononucleosis is characterized by a 7-day prodromal illness followed by a 4-day to 3-week acute illness characterized by fever, headache, malaise, pharyngitis, cervical lymphadenopathy, and mononuclear leukocytosis with atypical lymphocytes. Splenic and hepatomegaly may be present with transient hepatic dysfunction.^{[143], [146]} The neurological complications of infectious mononucleosis

include the Guillain-Barre syndrome, an aseptic meningitis or encephalitis of which nonfebrile seizures are a common presenting manifestation, and cranial nerve palsies, the most common of which is an isolated or bilateral facial nerve palsy.^[146] Overall, meningoencephalitis is the most common neurological complication, whereas transverse myelitis is the least common.

CNS Lymphoma. EBV is detectable from a majority of primary central nervous system lymphomas in AIDS patients and to a lesser degree from primary CNS lymphomas in immunocompetent individuals.^[147] The clinical presentation is that of progressive personality changes, seizures, and signs of increased intracranial pressure.^[148]

Chronic Fatigue Syndrome. Chronic fatigue syndrome is characterized by debilitating fatigue accompanied by a variety of symptoms including cognitive difficulty,

myalgias, and arthralgias.^[149]

Differential Diagnosis. The diagnosis of infectious mononucleosis is based on a positive heterophil antibody test, the appearance of atypical lymphocytes in the blood at 1 to 4 weeks after onset of disease, and/or by changes in EBV-specific antibodies. An acute infection is documented by detection of antiviral capsid antigen (VCA) titers of 1:320 or higher, the presence of anti-D (i.e., diffuse component of EBV-induced early antigen complex), or EBV VCA IgM antibodies and the absence of antibodies to virus-associated nuclear antigen (anti-EBNA IgG). In acute and convalescent paired sera, fourfold or greater increments in anti-VCA or anti-D titers, or a late decrease in anti-VCA titers or loss of anti-D titers, and the appearance of antibodies to virus-associated nuclear antigen (anti-EBNA IgG) denote a recent infection. Anti-VCA titers peak early and then decline to persistent lower levels. Anti-D responses and virus-specific IgM antibodies are present for only a few weeks. Anti-EBNA antibodies appear late in convalescence and persist for life.^[146] In patients in whom neurological complications of infectious mononucleosis are suspected, the combination of serological tests and PCR performed on cerebrospinal fluid for the EBV DNA genome is recommended. If PCR for EBV DNA on CSF is negative, an acute EBV infection can be documented by evidence of positive IgM antibody titers to the viral capsid antigen early in the disease course, with a fourfold decrease in IgG antibody titers to the viral capsid antigen corresponding to a fourfold or greater increase in antibody to Epstein-Barr nuclear antigen between the acute and convalescent sera. A distinction between latent and symptomatic EBV infection cannot be made based strictly on positive results of PCR on CSF for EBV DNA.^[150]

The diagnosis of primary CNS lymphoma is based on CT or MRI evidence of a focal enhancing mass lesion or lesions, and typically an unsuccessful response to antitoxo-plasma therapy, because the neuroimaging appearance of *Toxoplasma gondii* encephalitis and primary CNS lymphoma is similar. The gold standard for the diagnosis has been brain biopsy; however, the polymerase chain reaction technique is both sensitive and specific in making the diagnosis. EBV DNA was detected by PCR in the CSF from seven of eight patients with primary CNS lymphoma diagnosed by brain biopsy (87.5 percent sensitivity) but in none of the 11 controls with brain mass lesions (100 percent specificity).^[147] Although there are reports of patients with chronic fatigue syndrome and high antibody titers to viral capsid antigen and early antigen of EBV, to date there is no scientific evidence that the reactivation of EBV is involved in the chronic fatigue syndrome.^[151]

Management. Although there are no EBV antiviral agents, ganciclovir is known to inhibit EBV replication in vitro, and there are a few reports of successful treatment of EBV meningoencephalitis with ganciclovir in transplant recipients.^[152] Primary CNS lymphoma is treated with radiation therapy.

JC Virus

Epidemiology and Risk Factors. The JC virus is ubiquitous; antibodies to the virus are present in up to 85 percent of individuals by the age of 9 years.^[153] The JC virus is the etiological agent of progressive multifocal leukoencephalopathy (PML).

Pathogenesis and Pathophysiology. The kidneys are thought to be the site of latent JC viral persistence. Reactivation of the virus associated with immunosuppression results in hematogenous dissemination of the virus to the brain. Foci of PML are frequently located in proximity to blood vessels.^[154] Progressive multifocal leukoencephalopathy occurs in patients with impaired cell-mediated immunity such as those with AIDS, chronic lymphocytic leukemia, Hodgkin's disease, other lymphomas, systemic lupus erythematosus, organ transplantation, and sarcoidosis.^[153], ^[154] The virus preferentially infects the myelin-producing oligodendrocytes, resulting in cell lysis and demyelination.^[154]

Clinical Features and Associated Findings. Focal neurological deficits (hemiparesis, dysarthria, and cerebellar limb and gait ataxia), seizure activity, and cognitive impairment characterized by memory impairment, psychomotor retardation, and inattentiveness characterize the clinical presentation of PML.^[154]

Differential Diagnosis. On CT scan, PML appears as single or multiple nonenhancing, hypodense lesions in the white matter, most commonly in the parietal-occipital regions. On T2-weighted MRI scans, the lesions have increased signal intensity and do not enhance after contrast administration. Examination of the cerebrospinal fluid is usually normal.^[154] The polymerase chain reaction technique can detect JC virus DNA in CSF with a reported sensitivity of 75 percent and a specificity of 96 percent.^[155] Serum and CSF antibody titers for JC virus are not useful in establishing the diagnosis of PML because 80 percent of the population show antibodies to JC virus by adulthood.^[154] Brain biopsy should be used for diagnosis in patients who have suspicious white matter lesions on MRI and in whom JC virus is not detected by PCR on CSF.^[155]

Management. There is no proven therapy for PML, but clinical trials are ongoing. There is a correlation between the CD4 T-cell count and survival, in that patients with higher CD4 T-cell counts survive longer. Notable improvement in PML has been observed in AIDS patients treated with high-dose 3-azido-3-deoxythymidine (AZT), and it is hypothesized that the AZT-induced elevation of CD4 T-cell counts improves cell-mediated immunity sufficiently

to resist the JC virus infection.^[154] The average length of survival from the onset of symptoms to death is 1 to 4 months, but a small percentage of patients reportedly have improved spontaneously and survived for several years.^[154]

ACKNOWLEDGMENT

The assistance of Mrs. Linda Hagan in the preparation of this manuscript is greatly appreciated.

BACTERIAL INFECTIONS

Acute Bacterial Meningitis

Epidemiology and Risk Factors. There are approximately 25,000 cases of bacterial meningitis in the United States each year, but this disease is much more prevalent in developing countries. Group B streptococci and gram-negative enteric bacilli are the etiological organisms of the majority of cases of bacterial meningitis during the neonatal period in developed countries. In underdeveloped countries, gram-negative bacilli, predominantly *Escherichia coli*, are the most common pathogens.^[1] Risk factors that predispose the newborn to bacterial meningitis include maternal infections, particularly of the urinary tract and uterus, obstetrical risk factors, including prolonged rupture of membranes and birth trauma, prematurity, low birth weight (less than 2500 g), congenital anomalies, perinatal hypoxia/asphyxia, cardiopulmonary resuscitation and monitoring, prolonged ventilatory support, and intravenous lines.^[1] After the neonatal period, *Streptococcus pneumoniae* and *Neisseria meningitidis* are the most common etiological agents of bacterial meningitis. *Haemophilus influenzae* type b (Hib) was the leading cause of bacterial meningitis in young children before the widespread use of the Hib conjugate vaccine. The latter has resulted in a marked reduction in the incidence of invasive infections caused by Hib in the United States. *N. meningitidis* causes meningitis primarily in children and young adults, with the majority of cases occurring in individuals under age 30. Major epidemics are heralded by disease occurring in older age groups. The "meningitis belt" of sub-Saharan Africa refers to areas of Africa in which there are repeated epidemics of serogroup A meningococcal meningitis.^[2] Annual outbreaks of meningitis occur in the meningitis belt in late April and early May when the dry desert winds have ceased and temperatures are high throughout the day. The epidemic tends to end with the onset of the rainy season. Transmission of meningococci is facilitated by airborne droplets, and the nasopharynx is the natural reservoir for this organism. During periods of low humidity, an alteration in the nasopharyngeal mucosal barrier predisposes the individual to infection. In addition, crowding, the presence of other respiratory pathogens, poor hygiene, and other poorly defined environmental factors contribute to the development of an epidemic of meningococcal meningitis.^[2] Colonization of the nasopharynx in an individual may result in an asymptomatic carrier state or invasive infection.

S. pneumoniae is the most common causative organism of community-acquired bacterial meningitis in the adult. Pneumonia and acute and chronic otitis media are important antecedent events. Chronic disease, specifically alcoholism, sickle cell anemia, diabetes, renal failure, cirrhosis, splenectomy, hypogammaglobulinemia, and organ transplantation are predisposing conditions for pneumococcal bacteremia and meningitis. The pneumococci are a common cause of recurrent meningitis in patients with head trauma and cerebrospinal fluid (CSF) rhinorrhea. In the older adult (50 years of age and older), *S. pneumoniae* is likely to cause meningitis in association with pneumonia or otitis media, and gram-negative bacilli are the likely organisms to cause meningitis in association with chronic lung disease, sinusitis, a neurosurgical procedure, or a

chronic urinary tract infection.^[3] The most common gram-negative bacilli causing meningitis in the older adult are *E. coli*, *Klebsiella pneumoniae*, *H. influenzae*, *Pseudomonas* organisms, *Enterobacter* species, and *Serratia* species.^[3] *Listeria monocytogenes* is an important causative organism of neonatal meningitis and of meningitis in patients that are diabetic, alcoholic, elderly, or immunosuppressed, especially transplant recipients.^[3] Infection with *L. monocytogenes* may be acquired through the consumption of soft cheeses, raw vegetables, seafood, cole slaw, and undercooked chicken and delicatessen meats. The staphylococci are the etiological organisms of meningitis primarily in the neurosurgical patient. *S. aureus* and coagulase-negative staphylococci are the predominant organisms causing infections in patients with CSF shunts or subcutaneous Ommaya reservoirs.

Pathogenesis and Pathophysiology. The most common bacteria that cause meningitis, *N. meningitidis* and *S. pneumoniae*, initially colonize the nasopharynx by attaching to the nasopharyngeal epithelial cells. The organisms are able to attach to the nasopharyngeal epithelial cells via an interaction between bacterial surface structures, such as the fimbriae of *N. meningitidis* and host cell surface receptors. The bacteria are then either carried across the cell in membrane-bound vacuoles to the intravascular space or invade the intravascular space by creating separations in the apical tight junctions of columnar epithelial cells.^[4] *S. pneumoniae* and *N. meningitidis* are both encapsulated bacteria, and once they gain access to the bloodstream, they are successful in avoiding phagocytosis by neutrophils and classic complement-mediated bactericidal activity because of the presence of the polysaccharide capsule. Bacteria that are able to survive in the circulation enter the CSF from the bloodstream through the choroid plexus of the lateral ventricles and other areas of altered blood-brain barrier permeability. The CSF is an area of impaired host defense because of a lack of sufficient numbers of complement components and immunoglobulins for the opsonization of bacteria.^[4] Normal uninfected CSF contains no phagocytic cells, has a low protein concentration, contains no IgM, and has low concentrations of C₃ and C₄.^[4] In addition, the fluid medium of the CSF impairs the phagocytosis of bacteria by neutrophils.^[4] Bacteria multiply rapidly in the subarachnoid space. Both the multiplication of bacteria and the lysis of bacteria by bactericidal antibiotics result in the release of bacterial cell wall components. These induce the formation of the inflammatory cytokines, interleukin-1 (IL-1) and tumor necrosis factor (TNF), by monocytes, macrophages, brain astrocytes, and microglial cells, which leads to altered blood-brain barrier permeability and the recruitment of polymorphonuclear leukocytes. This process results in the formation of a purulent exudate in the subarachnoid space, which is the basis for the neurological complications of bacterial meningitis. The inflammatory cytokines, IL-1 and TNF, that are produced in response to the release of bacterial cell wall components induce the formation of leukocyte adhesion molecules on vascular endothelial cells. The adherence of neutrophils to vascular endothelial cells is a necessary prerequisite for neutrophils to traverse the blood-brain barrier. It is not clear what role, if any, neutrophils play in eradicating the infection in the subarachnoid space. Large numbers of leukocytes in the subarachnoid space contribute to the purulent exudate and obstruct the flow of CSF. Adherence of leukocytes to the cerebral capillary endothelial cells increases the permeability of blood vessels, allowing for the leakage of plasma proteins through open intercellular junctions that lead to vasogenic brain edema. The leukocytes that successfully migrate into the CSF can subsequently be stimulated by the inflammatory cytokines to degranulate and release toxic oxygen metabolites, producing cytotoxic cerebral edema. Interleukin-1 is a chemoattractant for neutrophils.^[5] Interleukin-1 may also have a role in the altered level of consciousness and the production of fever in bacterial meningitis. It has been demonstrated that IL-1 facilitates slow-wave sleep and produces fever by its effect on the hypothalamus.^[6] Other inflammatory cytokines, including interleukin-6 and interleukin-8, also have a role in the induction of meningeal inflammation, but the role of these cytokines has not been studied as extensively as that of IL-1 and TNF. Platelet activating factor (PAF) also has a prominent role in increasing blood-brain barrier permeability.^[14]

The alteration in blood-brain barrier permeability during bacterial meningitis results in vasogenic cerebral edema, which contributes to increased intracranial pressure. It also allows for the leakage of plasma proteins into the CSF that contribute to the inflammatory exudate in the subarachnoid space.^[7] The purulent exudate in the subarachnoid space interferes with the resorptive function of the arachnoid granulations. As resorption is obstructed, CSF dynamics are altered, and there is transepithelial movement of fluid from the ventricular system into the brain parenchyma, which contributes to interstitial edema. The purulent exudate in the basal cisterns obstructs CSF outflow through the ventricles, also contributing to interstitial edema.

An increase in intracranial pressure affects cerebral perfusion pressure (CPP), which is defined as the difference between the mean arterial pressure (MAP) and the intracranial pressure (ICP) (CPP = MAP-ICP). Cerebral perfusion pressure is also adversely affected by a loss of cerebral autoregulation. Cerebral blood flow is initially increased in bacterial meningitis; however, shortly thereafter cerebral blood flow begins to decrease. Cerebral blood flow is normally protected through cerebrovascular autoregulation. There is dilatation or constriction of cerebral resistance vessels in response to alterations in CPP, as a result of either changes in the MAP or changes in ICP.^[8] The loss of cerebral autoregulation means that cerebral blood flow decreases when systemic blood pressure decreases and increases when systemic blood pressure increases. Because patients with bacteremia and bacterial meningitis are at risk for hypotension, the loss of cerebral autoregulation also puts them at risk for decreased cerebral blood flow. Cerebral blood flow is also affected by narrowing of large arteries at the base of the brain due to encroachment by the purulent exudate in the subarachnoid space. Furthermore, infiltration of the arterial walls by inflammatory cells with secondary intimal thickening, and thrombosis of the major sinuses and thrombophlebitis of the cerebral cortical veins contribute to diminished cerebral blood flow.

Clinical Features and Differential Diagnosis. The classic presentation of bacterial meningitis is headache, fever, stiff neck, and an altered level of consciousness, but

the clinical symptoms and signs may vary depending on the age of the patient and the duration of illness before presentation. The symptoms and signs of bacterial meningitis in the neonate are often subtle and typically nonspecific, and include fever or hypothermia, lethargy, seizures, irritability, bulging fontanel, poor feeding, vomiting, and respiratory distress. Meningitis should always be considered when sepsis is suspected in the neonate.^[9] In children and adults, the symptoms and signs of bacterial meningitis are fever, headache, vomiting, photophobia, nuchal rigidity, lethargy, confusion, or coma. Meningitis in children typically presents as either a subacute infection that gets progressively worse over several days, following an upper respiratory tract or ear infection or as an acute fulminant illness that develops rapidly in a few hours. The typical rash of meningococemia is a petechial-purpuric rash that develops on the trunk, lower extremities, mucous membranes, conjunctiva, and occasionally on the palms and soles. A petechial, purpuric, or erythematous maculopapular rash is also seen in enteroviral meningitis, *N. gonorrhoeae* sepsis, *H. influenzae* type b and pneumococcal meningitis, Rocky Mountain spotted fever, and *S. aureus* endocarditis. Children with bacterial meningitis

may also be ataxic as a result of labyrinthine dysfunction or vestibular neuronitis. In adults, an upper respiratory tract infection frequently precedes the development of meningeal symptoms, and its presence should be sought in the history.^[1], ^[16] Adults typically complain of headache, photophobia, and stiff neck, and they may have a rapid progression from lethargy to stupor and coma. The clinical presentation of meningitis in an older adult consists of fever and confusion, stupor, or coma.

Cranial nerve palsies, and most notably sensorineural hearing loss, are a common complication of bacterial meningitis and may be present early in the course of the illness. A stiff neck is the pathognomonic sign of meningeal irritation, resulting from a purulent exudate or hemorrhage in the subarachnoid space. Nuchal rigidity or meningismus is present when the neck resists passive flexion. Kernig's sign is also a classic sign of meningeal irritation, and as originally described by Kernig, it requires the patient to be in the seated position. Kernig noted that attempts to passively extend the knee while the patient was seated were met with resistance in the presence of meningitis so that a contraction of the extremities was maintained.^[17], ^[18] Jozef Brudzinski described at least five different meningeal signs. His best known sign, the nape of the neck sign, is elicited with the patient in the supine position and is positive when passive flexion of the neck results in spontaneous flexion of the hips and knees.^[18], ^[19]

Seizures occur in 40 percent of patients with bacterial meningitis typically during the first week of illness. The etiology of seizure activity can be attributed to either one or a combination of the following: (1) fever; (2) cerebrovascular disease consisting of either focal arterial ischemia, infarction or cortical venous thrombosis with hemorrhage; (3) hyponatremia; (4) subdural effusion or empyema producing a mass effect; and (5) antimicrobial agents (e.g., imipenem, penicillin).^[16] Raised ICP is an expected complication of bacterial meningitis and presents as one or a combination of the following clinical signs: (1) an altered level of consciousness; (2) the Cushing reflex--bradycardia, hypertension, and irregular respirations^[20]; (3) dilated, nonreactive pupil or pupils; (4) unilateral or bilateral cranial nerve six palsies; (5) papilledema; (6) neck stiffness; (7) hiccups; (8) projectile vomiting; and, (9) decerebrate posturing.^[16] Acute ischemic stroke may occur in the course of bacterial meningitis as a result of narrowing of the large arteries at the base of the brain. This may occur from encroachment by a purulent exudate in the subarachnoid space or infiltration of the arterial wall by inflammatory cells (vasculitis). Vasospasm, thrombotic or stenotic occlusion of branches of the middle cerebral artery, and septic venous sinus thrombosis with thrombophlebitis of cortical veins may also occur.^[1]

The differential diagnosis of this clinical presentation includes viral meningoencephalitis, fungal meningitis, tuberculous meningitis, focal intracranial mass lesions, subarachnoid hemorrhage, Rocky Mountain spotted fever, and neuroleptic malignant syndrome.

Evaluation. The gold standard for the diagnosis of bacterial meningitis is the examination of the CSF. The classic CSF abnormalities in bacterial meningitis are (1) an increased opening pressure; (2) a polymorphonuclear leukocytic pleocytosis; (3) a decreased glucose concentration; and (4) an increased protein concentration. Raised ICP is an expected complication of bacterial meningitis and can theoretically contribute to brain herniation following lumbar puncture. When there are clinical signs of raised ICP and urgent lumbar puncture is indicated, a bolus of mannitol 1 g/kg of body weight can be given intravenously and the lumbar puncture can be performed 20 minutes later. In addition, the patient can be intubated and hyperventilated. Alternatively, lumbar puncture can be deferred and blood cultures obtained until the raised intracranial pressure can be treated. Regardless, the lumbar puncture should be performed with a 22-gauge needle.^[21] When obtaining CSF for analysis it is important to remember that adults have approximately 150 ml of CSF, but infants and children have smaller amounts, in the range of 30 to 60 ml in the neonate and 100 ml in the adolescent.^[22] The volume of CSF in a child 4 to 13 years of age is in the range of 65 to 140 ml, with an average volume of 90 ml.^[23] Approximately 10 to 12 ml of CSF should be withdrawn from an adult, and the withdrawal of 3 to 5 ml is recommended in the neonate and child.^[22] The CSF glucose concentration is low when the value is less than 40 mg/dl or when the CSF/ blood glucose ratio is less than 0.6. When an ampule of 50 ml of 50 percent glucose (D50) has been given enroute to the emergency room, 30 minutes is required for the ampule of D50 to influence the CSF glucose concentration. The CSF white blood cell (WBC) count is usually more than 100 cells/shmm³ and is often more than 1000 WBCs/ mm³ in bacterial meningitis. Although there is typically a predominance of polymorphonuclear leukocytes in the CSF in bacterial meningitis, a predominance of lymphocytes has been reported in cases of acute bacterial meningitis when the CSF WBC concentration was less than 1000/mm³ and in bacterial meningitis due to *L. monocytogenes*.^[24], ^[25] The initial CSF examination in neonatal bacterial meningitis may have an absence of pleocytosis and normal glucose and protein concentrations. A Gram stain of the CSF should be examined carefully, and a high index of suspicion for meningitis should be maintained in the neonate with fever, seizure activity, irritability, lethargy, and/or

respiratory distress.^[26], ^[27] Oral antimicrobial therapy administered before lumbar puncture will not significantly alter the CSF WBC count or glucose concentration but will decrease the likelihood of identifying the organism on Gram's stain or isolating it in culture.^[21] The latex particle agglutination test for the detection of bacterial antigens of *H. influenzae* type b, *S. pneumoniae*, *N. meningitidis*, group B streptococcus, and *E. coli* K1 strains in the CSF is very useful in making a rapid diagnosis of bacterial meningitis. It is also helpful in making the diagnosis of bacterial meningitis in patients who were pretreated with antibiotics and in the patient whose Gram's stain and CSF culture are negative. The Limulus amebocyte lysate test is very sensitive in detecting gram-negative bacterial meningitis. It has a 77 to 99 percent sensitivity for the detection of gram-negative endotoxin in the CSF.^[21] A good rule is that the Gram's stain and bacterial culture should be negative in the CSF obtained 24 hours after the initiation of intravenous antimicrobial therapy, if the organism is sensitive to that antibiotic.

Management. Empiric therapy of bacterial meningitis in the neonate should include the combination of ampicillin (50 mg/kg q 6 to 8 hr) and either cefotaxime (50 mg/kg q 8 to 12 hr) or an aminoglycoside, such as gentamicin (2.5 mg/kg q 8 to 12 hr) or amikacin (10 mg/kg q 8 to 12 hr).^[1] Empiric therapy of bacterial meningitis in infants 4 to 12 weeks of age requires antimicrobial agents that are active against the likely pathogens of the neonatal age group as well as those that cause infection in infants and children. An appropriate regimen in this age group is ampicillin and either cefotaxime or ceftriaxone (100 mg/kg/d intravenously in divided doses q 12 hr). A third-generation cephalosporin, either cefotaxime (225 mg/kg/d intravenously in divided doses q 6 hr) or ceftriaxone (100 mg/kg/d intravenously in divided doses q 12 hr) plus vancomycin (40 mg/kg/d intravenously in divided doses q 6 hr) is recommended for empiric therapy of bacterial meningitis in the older infant and child. Empirical therapy of bacterial meningitis in adults should include a combination of ceftriaxone (2 g intravenously twice daily) or cefotaxime (8 to 12 g/d intravenously in divided doses q 4 hr) plus vancomycin (500 mg intravenously q 6 hr). In the older adult and in the immunocompromised adult in whom *L. monocytogenes* may be the etiological organism, ampicillin (12 g/d in divided doses q 4 hr) should be added to this regimen. In patients who have recently undergone a neurosurgical procedure or who are immunocompromised, *Pseudomonas aeruginosa* may be the etiological agent, and ceftazidime (6 g/d intravenously in divided doses q 8 hr) should be substituted for cefotaxime or ceftriaxone. Once the causative organism has been identified, antimicrobial therapy can be modified based on the recommendations for that specific organism. Recommendations for antimicrobial therapy based on the infecting organism are listed in [Table 42-1](#).

The American Academy of Pediatrics recommends the consideration of dexamethasone for bacterial meningitis in infants and children 2 months of age and older. The recommended dose is 0.6 mg/kg/d in four divided doses (0.15 mg/kg/dose) given intravenously for the first 4 days of antimicrobial therapy.^[28] The first dose of dexamethasone should be administered 20 minutes before the first dose of antimicrobial therapy. It is also entirely reasonable to use

TABLE 42-1 -- ANTIMICROBIAL THERAPY BASED ON ETIOLOGICAL ORGANISM

Organism	Antibiotic and Dose (Intravenous Unless Indicated)		
	Infants (> 2000 g)	Children	Adults
Group B streptococcus	Ampicillin 50 mg/kg every 6 hr plus amikacin 10 mg/kg every 8 hr or gentamicin 2.5 mg/kg every 8 hr		
<i>Neisseria meningitidis</i>		Penicillin G 250,000 to 400,000 U/kg/d (divided every 4 hr) plus (at end of therapy) oral rifampin, older than 1 yr: 10 mg/kg every 12 hr for 2 d. Younger than 1 yr: 5 mg/kg every 12 hr for 2 d	Penicillin G 20 to 24 million U/d (divided every 4 hr) plus (at end of therapy) oral rifampin 600 mg every 12 hr for 2 d
<i>Streptococcus pneumoniae</i>		Cefotaxime 225 mg/kg/d (divided every 6 hr) of ceftriaxone 100 mg/kg/d (in once or twice daily dosing interval) plus vancomycin 40 mg/kg/d (every 6 hr dosing interval)	Cefotaxime 8 to 12 g/d (divided every 4 hr) or ceftriaxone 4 g/d (2 g every 12 hr) + vancomycin 2 g/d (in a 6 hr or 12 hr dosing interval)
Enteric gram-negative bacilli (except <i>Pseudomonas aeruginosa</i>)	Cefotaxime 50 mg/kg every 8 hr plus amikacin or gentamicin	Cefotaxime or ceftriaxone (as above)	Cefotaxime or ceftriaxone (as above)
<i>Pseudomonas aeruginosa</i>	Ceftazidime 50 mg/kg every 8 hr	Ceftazidime 150 mg/kg/d (every 8 hr dosing interval)	Ceftazidime 6 g/d (every 8 hr dosing interval)

<i>Listeria monocytogenes</i>	Ampicillin 50 mg/kg every 6 hr plus amikacin or gentamicin for 3 to 5 d	Ampicillin 150 to 200 mg/kg/d (every 4 hr dosing interval)	Ampicillin 12 g/d (divided every 4 hr)
<i>Haemophilus influenzae</i> type b	Cefotaxime	Cefotaxime or ceftioxone	Cefotaxime or ceftriaxone
<i>Staphylococcus aureus</i> Methicillin-sensitive	Methicillin 50 mg/kg every 6 hr	Oxacillin 200 to 300 mg/kg/d (divided every 4 hr)	Oxacillin 12 g/d (divided every 4 hr)
<i>Staphylococcus aureus</i> Methicillin-resistant	Vancomycin 15 mg/kg every 8 hr	Vancomycin 40 mg/kg/d (divided every 6 hr)	Vancomycin 2 g/d (divided every 6 hr)

dexamethasone therapy in adults with bacterial meningitis in the same dose as recommended for children. Dexamethasone is beneficial in preventing the neurological complications of bacterial meningitis by decreasing meningeal inflammation. Dexamethasone inhibits the synthesis of the inflammatory cytokines, interleukin-1 and tumor necrosis factor, produced by brain astrocytes and microglial cells in response to bacterial cell wall components in the subarachnoid space. As discussed earlier, the inflammatory cytokines increase the permeability of the blood-brain barrier and recruit polymorphonuclear leukocytes from the bloodstream to the CSF. The result is the production of a purulent exudate in the subarachnoid space. Although the majority of patients in the clinical trials evaluating the efficacy of dexamethasone in bacterial meningitis have been infants and children, the production and the role of the inflammatory cytokines in the neurological complications of this infection are the same in infants, children, and adults. It is therefore reasonable to recommend dexamethasone therapy in adults. In the single clinical trial that evaluated the efficacy of dexamethasone in pneumococcal meningitis in adults, patient mortality was reduced despite the use of an ampicillin dose that is now considered sub-therapeutic.^[29] Dexamethasone appears to be reasonably safe. The third-generation cephalosporins penetrate the CSF extremely well even in the presence of dexamethasone.^[30],^[31] The penetration of vancomycin, however, may be adversely affected by dexamethasone therapy since meningeal inflammation improves the penetration of vancomycin into the CSF. The clinical significance of this is unclear. Consideration should therefore be given to the use of higher doses of vancomycin (60 mg/kg/d in divided doses q 6 hr) or intrathecal vancomycin in cases of highly penicillin-resistant and cephalosporin-resistant pneumococcal meningitis when dexamethasone is used concomitantly with antimicrobial therapy. The use of an H₂ antagonist with dexamethasone is recommended to avoid gastrointestinal bleeding.

The majority of children with bacterial meningitis are hyponatremic with serum sodium concentrations less than 135 mEq/L at the time of admission owing to the syndrome of inappropriate antidiuretic hormone secretion (SIADH). The time-honored treatment of SIADH was fluid restriction. This practice, however, has recently received renewed attention because of the knowledge that autoregulation of cerebral blood flow is lost in the course of bacterial meningitis. A decrease in the mean systemic arterial pressure is therefore associated with a decrease in the cerebral blood flow. In experimental pneumococcal meningitis, fluid-restricted rabbits had a greater decrease in MAP and cerebral blood flow than did euvoletic rabbits.^[32] The present recommendations are to limit the initial rate of intravenous fluid administration to approximately three quarters of the normal maintenance requirements (or 1000 to 1200 ml/m² / 24 hr). The intravenous fluid should be a multielectrolyte solution containing between one quarter and one half normal saline and potassium at 20 to 40 mEq/L in 5 percent dextrose. Once the serum sodium concentration increases above 135 mEq/L, the volume of the fluids administered can be gradually increased.^[33],^[34]

The development of seizure activity should be anticipated in the patient with bacterial meningitis. Seizure activity occurs in approximately 30 to 40 percent of children with acute bacterial meningitis and in more than 30 percent of adults with pneumococcal meningitis, typically occurring in the first few days of the illness. There is an increased risk of epilepsy following bacterial meningitis especially in those individuals who have seizures in the first few days of infection.^[35] Raised ICP is an expected complication of bacterial meningitis and should be anticipated at the time of the initial lumbar puncture. The ICP should be measured by an ICP monitoring device. The treatment of raised ICP in bacterial meningitis includes one or more of the following: (1) elevation of the head of the bed 30 degrees; (2) hyperventilation to maintain the PaCO₂ between 25 to 33 mm Hg; (3) mannitol 1.0 g/kg bolus intravenous injection, then 0.25 to 0.5 g/kg intravenous every 3 to 5 hours to achieve a serum osmolarity of 295 to 320 mOsm/L; (4) dexamethasone 0.15 mg/kg q 6 hr; and (5) pentobarbital coma with a loading dose 5 to 10 mg/kg administered intravenously at a rate of 1 mg/kg/min and a maintenance dose of 1 to 3 mg/kg/hr.^[36],^[37] Subdural effusions commonly develop in the course of bacterial meningitis in children when the infection in the adjacent subarachnoid space leads to an increase in the permeability of the thin-walled capillaries and veins in the inner layer of the dura. The result is leakage of albumin-rich fluid into the subdural space. This is usually a self-limited process, and as the inflammatory process subsides, fluid formation ceases and the fluid in the subdural space is reabsorbed.^[34],^[38],^[39] The indications for aspiration of a subdural fluid collection include the clinical suspicion of infected fluid (prolonged fever), a rapidly enlarging head circumference in a child without hydrocephalus, focal neurological findings, or clinical signs of increased ICP.^[34]

Brain Abscess

Epidemiology and Risk Factors. Brain abscess is a rare disease in immunocompetent individuals. In adults, otitis media and paranasal sinusitis (frontal, ethmoidal, or sphenoidal sinuses) are the most common predisposing conditions for brain abscess formation. In children, otitis media and cyanotic congenital heart disease are the most common predisposing conditions for brain abscess formation. Individuals with the acquired immunodeficiency syndrome (AIDS) are at increased risk for focal intracranial infections caused by *Toxoplasma gondii*. Organ transplant recipients are at risk for brain abscesses caused by *Aspergillus fumigatus*. Patients receiving chronic corticosteroid therapy and those who are immunosuppressed from bone marrow transplantation are at a particular risk for CNS candidiasis manifested as multiple intraparenchymal microabscesses mainly in the territory of the middle cerebral artery. Brain abscesses may develop as a result of cranial trauma, either penetrating brain injuries or neurosurgical procedures, of which the most common is craniotomy. The reported incidence of brain abscess following clean neurosurgical procedures is 6 to 7 per 10,000 cases.^[40] A brain abscess may develop as the result of hematogenous spread of infection from a remote site such as chronic pyogenic lung diseases, wound and skin infections, osteomyelitis,

intra-abdominal and pelvic infections, and endocarditis. Finally, pulmonary arteriovenous malformation is a predisposing condition for brain abscess formation.

Pathogenesis and Pathophysiology. A brain abscess may develop in association with any of the following: (1) direct spread from a contiguous cranial site of infection such as otitis media, odontogenic infections, sinusitis or mastoiditis, or retrograde septic thrombophlebitis from these sites as well as facial and scalp infections; (2) following cranial trauma; (3) hematogenous spread from a remote infection site; and, (4) immunosuppression either from neutropenia, organ or bone marrow transplantation, lymphoma, leukemia or AIDS. Approximately 20 percent of brain abscesses are said to be cryptogenic, with no predisposing factor. The results of animal experiments suggest that in order for brain abscesses to form, there must be a pre-existing area of ischemia, necrosis, or hypoxia in brain tissue.^[41] Intact brain parenchyma is relatively resistant to infection.^[42] Once bacteria have established an infection, brain abscess formation evolves through four stages regardless of the infecting organism. These stages were described in animal models of brain abscesses, and have been shown to correlate with human brain abscess evolution observed by computed tomography (CT) imaging. These stages are early cerebritis, late cerebritis, early capsule formation, and late capsule formation. The early cerebritis stage (days 1 to 3 following intracerebral inoculation with alpha-hemolytic streptococci in dogs) is characterized by perivascular infiltration of inflammatory cells composed of polymorphonuclear leukocytes, plasma cells, and mononuclear cells that surround a central core of coagulative necrosis. Marked cerebral edema surrounds the lesion at this stage.^[43],^[44] The CT scan reveals a low-density lesion with faint contrast enhancement at its edge. The late cerebritis stage (days 4 to 9) is characterized by a lesion with a necrotic center surrounded by an inflammatory infiltrate of macrophages and fibroblasts. Rapid new vessel formation occurs around the developing abscess. A thin capsule of fibroblasts and reticular fibers gradually develops, and the area is surrounded by cerebral edema. The CT scan image demonstrates a low-density lesion surrounded by a prominent ring of enhancement following contrast administration. In the stage of early capsule formation (days 10 to 13), the necrotic center decreases in size, and the inflammatory infiltrate changes in character and contains an increasing number of fibroblasts and macrophages. Mature collagen evolves from reticulin precursors, forming a capsule that is better developed on the cortical than the ventricular side of the lesion. The CT scan image shows an area of low density, and the diameter of ring-contrast enhancement has decreased in size. The stage of late capsule formation (day 14 and later) is characterized by a well-formed necrotic center surrounded by a dense collagenous capsule. On the CT scan image, the low-density lesion is surrounded by a sharply demarcated, dense ring of contrast enhancement. The above-mentioned description of brain abscess formation may be modified slightly by different microorganisms and altered in the immunocompromised host. Depending on the etiologic organism and the predisposing condition leading to infection, there may be delayed or incomplete encapsulation of the abscess cavity, or the abscess may enlarge more quickly than described earlier.^[45]

Clinical Features and Differential Diagnosis. A brain abscess presents as an expanding focal infectious mass lesion. The most common clinical presentation is headache, either hemicranial or generalized, fever, vomiting, a focal neurological deficit, or focal or generalized seizure activity. The findings on neurological examination are related both to the site of the abscess and to the degree of raised ICP. Patients with increased ICP will have alterations in consciousness ranging

from lethargy to irritability, confusion, or coma. There may be papilledema, and deficits of cranial nerves III or VI, or both. If the abscess has ruptured into the ventricular system or if there has been spread of infection to the subarachnoid space, there may be signs of meningitis. The differential diagnosis of this clinical presentation includes herpes simplex virus encephalitis, subdural empyema, cranial epidural abscess, a focal cerebral infarction with edema, a cerebral hemorrhage, a primary neurological tumor, or a metastatic tumor.

Evaluation. The diagnosis of a brain abscess is made through neuroimaging using either a cranial CT or MRI scan that demonstrates a ring-enhancing lesion. Typically, the cranial CT scan demonstrates the abscess as a low-density lesion with a sharply demarcated, dense ring of contrast enhancement surrounded by a variable hypodense region of edema. In the early and late stages of cerebritis, there is often diffusion of contrast medium into the low-density center of the abscess on delayed scans obtained 30 minutes after the administration of intravenous contrast. As the abscess matures, its margin becomes more defined and the enhancement around the abscess become more homogeneous. In the early and late stages of capsule formation, there is no significant inward diffusion of contrast on delayed scans. Cranial MRI scanning is superior to cranial CT scanning in detecting a lesion in the early cerebritis stage. On this type of image, the abscess appears as an area of hypointensity on T1-weighted images and hyperintensity on T2-weighted images with indistinct margins. When the abscess becomes encapsulated, it appears as a lesion of low intensity surrounded by an area of isointensity or hyperintensity on T1-weighted images. The T2-weighted MRI images reveal a hyperintense lesion surrounded by a rim of hypointensity with surrounding area of hyperintensity that represents edema. The T1-weighted MRI images obtained after intravenous gadolinium administration demonstrate ring enhancement of the abscess capsule.^[40] Patients with a brain abscess may have a peripheral leukocytosis or an elevated erythrocyte sedimentation rate; however, in a significant number of patients, the laboratory criteria for infection will be lacking. The serum C-reactive protein (CRP) concentration has been reported to be useful in distinguishing brain abscess from brain tumor. Patients with brain abscesses have an elevated CRP level, whereas those with a brain tumor will have low levels.^[40], ^[45] Indium-111-labeled leukocyte scintigraphy may also be useful in distinguishing between a brain abscess and tumor. This scan uses radiolabeled leukocytes to detect areas of active inflammation. False-positive results may occur when there has been leukocytic infiltration into a brain tumor, especially those with severe necrosis. A lumbar puncture is contraindicated in a patient with a brain abscess because of the risk of herniation. The etiological organism is rarely identified from CSF cultures obtained by lumbar puncture,

but it can be identified by CT- or MRI-guided stereotactic aspiration of the abscess. This approach is the procedure of choice for the identification of the infectious organism. All patients should also have a chest roentgenogram. Additionally, a CT scan of the head with bony windows for the evaluation of the paranasal sinuses, middle ear, and mastoids should be done when a contiguous site of infection is suspected as the source of the brain abscess. Blood cultures should be obtained when hematogenous dissemination from a remote site of infection is the likely etiology.

Management. The management of a brain abscess is directed at decreasing the mass effect associated with the abscess, draining the pus, and the use of antimicrobial therapy to treat the abscess and the primary source of infection.^[40] Surgical management of a brain abscess involves either complete extirpation of the abscess or aspiration of the abscess cavity through a burr hole with or without placement of a drainage catheter into the abscess cavity. The purulent material obtained at the time of aspiration allows for the identification of the infecting organism. Aspiration of the contents of an abscess cavity has a lower morbidity and a lower risk of seizures compared with complete excision. Complete excision removes the lesion from the parenchyma of the brain and allows for a rapid decompression but may cause damage to brain parenchyma. Complete excision is recommended when gas is present within the abscess cavity and for some fungal abscesses, particularly *Nocardia* species.

In the majority of patients with a brain abscess, stereotactic aspiration of the abscess should be performed for Gram's stain and bacterial culture, as well as fungal smear and culture. In patients with AIDS, however, the majority of focal infectious CNS lesions are caused by *T. gondii*, and in such cases, serum should be sent for antitoxoplasma IgG. The lesions of *T. gondii* are typically located at the gray-white junction in the cerebral hemispheres, in the deep white matter, and in the thalamus and basal ganglia. With contrast administration, the majority of lesions enhance in a ringed, nodular, or homogeneous pattern and are surrounded by edema. Cranial MRI scanning is superior to CT scanning in detecting the multiple lesions of toxoplasma abscesses. Thallium single photon emission computed tomography imaging may be helpful in distinguishing cerebral toxoplasmosis from primary CNS lymphoma. Focal areas of increased uptake are seen in patients with lymphoma. In patients with a detectable toxoplasma serology and more than one enhancing lesion on neuroimaging, a presumptive diagnosis of toxoplasma encephalitis can be made and a treatment trial with pyrimethamine and sulfadiazine or pyrimethamine and clindamycin can be initiated. The other group of patients that provide an exceptional diagnostic and therapeutic challenge are those not infected with HIV but who have multiple brain abscesses. In these patients, stereotactic aspiration of the largest lesion for purulent material for culture is recommended.

The etiological organism of a brain abscess can be predicted to some degree based on the location of the abscess and the predisposing condition. Streptococci, specifically *S. miller*, are the most frequent organisms isolated from frontal lobe abscesses associated with chronic sinusitis. Temporal lobe abscesses are most frequently secondary to chronic infections of the ear, and streptococci (anaerobic or aerobic), Enterobacteriaceae and Bacteroides species are the most commonly isolated bacteria. A brain abscess owing to chronic otitis media frequently yields multiple organisms in culture. The majority of brain abscesses secondary to trauma or craniotomy are caused by *S. aureus*.^[40] Viridans, anaerobic, and microaerophilic streptococci are the usual organisms isolated from brain abscesses caused by cyanotic congenital heart disease. A brain abscess in an immunocompromised individual may be from *Candida* species, *Nocardia asteroides*, *Aspergillus*, Zygomycetes, Enterobacteriaceae or *P. aeruginosa*.

A combination of vancomycin (2 g/d intravenously in an adult, 40 to 60 mg/kg/d in a child), a third-generation cephalosporin (cefotaxime, ceftriaxone, or ceftazidime), and metronidazole (500 mg q 6 hr intravenously for an adult and 7.5 mg/kg q 8 hr for a child) is the recommended empirical therapy for immunocompetent patients with brain abscesses. The final culture results and organism sensitivities are used to make the antibiotic coverage more specific. Aspergillosis should be considered in immunosuppressed patients with unremitting fever and multiple brain abscesses. A chest x-ray study may demonstrate pulmonary infiltrates and bronchoscopy may identify the infecting organism in some cases. Fungal brain abscesses are treated with amphotericin B; liposomal amphotericin B should be used for brain abscesses due to *Aspergillus* species. Corticosteroid therapy is recommended for the treatment of vasogenic cerebral edema that surrounds a brain abscess and to treat any mass effect. Because steroid therapy may decrease the penetration of antibiotics into brain tissue, it should be discontinued when the edema and mass effect improve or resolve. Abscesses that enlarge or do not become smaller during antimicrobial therapy may need repeat aspiration or excision.

Cranial and Spinal Subdural Empyema

Epidemiology and Risk Factors. Subdural empyema is a pyogenic infection in the space between the dura mater and the arachnoid and represents 13 to 20 percent of localized intracranial infections. The arachnoid is not a very strong barrier, and subdural empyema may breach the arachnoid and cause subpial infection.^[46] The most common predisposing condition that leads to the development of a subdural empyema is paranasal sinusitis, especially frontal sinusitis. Paranasal sinusitis is the primary cause of a subdural empyema in 50 to 80 percent of patients, and otitis media is the primary cause in 10 to 20 percent.^[47], ^[48] Superficial infections of the scalp and skull, craniotomy, or septic thrombophlebitis from sinusitis, otitis, or mastoiditis may extend to the subdural space causing empyema.^[46] Subdural empyema in infants usually represents an infected subdural effusion complicating a bacterial meningitis.^[48], ^[50] An empyema may rarely develop in the subdural area of the spinal cord.

Pathogenesis and Pathophysiology. The most important pathophysiological antecedent of a subdural empyema is septic thrombophlebitis of the mucosal veins of the sinuses that results in retrograde extension of infection

with drainage of bacteria into the regional dural veins, and then into the superior sagittal sinus.^[48], ^[51] Subdural empyema may also result from the direct infection of the subdural space during a neurosurgical procedure. Once the infection is established in the subdural space, evolution of an empyema tends to be remarkably rapid because the subdural space has no barriers. The infection can spread medially over the tentorium toward the falx and posteriorly to the infratentorial area.^[46], ^[51] Septic thrombophlebitis extends in a retrograde fashion from the dural sinuses to the cortical veins. Cortical venous infarction may follow and is largely responsible for the severe symptoms, particularly the focal signs, that develop during the course of the illness.^[51], ^[52] Cortical venous thrombosis and infarction cause hemorrhagic and ischemic necrosis of brain parenchyma that subsequently permits brain abscess formation. A co-existent cerebral abscess has been reported in up to 24 percent of cases of subdural empyema.^[46], ^[53] Spinal subdural empyema may be the result of hematogenous spread of infection from a distant site, trauma, spine surgery, or a dermal sinus tract that connects the skin and the dura.

Clinical Features. A patient with a cranial subdural empyema appears acutely ill with headache that is often localized initially to the side of infection and has fever, chills, and nuchal rigidity. In children and adults, the triad of sinusitis, fever, and an acute neurological deficit should be treated with a high index of suspicion for a

subdural empyema.^[46] A progressive disturbance of consciousness occurs as the subdural empyema produces a mass effect that results in increased ICP. Focal neurological deficits are present in 80 to 90 percent of patients and are caused by mass effect from the subdural collection of fluid and to cortical vein thrombophlebitis. Periorbital edema and erythema may be present in patients with a subdural empyema originating from the frontal sinus.^[46],^[52] Seizures, which are typically focal, occur in 30 to 60 percent of patients.^[46] Infants with subdural empyemas usually have an increase in their head size, a bulging fontanel, irritability, poor feeding followed by hemiparesis, convulsions, stupor, and coma.^[47] A spinal subdural empyema presents as fever with signs of rapidly progressive spinal cord compression. Backache may be present, but it is not as characteristic of the presentation of a spinal subdural empyema as it is of the presentation of spinal epidural abscess.

Differential Diagnosis and Evaluation. The differential diagnosis of the signs and symptoms of a cranial subdural empyema includes bacterial meningitis, superior sagittal sinus thrombosis, epidural abscess, and cerebral abscess.^[51] A lumbar puncture should not be performed in patients with the clinical signs of raised ICP or focal neurological deficits. In most series, bacteria are not demonstrated by microscopic examination or culture of CSF obtained by lumbar puncture in patients with a subdural empyema.^[51],^[52],^[53] Cranial MRI is the diagnostic procedure of choice to demonstrate the presence of a subdural empyema. The subdural empyema will have a mildly increased signal intensity on MRI T1-weighted images and a markedly increased signal intensity on T2-weighted images when compared with ventricular CSF.^[46] A benign subdural effusion can also be differentiated from an infected subdural empyema using a cranial MRI scan. A subdural effusion is isointense compared with CSF on MRI T1- and T2-weighted images, and a subdural empyema is hyperintense when compared with CSF on T2-weighted images.^[46] On a CT scan, a subdural empyema has the appearance of a crescent or lentiform-shaped area of low density adjacent to the inner border of the skull.^[54] The empyema consists of an inflammatory exudate and appears denser than CSF. MRI is the best neuroimaging procedure to demonstrate the presence of a spinal subdural empyema.

Management. The treatment of subdural empyema consists of intravenous antibiotic therapy, surgical drainage of the empyema and infected sinuses, and management of increased ICP when present. The majority of cranial subdural empyemas are caused by those organisms typically isolated from patients with chronic sinusitis or otitis. Aerobic streptococci are the causative organisms in 30 to 50 percent of patients with subdural empyema. Anaerobic organisms, particularly anaerobic and microaerophilic streptococci, are isolated from 15 to 25 percent of cases; staphylococci are isolated from 15 to 25 percent of cases; and aerobic gram-negative bacilli are isolated from 5 to 10 percent of cases.^[47],^[48] Empiric therapy must cover aerobic and anaerobic streptococci, staphylococci, and gram-negative bacilli. A combination of penicillin G (20 to 24 mIU/d adults, 400,000 U/kg/d for children and infants) or a third-generation cephalosporin (ceftriaxone or cefotaxime), metronidazole (600 mg/d adults, 22.5 mg/kg/d infants and children), and nafcillin (9 to 12 g/d adults, 200 mg/kg/d infants and children) or vancomycin is recommended (Table 42-2). Surgical drainage can be accomplished by either craniotomy or multiple burr holes.^[46] Intravenous antibiotics should be continued for at least 3 weeks after surgical drainage, and then oral antibiotic therapy can be substituted to complete a 6-week course of therapy. Reoperation for further irrigation and drainage of loculated pockets of pus is typically necessary. It is therefore recommended that the patient undergo frequent CT or MRI scans in order to evaluate whether resolution of the infection has occurred.^[46]

S. aureus is the causative organism in the majority of cases of spinal subdural empyema and such cases should undergo a laminectomy and dural incision with drainage. Extensive irrigation of the subdural space with bacitracin and either vancomycin or gentamicin is recommended. Intravenous antimicrobial therapy for 4 to 8 weeks, and often longer, is also recommended.^[55]

Cranial and Spinal Epidural Abscess

Epidemiology and Risk Factors. Cranial epidural abscesses develop in the space between the dura and inner table of the skull and are usually caused by the spread of infection from the frontal sinuses, middle ear, mastoid, or orbit.^[48] Epidural abscesses may also develop as a complication of a craniotomy or compound skull fracture. At present, the most common cause of a cranial epidural abscess is craniotomy that has been complicated by an infection of the wound, bone flap, or epidural space.^[46] Epidural abscesses may result from or be associated with an area of osteomyelitis. A spinal epidural abscess develops in the space outside the dura mater but within the spinal canal. The spinal

TABLE 42-2 -- ANTIMICROBIAL THERAPY FOR SUBDURAL EMPYEMA

Organism	Adult	Dosing Interval	Child	Dosing Interval
<i>Staphylococcus aureus</i> Methicillin-sensitive	Nafcillin 9 to 12 g/d	Every 4 hr	Nafcillin 200 mg/kg/d	Every 4 hr
<i>Staphylococcus aureus</i> Methicillin-resistant	Vancomycin 2 g/d	Every 12 hr	Vancomycin 40 to 60 mg/kg/d	Every 12 hr
Streptococci	Penicillin G 20 to 24 MU/d	Every 4 hr	Penicillin G 250,000 to 400,000 U/kg/d	Every 4 to 6 hr
Gram-negative bacilli	Ceftriaxone 4 to 6 g/d or Cefotaxime 8 to 12 g/d or Ceftazidime 6 g/d	Every 12 hr Every 4 hr Every 8 hr	Ceftriaxone 80 to 100 mg/kg/d or Cefotaxime 200 mg/kg/d or Ceftazidime 125 to 150 mg/kg/d	Every 12 hr Every 6 hr Every 8 hr
Anaerobes	Metronidazole 600 mg/d or Chloramphenicol 4 g/d	Every 8 hr Every 6 hr	Metronidazole 22.5 mg/kg/d or Chloramphenicol 100 mg/kg/d	Every 8 hr Every 6 hr

Reproduced with permission from Shapiro S: Cranial epidural abscess and cranial subdural empyema. In Roos KL (ed): Central Nervous System Infectious Diseases and Therapy. New York, Marcel Dekker, 1977, pp 499-506.

epidural space is only a true space posterior to the spinal cord and the spinal nerve roots. The anteroposterior width of the epidural space is greatest in the area where the spinal cord is smallest, that is from approximately T4 to T8, and from L3 to S2.^[56],^[57] The most common location for an epidural abscess is the posterior midthoracic region between the fourth and eighth thoracic vertebrae.^[58] The anterior epidural space is only a potential space because the dura is virtually adherent to the posterior surface of the vertebral bodies along the ventral aspect of the spinal canal from the first cervical to the second sacral vertebrae. Anterior abscesses usually occur at cervical levels.^[59] The most common etiology of a spinal epidural abscess is hematogenous spread of bacteria from a remote site of infection to the epidural space. This includes such sites as the skin, urinary tract, lungs, pelvis, cardiac valves, and pharynx. An epidural abscess may also develop by direct extension from a contiguous infection such as vertebral osteomyelitis. The latter disorder is a particularly common etiology for spinal epidural abscess formation in intravenous drug abusers. Immunosuppression from any cause, but most commonly from AIDS or diabetes mellitus, is a predisposing condition in approximately 50 percent of cases of spinal epidural abscesses.^[55] The formation of a small hematoma owing to mild blunt trauma may also provide a *locus minoris resistentiae* that may allow for hematogenous seeding of infection resulting in the formation of a spinal epidural abscess.

Pathogenesis and Pathophysiology. Infection in the frontal sinuses, middle ear, mastoid, or orbit is able to reach the epidural space through the retrograde spread of thrombophlebitis in the emissary veins that drain these areas, by way of direct spread of the infection through bone (osteomyelitis), or through direct infection of the epidural space during craniotomy.^[60] As stated earlier, hematogenous spread to the epidural space from a remote site of infection is an extremely rare cause of cranial epidural abscess but an extremely common cause of spinal epidural abscess.

A spinal epidural abscess may develop as a result of the hematogenous spread of infection from a distant focus of infection to the epidural space. There may also be hematogenous spread of infection to a vertebral body or disc that results in discitis and/or osteomyelitis that subsequently extends into the spinal epidural space. Infection of the epidural space may also occur from direct extension of infection from decubitus ulcers, infected abdominal wounds, or psoas abscesses.^[55] The pathophysiology of spinal cord dysfunction from spinal epidural abscess has been investigated in a rabbit model.^[61],^[62] The gross appearance of the spinal cord at the level of the epidural abscess is usually normal. Microscopically, scattered areas of softening, vacuolization of the cord, areas of necrosis with the disappearance of cells, loss of myelin, and axonal swelling are frequently seen. Myelomalacia occurring in the spinal cord beneath an epidural abscess results from the direct compression of neural tissue and inflammatory thrombosis in the intraspinal vessels with subsequent infarction.

Clinical Features. The clinical presentation of an intracranial epidural abscess is an unrelenting hemicranial headache or persistent fever that develops during or after treatment for frontal sinusitis, mastoiditis, or otitis media. Focal neurological deficits, seizures, and signs of increased ICP do not develop until the infection extends into the subdural space.^[51] Approximately 10 percent of epidural abscesses are associated with a subdural empyema.^[46] An epidural abscess that develops near the petrous bone and involves the fifth and sixth cranial nerves presents with ipsilateral facial pain and lateral rectus weakness (Gradenigo's syndrome). A spinal epidural abscess presents as fever and pain at the affected spinal level. Heusner^[63] described a characteristic clinical pattern of symptom progression. Back pain is

the initial symptom, which is followed by radicular pain in the extremities or pain in an intercostal thoracic dermatomal pattern within 2 to 3 days. As the disease progresses, paresis of appendicular muscles is associated with loss of sensation below the level of the lesion and the loss of bowel and bladder control. Finally, there is complete paralysis of appendicular muscles and a loss of all sensory modalities below the level of the lesion.

Evaluation. The MRI is the diagnostic procedure of choice to demonstrate a cranial epidural abscess because it is free from bony artifacts adjacent to the inner table of the skull, and is easily able to demonstrate extracerebral fluid collections. The epidural fluid will be of higher signal intensity on both MRI T1- and T2-weighted images than the ventricular CSF. Following the administration of gadolinium,

a significant enhancement of the dura on MRI T1- weighted images is seen.^[46] On the noncontrasted CT scan, an epidural abscess has the appearance of a poorly defined lentiform area of low density adjacent to the inner table of the skull. After the administration of contrast, the convex inner side of the low-density lesion enhances. This represents the inflamed dural membrane.^[51]

MRI is also the procedure of choice to demonstrate a spinal epidural abscess. A spinal epidural abscess extends three spinal segments on average and may extend for as long as 13 segments.^[55] MRI is able to visualize the entire extent of the epidural abscess in all directions and the degree of spinal cord compression. An epidural abscess is isointense to CSF on MRI T1-weighted images and hyperintense as compared with CSF on MRI T2-weighted images. Following the administration of gadolinium, enhancement of the lesion occurs. Because spinal epidural abscess is usually a result of the hematogenous seeding of the epidural space, there may be evidence of systemic illness with a peripheral leukocytosis or an elevation in the erythrocyte sedimentation rate. The examination of the CSF may be useful to determine the infecting organism. A lumbar puncture should not be performed, however, when the possibility of a lumbar abscess exists because of the risk for spread of the infection from the epidural space to the subarachnoid space.

Management. The primary treatment of a cranial epidural abscess is surgical debridement, Gram's stain and culture of the purulent material, and intravenous antibiotic therapy. Recommendations for the choice of empiric antibiotic therapy are the same as that described for empiric therapy of subdural empyema and should cover aerobic and anaerobic streptococci, staphylococci, gram-negative bacilli, and anaerobes.

An acute spinal epidural abscess must be managed with an immediate laminectomy and decompression and drainage of the epidural space, followed by 4 to 6 weeks of intravenous antibiotic therapy and then 2 to 3 months of oral antibiotic therapy.^[55] Empiric antibiotic therapy should include coverage for *S. aureus* because this organism is the etiological agent in the majority of spinal epidural abscesses. There is an increasing incidence, however, of spinal epidural abscess due to gram-negative aerobic bacilli, aerobic streptococci, anaerobes, and *Mycobacterium tuberculosis*. Empiric therapy should also include antituberculous chemotherapy, including isoniazid, rifampin, ethambutol, pyrazinamide and either streptomycin, rifabutin, or clofazimine. A tuberculous spinal epidural abscess is usually associated with vertebral osteomyelitis.

Cat-Scratch Disease

Cat-scratch disease is caused by the bacterium *Bartonella henselae* and begins with a cutaneous papule or pustule at the site of inoculation, usually a kitten scratch or bite, within a week of the injury. A regional adenopathy involving the head, neck, and upper extremity follows in 1 to 7 weeks. Fever and malaise occurs in approximately one third of patients. The diagnosis is made by demonstrating pleomorphic bacilli by Warthin-Starry silver stain of a lymph node biopsy or by polymerase chain reaction (PCR) amplification techniques on lymph node tissue. The neurological and ophthalmological manifestations associated with cat-scratch disease include (1) encephalopathy (in 2 to 4 percent of patients with cat-scratch disease) characterized by headache, restlessness, irritability, focal or generalized seizure activity, confusion, disorientation, and coma. Focal neurological deficits including disturbances of language, cranial nerve palsies, hemiplegia, and ataxia can occur; and (2) neuroretinitis, characterized by a painless, unilateral, sudden loss of visual acuity. On examination, papilledema is associated with macular exudates in a star formation. There is mounting evidence implicating *B. henselae* in HIV dementia and HIV-associated focal brain lesions, aseptic meningitis and neuropsychiatric disease. The serological test for anti-*Bartonella* antibodies cannot discriminate between anti-*Bartonella henselae* and anti-*Bartonella quintana* (the etiological agent of trench fever) antibodies. Examination of the CSF in cases of cat-scratch disease encephalopathy demonstrate an elevation of the protein concentration, a lymphocytic and rarely a leukocytic pleocytosis, and a normal glucose concentration. CSF cultures for *B. henselae* are negative. In patients with lymphadenopathy, biopsy of a lymph node may reveal the typical features of cat-scratch disease. Skin tests with the Hanger-Rose cat-scratch disease antigen are positive in the majority of patients. In a few patients with neuroretinitis associated with cat-scratch disease, *B. henselae* has been isolated from blood. Gram's stain reveals small, gram-negative, slightly curved rods. The physician should question the patient about the history of a scratch by a kitten or a cat and the appearance of any skin lesion. No clear guidelines exist for which patients should be treated and what antibiotic should be used. The majority of patients with cat-scratch disease without an associated neurological manifestation have a self-limited illness. The demonstration of *B. henselae* bacteremia associated with neuroretinitis has led to the recommendation that antimicrobial therapy be considered in these patients with either erythromycin, doxycycline, azithromycin, clarithromycin, or ofloxacin. As stated earlier, an increasing amount of evidence exists for *B. henselae* as an etiological agent in a small proportion of cases of HIV-associated dementia, neuropsychiatric illness, focal brain lesions, and aseptic meningitis. Antimicrobial therapy may benefit these patients, but firm recommendations cannot be made at this time.^[64]

Whipple's Disease

Whipple's disease is caused by the rod-shaped bacillus *Tropheryma whippelii* and presents with arthralgias, abdominal pain, fever, diarrhea, malabsorption, and weight loss.^[65], ^[66] Whipple's disease occurs predominantly in middle-aged men and most often in farmers. Approximately 6 to 7 percent of patients with Whipple's disease have neurological manifestations, but many cases of CNS involvement in Whipple's disease go unrecognized.^[66] The characteristic triad of Whipple's disease is dementia, ophthalmoplegia, and myoclonus.^[66] Nearly all cases of ophthalmoplegia involve a conjugate vertical gaze palsy. A peculiar mixture of

smooth convergent-divergent pendular oscillations of the eyes with synchronous rhythmical contractions of the jaw, oculomasticatory myorhythmia, is thought to be unique to Whipple's disease. The diagnosis of CNS Whipple's disease is difficult. Examination of the CSF may be normal or may demonstrate a mild pleocytosis. Para-aminosalicylic acid-positive cells are rarely identified in CSF, but if they are, CNS Whipple's disease is a strong possibility. Para-aminosalicylic acid staining of a CSF cytocentrifuged pellet should therefore be performed in all patients in whom CNS Whipple's disease is suspected.^[66] The para-aminosalicylic acid reagents will also stain *Mycobacterium avium* complex, *Histoplasma capsulatum*, and nonmicrobial glycoprotein. The PCR technique has allowed for the identification of *T. whippelii* from small intestinal biopsy tissue, lymph node tissue, and CSF.^[67] Brain biopsy is not routinely recommended for CNS Whipple's disease. *T. whippelii* infection of the duodenal mucosa can be detected by PCR in patients in whom an isolated extraintestinal disease exists and in patients with isolated CNS disease. It has been suggested, therefore, that a patient with suspected CNS Whipple's disease should undergo a duodenal tissue biopsy by endoscopy, and the material obtained should be examined by PCR for *T. whippelii*. PCR-based Whipple's disease diagnostic tests, however, are not yet standardized.^[66] Trimethoprim-sulfamethoxazole appears to be the most effective therapy for the treatment and prevention of CNS Whipple's disease. Treatment should be initiated with trimethoprim-sulfamethoxazole 160 mg/800 mg by mouth 2 to 3 times daily, procaine penicillin G 1.2 million units intramuscular injection daily, and streptomycin 1 g by intramuscular injection daily. Penicillin and streptomycin are continued for a total of 14 days. Trimethoprim-sulfamethoxazole should be continued for at least 1 year. Some clinicians continue antibiotic therapy for CNS Whipple's disease for at least 2 years, and some indefinitely.^[66]

MYCOBACTERIAL INFECTIONS

Mycobacterium tuberculosis

Epidemiology and Risk Factors. Chopin, Keats, Thoreau, Paginini, Modigliani, Elizabeth Browning, and Thomas Wolfe died of tuberculosis. ^[68] ^[69] ^[70] In the beginning of the 20th century, tuberculous meningitis was common; then after the Second World War a dramatic decrease in the incidence of tuberculosis occurred in the United States and Europe. Tuberculosis and CNS tuberculosis continued to be prevalent in developing countries. Beginning, however, in 1985 the incidence rates of tuberculosis began to increase in the United States. This resurgence of disease was concentrated among males, 25 to 44 years of age, and particularly among immigrants from areas with a high prevalence of tuberculosis infection. A marked increase in the incidence of tuberculosis in long-term residents of American nursing homes was also noted. CNS tuberculosis is considerably more frequent in individuals with AIDS and tuberculosis involving other organ systems than in immunocompetent persons with tuberculosis. In some parts of the world, the most common AIDS-associated CNS infection is tuberculous meningitis. ^[71]

Pathogenesis and Pathophysiology. Tuberculous meningitis does not develop acutely from the hematogenous spread of tubercle bacilli to the meninges from a pulmonary source of acute infection. Isolated miliary tubercles form in the parenchyma of the brain or the meninges during the hematogenous dissemination of tubercle bacilli during the course of the primary infection or episodically from the endogenous reactivation of latent tuberculosis elsewhere in the body. The tubercles tend to enlarge and are usually caseating. ^[72] The fate of these tubercles and the subsequent course of infection are at least, in part, a function of the immunological capacity of the host. Minute caseous foci may be completely eliminated by macrophages leaving no residua of infection. Larger caseous foci may shelter viable mycobacteria that cause reactivated disease only in the presence of impaired host immunity. ^[71] The propensity for a caseous lesion to produce meningitis is determined by its proximity to the subarachnoid space, the rate at which fibrous encapsulation develops, and the rate at which the lesions enlarge. Organisms proliferate in the caseous centers, eventually leading to the rupture of the tubercle. Subependymal caseous foci may remain quiescent for months or years but then cause meningitis through the discharge of bacilli and tuberculous antigens into the subarachnoid space. ^[72] ^[73] The neurological complications of tuberculous meningitis are initiated by a hypersensitivity reaction that occurs in the subarachnoid space when tuberculoproteins are released by the rupture of a caseous lesion. The exudate is located predominantly in the basilar cisterns and surrounds the cranial nerves and major blood vessels at the base of the brain. As the basilar cisterns are filled with a purulent exudate, the flow of CSF is blocked and an obstructive hydrocephalus may develop. The inflammatory exudate also obstructs the resorption of CSF by the arachnoid granulations, the result of which is a communicating hydrocephalus. Cerebral ischemia and infarction occur either as the result of vasculitis caused by direct invasion of the arterial walls by mycobacteria and inflammatory cells or by the compression of the blood vessels at the base of the brain from the inflammatory exudate. ^[72] ^[74] Cranial nerve abnormalities resulting from tuberculous meningitis may result from either mechanical compression of the nerve by the purulent exudate or as a result of vasculitic infarction of the nerve. ^[68] Border-zone encephalitis describes an inflammatory reaction in the brain tissue underlying areas of thick, adherent exudate. ^[68] ^[69] ^[70] ^[71] Tuberculous encephalopathy refers to the development of cerebral edema occasionally with perivascular demyelination or hemorrhagic leukoencephalopathy deep in the white matter of the brain at a distance from vascular abnormalities and purulent exudate. It is hypothesized that this is a purely allergic phenomenon mediated by tissue hypersensitivity, either to the bacilli or their antigens or possibly to a myelin-related antigen of brain tissue itself. ^[71]

Clinical Features. The clinical presentation of tuberculous meningitis is either an acute meningoencephalitis characterized by coma, raised intracranial pressure, seizures, and focal neurological deficits or a slowly progressive illness with persistent and intractable headache followed by confusion, lethargy, and cranial nerve deficits. Fever may or may not be present in the course of this infection. The sixth cranial nerve is the most frequently affected by

tuberculous meningitis followed by the third, fourth, seventh, and less commonly, the second, eighth, tenth, eleventh, and twelfth cranial nerves. ^[71] Hemiparesis may develop as a result of ischemic infarction in the medial striate and thalamoperforating arteries. The most commonly reported symptoms in children include nausea, vomiting, and behavioral changes. Seizures are an infrequent presenting sign, although more than 50 percent develop seizures during the initial hospitalization. ^[71] In patients with an acute meningoencephalitis syndrome, coma may evolve rapidly and is because of increased ICP from both cerebral edema and communicating and obstructive hydrocephalus. The clinical syndrome of tuberculous encephalopathy is characterized by convulsions, stupor, coma, involuntary movements, paralysis, and decerebrate spasms or rigidity with or without clinical signs of meningitis or CSF abnormalities of tuberculous meningitis. ^[72] The clinical presentation of tuberculous meningitis in HIV-infected individuals is similar to the clinical presentation in immunocompetent patients; however, HIV-infected patients are more likely to have an acellular spinal fluid at presentation and have a higher incidence of intracerebral mass lesions. ^[71]

Evaluation. The combination of an unrelenting headache (+/- low grade fever) with malaise and anorexia and a CSF lymphocytic pleocytosis with a mild decrease in the glucose concentration is suggestive of tuberculous meningitis. The initiation of therapy should not await bacteriological proof of tubercle bacilli by smear or culture. The development of hydrocephalus and the clinical scenario just described is additional strong evidence for tuberculous meningitis. The absence of radiographical evidence of pulmonary tuberculosis and/or a negative tuberculin skin test does not exclude the possibility of tuberculous meningitis. The classic "Ghon complex" refers to Anton Ghon's observation from autopsy specimens that the primary lesion of tuberculosis is in the lung with secondary infection in the tracheobronchial lymph nodes. ^[76] In addition to the primary complex, chest radiographic abnormalities suggestive of pulmonary tuberculosis are hilar adenopathy, a miliary pattern, upper lobe infiltrate, cavitations, and lobar consolidation. CNS disease may develop from caseous foci in organs other than the lung with subsequent hematogenous dissemination of virulent tubercle bacilli to the CNS. The adrenal gland, bone, genitourinary tract, and the mediastinal and abdominal lymph nodes are all potential sources of caseous foci, which may serve as "seed beds" for the later development of hematogenous dissemination of tubercle bacilli. ^[77] The intradermal tuberculin skin test is negative in 50 to 70 percent of patients with tuberculous meningitis and often becomes positive during the course of therapy. ^[73] ^[78] The classic CSF abnormalities in tuberculous meningitis are as follows: (1) an elevated opening lumbar pressure; (2) increased WBC count between 10 to 500 cells/mm³ with a predominance of lymphocytes; (3) an elevated protein concentration in the range of 100 to 500 mg/dL; (4) a decreased glucose concentration (the median glucose concentration is approximately 40 mg percent); and, (5) a positive culture in 75 percent of patients requiring 3 to 6 weeks for growth. A cobweb-like "skin" may form at the top of the CSF specimen and is the classic pellicle of tuberculous meningitis. Tubercle bacilli may become entangled in the skin of the pellicle and are more easily located by smear or culture of the pellicle than elsewhere in the CSF. ^[71] The last tube of CSF collected should be sent for acid-fast bacilli (AFB) smear. Positive smears are typically reported in only 10 to 40 percent of patients with tuberculous meningitis. The CSF chloride concentration and the bromide partition test have been disappointing in their ability to differentiate tuberculous meningitis from other etiologies of lymphocytic meningitis. The CSF chloride concentration typically decreases as the CSF protein concentration increases; therefore, this is a rather nonspecific test. The bromide partition test measures the ratio of serum to CSF bromide 24 hours after the oral administration of sodium bromide or the intravenous injection of radioactive bromide. ^[79] A low bromide partition ratio is seen in any infectious or inflammatory CNS disease that increases the permeability of the blood-CSF barrier. The concentration of tuberculostearic acid in CSF has been reported to be a sensitive marker for CNS tuberculosis and enjoyed a brief period of popularity, even though it was extremely difficult to find a laboratory that was able to run this assay. The PCR technique and other molecular diagnostic techniques for the detection of *M. tuberculosis* DNA in the CSF hold the greatest promise. ^[87] The sensitivity of the PCR technique for the detection of *M. tuberculosis* DNA in CSF is approximately 54 percent; however, false-positive results occur with rates of 3 to 20 percent. ^[71]

Management. The American Academy of Pediatrics recommends a combination of isoniazid (INH), rifampin, pyrazinamide, and streptomycin as the initial therapy of tuberculous meningitis in children. ^[80] The doses are listed in [Table 42-3](#). When antimicrobial sensitivities are known, the treatment regimen may be altered. Standard therapy uses four drugs for 2 months followed by INH and rifampin alone for 6 to 9 months. Most drug regimens include isoniazid, rifampin, and pyrazinamide and either ethambutol or streptomycin (in children too young to be monitored for visual acuity). ^[81] When the results of drug susceptibility studies are available, and if the organism is sensitive to INH and rifampin, ethambutol and pyrazinamide are continued

TABLE 42-3 -- EMPIRICAL THERAPY FOR TUBERCULOUS MENINGITIS

Drug	Dosage	
	Children	Adults
Isoniazid (INH)	10 mg/kg/d once daily	300 mg/d
Pyridoxine		50 mg/d
Rifampin	10 mg/kg/d	600 mg/d
Pyrazinamide	30 mg/kg/d	30 mg/kg/d
Ethambutol*	15 to 25 mg/kg/d	15 to 25 mg/kg/d
Streptomycin	20 to 40 mg/kg/d	

Corticosteroids		
Dexamethasone	0.15 mg/kg every 6 hr	0.15 mg/kg every 6 hr
Prednisone§	1 mg/kg/d	1 mg/kg/d

*When antimicrobial resistance is suspected.

The American Academy of Pediatrics recommends a combination of INH, rifampin, pyrazinamide, and streptomycin for tuberculous meningitis in children.

For altered consciousness, papilledema, focal neurological signs, impending herniation, spinal block, hydrocephalus.

§For intractable headache, papilledema with otherwise normal neurological examination .

TABLE 42-4 -- ANTITUBERCULOUS CHEMOTHERAPY IN HIV-INFECTED INDIVIDUALS

Isoniazid	10 to 15 mg/kg/d
Rifampin	10 to 15 mg/kg/d
Pyridoxine <i>plus</i>	50 mg/d
Ethambutol <i>or</i>	25 mg/kg/d
Pyrazinamide <i>plus</i>	20 to 30 mg/kg/d
Streptomycin <i>or</i>	20 to 40 mg/kg/d
Rifabutin <i>or</i>	300 mg/d
Clofazimine	300 mg/d

for only 2 months, and then INH and rifampin are continued for a total of 9 to 12 months. Empiric therapy for tuberculous meningitis in HIV-infected individuals should include a combination of INH, pyridoxine, and rifampin plus ethambutol or pyrazinamide and either streptomycin or rifabutin or clofazimine ([Table 42-4](#)). Corticosteroid therapy decreases meningeal inflammation. Isoniazid and pyrazinamide penetrate the CSF with or without meningeal inflammation, but the penetration of rifampin, streptomycin, and ethambutol is considerably better in the presence of meningeal inflammation. Dexamethasone therapy is recommended for patients with altered consciousness, papilledema, focal neurological signs, impending herniation, spinal block, and hydrocephalus. In addition, as patients are treated for tuberculous meningitis, the slow resolution of the inflammatory exudate in the basilar cisterns may obstruct the flow and resorption of CSF with the subsequent development of hydrocephalus. These patients may benefit from a short course of oral prednisone. A basic principle of management for patients with organisms that are resistant to one or more drugs is the administration of at least two agents to which a demonstrated susceptibility exists. For example, for patients with isolated INH resistance, INH should be discontinued and pyrazinamide and rifampin continued for the entire course of therapy. ^[81]

Mycobacterium avium

CNS disease from *M. avium* is a result of the hematogenous dissemination of this organism from a respiratory or gastrointestinal source of infection. *M. avium* and *M. intracellulare* are separate species, but their separation has no clinical value, and therefore, they are considered together in this section. Infection with these species of mycobacteria occurs primarily in patients with advanced HIV disease, generally in patients with fewer than 50 CD4⁺ cells/μl. Infection of the CNS can present as meningitis, meningoencephalitis, rhombencephalitis, brain abscess, or cranial neuropathies. Neuroimaging may demonstrate meningeal enhancement, hydrocephalus, or single or multiple enhancing lesions. Diagnosis is made by acid-fast smear and culture of the CSF or brain abscess aspirate. There have been few randomized, comparative controlled treatment trials for *M. avium* and *M. intracellulare* CNS infections. Clarithromycin and azithromycin have excellent activity in the therapy of disseminated *M. avium* disease in HIV-infected individuals, but their therapy in *M. avium* CNS infections has not been studied. Rifabutin is efficacious for the prophylaxis of disseminated *M. avium* infection in HIV patients and has been shown to increase survival in HIV-infected individuals with disseminated disease when used at higher doses (450 to 600 mg). The treatment of a CNS complication of disseminated disease should include at least a four-drug regimen, which at present is clarithromycin (500 mg twice daily), rifampin (600 mg daily), ethambutol (25 mg/kg/d for 2 months then 15 mg/kg/d), and streptomycin (0.75 to 1.0 g at least three times per week). A combination of azithromycin (250 mg/d), rifabutin (300 mg daily), and ethambutol and streptomycin has been recommended as an alternative treatment regimen. Treatment is continued until cultures are negative for at least 12 months and will likely need to be continued for the life of the patient. ^[82]

SPIROCHETE INFECTIONS

Neurosyphilis

The origin of the name syphilis is from a poem titled "Syphilis sive morbus Gallicus" by an Italian physician, Girolamo Fracastoro. The poem is about a shepherd boy named Syphilus who lives in the time of King Alcithous of Haiti. When Syphilus loses his sheep because of a drought, he blames the Sun God and convinces the natives of Haiti to offer sacrifices to King Alcithous, rather than to the Sun God. The angered Sun God revenges himself by sending a plague to the island natives. The shepherd boy Syphilus is, of course, the very first victim.^[83] One of the Pinzon brothers who sailed with Christopher Columbus as captains of the Nina and the Pinta is historically blamed for bringing syphilis to Spain. The first documented case of syphilis in the colonized New World occurred in Connecticut in 1646.^[83] The term neurosyphilis describes any of six neurosyphilitic syndromes including asymptomatic neurosyphilis, acute symptomatic syphilitic meningitis, meningovascularitis, parenchymatous neurosyphilis (dementia paralytica or tabes dorsalis), CNS gummata, and congenital neurosyphilis.^[84]

Epidemiology and Risk Factors. In the preantibiotic era, tabes dorsalis was the most common form of neurosyphilis. Over the past decade, an increasing number of patients with asymptomatic or symptomatic syphilitic meningitis, meningovascularitis, and syphilitic eye disease have been reported. The increasing number of cases of early neurosyphilis are occurring in individuals infected with HIV.^{[85][86][87][88]}

Pathogenesis and Pathophysiology. Primary syphilis is defined by the appearance of a painless chancre at the site of inoculation. If untreated, the chancre will heal within 3 to 6 weeks, after which most patients progress to the secondary stage of disease in which systemic spirochetemia becomes manifest by skin rash and flu-like symptoms with lethargy, fever, headache, and sore throat. The skin

rash is typically nonpuritic and widespread but is most marked on the palms and soles. There may be generalized lymphadenopathy. Untreated, secondary syphilis also resolves over a period of weeks to months. A period of latency during which there are no clinical manifestations of syphilis occurs, but there is historical and serological evidence of syphilis. About one third of patients with untreated latent syphilis develop tertiary manifestations of the disease after a variable period ranging from months to years. Tertiary syphilis may present as either cardiovascular syphilis, gummatous syphilis, or neurosyphilis.^[89] Invasion of the CNS by *T. pallidum* occurs early in the course of infection. Clinical neurosyphilis may present at any point in the natural history of infection beyond the primary stage.^[90] During the early stages of *T. pallidum* CNS infection, pathological changes are limited to perivascular infiltration of the meninges with lymphocytes and plasma cells. Focal meningeal inflammation may lead to the formation of hypertrophic meninges or gummata. Inflammatory cells invade blood vessel walls causing arteritis and eventually luminal occlusion by thrombosis, ischemia, and infarction.^[90] Parenchymal involvement occurs in late neurosyphilis and is characterized by neuronal degeneration and loss, and gliosis. The brain becomes atrophic, and the meninges are thickened and cloudy.^[91] In tabes dorsalis the preganglionic portion of the dorsal roots are infiltrated with lymphocytes and plasma cells, and the posterior columns of the spinal cord become atrophic.^[91]

Clinical Features and Evaluation. Asymptomatic neurosyphilis is defined by an abnormal CSF evaluation including a mild lymphocytic or mononuclear pleocytosis, an elevated protein concentration, and a reactive CSF venereal disease research laboratory (VDRL) test in a patient without neurological signs or symptoms.^[85]

Acute symptomatic syphilitic meningitis was first described by H. Houston Merritt in 1935.^[92] The most common symptoms of syphilitic meningitis are headache, nausea and vomiting, and stiff neck. In Merritt's review, papilledema was frequently present resulting from acute hydrocephalus associated with meningeal inflammation with increased ICP. Papilledema is not a common finding today. Abnormalities of cranial nerves II, VI, VII, and VIII are common. The meningeal symptoms typically develop within 1 to 2 years of the initial infection.^[85] Examination of the CSF in cases of syphilitic meningitis reveals an increased opening pressure, a lymphocytic pleocytosis, a normal or slightly decreased glucose concentration, an elevated protein concentration, and a positive VDRL test. A nonreactive CSF-VDRL test does not rule out neurosyphilis. A reactive CSF-VDRL test virtually confirms the diagnosis of neurosyphilis except when the CSF is blood tinged. Blood in the CSF may give a false-positive CSF-VDRL test.^[84]

Meningovascular syphilis is defined by the appearance of focal neurological signs from an inflammatory, obliterative endarteritis involving small and medium-sized arteries associated with signs of meningeal inflammation. The middle cerebral artery is commonly involved and its involvement is clinically manifest by the so-called luetic hemiplegia. Examination of the CSF may reveal an isolated elevation of protein concentration or a mild pleocytosis and a reactive VDRL. Cerebral angiography may demonstrate a nonspecific pattern of diffuse narrowing of intracerebral arteries and arterioles. Neuroimaging may demonstrate multiple areas of infarction. The peak incidence for the development of meningovascular syphilis is 5 to 7 years after the primary infection.^[89] Syphilitic arteritis can also develop in any intraspinal artery, resulting in acute transverse myelitis with paraplegia, sensory level, and loss of sphincter control.^[91]

Dementia paralytica is manifest as a slow deterioration in cognitive functioning with impaired memory, loss of insight and judgment, language abnormalities, loss of appendicular strength, tremor of the tongue and hands, pupillary abnormalities, and loss of bowel and bladder control. The syndrome of dementia paralytica typically occurs 10 to 20 years after primary infection. Examination of the CSF at this stage demonstrates one or a combination of the following: (1) a positive VDRL test, (2) lymphocytic pleocytosis, (3) an elevated protein concentration.^[85]

Tabes dorsalis is characterized by paresthesias or dysesthesias in a radicular distribution.^[91] As the disease progresses, proprioceptive and vibratory sense is lost due to neuronal degeneration and infiltration of inflammatory cells into the dorsal columns and posterior spinal nerve roots of the spinal cord. Loss of the pupillary reaction to light with preservation of pupillary constriction to accommodation-- the Argyll-Robertson pupillary abnormality--may be present. The patient has a broad-based, foot-slapping gait. The peak incidence for tabes dorsalis is 15 to 20 years following the primary infection.^[89] It has been suggested that the lancinating pains typically attributed to tabes dorsalis in the past were due to the heavy metal therapy used to treat neurosyphilis in the preantibiotic era and not the primary infection.^[91]

Gummatous neurosyphilis is characterized by gummata located in the basal cisterns, leptomeninges, or within the parenchyma. They produce focal neurological deficits and cranial nerve palsies by exerting pressure on adjacent structures.^[91]

Diagnosis. The serological tests for syphilis can be grouped into two categories: treponemal tests that detect specific antibodies against *T. pallidum* and which include the fluorescent treponemal antibody absorption test (FTA-ABS) and the microhemagglutination-*Treponema pallidum* test (MHA-TP), and nontreponemal tests, which detect antibodies to lipids found on the membranes of *T. pallidum* using cardiolipin-lecithin-cholesterol antigens. The nontreponemal tests in routine use today include the VDRL and the rapid plasma reagin test (RPR). The FTA-ABS test is the first serological test to become positive after inoculation. The FTA-ABS and the MHA-TP tests are nonquantitative; they are either positive or negative. The VDRL test may be quantitated by serial dilutions of serum, and the titer is reported as the greatest serum dilution that produces a positive result. The VDRL titer reaches low levels in late syphilis and may eventually become nonreactive.^[85] The causes of biological false-positive VDRL and FTA-ABS tests are listed in [Table 42-5](#). Most false-positive VDRL tests have a low titer of 1:8 or less.^[85] In a patient with presumed neurosyphilis, a serological test for syphilis, either the FTA-ABS test or the MHA-TP test, is performed initially. Because the VDRL test may become nonreactive in later stages of syphilis, only about 70 percent of patients

TABLE 42-5 -- CAUSES OF FALSE-POSITIVE SEROLOGICAL TESTS FOR SYPHILIS

FALSE-POSITIVE FLUORESCENT TREPONEMAL ANTIBODY ABSORPTION (FTA-ABS) TEST

Technical error
Lyme borreliosis
Genital herpes simplex

with neurosyphilis have a positive VDRL test. A CSF examination should be performed in patients with a reactive MHA-TP or FTA-ABS. The diagnosis of neurosyphilis is made in the presence of a reactive serological test with either neurological manifestations consistent with neurosyphilis or CSF evidence of a lymphocytic pleocytosis and an elevated protein concentration, and/or a positive CSF- VDRL test. Most clinicians treat patients for neurosyphilis when they have a positive serological test and a CSF lymphocytic pleocytosis with an elevated protein concentration whether the CSF-VDRL is reactive or not. A reactive CSF-VDRL establishes the diagnosis but a nonreactive test does not exclude the diagnosis. Screening for the presence of syphilis in HIV-1-infected individuals should be performed by the serum FTA-ABS test as the nontreponemal tests for syphilis may be falsely negative in HIV-infected individuals. A loss of reactivity to the treponemal tests in individuals infected with HIV-1 with advanced immunosuppression occurs.^[88] In HIV-infected individuals with neurosyphilis, the CSF should demonstrate a lymphocytic pleocytosis and an elevated protein concentration. When the CSF-VDRL is negative, a CSF FTA-ABS or CSF MHA-TP should be obtained. The lack of CSF FTA-ABS or CSF MHA-TP reactivity excludes a diagnosis of neurosyphilis. The CSF FTA-ABS and CSF MHA-TP are not routinely recommended for the screening of neurosyphilis in non-HIV-infected individuals because reactivity of these tests on CSF does not establish the diagnosis of neurosyphilis.^[91]

Management. Primary, secondary, and latent syphilis are treated with benzathine penicillin; neurosyphilis is treated with intravenous aqueous crystalline penicillin G 2 to 4 million units every 4 hr for 10 to 14 days. An alternate regimen is procaine penicillin, 2.4 million units intramuscularly daily with probenecid, 500 mg orally four times a day, both for 10 to 14 days. Patients with a history of penicillin allergies should be skin tested and desensitized if necessary.^{[85], [91]} The frequency with which intravenous antibiotics are unsuccessful in the therapy of neurosyphilis is extremely low. In those instances in which a progression of clinical disease or persistence of a CSF lymphocytic pleocytosis or a reactive CSF-VDRL is present, re-treatment of the patient with an additional 24 million units/d for 10 days is reasonable. The initial CSF pleocytosis will resolve 6 months after penicillin therapy in 80 percent of patients. Serial CSF-VDRL titers should decrease with treatment. Re-examination of the CSF should occur in HIV-infected patients with neurosyphilis.

Lyme Disease

Epidemiology and Risk Factors. The Swedish dermatologist, Afzelius, first described an expanding ringlike skin lesion following a tick bite in 1910. He called this lesion erythema chronicum migrans.^{[93], [94]} The first case report of erythema migrans in the United States involved a physician in Wisconsin who was bitten by a tick while hunting. This was reported in 1970.^[95] In the mid-1970s a number of children and adults from Lyme, Old Lyme, and Haddam, Connecticut, presented with recurrent attacks of asymmetric large joint pain and swelling that was often preceded by an erythematous expanding plaque-like skin lesion with central clearing.^[96] This disease was termed Lyme arthritis. Lyme arthritis was later renamed Lyme disease. In 1979, Andrew Spielman, while searching for the tick vector of human babesiosis, named one tick suspect, *Ixodes dammini*, in honor of the distinguished Harvard pathologist Gustave Dammin.^{[96], [97]} This tick would later be identified as the vector of Lyme disease.^[96] In 1981, Willi Burgdorfer isolated the Lyme spirochete from ticks collected on Shelter Island.^[98] By 1983, two separate groups headed by Steere^[99] and Benach^[100] cultured *Borrelia burgdorferi* from patients with Lyme disease, conclusively establishing this organism as the infectious agent.^{[94], [96]}

In Canada, Lyme disease occurs in Ontario and Manitoba; in the United States the highest incidence of Lyme disease has been reported in Connecticut, Delaware, Maryland, New Jersey, New York, Pennsylvania, Rhode Island, and Wisconsin. The tick vector in the Northeast and Midwest is the black-legged tick, *I. scapularis*, which has a northern (*I. dammini*) and southern form.^[94] The usual vector of Lyme disease on the West Coast is *I. pacificus*; the frequency of Lyme disease is much lower on the West Coast than in the Northeast.

Pathogenesis and Pathophysiology. Lyme disease is caused by invasion of the CNS by the spirochete, *B. burgdorferi*. The pathophysiology of Lyme disease bears several similarities to the pathophysiology of syphilis. The organism initially invades the body through intradermal inoculation.

This occurs through a tick bite. *B. burgdorferi* is transmitted through the mouth parts of the tick. The tick bite is painless. Transmission of infection occurs only after prolonged attachment and feeding over 24 hours. Humans are most likely to be bitten in the late spring and early summer.^[94] Similar to syphilis, inoculation is followed by a spirochetemia with wide dissemination, and like syphilis, invasion of the CNS initially presents as a meningitis. The various neurological syndromes are felt to result not only from infection of the CNS by *B. burgdorferi*, but also from the reaction of the immune system to the spirochete and the associated inflammatory response. The spirochetes activate T-cell subsets and induce cytokine production (including interleukins 1 and 6, and tumor necrosis factor alpha). In addition, they cause production of autoantibodies to axonal proteins, gangliosides, neurons, myelin components, and cardiolipin.^[94]

Clinical Features. The neurological manifestations of Lyme disease are classically divided into early syndromes and late syndromes. The early syndromes include meningitis, facial nerve and other cranial nerve palsies, and radiculoneuritis. Delayed syndromes include sensorimotor polyradiculoneuropathy, encephalopathy, and encephalomyelitis.^{[94], [101], [102]}

MENINGITIS

Signs and symptoms of meningitis may develop while the characteristic skin lesion, erythema migrans, is still present and typically occurs within 12 weeks of infection. Most patients complain of headache and fatigue and some may have severe pain between the scapule, severe fatigue, myalgias, and arthralgias. The diagnosis of Lyme disease is made by the examination of the CSF that demonstrates a lymphocytic pleocytosis with a normal glucose concentration and a mildly to moderately elevated protein concentration. Paired samples of serum and CSF should be sent to detect the intrathecal production of *B. burgdorferi* antibody (usually IgG or IgA). Intrathecal anti-*Borrelia burgdorferi* antibody production can be detected in 50 to 90 percent of cases. CSF PCR can be used to amplify *B. burgdorferi* DNA and is positive in 30 to 40 percent of patients with Lyme meningitis.^{[94], [101]} Culture of the organism from CSF is rarely positive.

FACIAL NERVE AND OTHER CRANIAL NERVE PALSIES

The most frequent neurological abnormality in patients with Lyme disease is facial nerve palsy that is unilateral or bilateral and most often occurs within 4 weeks of the appearance of erythema migrans. Patients may also complain of headache and fatigue. Other cranial nerves may also be involved in Lyme disease, including II,

III, IV, V, VI, VIII, and IX to XII, although involvement of these cranial nerves is rare.^[94] The most useful diagnostic tests for patients with a facial nerve palsy are a serum Lyme enzyme-linked immunosorbent assay (ELISA), Western blot, and a CSF examination. The CSF may demonstrate a lymphocytic pleocytosis and intrathecal antibody production of anti- *Borrelia burgdorferi* antibodies, although the latter is found in less than 10 percent.^[94] In patients with a facial nerve palsy and a normal CSF examination, oral doxycycline (100 mg orally, twice daily for 2 weeks) can be used, however, patients with a facial nerve palsy and a CSF pleocytosis should be treated with intravenous ceftriaxone.^[101]

RADICULONEURITIS

Early in the course of spirochetemia, patients may complain of severe sharp, jabbing, or deep and boring pain in a radicular nerve distribution. Often, the limb that was the site of the tick bite is the site of the pain.^[102] Within days to weeks there may be sensory loss, weakness, or hyporeflexia in the limb. There may be clinical signs of an associated myelitis characterized by sphincter dysfunction or Babinski's sign. Patients may also have a facial nerve palsy. The diagnosis is made by the examination of CSF and through electromyography (EMG). The majority of patients have a CSF lymphocytic pleocytosis, an increased CSF protein concentration, and evidence of intrathecal production of anti- *Borrelia burgdorferi* antibody.^[102] The majority of patients also have a positive Lyme serology and Western blot.^[101] The abnormalities on EMG are consistent with a polyradiculopathy with a predominantly axonal process.^[94] Some patients may have a clinical presentation suggestive of the Guillain-Barre syndrome with areflexia and a predominantly motor involvement. EMG findings of a primarily axonal process and CSF evidence of a lymphocytic pleocytosis, however, are not consistent with a diagnosis of Guillain-Barre. Guillain-Barre syndrome may occur as a postinfectious complication of Lyme disease. In these patients, the EMG does show changes typical of a demyelinating process, and examination of the CSF demonstrates the characteristic cytoalbuminological dissociation.^[94]

ENCEPHALOPATHY

Encephalopathy was initially described in patients with systemic manifestations of Lyme disease and in particular, arthritis. The patients have a mild confusional state characterized by difficulty with memory and cognitive slowing often accompanied by fatigue and malaise. Neuropsychological testing is abnormal, but CSF abnormalities may or may not be present. Pleocytosis is reported in 5 percent of patients, and intrathecal anti- *Borrelia burgdorferi* antibody production is present in less than 50 percent of patients.^[94], ^[102] Active neurological involvement that is suggested by CSF abnormalities, the psychological consequences of chronic illness, and possibly residual neurological deficits of a past infection with Lyme disease may affect a patient's perception of cognitive dysfunction. In addition, evidence from quantitative analysis of SPECT scans suggests that Lyme encephalopathy patients with measurable memory deficits have reduced perfusion affecting primarily subcortical frontotemporal white matter and basal ganglia.^[103]

SENSORIMOTOR POLYRADICULONEUROPATHY

Patients with chronic Lyme radiculoneuropathy present with sensory symptoms, particularly distal paresthesias in a

stocking and glove or a stocking distribution. A less common presentation is pain in the distribution of the cervical, thoracic, or lumbosacral dermatomes. This syndrome is distinct from the painful symptoms of radiculoneuritis that occurs within a few weeks of infection with *B. burgdorferi*. Although patients with a chronic radiculopathy complain of pain, it is much less severe than in the acute radiculoneuritis form. Electrophysiological studies demonstrate a mild sensorimotor radiculoneuropathy with axonal loss, minor decreases in the distal compound action potential amplitudes (sensory greater than motor), little or no slowing of nerve conduction velocities, and mild to moderate distal and paraspinal muscle denervation.^[101] In patients who complain of paresthesias, mildly prolonged distal motor or sensory latencies and mild slowing of distal motor conduction velocities is present.^[94] These patients do not typically have a facial nerve palsy, and examination of the CSF is usually normal.^[94]

ENCEPHALOMYELITIS

A very rare, late neurological syndrome in North American Lyme disease affects both the brain and spinal cord white matter. Examination of the CSF demonstrates a lymphocytic pleocytosis, a mildly elevated protein concentration and the intrathecal production of anti- *Borrelia burgdorferi* antibodies.^[102]

Evaluation. The diagnosis of CNS Lyme disease begins with asking the patient about a history of a tick bite, whether there was travel to an endemic area, and if the skin lesion was characteristic of erythema migrans. This lesion begins as a painless macule, which continues to expand until it becomes an annular erythematous plaque. It occurs at the site of a tick bite an average of 8 to 9 days after infection. As the lesion expands, the center may become clear, vesicular, or edematous forming a bull's-eye lesion.^[94] Serum should be sent for ELISA and Western blot testing. A positive serology is indicative of exposure to the organism and should not be considered proof of active infection.^[102] Interpretation of the serological test is further confounded by the evidence that seronegative Lyme cases exist. CNS infection is most readily confirmed if the paired serum and CSF anti- *Borrelia burgdorferi* antibody titer demonstrates the intrathecal production of these antibodies. Other CSF abnormalities suggestive of Lyme disease are a mononuclear or lymphocytic pleocytosis, an elevated protein concentration, and a normal glucose concentration. As described in the specific clinical features of each neurological syndrome, the CSF is almost always abnormal in Lyme meningitis and early radiculoneuritis. The CSF is at times abnormal with an isolated facial nerve palsy or with encephalomyelitis and can be normal or abnormal when encephalopathy is present. The CSF is typically normal in chronic Lyme disease sensorimotor polyradiculoneuropathy.^[94]

Management. Facial nerve palsy without CSF abnormalities may be treated with oral doxycycline 100 mg twice a day for 2 weeks. Intravenous ceftriaxone is the drug of choice for all other neurological syndromes of Lyme disease. The adult dose is 2 g/d, and the pediatric dose is 75 to 100 mg/kg/d. Treatment with ceftriaxone should be continued for at least 2 weeks, and many physicians prefer 4 weeks of therapy.^[101]

OTHER TICKBORNE INFECTIONS

Ehrlichiosis

Ehrlichia are small gram-negative pleomorphic coccobacilli that primarily infect circulating leukocytes and other cells derived from the hematopoietic system.^[104] There are two species of ehrlichia that cause human disease. *Ehrlichia chaffeensis* is the causative organism of human monocytic ehrlichiosis, and an organism that is closely related to or nearly identical to *E. equi* and *E. phagocytophila* is the causative agent of granulocytic ehrlichiosis.^[104] *E. chaffeensis* infects mononuclear phagocytes in the blood and tissues, and the granulocytic *Ehrlichia* species infects granulocytic phagocytes in blood and tissues.^[104] The infectious agents of human ehrlichiosis and Lyme disease are both transmitted by tick bites. Most cases of human granulocytic ehrlichiosis have been identified in Wisconsin, Minnesota, New York, Connecticut, and Massachusetts, and most cases of human monocytic ehrlichiosis have been identified in the southeastern and south-central United States.^[106]

The pathogenesis of the diseases caused by ehrlichiae are not well understood at this time. It is clear, however, that the ehrlichiae damage and lyse host phagocytic cells once they have attached to these cells resulting in leukopenia and thrombocytopenia.^[106] Patients with human granulocytic ehrlichiosis present with a febrile illness associated with myalgia, headache, malaise and occasionally nausea, vomiting, or a cough. The clinical presentation may be helpful in distinguishing Lyme disease from human granulocytic ehrlichiosis. Nausea, vomiting, and cough are very infrequent in Lyme disease. Fatigue is more often a complaint with Lyme disease than with human granulocytic ehrlichiosis.^[106] The incubation period is approximately 7 days following a tick bite, and approximately 20 percent of patients with ehrlichiosis have a rash that consists of a maculopapular eruption or petechiae.^[107] Despite the different causative agents of monocytic and granulocytic ehrlichioses, the clinical and laboratory manifestations of the infections are similar. Neurological manifestations of both include severe headache, lethargy, confusion, coma, and seizure activity. The most common CSF abnormalities are lymphocytic pleocytosis with an elevated protein concentration and a borderline low CSF glucose concentration.^[108] Laboratory evidence of leukopenia, thrombocytopenia, and anemia, and mild to moderate elevations in levels of aspartate and alanine aminotransferases, alkaline phosphatase, and lactate dehydrogenase are present.^[104]

Monocytic and granulocytic ehrlichiosis are separate diseases caused by different etiological agents; therefore, laboratory diagnosis requires different tests for each. The current CDC recommendation for the serological diagnosis of monocytic ehrlichiosis is a fourfold increase in *E. chaffeensis* antibody titer (a minimum titer of 64) or a single high-serum antibody titer (greater than or equal to 128) in

patients with a clinically compatible history. The current CDC recommendation for serological confirmation of human granulocytic ehrlichiosis requires a serological reaction or a four-fold increase in titer to *E. equi* antigen. A minimum titer of 80 is required.^[104] Diagnosis during the acute phase of the illness can also be made by PCR amplification of the agent of human granulocytic ehrlichiosis DNA from blood.^[106] Co-infections with *B. burgdorferi* and the agent of human granulocytic ehrlichiosis can occur.

Ehrlichioses must be treated with doxycycline. *E. chaffeensis* is susceptible only to doxycycline. Doxycycline is also the recommended agent for human granulocytic ehrlichiosis. The recommended dose in children and adults is 100 mg twice daily for adults or 3 mg/kg/d in two divided doses for children. Doxycycline can be given by either the oral or intravenous route.^[104]

Rocky Mountain Spotted Fever

Rocky Mountain spotted fever is a rickettsial disease caused by *Rickettsia rickettsi*, a small intracellular parasite. Infection is acquired by a tick bite. The majority of infections are acquired in the south Atlantic coastal and the western and southern central states with the highest incidence in Virginia, North Carolina, South Carolina, Oklahoma, and Tennessee. The disease typically occurs during spring and summer. Fever, rash, and a history of exposure to ticks is the classic triad of Rocky Mountain spotted fever. The illness usually begins 5 to 7 days after the tick bite. The majority of patients have fever, severe frontal headache, malaise, myalgia, and vomiting. An altered level of consciousness and meningismus may develop during the course of the illness in addition to abdominal pain, hepatosplenomegaly, respiratory failure, renal dysfunction, and myocarditis.

The classic rash of Rocky Mountain spotted fever first appears as macules on the wrists and ankles and subsequently spreads to involve the trunk, face, palms, and soles. The rash appears 1 to 15 days after the onset of the illness.^[107] The rash is initially a diffuse erythematous maculopapular rash that blanches with pressure. It progresses to a petechial rash, then to a purpuric rash, and if untreated, to skin necrosis or gangrene. The rash begins on the wrists and ankles and then spreads distally and proximally within a few hours. Ten percent of patients do not have a rash (spotless Rocky Mountain spotted fever). Neurological manifestations of Rocky Mountain spotted fever include severe bifrontal headache that is unresponsive to common analgesics, delirium, confusion, seizures, coma, hyperreflexia, spastic paraparesis or quadraparesis, facial diplegia, nystagmus, and/or ataxia. Stupor and coma occur in approximately 25 percent of patients and are associated with a poorer prognosis than those cases without signs of encephalitis. Laboratory abnormalities in patients with Rocky Mountain spotted fever include thrombocytopenia, hyponatremia, and elevated liver enzyme abnormalities. CSF abnormalities include a mild (rarely more than 100 cells/mm³) lymphocytic pleocytosis and an elevated protein concentration. In the acute stage, the diagnosis of Rocky Mountain spotted fever can be made by skin biopsy with

TABLE 42-6 -- RECOMMENDED ANTIMICROBIAL THERAPY OF ROCKY MOUNTAIN SPOTTED FEVER

Antibiotic	Dosage	Duration of Therapy
Tetracycline-Child*	25 to 50 mg/kg/d (oral dose) in 4 divided doses	7 to 10 days
Tetracycline-Adult	500 mg (oral dose) 4 times daily	7 to 10 days
Doxycycline-Adult	100 mg (oral dose) 2 times daily	7 to 10 days
Chloramphenicol (for children under 8 years of age)	50 mg/kg/d IV in 4 divided doses	7 to 10 days

*Not recommended for children under the age of 8 years to avoid staining of the teeth.

the demonstration of rickettsiae in the endothelial cells of blood vessels by immunofluorescence. Serological tests are useful for the confirmation of the diagnosis and include an indirect immunofluorescent antibody assay (IFA), an indirect hemagglutination assay (IHA), latex agglutination (LA), and complement fixation (CF). According to the Centers for Disease Control and Prevention, diagnostic titers for Rocky Mountain spotted fever include a titer of 1:64 for IFA, 1:16 for CF, and a four-fold increase between acute and convalescent sera for LA and IHA. The PCR is also under development for the diagnosis of this disease. The treatment of Rocky Mountain spotted fever is outlined in [Table 42-6](#).^[109]

Babesiosis

Babesiosis is a malaria-like illness caused by a protozoan parasite and transmitted by a tick bite. Most human cases of babesiosis have occurred during the summer months in the northeastern United States, Maryland, Virginia, Georgia, Wisconsin, Minnesota, California, and Washington. Symptoms of babesiosis typically begin approximately 1 week after a tick bite and include malaise, anorexia, and fatigue followed several days later by fever, drenching sweats, myalgia, and headache. The clinical spectrum ranges from a mild self-limited illness to a serious disease with hemolytic anemia, renal failure, and hypotension primarily in patients of advanced age or in those with underlying chronic disease. Babesiosis can be diagnosed by examining Wright-stained or Giemsa-stained peripheral blood smears. The parasites invade erythrocytes and appear as small intraerythrocytic ring forms resembling the causative organism of malaria, *Plasmodium falciparum*. An indirect immunofluorescence test titer of greater than or equal to 1:64 is considered positive for babesiosis, although most patients with acute illness have titers of greater than or equal to 1:1024. The recommended treatment for this illness consists of a 7-day course of oral quinine plus clindamycin (by the intravenous or oral route).^[107]

FUNGAL INFECTIONS

As a general rule, fungal infections occur in individuals who are immunosuppressed as a result of (1) AIDS; (2) organ transplantation; (3) immunosuppressive chemotherapy or chronic corticosteroid therapy; and (4) chronic disease. The single exception to this generalization is cryptococcal meningitis, which may occur in healthy individuals. The fungus-causing infection can be predicted to some degree based on the predisposing condition. For example, individuals with AIDS are at risk for meningitis due to *Cryptococcus neoformans*, and *Histoplasma capsulatum*. Cryptococcal meningitis is the most common life-threatening opportunistic fungal infection in patients with AIDS and occurs in 5 to 10 percent of patients, typically when their circulating CD4+ T lymphocyte count is less than 100 cells/mm³.^[110] In patients who have undergone organ transplantation, two fungi are responsible for the majority of CNS fungal infections. Fungal meningitis in these patients is typically due to *C. neoformans*, and fungal brain abscesses are often due to *Aspergillus fumigatus*. Patients receiving chronic corticosteroid therapy and patients who have received bone marrow transplantation are at risk for CNS candidiasis. *Candida* tend to cause intraparenchymal microabscesses mainly in the territory of the middle cerebral artery. Individuals with granulocytopenia for any reason are at risk for infections due to *Candida*, *Aspergillus fumigatus* and the Zygomycetes organisms (mucormycosis).^[111] Intravenous drug abusers are at a particular risk for fungal brain abscesses due to Zygomycetes and *Candida*. *Coccidioides immitis* is a dimorphic fungus that is endemic to the desert areas of Southwest, specifically California, Arizona, New Mexico, and Texas. The disease is acquired by inhaling the infectious particles, but less than 1 percent of individuals who develop a primary infection develop disseminated disease. Coccidioidomycosis should be considered in the differential diagnosis of any febrile illness in a transplant recipient in an endemic area for this fungus.^[112] The fungus *Blastomyces dermatitidis* is found principally in North America in the Mississippi, Ohio, and St. Lawrence river basins, the Great Lakes area, and the southeastern United States. Infection is most likely to be acquired as a result of occupational exposure to contaminated soil.^[113] CNS involvement by this fungus is nearly always the result of hematogenous spread from a pulmonary source or occurs as result of infection in contiguous structures or with osteomyelitis.^[114]

Cryptococcus neoformans

Cryptococcus neoformans is an encapsulated yeastlike fungus. Infection is acquired through direct exposure to bird droppings. The infection is initially characterized by a localized pneumonitis, but when dissemination occurs the CNS is a preferential site for disease presumably because the CSF is a good culture media for cryptococci.^[115] The most common symptoms of cryptococcal meningitis are headache, fever, and malaise. Cryptococcal skin lesions may precede the development of meningitis, and when they are present, are an indication for lumbar puncture, even in the absence of signs and symptoms of meningitis.^[116] Diagnosis is made by the examination of the CSF, and the following are typical abnormalities: (1) normal or slightly elevated opening pressure; (2) lymphocytic pleocytosis (usually of less than 100 cells/mm³); (3) elevated protein concentration; (4) decreased glucose concentration; and (5) positive cryptococcal antigen. The cryptococcal antigen is a highly sensitive and specific test and should be performed on all CSF specimens. A reactive CSF cryptococcal antigen test establishes the diagnosis. *C. neoformans* can also be grown in culture of CSF.

The treatment of cryptococcal meningitis in immunocompetent patients includes a combination of intravenous amphotericin B (0.5 mg/kg/d) plus oral flucytosine (25 mg/kg four times daily) for 6 weeks. The therapy of cryptococcal meningitis in patients with AIDS includes a combination of intravenous amphotericin B (0.5 to 0.8 mg/kg/d) for at least 2 weeks followed by fluconazole (400 mg/d) for 10 to 12 weeks at which point the CSF should be recultured. When the CSF culture is sterile, the patient is switched to maintenance fluconazole therapy for life. The dose is 200 mg/d.

Histoplasma capsulatum

Histoplasma capsulatum is a dimorphic fungus that is endemic to the Ohio and Mississippi river valleys of the central United States. The fungus is acquired by inhalation. Dissemination is rare and occurs primarily in patients with defective cellular immunity, such as patients with AIDS, patients with lymphoreticular malignancies, and organ transplant recipients.^[117] The most common presentation of CNS histoplasmosis is meningitis. The typical presentation includes fever, sweats, weight loss, headache, mental status abnormalities (including decreased level of consciousness, confusion, personality changes, and/or memory impairment), cranial nerve palsies, stroke, or seizures.^[118] CNS histoplasmosis may also be a solitary abscess or multiple lesions, but meningitis is the much more common presentation. The majority of patients with CNS histoplasmosis have an abnormal neuroimaging study with meningeal enhancement, hydrocephalus, solitary or disseminated contrast-enhancing lesions, or various combinations of these entities. Chest radiographs should be obtained. The most common roentgenogram abnormalities in histoplasmosis are diffuse or focal pulmonary infiltrates. *Histoplasma* polysaccharide antigen (HPA) in urine, blood and CSF may allow for a rapid diagnosis. The presence of the HPA in CSF is a reliable indicator of CNS involvement; however, cross reactions with *C. immitis*, *C. neoformans* and *Candida* have been reported.^[119] Serological tests for anti-*Histoplasma capsulatum* antibodies may be helpful. They may also be misleading and can be negative in 10 to 25 percent of patients with disseminated histoplasmosis or falsely positive in patients with other fungal diseases or tuberculosis. Antibodies remain elevated for several years despite resolution of histoplasmosis and may lead to a misdiagnosis of patients with neurological illnesses caused by other diseases.^[120] Examination of the CSF typically reveals a lymphocytic pleocytosis (less than or equal to 100 cells/

mm³), although a predominance of polymorphonuclear leukocytes may also occur. The CSF protein concentration is increased, and the CSF glucose concentration is usually decreased. It is rare to identify the fungus on CSF india ink stain. The CSF culture, however, is frequently positive, as are blood, bone marrow, and urine cultures. In general, when fungal meningitis is suspected, multiple cultures of lumbar fluid should be obtained to identify the organism. Consideration should also be given to obtaining CSF by a cisternal puncture. In cases of *H. capsulatum* meningitis, one CSF culture out of several is typically positive, stressing the need for repeated attempts to isolate the fungus using large volumes of centrifuged CSF.^[121] Intravenous amphotericin B (0.75 to 1.0 mg/kg/d) remains the mainstay of treatment of CNS histoplasmosis. A total dose of 30 mg/kg is recommended. Oral itraconazole (200 mg twice daily for several weeks) is useful in patients who relapse after a course of amphotericin B is completed and for chronic suppressive therapy in patients with AIDS.^[122]

Coccidioides immitis

Coccidioides immitis is a dimorphic fungus that is endemic to the desert areas of the Southwest, specifically California, Arizona, New Mexico, and Texas. *C. immitis* grows as a mycelia that releases air-borne arthroconidia, which when inhaled and in the alveoli transform into spherules containing endospores. Infection is most often either asymptomatic or a limited pneumonitis with fever and cough. Dissemination occurs in less than 1 percent of patients, and CNS disease is primarily a meningitis. A predisposition to disseminated disease has been associated with the following: (1) pregnancy--infection that is acquired during the third trimester is associated with an increased risk of severe disease; (2) hemodialysis; (3) immunosuppressive therapy; (4) extremes of age; (5) race--patients of African-American, Hispanic, and Filipino descent have a higher risk of dissemination; (6) AIDS; and (7) organ transplantation.^[123] Meningitis is a common initial presentation of coccidioidomycosis in AIDS patients. The most common symptoms and signs of *C. immitis* meningitis are headache, change in mental status (particularly lethargy and confusion), low-grade fever, and weight loss.^[124] There may be evidence of skin lesions, and biopsy of these with visualization of typical *C. immitis* spherules makes the diagnosis. The coccidioidal skin test has no role in the diagnostic evaluation of a CNS infection because false-negative results are common, and positive results only indicate prior exposure to the fungus.^[125] The diagnosis of *C. immitis* meningitis is made by examination of the CSF. The complement fixation antibody test on CSF is reported to have a specificity of 100 percent and a sensitivity of 75 percent in the setting of active disease.^[126] Coccidioidal meningitis can present as an eosinophilic meningitis.^[127] Positive cultures may be obtained in up to one third of patients. *C. immitis* meningitis is treated with a combination of intravenous amphotericin B (0.5 to 0.75 mg/kg/d) plus intrathecal amphotericin B (0.25 to 0.75 mg/d three times weekly). Intravenous amphotericin B is continued for at least a year after obtaining a normal CSF. Intrathecal amphotericin B is continued for 3 months, followed by a tapering course. The CSF glucose and protein concentrations can remain abnormal for years, and the CSF cell count is unreliable because it may decrease spontaneously in untreated CNS coccidioidomycosis. A sudden rise in cell count or CSF complement fixation antibody titer, however, is a sign of a relapse, and more intense antifungal therapy should be administered in this instance.^[128]

Blastomyces dermatitidis

As discussed previously, infection with *Blastomyces dermatitidis* is primarily associated with outdoor activities including occupational exposure such as construction work, mining, and recreational activities. The AIDS epidemic has not affected the epidemiology of blastomycosis.^[129] Initial infection with this fungus is essentially a pulmonary disease. The chest radiograph demonstrates nonspecific infiltrates predominantly at the bases.^[130] Dissemination to the CNS presents as single or multiple intracranial abscesses or granulomas, cranial and spinal extradural abscesses and acute or chronic meningitis. Meningitis due to *B. dermatitidis* presents as a subacute infection with headache, anorexia, and weight loss. *B. dermatitidis* brain abscess or abscesses present with focal neurological deficits, seizures, and signs of increased ICP. Neuroimaging demonstrates evidence of a single or multiple homogeneously enhancing lesions. Chronic blastomycotic meningitis predominantly involves the basilar meninges and may be associated with hydrocephalus.^[131] The one exception to the rule that fungal meningitis presents with a lymphocytic

pleocytosis is *B. dermatitidis* meningitis, which may present with a polymorphonuclear leukocytic pleocytosis. A CSF cell count of greater than 5000 cells/mm³ is not uncommon. The CSF glucose concentration may be markedly decreased, and the protein concentration is typically elevated. It is rare to identify *B. dermatitidis* from CSF obtained by lumbar puncture. Culture of cisternal or ventricular CSF has a better yield. There is no reliable *B. dermatitidis* antigen detection test available.^[115] Treatment requires the administration of intravenous amphotericin B (0.5 to 0.8 mg/kg/d). Lifelong suppressive therapy with itraconazole in AIDS patients is recommended.

Aspergillus fumigatus

Aspergillus species are ubiquitous, and infection is acquired by inhaling conidia. CNS aspergillosis is rare in immunocompetent individuals. Isolated aspergilloma are unusual, except in intravenous drug abusers. Individuals who are granulocytopenic and those who have received organ transplantation are at risk for brain abscesses owing to aspergillosis. CNS aspergillosis typically occurs preferentially in major vascular territories and presents as isolated or multiple ischemic infarctions or subarachnoid hemorrhage from a ruptured mycotic aneurysm.^[115] The majority of patients with aspergillosis will have an unremitting fever, despite broad-spectrum antibiotics, and pulmonary infiltrates on chest radiographs.^[118] The diagnosis is made

through sputum culture or lung tissue biopsy culture. CSF analysis is usually not helpful because meningitis is unusual.^[115] *Aspergillus* is rarely, if ever, cultured from blood. Treatment should include intravenous amphotericin B (0.8 to 1.0 mg/kg/d) plus flucytosine (100 mg/kg/d in four divided doses).

Candida

CNS candidiasis occurs in patients who have undergone organ transplantation, those receiving chronic corticosteroid therapy, those with a prolonged stay in the intensive care unit requiring invasive monitoring devices, and those who are treated with broad-spectrum antibiotics. CNS infections due to *Candida* present as either meningitis or cerebritis from multiple small parenchymal abscesses.^[115] CNS infection due to *Candida* often occurs in conjunction with fungemia.^[119] The majority of patients with CNS *Candida* infections have positive fungal blood cultures and are neutropenic.^[119] Scattered, irregular ring-enhancing lesions surrounded by edema may be present on neuroimaging studies. A definitive diagnosis is made through CSF or tissue biopsy and culture. Standard therapy includes intravenous amphotericin B (0.5 to 0.7 mg/kg/d) plus flucytosine (100 mg/kg/d in four divided doses).

Zygomycetes

The Mucoraceae are in the Zygomycetes class and cause the disease mucormycosis. This disorder is typically an acute fulminant CNS infection that occurs primarily in immunocompetent patients with ketoacidosis and in diabetic transplant recipients receiving immunosuppressive agents. The infection tends to originate in the palate or paranasal sinuses and spreads through the orbits and paranasal sinuses into the brain. The infection is often manifest by a black eschar on the palate or nasal mucosa with a blackish purulent discharge from the involved areas. Examination of the CSF demonstrates an elevated opening pressure, a pleocytosis with a predominance of polymorphonuclear cells, a normal glucose concentration, and an elevated protein concentration. Diagnosis is made by a biopsy of the black eschar.^[120] The treatment of CNS mucormycosis involves debridement of all devitalized tissues and high-dose amphotericin B (1.0 mg/kg/d).^[115]

AMEBIC INFECTIONS

Naegleria and *Acanthamoeba* are free-living amoebae that infect the CNS. *Naegleria fowleri* causes an acute fulminant meningoencephalitis, known as primary amoebic meningoencephalitis (PAM), and is acquired by swimming or waterskiing in small, shallow freshwater lakes as a result of direct contamination through the nasal cavity. Infection with this organism has also been acquired from swimming in chlorinated pools; presumably, the organism gets into the pool through cracks in the pool. In Africa, cases have been reported during the dry and windy season by inhalation of dust containing amoebic cysts. ^[109]

Acanthamoeba CNS infections are generally not water related and occur in immunosuppressed and debilitated individuals. This organism has been isolated from the nasopharynx of asymptomatic individuals. *Acanthamoeba* keratitis has been reported in healthy contact lens wearers. ^[109]

N. fowleri invades the nasal mucosa and ascends to the brain through the cribriform plate via the fila olfactoria, extensions of the olfactory nerves. ^[121] Amoebae can then spread throughout the meninges. The temporal and frontal lobes are most severely affected. *Acanthamoeba* spp. reach the nervous system through the bloodstream from a distant site of infection or from a corneal infection of the eye and typically cause a subacute or chronic meningoencephalitis, or inflammatory lesions in multiple areas of the brain, particularly the white matter, the basal ganglia, the brain stem and the cerebellum. A necrotizing vasculitis is common owing to invasion of arterial walls by trophozoites. ^[121]

The incubation period for infection by *N. fowleri* is usually 4 to 7 days. The patient presents with severe bifrontal headache, high fever, nausea, vomiting, and meningismus, a clinical presentation resembling bacterial meningitis. Twenty-four to forty-eight hours later, signs of encephalitis with focal neurological deficits, confusion, delirium, stupor, and finally coma occur. Meningoencephalitis due to *Naegleria* is typically a fatal disease with death occurring within 2 to 4 days. Because of involvement of the olfactory bulbs and tracts, early symptoms of abnormal smell or taste sensation have been reported. The incubation period of *Acanthamoeba* is longer than that of *Naegleria* infections and is typically weeks to months. The insidious onset of symptoms and signs of focal encephalitis or focal mass lesions follows. The presentation may include seizures, hemiparesis, visual disturbances, headache, low-grade fever, and ataxia.

A diagnosis of *N. fowleri* meningoencephalitis is rarely made while the patient is alive. Examination of the CSF demonstrates a leukocytosis with a neutrophilic predominance, an increased protein concentration, and a decreased glucose concentration. The amoeboid movements of the trophozoites can be seen on fresh or wet unstained specimens of CSF. Trophozoites can also be demonstrated in the brain by light or electron microscopy. Serological tests for *Naegleria* are of limited value because patients usually die before the results are available. In contrast, serological tests for *Acanthamoeba* infections are helpful in diagnosis. Neuroimaging scans may demonstrate one or multiple abscesses of *Acanthamoeba*. Examination of the CSF shows a mild lymphocytic pleocytosis with a normal to decreased glucose concentration and a mild increase in protein concentration. ^[109]

The drug of choice for acute *N. fowleri* meningoencephalitis is intravenous amphotericin B (1 mg/kg/d) for at least 2 to 3 weeks. A few survivors of this infection have been documented, but one survivor required treatment with a combination of intravenous and intrathecal amphotericin B, intravenous and intrathecal miconazole, and rifampin, sulfisoxazole, and dexamethasone. The outcome may be improved by adding intrathecal amphotericin B (0.5 mg on alternate days) to parenteral amphotericin B. ^{[109], [122], [123]} *Acanthamoeba* abscesses are treated with surgical excision

and amphotericin B. Although amphotericin B is amoebicidal for *N. fowleri*, it is much less active against *Acanthamoeba*. ^[121] No effective vaccine for free-living amoebae infections exist. Children should be prevented from swimming in contaminated fresh water, and *Acanthamoeba* keratitis can be prevented by using appropriate antimicrobial contact lens cleaning solutions. ^[121]

NEUROCYSTICERCOSIS

Epidemiology and Risk Factors. Neurocysticercosis is considered the most common parasitic disease of the CNS. In countries where this infection is endemic, it is the most common cause of late-onset epilepsy. Humans acquire cysticercosis by the ingestion of food contaminated with *Taenia solium* eggs, most often undercooked pork but also water and vegetables contaminated with human feces. ^[124]

Pathogenesis and Pathophysiology. After food contaminated with *T. solium* eggs is ingested, the eggs hatch into oncospheres in the stomach of the host. Oncospheres cross the intestinal wall, enter the bloodstream, and are carried to the eye, skeletal muscle, and the CNS. After 2 months, cysticerci develop in the brain parenchyma, subarachnoid space, ventricular space, or spinal cord. When the parasite invades the CNS, it may either stimulate an intense inflammatory response or the inflammatory response may develop so slowly that the cysticerci may live in the CNS for several years. When the parasite lodges in the brain parenchyma, the inflammatory response results in a thin capsule of fibrous tissue surrounding the cyst. With the passage of time, the capsule thickens. The parasite may be destroyed, and the site where the cyst was located is replaced by a granuloma composed of astroglial and fibrous tissue that subsequently becomes mineralized with deposits of calcium salts. The process of calcification of the granuloma takes several years after the disappearance of the parasite. ^[124] In any individual, one or several hundred cysticerci may exist. Cysts that develop in the subarachnoid space are associated with an inflammatory response in the subarachnoid space with subsequent fibrosis of the arachnoid membranes. Hydrocephalus is a complication of the inflammation and fibrosis in the subarachnoid space that interferes with the normal CSF resorption in the arachnoid granulations. Cysts that grow in the sylvian fissure and the subarachnoid space at the base of the skull may grow as large as 10 to 15 cm. A single cyst that is lodged inside the fourth ventricle can produce a valve mechanism on the outflow of CSF and can lead to subacute hydrocephalus with episodes of sudden increases in ICP related to movements of the head. This ventricular form of neurocysticercosis is the result of the arrival of the oncospheres at the choroid plexus of the lateral ventricles via the bloodstream with the parasites remaining in the ependyma of the choroid plexus. In meningeal and spinal cord cysticercosis, the oncospheres also enter the CNS at the choroid plexus, but the passage of the parasites along the CSF pathways is rapid, and the oncospheres hatch in the arachnoid membranes along the neural axis and evolve into cysticerci. ^[124]

Clinical Features. The diagnosis of neurocysticercosis should be considered in any patient who is a resident or immigrant from areas endemic for cysticercosis, or who has traveled to areas endemic for cysticercosis, and has new onset partial seizures, with or without secondary generalization, cognitive impairment, confusion, stupor, or signs of raised ICP. In the majority of patients, the clinical manifestation of parenchymal granulomas is partial seizures. Patients with meningeal cysticercosis may present with headache, vertigo, vomiting, papilledema, an altered level of consciousness, and gait disturbances due to the intense and widespread immune response in the subarachnoid space and the subsequent development of hydrocephalus. Cysticerci located in the spinal canal may manifest with signs and symptoms similar to an intraspinal tumor. ^[124]

Evaluation. The lesions of neurocysticercosis are readily visualized by CT and MRI. Granulomas are the most common finding in patients with neurocysticercosis. A very early sign of cyst death is hypointensity of the vesicular fluid on MRI T2-weighted images when compared with CSF. The ELISA and the complement fixation test (CF) can be performed on CSF and are highly specific and sensitive for the detection of anticysticercus antibodies. It is recommended that both tests be done on the CSF to increase the probability of diagnosis. These CSF immunodiagnostic tests are also useful to distinguish the inactive sequelae of neurocysticercosis, such as granulomas and calcifications, from the active forms. The test results are negative in the absence of active forms of the parasite. These tests remain positive for a few months in patients who are successfully treated with an anticysticercus drug after the disappearance of cysts. Serum immunodiagnostic tests lack reliability for the diagnosis of neurocysticercosis. About 30 percent of healthy individuals from endemic areas will have positive serology. In addition, patients with parenchymal or ventricular neurocysticercosis with positive immunodiagnostic tests on CSF may have negative serology. ^[124]

Management. Albendazole and praziquantel are cysticidal. Approximately 85 percent of parenchymal cysts are destroyed by a single course of albendazole, and approximately 75 percent are destroyed by a single course of praziquantel. The sequential use of two drugs increases the possibility of successful elimination of parasites to more than 95 percent of parenchymal cysticerci; therefore, a trial of cysticidal therapy is recommended before surgery is attempted. The dose of albendazole is 15 mg/kg/d in two doses for 8 days. For the first 4 days of therapy, dexamethasone therapy is also recommended to decrease the inflammatory reaction due to the destruction of the parasites. If the lesions persist unchanged on neuroimaging study 3 months after therapy is completed, praziquantel 50 mg/kg/d in three divided doses for 15 days is recommended. Dexamethasone is not recommended with praziquantel because dexamethasone reduces the plasma concentration of praziquantel by 50 percent, thereby decreasing its efficacy. During the first few days of cysticidal therapy, headache, vomiting, or seizures may develop owing to an intense inflammatory response from the host to the acute death of the parasites. These symptoms are particularly intense in patients with many cysts. In the management of parenchymal cysticercosis, a differentiation must be made between active and inactive forms of the parasite, such as granulomas

...

and calcification, because no response to cysticidal therapy will occur in inactive disease. Seizure activity secondary to parenchymal cysts should be managed with anticonvulsants. Parenchymal cysts that are destroyed by cysticidal therapy, without leaving granulomas, do not result in long-term seizure disorders. In these patients, the early withdrawal of antiepileptic drugs is recommended. A seizure disorder that is secondary to granulomas requires long-term anticonvulsant therapy. ^[124]

MALARIA

Human malaria is caused by one of four species of *Plasmodium*. The majority of cases of malaria worldwide are caused by *P. falciparum*, and *P. falciparum* is the only species that causes cerebral malaria. Malaria is transmitted to healthy individuals through the bite of an infected mosquito. ^[125] The World Health Organization defines cerebral malaria as "unrousable coma not attributed to any other cause in a patient with *P. falciparum* malaria." ^[126] Malaria can be transmitted by the bite of an *Anopheles* mosquito, through blood transfusions, and by intravenous injections with blood-contaminated needles. The incidence of cerebral malaria in a population is determined by the population's immunity. In holoendemic areas, which are areas of the world where significant transmission of malaria occurs annually with little change from year to year, native adults rarely develop cerebral malaria. Persons at risk for severe malaria in these areas are children from 1 to 4 years of age, new residents from nonendemic areas, returning residents that have lived abroad for years, residents who were maintained on chemoprophylaxis but have stopped, and pregnant women. Travelers to endemic areas are at high risk for infection. Infected mosquitoes can be transported from endemic areas via airplane, and travelers may acquire malaria during brief stopovers without disembarking from the airplane. *P. falciparum* malaria requires a minimum of 8 days for incubation, and 95 percent of all infections present within 4 weeks of the last mosquito exposure. ^[125]

Systemic signs of malaria include jaundice, retinal hemorrhage, hepatosplenomegaly, fatigue, diarrhea, vomiting, abdominal pain, chest pain, cough, myalgia, and arthralgia. The majority of patients are febrile. Cerebral malaria presents with headache followed by an altered level of consciousness, and convulsions. On neurological examination, upper motor neuron signs are common as is decerebrate or decorticate posturing, delirium, hallucinations, delusions, and disorders of dysconjugate gaze. Coma is often associated with shock, acidosis, noncardiogenic pulmonary edema, hemolysis, anemia, renal insufficiency, and hypoglycemia. These are all potentially treatable complications. ^[127] Diagnosis is made by examining a blood smear for parasites. Blood smear should be examined every 12 to 24 hours for a period of 2 to 3 days, and the number of intraerythrocytic parasites should be counted.

In the United States, parenteral quinidine is the drug of choice for the treatment of cerebral malaria. Cerebral malaria is treated with a loading dose of 10 mg/kg of intravenous quinidine gluconate over a period of 1 to 2 hours followed by continuous infusion of 0.02 mg/kg/min. Loading doses of quinidine are not recommended for patients who have received mefloquine, quinine, or quinidine in the 24 hours before initiation of therapy. When the patient is able to take oral medication, therapy can be changed to one of the oral antimalarial agents to complete a total of 7 days of treatment from the initiation of intravenous therapy. ^[125] Quinidine is cardiotoxic, and patients receiving parenteral forms of this agent should be monitored for arrhythmias, prolongation of the QT interval, and widening of the QRS complex. Recommendations for malaria chemoprophylaxis depend on the area to which the individual plans to travel. In the few areas where the parasite remains sensitive to chloroquine, this antimalarial agent should be taken in a weekly dose of 300 mg base. Chemoprophylaxis should begin 2 weeks before departure and should continue for 6 weeks after return. In areas where the parasite is resistant to chloroquine, mefloquine is recommended at a once per week oral dose of 250 mg beginning 2 weeks before departure and continued for 4 weeks after return. ^[128]

ACKNOWLEDGMENT

The technical assistance of Mrs. Linda Hagan in the preparation of this chapter is greatly appreciated.

Chapter 43 - Transmissible Spongiform Encephalopathy

Paul Brown

History and Overview

Sporadic Disease

Familial Disease

Iatrogenic Disease

New Variant Creutzfeldt-Jakob Disease (nv CJD)

Reviews and Selected Updates

References

[PreviousNext](#)

HISTORY AND OVERVIEW

First described in humans in the 1920s, spongiform encephalopathy is now known to encompass a group of noninflammatory degenerative disorders characterized neuropathologically by a diffuse spongiosis and amyloid protein deposition in the brain. These disorders include kuru, Creutzfeldt-Jakob disease (CJD), Gerstmann-Straussler-Scheinker syndrome (GSS), and fatal familial insomnia (FFI). The report in 1966 that kuru, an epidemic ataxic illness limited to the eastern highlands of Papua New Guinea, could be experimentally transmitted to the chimpanzee^[1] opened a new dimension in the study of neurodegenerative disease and led to further experiments using a variety of primates and laboratory rodents. These studies established the transmissible nature of all members of the group that we call the transmissible spongiform encephalopathies (TSE) but are also known as infectious cerebral amyloidoses, or prion diseases.^{[2][3][4]}

The precise nature of the infectious agents that cause these diseases remains elusive. An early landmark experiment showed that infectivity was not decreased by levels of ionizing irradiation that destroy the biological function of nucleic acid,^[5] and this led to a number of hypotheses about non-nucleic acid replication by membrane-complexed polysaccharides or proteins. In the 1980s, the protein hypothesis was bolstered by the demonstration that highly purified brain extracts contained a host-encoded membrane-bound glycoprotein (PrP) that was inseparable from infectivity^[6]; more recently, mutations in its encoding gene (*PRNP*) on chromosome 20 have been shown to be linked to familial forms of disease.^[7]

The primary structure of the protein in patients with sporadic and iatrogenic forms of TSE does not differ from that of the protein in healthy individuals. In consequence, the functional differences between the protein in normal and affected individuals--solubility, proteinase resistance, ease of separation from cell membranes, and, most importantly, ability to replicate (infectivity)--are thought to reside in post-translational tertiary or quaternary alterations in protein folding. These have not yet been characterized, and a great deal of discussion surrounds the mechanism by which such alterations could endow the protein with replicative capacity. Two currently popular theories invoke (1) a heterodimer formation of normal and abnormal molecular isoforms that impose a conformational restraint on newly synthesized protein,^[8] and (2) a mineral-induced nucleation of abnormal protein polymer formation akin to that of crystallization.^[9]

The occurrence of spongiform encephalopathy extends well beyond the confines of human medicine. Ever since the early eighteenth century, a spongiform illness called scrapie has been known to affect sheep and goats, and in past decades similar diseases have been identified in mink, cats, and ungulates, most recently as the cause of a dramatic epidemic of spongiform encephalopathy in British cattle. The disease in each of these species appears to have resulted from the contamination of animal feed with meat and bone meal processed from scrapie-infected sheep carcasses, and there is mounting evidence that a small but increasing number of British cases with new variant CJD are due to a further species-jumping transmission to humans, presumably from BSE-contaminated beef products. Apart from these cases, CJD in humans may be broadly categorized as sporadic (for which no evident cause can be determined), familial (associated with mutations in the *PRNP* gene), and iatrogenic (caused by human-to-human cross-contaminating medical accidents).

SPORADIC DISEASE

Pathogenesis and Pathophysiology. The original event in sporadic infections presumably occurs within the brain itself, possibly as the result of a rare (one in a million) stochastic conversion of the alpha-helix-rich normal protein

molecule into an amyloidogenic beta-pleated "prion" configuration that polymerizes into amyloid deposits that cause or at least contribute to neuronal death. ^[9] No foreign nucleic acid has ever been shown to participate in this pathogenetic process, and thus the earlier concept that these diseases might be due to an exogenous "slow" or "unconventional" virus no longer seems tenable.

The synaptic region appears to be the primary site of this pathological process, but extracellular aggregation can also produce microscopically visible amyloid plaques. The subsequent spread of infectious molecules is as puzzling as the original event, but tissue sampling has demonstrated widespread infectivity not only within the brain (which contains by far the highest concentration of the infectious agent) but also in the spinal cord, cerebrospinal fluid, and (at much lower levels of infectivity) many peripheral organs, ^[11] as well as in circulating white blood cells. ^[12] Infectivity has never been reproducibly demonstrated in any external secretion or excretion (urine, feces, tears, or saliva).

Epidemiology and Risk Factors. The sporadic form of the disease, which accounts for approximately 90 percent of all cases of spongiform encephalopathy, occurs in a completely random distribution in all studied populations of the world at an annual frequency of about one case per million people. There is no documented instance of the disease being "caught" from normal contact with other humans (whether in the preclinical or clinical stages of illness), nor is there any indication (by seasonality, geographical distribution, or disease "clusters") of a nonhuman environmental source of infection. For the present, therefore, each such case must be considered a "de novo" event that has no antecedent cause or subsequent links to any chain of infection.

Clinical Features and Associated Disorders. ^[11] The disease affects males and females equally and typically becomes manifest in late middle age. Peak incidence occurs

Figure 43-1 (Figure Not Available) Age at onset of sporadic Creutzfeldt-Jakob disease (based on the NIH series of 232 experimentally transmitted cases).

TABLE 43-1 -- SPORADIC CREUTZFELDT-JAKOB DISEASE: OVERALL CHARACTERISTICS OF THE NIH SERIES OF 232 EXPERIMENTALLY TRANSMITTED CASES

Male-to-female ratio	1.1
Median age at onset (range)	60 yr (16-82)
Neurological debut (%)	
Gradual (weeks to months)	86
Rapid (sudden to days)	14
Mental deterioration only	37
Mixed mental and neurological	34
Neurological signs only	29
Median duration of illness (range)	4.5 mo (1-130)

From Brown P Gibbs C Jr, Podgers-Johnson P, et al Human spongiform encephalopathy The National Institutes of Health series of 300 cases of experimentally transmitted disease. *Ann Neurol* 1994 35:513-529.

in the 55- to 70-year-old age group, and the disease has a bell-shaped distribution curve that is skewed toward the younger age groups, including rare cases in adolescents (Fig. 43-1 (Figure Not Available)). The earliest symptoms, which usually appear gradually over a period of weeks (but can occur suddenly), are limited to mental deterioration in about a third of patients, physical disabilities in another third, and mixed mental and physical abnormalities in the remaining third ([Table 43-1](#)). The frequencies of various symptoms at the onset of illness, at medical presentation, and at an advanced stage of disease are shown in [Table 43-2](#) . Memory loss and either cerebellar or visual-oculomotor signs are comparatively frequent at the outset, and as the illness evolves these are joined by pyramidal and extrapyramidal signs and a variety of involuntary movements, especially myoclonus; progressive mental deterioration terminates in mutism and global dementia. Death commonly occurs within 6 months

TABLE 43-2 -- SPORADIC CREUTZFELDT-JAKOB DISEASE: SYMPTOMATOLOGY OF THE NIH SERIES OF 232 EXPERIMENTALLY TRANSMITTED CASES

Symptoms/Signs	Percentage of Patients with Symptoms or Signs		
	At Onset	On First Examination	During Course
Mental deterioration	71	84	100
Memory loss	52	65	100
Behavioral abnormalities	29	38	55
Higher cortical function	16	36	73
Cerebellar	33	54	70

From Brown g Gibbs C Jr, Rodgers-Johnson P, et al: Human spongiform encephalopathy: The National Institutes of Health series of 300 cases of experimentally transmitted disease. *Ann Neurol* 1994 35:513-529.

Figure 43-2 (Figure Not Available) Duration of illness of sporadic Creutzfeldt-Jakob disease (based on the NIH series of 232 experimentally transmitted cases).

of the onset of illness, but a significant proportion of patients have more acute courses of a month or two, and about 10 percent have an extended course of 2 or more

years (Fig. 43-2 (Figure Not Available)).

This description applies to the great majority of patients, but the literature is replete with case reports illustrating unusual variations on the theme. Among these are sudden or stuttering onsets that suggest a cerebrovascular accident or multiple sclerosis and syndromes that span a range of appearances from the Wernicke-Korsakoff syndrome or bulbar palsy to parkinsonism and amyotrophic lateral sclerosis. All represent the extremes in a continuum of multisystem disease based on the topographically unpredictable cerebral pathology of spongiform encephalopathy.

Evaluation. The electroencephalogram (EEG) is the most accessible and most valuable laboratory adjunct to a correct diagnosis. Early in the course of illness, the EEG may be normal or may show only some background slowing, and terminally it may simply reflect a dying brain. However, in the fully developed phase of disease, most patients show some form of periodic activity (Fig. 43-3). In its most pathognomonic form, the 1- to 2-cycle per second slow wave triphasic spiking activity resembles an electrocardiogram; less specific but still suggestive is a "burst-suppression" pattern in which short runs of high voltage spikes alternate with periods of near electrical silence.

Another useful laboratory examination is an electrophoretic test on cerebrospinal fluid (CSF). Several years ago, a pair of "novel" proteins was identified in silver-stained two-dimensional electrophoretic gels of CSF samples from patients with CJD.^[13] They have been identified as members of the protein kinase C-inhibitor (14-3-3) family of proteins, permitting the development of an immunological test that requires only one-dimensional electrophoresis and Western blotting using an anti-14-3-3 antibody.^[14] As shown by Zerr and colleagues, these proteins appear in CSF as a result of neuronal cell death, and although they have no structural or biological relationship to the "prion" protein, nevertheless they show a high degree of sensitivity and specificity for CJD, being present in about 90 percent of cases and in only about 10 percent of cases of other neurological disorders, most of which can be easily distinguished from CJD on clinical grounds.

Brain biopsy reveals spongiform change in 95 percent of patients,^[11] but is almost never necessary to validate a clinical diagnosis and can be attended by significant morbidity and mortality. Other laboratory procedures are useful mainly to exclude diagnostic alternatives rather than make a positive diagnosis: This is equally true for the routine analysis of CSF, which is normal or at most shows a slight elevation of total protein (<100 mg/dl), and for various radiographic scanning procedures that may be normal or reveal only nonspecific imaging deficits. However, a study by Finkenstaedt and colleagues suggests that in magnetic resonance imaging (MRI), an abnormally high signal in the basal ganglia may be a diagnostic clue for CJD.

Differential Diagnosis. The spectrum of diseases with which spongiform encephalopathies can be mistaken is not surprising in view of the variable distribution of neuropathological changes found at autopsy. As always, the guiding principle in differential diagnosis should be the investigation of all potentially treatable diseases before winnowing through untreatable neurodegenerative alternatives.

From a practical viewpoint, differential diagnosis can be separated into two categories: first and most important are diseases that can mimic the onset and early course of spongiform encephalopathy; the second category comprises diseases that can be confused with later stages of the illness. In the first category are drug toxicities (bismuth, lithium, cyclical antidepressives), infections (herpes simplex encephalitis, cryptococcal meningoencephalitis, multiple cerebral abscesses), cerebrovascular accidents, neoplasms, normal pressure hydrocephalus, hyperparathyroidism, Wernicke-Korsakoff's syndrome, and vitamin B₁₂ deficiency. In the second category are Parkinson's disease with dementia, amyotrophic lateral sclerosis with dementia, progressive supranuclear palsy, olivopontocerebellar atrophy, Huntington's

..

Figure 43-3 Periodic electroencephalographic recordings in sporadic Creutzfeldt-Jakob disease. Upper tracing shows a "burst-suppression" pattern, and lower tracing shows a 1- to 2-cycle/sec triphasic sharp wave pattern.

disease, Ramsay Hunt syndrome, Pick's disease, and that most difficult of all differential diagnostic problems, Alzheimer's disease, which sometimes cannot be resolved short of necropsy.

Management, Treatment, and Prevention. During hospitalization, "universal precautions" should be followed in managing the patient, including the handling and disposal of tissues, excretions, and other contaminated material.^[15] Ordinary surface contact is not hazardous, but if blood or spinal fluid is involved, the exposed area of the worker's skin should be swabbed with bleach and then, after a minute or so, thoroughly washed with detergent and water. The golden rule is to avoid penetrating injury with anything that has penetrated the patient (e.g., needles), just as for patients with AIDS or hepatitis.

Despite early claims of clinical improvement in a few patients with CJD who had been treated with the antiviral drugs amantadine or vidarabine, subsequent experience, both published and unpublished, has failed to validate these successes, showing at best only temporary pauses in the progression of disease or, more often, total ineffectiveness. Thus, management of the patient with CJD is limited to good nursing care and the suppression of myo- clonus or seizures, if they occur, with a benzodiazepine or anticonvulsant. Like all patients who become progressively helpless and bedridden, death is usually the result of sepsis from respiratory, skin, or urinary infections, or, when swallowing becomes difficult, from aspiration.

FAMILIAL DISEASE

Pathogenesis and Pathophysiology. The molecular genetic basis for inherited disease remains to be defined. It seems probable that mutation-induced alterations in the primary amino acid structure of PrP facilitate its transition from an alpha helix to a beta-pleated sheet configuration. If the magnitude of facilitation were a million-fold, the one per million occurrence of sporadic disease would assume the appearance of a fully penetrant inherited disease linked to the mutation.^[16] This explanation is unencumbered by any experimental evidence but is nonetheless consistent with the observed frequencies of the two forms of disease.

Epidemiology and Risk Factors. About 10 percent of cases of spongiform encephalopathy are familial and are associated with one of more than 20 mutations so far identified in the gene that encodes the amyloidogenic prion protein (Fig. 43-4). All are inherited in an autosomal dominant genetic pattern, and all are experimentally transmissible.

Like sporadic disease, familial disease affects men and women equally, but its temporospatial distribution is determined by the origins and migrations of affected families. All "case clusters" of spongiform encephalopathy have a familial basis, for example those in rural Slovakia and among Sephardic Jews, whose migrations have created high incidence pockets of disease in Israel, North Africa, and (via the Spanish Inquisition), Chile. More typically, in the highly mobile world of today, familial cases are geographically scattered, and individual patients may have lost all contact with and knowledge of their ancestors, leading to the mistaken appearance of sporadic mutation-positive cases.

Clinical Features and Associated Disorders.^[17] Familial disease can present as CJD, GSS, FFI, or as atypical Alzheimer-like syndromes, depending on which of the mutations is present in the family. For example, point mutations at codons 200 or 210 usually produce an illness that begins 5 to 10 years earlier but in other respects is indistinguishable from sporadic CJD, whereas repetitive octapeptide encoding insert mutations cause illnesses that may begin as early as the third or fourth decade of life and produce a very slowly evolving dementia that ends in death after a period of 10 to 15 years with little or no brain pathology.^[18] Other mutations can produce a wide spectrum of intermediate disease syndromes.

GSS typically begins in members of affected families between the ages of 40 and 55 years as a slowly evolving ataxia, sometimes with associated mental deterioration, and progresses through a multisystem array of symptoms, including dementia and myoclonus, finally terminating fatally after an average duration of 5 to 10 years. It is characterized neuropathologically by a profusion of multifocal amyloid plaques in the cerebellum, with or without spongiform change. The classic syndrome (including Gerstmann's original case) is associated with a point mutation at codon 102,^[19] but more recently, variants of GSS have been described with mutations at codon 105 (with spastic paraparesis),^[20] at codon 117 (with pseudobulbar signs),^[21] and at codons 145, 198, or 217 (with neuropathological features of both GSS and Alzheimer's disease).^{[22], [23]}

FFI is the most recently admitted member of the spongiform encephalopathy group and is unusual in that patients

Figure 43-4 Mutations in the chromosome 20 PRNP gene that are known to be associated with familial spongiform encephalopathy. Three polymorphisms are also shown: an octapeptide-encoding deletion between codons 51 and 91; a methionine-valine alternative at codon 129; and a glutamic acid-lysine alternative at codon 219. The one, two, and four octapeptide-coding insert mutations (broken line boxes) have been identified in individuals with Creutzfeldt-Jakob disease in whom familial disease has not been established. CJD, Creutzfeldt-Jakob disease; GSS, Gerstmann-Strausler-Scheinker disease; FFI, fatal familial insomnia; Alz, Alzheimer-like disease.

typically show early and pronounced autonomic and endocrine dysfunction, including intractable insomnia (often associated with daytime somnolence), and unexplained disorders of temperature, cardiovascular, and respiratory regulation. Later in the course of the illness, more typical features of CJD supervene (pyramidal and extrapyramidal signs, cerebellar ataxia, and myoclonus), and death occurs after an average duration of 1 to 2 years.^[24] At autopsy, severe neuronal loss and astrogliosis are seen in the mediodorsal and anterior ventral thalamic nuclei, with variable pathology in the neocortex. The disease is caused by a mutation at codon 178, but curiously, it occurs only when the mutant allele specifies valine at polymorphic codon 129; when methionine is specified by codon 129, the pathogenic codon 178 mutation produces a CJD-like phenotype.^[25]

From both diagnostic and genetic standpoints, it is important to remember that these clinical stereotypes have many exceptions, that significant phenotypic heterogeneity is the rule even among members of the same family, and that no matter what mutational phenotype is typical, at least one family member will have died from an illness that closely resembles sporadic CJD.

Evaluation. In addition to the EEG and CSF tests described for patients with sporadic disease, familial disease offers the possibility of identifying the specific causative mutation by molecular genetic analysis of DNA obtained from white blood cells in an anticoagulated blood specimen. Identification of the responsible mutation is not a mere academic exercise but has practical prognostic value for the patient's family: first, it permits a rough estimate of the likely age at onset and duration of illness, and second, it can have a crucial impact in counseling about the risk of disease inheritance because some mutations are not fully penetrant. For example, mutations at codons 200 and 210 have a penetrance of only 50 percent, so that although the mutation will be transmitted as an autosomal dominant trait, only half of the individuals who carry the mutation will become sick.^{[26], [27]}

Management, Treatment, and Prevention. The care and outlook for patients with familial disease are no different from those for patients with sporadic disease; however, familial disease can be prevented in subsequent generations through the use of molecular genetic testing of amniotic fluid and elective therapeutic abortion of fetuses found to carry a lethal mutation.^[28] This option should be carefully explained to family members for their ethical and medical consideration.

IATROGENIC DISEASE

Pathogenesis and Pathophysiology. Iatrogenic disease poses no difficulty in regard to pathogenesis; when the infectious agent is accidentally introduced into the body, whether directly into the nervous system or by peripheral routes, the seed is sown for its replication and spread, and the disease eventually appears when infectivity and neuropathology have reached a high enough level. The length of the incubation period between the infecting event and the onset of symptomatic disease ranges from about 2 years in cases in which infection is introduced directly into the brain, to an average of nearly 15 years in those who are inoculated subcutaneously (and some incubation periods are as long as 20 to 30 years).

Epidemiology. Iatrogenic disease, which is fortunately still rare but is increasing every year, is the only category of these diseases that may be said to lend itself to the kind of traditional detective work practiced by field epidemiologists. The first case was recognized in the early 1970s in a U.S. recipient of a corneal graft from a patient who was later discovered to have died from CJD^[29]; soon afterward, two cases occurred in Swiss patients who had undergone stereotactic electroencephalography with needles that had been previously used in a patient with CJD.^[30] A few years later, retrospective analysis of a series of British neurosurgical cases revealed that three of the patients had probably been infected by surgical instruments contaminated in an earlier operation on a CJD patient.^[31] These few reports constituted the totality of iatrogenic disease until the past decade, when separate outbreaks of disease were traced to contaminated batches of pituitary hormones and dura mater grafts obtained from human cadavers.^[32], ^[33] There are currently nearly 200 recognized cases of iatrogenic disease from all causes, and a few cases of CJD in patients treated with growth hormone continue to appear each year, with increasingly longer incubation periods between the cessation of cadaveric hormone therapy in 1985 and the onset of CJD ([Table 43-3](#)).

Clinical Features and Associated Disorders. Iatrogenic disease syndromes are significantly influenced by

TABLE 43-3 -- IATROGENIC CREUTZFELDT-JAKOB DISEASE

Mode of Infection	Number of Patients	Agent Entry into Brain	Mean Incubation Period (range)	Clinical Presentation
Corneal transplant	2	Optic nerve	17 mo (16, 18)	Dementia/cerebellar
Stereotactic EEG	2	Intra-cerebral	18 mo (16, 20)	Dementia/cerebellar
Neurosurgery	4	Intra-cerebral	20 mo (15-28)	Visual, dementia/cerebellar
Dura mater graft	68	Cerebral surface	3.5 yr (1.5-16)	Cerebellar (visual, dementia)
Gonadotrophin	4	Hematogenous	13 yr* (12-16)	Cerebellar
Growth hormone	103	Hematogenous	12 yr* (5-30)	Cerebellar

* Calculated from mid-point of therapy to onset of CJD.

different routes of infection.^[33] Introduction of the infectious agent into the brain parenchyma, directly or via the optic nerve, produces an illness that is in all respects similar to sporadic CJD. Introduction of the agent into the brain by a peripheral route of infection (hormone therapy) produces a distinctively different illness that begins with ataxia and even in its later stages may not include significant mental deterioration; this syndrome is strongly reminiscent of kuru, which was also acquired through peripheral routes of infection. Application of the agent to the brain surface through dura mater grafts produces an illness with intermediate characteristics, comprising either prominent cerebellar/visual or demential features. The duration of illness is unrelated to the route of infection, and the disease runs a course similar to that of sporadic CJD.

Evaluation. Periodic EEG activity has been seen in about half of all patients, and the CSF tests positive for the "14-3-3" proteins in most patients in whom it has been examined; this positive result was especially important in some of the earlier hormone-treated cases, when the link between hormone contamination and CJD was still tenuous.

Management, Treatment, and Prevention. Good nursing care and attention to symptomatic relief of movement disorders remain the only palliative measures available for these unfortunate victims of our own mistakes. The prevention of future episodes of iatrogenic disease is therefore an object of increasingly close scrutiny by physicians, research scientists, and government regulatory agencies alike.

In the past, neurosurgical instruments were subjected to the standard 15 to 30 minutes of steam autoclaving at 131° C; EEG needles were disinfected with benzene, ethanol, and formaldehyde vapor; cadaveric pituitary tissue extracts were sequentially passed through glacial acetic acid, acetone, and dilute NaOH; and dura mater grafts were irradiated. We know now that none of these procedures can be fully guaranteed to inactivate the infectious agent.^[34] ^[35] ^[36] ^[37]

Therefore, the time and temperature requirement for steam autoclaving of neurosurgical instruments has been raised to 1 hour at 134° C, stereotactic EEG needles are discarded after each use, and pituitary hormones are made with recombinant technology rather than from cadaveric sources. Dura mater grafts are exposed to high (1N) concentrations of NaOH or avoided in favor of synthetic membrane patches. Renewed attention is being paid to other potential sources of infection from human-to-human transfers of tissue, tissue extracts, and blood or plasma derivatives; donors at higher than usual risk of CJD such as growth hormone recipients or members of CJD families are screened out, and chemical or filtration processing steps are being devised to eliminate any potential contamination of biological products.

NEW VARIANT CREUTZFELDT-JAKOB DISEASE (nvCJD)

Epidemiology. In 1996, a report by Will and colleagues described a distinctive cliniconeuropathological variant of CJD in 10 patients living in the United Kingdom. It was suggested that this variant syndrome might be due to the consumption of beef contaminated by the agent of bovine spongiform encephalopathy (BSE, or "mad cow disease") that had been killing cattle in epidemic fashion for the previous decade. Several additional cases have occurred each year since then, bringing the total to 24, and it is hoped that this continuing accumulation does not presage an epidemic "echo" in the human United Kingdom population, but it is still too early to know.

Clinical Features. The distinctive features of nvCJD are the young age at onset of illness (the average is 27 years, with no patient older than 50 years of age), a psychiatric or sensory disturbance on clinical presentation in the majority of patients, and a long duration of illness (median, 14 months). In its evolution, the disease shares with typical sporadic CJD the features of progressive dementia, myoclonus, and multisystem neurological deficits.

Laboratory Evaluation. None of the nvCJD patients has shown periodic EEG activity, nor has the CSF "14-3-3" protein test proved to be as helpful as in sporadic cases of CJD. MRI studies in several cases suggest that an abnormally high symmetrical signal in the posterior thalamus (pulvinar) may be a strong diagnostic clue, but additional cases need to be studied before this can be stated with any assurance. Neuropathological examination (without which a definitive diagnosis cannot be made) reveals diffuse spongiform changes that are especially severe in the basal ganglia, posterior thalamus, and cerebellum, with the presence of myriad amyloid plaques surrounded by halos of vacuolation--the so-called "florid" or "daisy" plaques.

Management, Treatment, and Prevention. The management, treatment, and prevention of nvCJD are similar to those other varieties of TSE, with the understanding that measures taken by the United Kingdom to prevent BSE-contaminated tissue from reaching the human food

85

chain should make even British beef safe to eat at the present time. Neither BSE nor nvCJD has been found in the United States.

DEFINITIONS AND HISTORY

In 1981, the Centers for Disease Control and Prevention (CDC) reported the occurrence of *Pneumocystis carini* pneumonia (PCP) in five Los Angeles homosexual men. Within months of this report, clusters of similar cases of young, previously healthy homosexual men, who had developed unusual neoplasms and unexplained opportunistic infections (OIs), were reported in New York and California. The disorder, which had the clinical and immunological hallmarks of a cell-mediated immunodeficiency (development of OIs, depressed numbers of circulating T-helper cells, with "reversed T4/T8 ratios"), was termed the gay related immune deficiency (GRID) syndrome. By the following year, the same syndrome complex was recognized in recipients of blood or blood products (mostly hemophiliacs) and in Haitians. Shortly thereafter, other high-risk groups were identified, namely men and women intravenous drug users and women whose only risk factor was sexual contact with men who were intravenous drug users, bisexuals, or both. These women's children were also a high-risk group. The disorder was renamed the acquired immunodeficiency syndrome (AIDS). Its epidemic nature was appreciated as increased numbers of cases were identified from specific geographic regions in the United States, Europe, and Africa. It was also appreciated that transmission of the disorder was from sexual contact, via mother to infant, or through bloodborne mechanisms. The agent, at that time, was thought to be most likely a virus that could survive the processing of blood factor VIII.

The etiological agent of AIDS, a retrovirus, was isolated in 1983^{[1][2][3]} and named the human immunodeficiency virus (HIV) in 1986.^[4] Once the agent was identified, studies confirmed the presence of HIV in sera that had been collected in central Africa in 1959 and the United States in 1968. It was not, however, until the early 1980s that HIV-1 infection began to reach epidemic proportions. Since then the epidemic has expanded relentlessly. From its beginning until January 1, 1996, an estimated 30.6 million people worldwide have been infected with HIV-1.

As a matter of definition, all individuals with AIDS are necessarily infected by the HIV virus. However, patients with HIV infection do not qualify for classification as having AIDS unless certain criteria are fulfilled ([Table 44-1](#) , see later discussion). In certain settings (pediatric cases), the actual demonstration of HIV infection per CDC definition, however, is not required for the diagnosis of AIDS (see [Table 44-1](#)).

Nervous system involvement complicating the course of AIDS was recognized in the very early years of the epidemic. In fact, the first reports of neurological complications appeared when the disorder was still termed GRID and thought to be restricted to homosexual males. Initially, in adults, neurological complications were believed to be caused strictly by central nervous system (CNS) OIs and neoplasms as a consequence of the immunodeficiency.^[5] However, in 1985 distinct primary HIV-1-associated neurological disorders, unrelated to secondary infections or neoplasms, were described. In that same year HIV-1 was isolated from brain, spinal cord, cerebrospinal fluid, and peripheral nerves.^{[6][7]} Between 1985 and 1988, further evidence from clinical, virological, and neuropathological studies indicated that neurological impairment in HIV- 1-infected patients, referred to as AIDS-dementia complex

Isosporiasis, chronic intestinal (>1 month duration)
Kaposi's sarcoma
Lymphoma, Burkitt's (or equivalent term)
Mycobacterial disease

in adults^[1] and AIDS encephalopathy/shpgressive encephalopathy in children,^[2] was associated with primary HIV-1 CNS infection. These studies included the following: (1) recovery of RNA and DNA in brain; (2) demonstration of intrathecal synthesis of anti-HIV antibodies; (3) localization of HIV-1 antigen in brain macrophages and monocytes by immunocytochemistry; (4) identification of viral particles within multinucleated giant cells and macrophages by electron microscopy; and (5) demonstration of increased levels of HIV-1 DNA in the brain compared with other organs by Southern blot analysis.^[10]^[11]^[12]^[13]^[14]^[15] HIV-1 was also shown to belong to the lentivirus subfamily of retroviruses. In 1987, HIV/AIDS encephalopathy was recognized by the CDC as a major complication of HIV-1 infection and designated as one of the AIDS-defining conditions, that is a condition that is specific enough to diagnose AIDS in the context of documented HIV infection (see [Table 44-1](#)).^[16]

It is now well recognized that neurological disease at every anatomic level is a common complication of HIV-1 infection and neurological symptoms and signs may be the initial manifestation of HIV/AIDS.^[17]^[18] Primary HIV- 1-associated clinical syndromes are diverse and can occur not only at the onset but at different times during the course of infection. For example, a self-limited "aseptic meningitis"^[19] may occur soon after initial infection as may an acute encephalopathy,^[20] myelopathy,^[21] or neuropathy. During the next stage of HIV-1 disease (mild immune dysfunction), neurological complications such as "aseptic" meningitis, inflammatory demyelinating polyradiculopathy, myopathy, or zoster radiculitis may occur. With advancing HIV-1 disease (moderate to severe immunodeficiency), signs and symptoms of cognitive dysfunction, dementia, myelopathy, sensory neuropathy, and myopathy become more prevalent, as do nervous system OIs and neoplasms.^[22]

In general, neurological involvement becomes increasingly more frequent with progression of HIV-1 disease

and as the immunodeficiency worsens, the prevalence of associated neurological disorders increases. In 1992, it was estimated that 37 to 77 percent of the approximately 154,000 persons alive with AIDS in the United States had an associated neurological condition.^[23] As the number of patients with AIDS increases and as medical therapies for primary HIV-1 disease and its complications lengthen survival, it can be anticipated that HIV-1-associated neurological disorders will be among the commonest neurological conditions seen by neurologists. These grim statistics also unfortunately apply to children. It is estimated that there are 15,000 to 20,000 HIV-1-infected children in the United States. It can be anticipated that HIV-1-associated CNS disease will become one of the leading causes of mental deficiency and developmental disabilities among infants and children in some areas of our country. This chapter first presents a review of the HIV virus, an overview of its general role in disease and the clinical criteria for AIDS. This is followed by a detailed account of HIV- 1-related neurological disorders and a brief summary of the neurological malignancies and OIs that occur in the setting of AIDS.

HUMAN IMMUNODEFICIENCY VIRUS: BIOLOGY AND GENERAL MEDICAL OVERVIEW OF SEROCONVERSION AND EARLY INFECTION

Pathogenesis and Pathophysiology. HIV-1, the etiological agent of AIDS, is a non-oncovirus ribonucleic acid (RNA) retrovirus that belongs to the *lentivirinae* genus of the Retroviridae family. Lentiviruses are species specific, having long periods of clinical latency and mechanisms to evade immune clearance. They target specific organs and cause persistent infection and multisystem disease in their natural hosts. Lentiviruses characteristically cause neurological disease.

HIV-1, as other human retroviruses, is an enveloped virus containing RNA genomes of positive polarity. Structurally, HIV-1 is similar to other retroviruses ([Fig. 44-1](#)).

Figure 44-1 A schematic depiction of the HIV-1 virion. Virion protein components of the envelope and nucleocapsid are indicated. (Modified from Greene WC: *The molecular biology of human immunodeficiency virus type 1 infection*. N Engl J Med 1991;324:308-317.)

There are two copies of the single-stranded RNA and polymerase in the central cylindrical core, which also contains four nucleocapsid proteins, p24, p17, p9, and p7. The nucleoprotein core is surrounded by a lipid bilayer membrane. The viral genome contains three major segments coding for the structural proteins: *GAG* (the internal core protein), *POL* (the polymerase), and *ENV* (the envelope protein complex) ([Fig. 44-2](#)). These are situated in a left-to-right 5

-to-3 order. The *GAG* gene encodes the internal core proteins of the virion particle. The *POL* gene encodes the polymerase reverse transcriptase, a ribonuclease that copies the viral RNA into DNA, a ribonuclease (RNase H) that degrades the viral RNA once an initial DNA copy has been synthesized, and an endonuclease (integrase) that is responsible for integration of the DNA copy into the host cell chromosome. *POL* also encodes a protease that is required for the processing of the mature *GAG* and *POL* products from their polyprotein precursors during virion assembly. The *ENV* gene codes for the surface envelope glycoprotein complex, gp120/gp41, which mediates binding of the virus to the host target cell. Long terminal repeats are situated at each end of the retroviral genome and are involved in the regulation of viral expression and the initiation and termination of viral RNA transcription.

In general, retroviruses capable of replication contain only three genes (*GAG*, *POL*, and *ENV*). However, the viral genome of HIV-1 is more complex and contains additional genes for regulatory proteins. *TAT* and *REV* regulate viral gene expression and are essential for virus replication. *TAT*, a transcriptional activator, stimulates the synthesis of HIV messenger RNAs early in the viral life cycle. *REV* modulates the pattern of viral RNAs expressed in infected cells and allows ordered production of viral proteins during the virus life cycle. The genes termed *VIF*, *VPR*, *VPR*, and *NEF* encode products that enhance the ability of the virus to productively infect host target cells and maximize the efficiency of viral replication. It is believed that the actions of these "additional" genes contribute to HIV-1's pathogenicity.

The outer envelope of HIV-1 is derived from the host cell lipid bilayer during viral budding and in which viral

Figure 44-2 HIV-1 genomic structure. (Modified from Staprans SI, Feinberg MB: *Natural history and immunopathogenesis of HIV-1 disease*. In Sande MA, Volberding PA [eds]. *The Medical Management of AIDS*, 5th ed. Philadelphia, W.B. Saunders, 1997, pp 29-55.)

glycoproteins (coded by the gene, *ENV*) are inserted. Electron microscopy has revealed that the HIV virion has an icosahedral structure containing 72 external spikes. These envelope spikes are responsible for binding to the receptor on the host cell and are important in cellular entry. They are composed of two components, gp120/gp41. Gp120, the external protein, contains the receptor-binding determinants of the virus. The transmembrane protein, gp41, serves to anchor the envelope glycoprotein complex at the surface of the viral lipid bilayer and is responsible for cell entry through fusion with the cell membrane. The HIV-1 lipid bilayer also contains host proteins including class I and class II histocompatibility antigens acquired during viral budding. Once within the cytoplasm of the host cell,

Figure 44-3 (Figure Not Available) The human immunodeficiency virus life cycle (RNA-binding proteins: Tat, Rev; Retroviral genes: env, nef, gag, pol; RT, reverse transcriptase). (Reproduced with permission from Folks TM, Hart CE: *The life cycle of human immunodeficiency virus type 1*. In DeVita VT, Hellman S, Rosenberg SA [eds]. *AIDS: Biology, Diagnosis, Treatment and Prevention*, 4th ed. Philadelphia, Lippincott-Raven, 1997, p 31.)

the envelope of the virus is shed, its contents are released, and reverse transcription occurs. Reverse transcriptase enables the transcription of DNA from genomic RNA (contrary to the conventional informational flow from DNA to RNA to protein). The provirus DNA is then integrated into the host cell's DNA, where it may replicate, remain latent, or replicate at a restricted rate. When activated, the proviral DNA transcribes genomic and messenger RNA ([Fig. 44-3](#) (Figure Not Available)). After the viral proteins are synthesized, new virions are assembled. The virus matures by budding from the surface of cells or into vacuoles within the cells.

HIV-1 targets, infects, and damages cells that have critically important functions in the host immune response. Cell types susceptible to HIV-1 infection, in vitro and in

Figure 44-4 HIV-1 natural history. (Modified from Staprans SI, Feinberg MB: *Natural history and immunopathogenesis of HIV-1 disease*. In Sande MA, Volberding PA [eds]. *The Medical Management of AIDS*, 5th ed. Philadelphia, W.B. Saunders, 1997, pp 29-55.)

vivo, are those that express the CD4+ surface receptor. This target cell preference results from the identity (high affinity binding) of HIV-1 gp120 to the receptor molecule, CD4+, that is used by HIV-1 during the initial stages of virus infection of host cells. Human CD4+ T-lymphocytes, monocytes/macrophages, and dendritic cells are the major cellular targets of HIV-1 infection in vivo.^[24] The CD4+ T- cell molecule is essential in interactions between helper- inducer T lymphocytes and antigen-presenting cells. It facilitates efficient recognition of antigens by CD4+ T cells, an obligate step in the generation of host immune responses. CD4+ lymphocytes serve as both essential regulators and effectors of the normal immune response. For example, they are involved in activation of macrophages, induction of cytotoxic T-lymphocyte function, natural killer and suppressor cell function, induction of B cells (dysfunction of which leads to impairment of the humoral arm of the immune system), growth and differentiation of lymphoid cells, regulation of hematopoietic colony stimulation factors, and other factors inducing nonlymphoid cell function. It is noteworthy that the CD4+ molecule is expressed at a very early stage of T cell development, even on immature thymic T cells. Therefore CD4+ T-cells appear to be susceptible to HIV-1 infection and consequent destruction at essentially all stages of differentiation. The progressive loss of these critically important cells and basic components of the immune system ultimately leads to development of profound immunodeficiency, characteristic of advanced HIV-1 infection and eventually in AIDS.

Despite the enormous wealth of information accrued during the past decade concerning molecular properties and actions of the retrovirus, many fundamental questions remain concerning immunopathogenetic events. The following overview traces some of the major events once HIV- 1 is transmitted to the host ([Fig. 44-4](#)). In-depth reviews that discuss postulated HIV's virological and immunological mechanisms have been published.^[25] The virus, free or within cells, enters the blood or lymphatic vessels and is delivered to lymphoid tissue. It is suggested that macrophages may be the first target cell of HIV-1 early after invasion. Macrophages deliver HIV-1 to lymph nodes and other lymphoid tissue and may serve as a reservoir for HIV-1. A selection of HIV-1 strains may occur during this acute infection stage. Studies of HIV-1 isolates from donor- recipient transmission pairs show that donors have heterogeneous viral populations. In contrast, viral isolates from the newly infected person are predominantly homogeneous in their envelope sequences and these viruses are mainly macrophage-tropic.^[26]

HIV-1 then enters the lymphoid tissue and an active immune response is mounted. A preferential infection of cells that are responding to or are proliferating in response to antigenic stimulation occurs. This leads to new cycles of HIV-1 replication and target cell infection.^[27] Viral spread occurs to T cells and macrophages, and during the weeks after the initial infection, more cells are infected and more are lost. There is an increase in viral burden and an associated decline in the CD4+ lymphocyte counts. At this point, some individuals may develop symptomatic acute primary infection with both systemic and neurological signs (see later discussion). It is believed that a host immune response, cell-mediated and humoral, is mounted and controls the infection to some degree. Clinical symptoms of the acute illness resolve, and the amount of virus in peripheral blood falls. Monocytes, macrophages, and follicular dendritic cells are able though to foster viral replication

without cell death. These cells may serve as a reservoir for the retrovirus, allowing transport and dissemination (and possibly persistent infection) of the virus to nonlymphoid tissues such as the brain and other organ systems with subsequent development of organ-specific HIV-1-related disorders. For example, HIV-1 infection

of gut epithelium may contribute to the diarrhea-wasting syndrome seen commonly in patients with more advanced HIV-1 infection, whereas infection of bone marrow progenitor cells may contribute to hematological abnormalities observed clinically in symptomatic HIV-1-infected patients. HIV-1 infection of these diverse organ cells may not be mediated by the CD4+ receptor but by others such as the glycolipid galactosylceramide.

After the acute symptomatic or asymptomatic primary infection, there is a period of clinical latency. Patients enter a chronic clinically asymptomatic or minimally symptomatic period. Recent studies show that even during the clinically "latent" period of disease there is a high rate of viral expression and replication in lymphoid tissue.^[28] In the stage of early and intermediate HIV-1 disease ([Table 44-2](#)), the greatest concentration of HIV-1-infected cells is still found in the lymphoid organs (lymph nodes, adenoids, tonsils, spleen). There is, however, involvement of nonlymphoid tissues as well.^[29] A very dynamic pattern of HIV-1 replication and turnover may occur. Ho et al. estimated that approximately 1 billion new virions are produced daily with replication occurring in lymph tissue.^[28] At the same time, about 1 to 2 billion new CD4+ cells are produced. Persistence of virus in lymphoid tissue can cause chronic stimulation of the immune system.^[30] This may lead to dysfunction and destruction of the responding T cells. Even before the occurrence of a very marked decline in CD4+ cell numbers, specific defects in T-cell function can be noted. The effect on the immune system is widespread, affecting multiple aspects of lymphocytic function, the interaction of T cell with antigen presenting cells, and disruption of lymphoid tissue architecture.

As CD4+ lymphocytes are lost as a result of virus- induced damage, the host's immune system attempts to compensate for depleted T cells by producing more cells, which become infected. It is hypothesized that homeostatic mechanisms exist to maintain a "normal" T-cell count. This hypothesis implies that the selective loss of CD4+ cells will induce production of both CD4+ and CD8+ cells in order to maintain homeostasis of T-cell number (referred to as "blind homeostasis"). CD4+ and CD8+ cells continue to be produced to maintain the total lymphocyte count as CD4+ cells are lost. This results in CD4+ cell lymphopenia and CD8+ lymphocytosis.^[31] CD8+ lymphocytosis may in itself cause symptomatic complications. Approximately 18 months before the development of AIDS, this mechanism breaks down, resulting in lymphopenia. An increase in the rate of loss of CD4+ lymphocytes and

TABLE 44-2 -- STAGES OF HIV-1 DISEASE AS RELATED TO CD4+ COUNT

Early HIV-1 infection	CD4+ 500 cells/mm ³
Intermediate HIV-1 infection	CD4+ 200-500 cells/mm ³
AIDS	CD4+ 200 cells/mm ²

perhaps in the appearance of more virulent viral phenotypes heralds the progression to AIDS.^[32]

The exact mechanisms by which HIV-1 infection leads to progressive loss of circulating CD4+ lymphocytes is not completely defined. Both direct and indirect mechanisms have been postulated. Several studies suggest that the pathogenicity of HIV-1 strains increases during the course of infection, as evidenced by the formation of a syncytial cell in vitro.^[33] Formation of syncytia makes the cells ineffective, and there may be downregulation of CD4+ receptors. Replication of the virus depends on reverse transcriptase, and copies of the viral genome by this process are imprecise resulting in production of variant viruses during replication. This mechanism could explain the altered pathogenicity and result in the formation of syncytial cell in vitro. This process could also lead to resistance or altered sensitivity to antiviral agents. Even without the formation of syncytia, high rates of viral replication can lead to cell dysfunction and death.^[34] Moreover, gp120 may itself activate cells, which in turn leads to production of cytokines that may adversely affect the function of other cells.

Regarding the pathophysiology of HIV-1 in children, a bimodal evolution of disease progression is noted (see later discussion). Infants with rapid disease progression (the first form) have high levels of detectable virus at birth and manifest severe clinical symptoms and immunologic abnormalities within the first years of life. Some of these infants may lack anti-HIV-1 antibodies. This rapidly progressive course may reflect the effects of HIV-1 on the developing fetal thymus and immune system. In some cases, however, high levels of viral expression is found with normal CD4+ cell counts suggesting that in this subset of children early HIV-1 thymic infection may have impaired and resulted in immunological tolerance.

In children with slowly progressive disease (the second form), there is the occurrence of more frequent and severe infections with common childhood pathogens followed later by OIs. Although the principal target of HIV-1 is the human peripheral blood CD4+ T-lymphocyte, in children one of the first immunological abnormalities is impairment of B-cell function. This is manifested by polyclonal hypergammaglobulinemia, spontaneous B-cell proliferation, and increased in vitro spontaneous production of immunoglobulin (the development of polyclonal hypergammaglobulinemia may also be noted in adults).^[35] Although the quantity of immunoglobulins is elevated, there are diminished in vivo vaccine responses to both T-cell dependent and T-cell independent antigens as well as decreased responses to B- cell mitogens.^[36] In vitro studies demonstrate diminished lymphocyte proliferation to B-cell mitogens. The decreased antibody responses predispose these infants and children to serious bacterial infections, which at times may be overwhelming. The B-cell activation may also result in polyclonal polymorphic B-cell lymphoproliferative disorders, such as lymphoid interstitial pneumonitis, parotitis, and unusual B-cell related complications such as B-cell lymphomas. Increased production of autoantibodies may also result from B-cell dysfunction. Circulating immune complexes, antinuclear antibodies, antibody to double-stranded DNA, red cell antibodies, and antiplatelet antibodies have been reported.

Epidemiology and Risk Factors. HIV-1 is transmitted

by either sexual contact, parenteral exposure to blood, blood products or body fluids, or from mother to infant. In the United States, western Europe, Australia, and in some Latin American countries, the majority of AIDS cases were initially among men infected through sex with other men. In the United States, the proportion that this group now represents has declined from approximately 72 percent in 1986 to 53 percent.^[37] It is estimated that 75 percent of HIV-1 infection worldwide is the result of heterosexual transmission. Heterosexual transmission predominates in sub-Saharan Africa, the Caribbean, Southeast Asia (Thailand), and India. At present in the United States, the number of women with heterosexually acquired infection continues to rise.

In the United States, western Europe, and Latin America, intravenous drug use (sharing of contaminated needles/equipment) was and remains a significant risk factor for transmission.^[38] About 24 percent of AIDS cases in the United States are related to intravenous drug use, up 17 percent in the past 8 years. Iatrogenic spread of infection by the reuse of contaminated needles is also reported.^[39] Since HIV-1 donor blood screening has been instituted, transfusion-acquired HIV-1 infection is now rare in developed countries, but unfortunately it still occurs and accounts for a proportion of cases in undeveloped nations.

Maternal-to-infant transmission can occur in utero, during labor and delivery, or postnatally by breast-feeding.^[40] Both the risk factors of mother-to-infant transmission and its timing are under active investigation. In utero transmission before 20 weeks of gestation is well documented. However, current evidence suggests that transmission during the third trimester and at parturition may be most common.^[40]^[41]^[42]^[43]^[44]^[45]^[46]^[47]^[48]^[49]^[50] The rate of mother-to-infant infection is estimated at about 25 percent (range 13 to 45 percent).^[51] Maternal factors reported to be associated with increased risk of transmission include low CD4+ counts, high viral titers, advanced primary HIV-1 disease, AIDS, placental membrane inflammation, premature rupture of membranes, premature delivery, increased exposure of the infant to maternal blood, and low vitamin A.^[39]^[40]^[41]^[45]^[52]^[53]^[54]

The World Health Organization estimates that from the beginning of the pandemic until January 1, 1996, 30.6 million people worldwide have been infected with HIV-1. Of these, 27.4 million were adults (15.8 million men; 11.7 million women) and 3.2 million were children. An estimated 10.4 million persons have developed AIDS, and 9.2 million people have died from AIDS. In the United States, since the beginning of the epidemic until June 1996, greater than 440,000 cases of AIDS had been reported to the CDC, and about 350,000 from North America have died. It is estimated that between 1 to 1.5 million people in the United States are HIV-1 infected. Statistical models of HIV-1 transmission in the United States suggest that transmission peaked among homosexual males in 1984 and among intravenous drug users between 1984 to 1986. Transmission by heterosexual contact is stable or increasing.^[55] A progressively larger proportion of recent AIDS cases is in women.

The worldwide increase in the number of AIDS cases in women of childbearing age is paralleled by an increasing number of children with vertically transmitted HIV-1 infection. At present, maternal-infant transmission accounts for virtually all reported new pediatric cases in the United States. The true number of HIV-1 infected children is unknown because systems have relied mostly on identification of children with clinical manifestations of AIDS. Reports based on seroprevalence and AIDS mortality data suggest that 1500 to 2000 infected children are born each year and there are 15,000 to 20,000 HIV-1-infected infants and children in the United States.^[56] Worldwide, an estimated 3.2 million children have been infected with HIV-1, and 2.4 million children have developed AIDS. During the 1995 calendar year, over 500,000 HIV-1-infected infants were born (about 1400 per day) and an estimated 400,000 children developed AIDS. By the year 2000, it is projected that over 3

million women and children worldwide will die from HIV-1-related disease and cumulatively 10 million children will be born infected. ^[40], ^[57]

Although adolescents comprise only about 1 percent of total AIDS cases in the United States, approximately 20 percent of total AIDS cases are in the young adult age group (up to 29 years of age). Given that it may take about 10 years between infection with HIV-1 and the onset of symptoms, it can be assumed that many of these persons were infected as adolescents. In fact, it is estimated that at least 50 percent of the worldwide HIV-1 population were infected between ages 15 and 24 years. ^[58] In the United States and Europe, transfusion-acquired HIV-1 infection had been the most common cause of adolescent HIV-1 infection. However, since HIV donor blood screening has been instituted, the percentage of all cases that this group now represents has declined. At present, the most common risk factors for adolescents include sexual exposure and intravenous drug use. ^[39] It is estimated that approximately 65 percent of adolescents ages 13 to 19 years and 90 percent of 20- to 24-year-olds with AIDS were infected through these means. ^[59], ^[59] Because of improved medical management and the differential natural history of pediatric AIDS, an increasing number of vertically infected children are living into adolescence and even young adulthood. It is anticipated that the percentage that this group represents will continue to rise as more effective therapies for HIV-1 and its associated disorders lengthen survival.

Clinical Features and Associated Disorders. Within 2 to 6 weeks after HIV-1 infection, virus can be detected in the blood (see [Fig. 44-4](#)). ^[60] Primary HIV-1 infection may be associated with constitutional, dermatological, gastrointestinal, as well as neurological signs and symptoms ([Table 44-3](#)). A self-limiting acute viral syndrome (fever, myalgia, arthralgia, lymphadenopathy, maculopapular rash, and aseptic meningitis [see later discussion]) is described in a subset of patients a few weeks after primary infection and may last from 1 to 2 weeks. ^[61] The HIV-1 rash is characterized as an erythematous, nonpruritic, maculopapular rash that is symmetrical, may affect the face or trunk with or without involvement of the palms and soles, or may be generalized. Lesions may be 5 to 10 mm in diameter. Other patients are asymptomatic. Factors determining if a newly infected person will develop symptomatic primary infection are not clearly defined. Inoculum size, immunological state of the individual, transmission of HIV-1 from a person with late-stage disease, possibly viral strain differences, and other as yet undefined host factors may be important variables. It is suggested that those persons who

are symptomatic with the acute retroviral syndrome (especially those with symptomatic disease lasting more than 2 weeks), those with neurological signs and symptoms, or those who acquired HIV-1 from a person with late-stage disease may be more likely to have more rapid disease progression than those without these early symptoms. ^[62]

Clinical and laboratory features at the time of acute primary HIV-1 infection may also portend the subsequent course of disease. ^[62] Thrush, persistent fever, diarrhea, weight loss, oral hairy leukoplakia, cutaneous herpes zoster, and age greater than 35 years during this early phase of infection appear to be associated with more rapid disease progression. ^[63] Virological markers include infection with SI strain of virus, persistent p24 antigenemia, and high HIV RNA viremia after seroconversion. Immunological features that may have adverse prognostic significance include low p24 antibody titres, high gp120 antibody titres, presence of specific anti-HIV-1 IgM and IgA antibodies after infection, persistent low CD4+ lymphocyte count, high CD38 expression on CD8+ lymphocytes, and an oligoclonal T-cell response.

Within 6 months of infection, most infected persons have detectable levels of anti-HIV antibodies. ^[64] A stage of clinical latency follows. Signs and symptoms of progressive immune dysfunction or of HIV-1 itself generally develop from 6 months to several years thereafter. Mild to moderate clinical manifestations during the intermediate stage of disease (see [Table 44-2](#)) may include generalized lymphadenopathy, chronic diarrhea, night sweats, weight loss, fatigue, infections indicative of cell-mediated immunodeficiency (such as herpes zoster [see later discussion and Chapter 41], oral candidiasis, and oral hairy leukoplakia). These diverse clinical manifestations of HIV-1 infection may in part reflect the immunological response to the rapid and extensive dissemination of HIV-1.

The time to occurrence of AIDS is variable. A small percentage of patients may develop an AIDS-defining condition (see [Table 44-1](#)) during the first 2 years of infection, whereas some infected people remain healthy for more than 15 years. In the absence of treatment, about 50 percent of adults will develop AIDS within 10 years after infection. ^[65] As the CD4+ count declines, more serious OIs develop. The risk of developing an AIDS-defining condition (see [Table 44-1](#)) increases as the duration of HIV-1 infection increases, and usually occurs in patients with less than 200 CD4+ cell/mm. ³

The natural history of vertically acquired HIV-1 infection in infants and children differs from that of adults. The adverse effects of HIV-1 on the developing immune system and nervous system often result in more rapid onset of clinical symptoms and progression to death. A bimodal evolution of symptomatic pediatric HIV-1 disease, with different rates of survival, is recognized from both clinical and data modeling studies. The first "hump" occurs in infancy, and the second (and larger "hump") later in childhood. ^[45], ^[52], ^[59], ^[66], ^[67], ^[68] There is probably a trimodal evolution with the third "hump" (albeit smaller) occurring in the pre- and early adolescent years. ^[46], ^[53], ^[66], ^[70] As in adults, latency to onset of symptoms in this group of children may be 10 years or more.

Infants in the first group develop symptomatic disease during the first years of life ("AIDS/HIV encephalopathy," [see later discussion] *Pneumocystis carini* pneumonitis [PCP], cytomegalovirus [CMV] infection, and/or wasting syndrome). The children in the second group have a more "benign" initial course (slower

progression). Evidence of lymphoproliferative processes characteristic of pediatric HIV-1 infection is frequent and includes lymphadenopathy, hepatosplenomegaly, and parotid gland enlargement. Multiple or recurrent bacterial infections, ranging from otitis media, pneumonia, and bone and joint infection to sepsis and meningitis are common in both groups, as is failure to thrive, persistent oral candidiasis, and chronic or recurrent diarrhea. Although these children have a form of HIV-1 disease that progresses more slowly, the disease may ultimately involve many organ systems including the CNS, cardiovascular system (cardiomyopathy), and kidneys. A polyclonal, polymorphic B-cell lymphoproliferative disorder is commonly described with nodular lymphoid lesions in the lung as well as other organs and with lymphoid infiltrate in both nodal and extranodal sites. With HIV-1 disease progression, T-cell abnormalities develop including lymphopenia, low absolute numbers of CD4+ cells, poor in vitro lymphocytic proliferation to T-cell mitogens and cutaneous anergy. Infections indicative of cell-mediated immune dysfunction occur. PCP is the most common OI and disseminated candidiasis, *Mycobacterium avium-intracellulare* (MAI), and disseminated invasive CMV are the next most frequent. As in adults, CMV may produce colitis, pneumonitis, or retinitis. Other infections include disseminated ulcerative herpes simplex infections, cryptosporidiosis, and more rarely, toxoplasmosis.

The 1993 revised CDC classification system for HIV-1 infection incorporates both clinical conditions and immunological parameters determined by CD4+ cell counts (see [Table 44-1](#)). There are three clinical categories: (A) asymptomatic infection, persistent generalized lymphadenopathy,

...

acute primary HIV-1 infection; (B) symptomatic conditions occurring in an HIV-1-infected person, excluding those conditions specified in categories A and C; and, (C) symptomatic conditions occurring in an HIV-1-infected person (AIDS-indicator diseases) (see [Table 44-1](#)). Immunological categories are stratified according to CD4+ cell counts: (1) CD4+ cell greater than or equal to 500 cells/mm³ (2) CD4+ cell 200 to 499 cells/mm³; and (3) CD4+ cells less than 200 cells/mm³ (AIDS-indicator counts).

For the purpose of epidemiological surveillance, the CDC initially defined AIDS in children under age 13 years with the same restrictive clinical case definition as adults (i.e., required documentation of an OI or an AIDS-related malignancy). Additionally, primary (congenital) or secondary immunodeficiency disorders and congenital infections had to be excluded. After HIV-1 was identified and with the advent of serological testing for the presence of anti-HIV-1 antibodies in 1985, only a small proportion of children with confirmed HIV-1 infection and HIV-1-related disease manifestations were found to fit the case definition criteria for AIDS. Subsequent revisions by the CDC broadened this definition. In 1985, biopsy-proven lymphoid interstitial pneumonitis was included as a pediatric AIDS indicator condition. In 1987, a major revision substantially expanded the criteria. This classification was based on laboratory evidence of HIV-1 infection, immunological function, and a spectrum of clinical manifestations ([Table 44-4](#)). The most recent CDC revision (1994) is based on three parameters: (A) infectious status; (B) clinical status; and (C) immunological status ([Table 44-5](#)). The revised classification system reflects the child's disease and establishes mutually exclusive categories.

Differential Diagnosis. Serological testing for anti-HIV-1 antibody (enzyme-linked immunosorbent assay [ELISA]), with a confirmatory Western blot, usually provides the diagnosis. However, during the stage of acute HIV-1 infection before seroconversion, there may be a false-positive heterophil, which can confuse the diagnosis. The clinical syndrome of acute HIV-1 infection in the adult is distinctive (see above). It contrasts to the distribution of rubella rash, which is characterized as an erythematous fine and mild maculopapular rash that rapidly spreads in a cephalocaudal fashion from face to extremities, is usually generalized within 1 day, and clears within 72 hours to 4 days. A rash is also unusual in Epstein-Barr virus or CMV infection (less than 5 percent of patients) unless antibiotics have been given.

The infant or child with vertically acquired HIV-1 infection may present with several clinical manifestations. Differential diagnosis, therefore, is dependent on the presenting signs and symptoms and the age of the child. Later in infancy and in childhood, if the presenting symptoms are chronic or recurrent infections or opportunistic infections, the most important and likely diagnosis is an immunodeficiency disorder. An appropriate history, examination, and immunological analysis, including HIV-1 serological testing, can usually rule out these conditions.

Evaluation. The goal of the diagnostic workup is to establish the presence of HIV-1 infection and determine the stage of the disease, extent of immune dysfunction, and presence or absence of neurological involvement. Accurate staging helps to formulate a prognosis, plan prophylactic

TABLE 44-4 -- CDC CLASSIFICATION SYSTEM FOR HIV IN CHILDREN (REVISED 1994)

CATEGORY N: NOT SYMPTOMATIC

Children who have no signs or symptoms considered to be the result of HIV infection or who have only one of the conditions listed in category A

CATEGORY A: MILDLY SYMPTOMATIC

Children with two or more of the conditions listed but none of the conditions listed in categories B and C:

Lymphadenopathy (0.5 cm at more than two sites; bilateral equals one site)

Hepatomegaly

Splenomegaly

Dermatitis

Parotitis

Recurrent or persistent upper respiratory infection, sinusitis, or otitis media

CATEGORY B: MODERATELY SYMPTOMATIC

Children who have symptomatic conditions other than those listed in category A or C that are attributed to HIV infection.

Examples of conditions in clinical category B include but are not limited to the following:

Anemia (<8 g/dl), neutropenia (<1000 cells/mm³), or thrombocytopenia (<100,000/mm³) persisting 30 d

Bacterial meningitis, pneumonia, or sepsis

Candidiasis, oropharyngeal thrush

Cardiomyopathy

Cytomegalovirus infection

Diarrhea, recurrent or chronic

Hepatitis

Herpes simplex virus (HSV) stomatitis, recurrent

HSV bronchitis, pneumonitis, or esophagitis

Herpes zoster (at least two distinct episodes or more than one dermatome)

Leiomyosarcoma

Lymphoid interstitial pneumonia (LIP)

Nephropathy

Nocardiosis

Persistent fever (lasting >1 month)

Toxoplasmosis, onset before 1 month of age

Varicella

CATEGORY C: SEVERELY SYMPTOMATIC

Children who have any condition listed in the 1987 surveillance case definition for acquired immunodeficiency syndrome (with the exception of LIP)

Serious bacterial infections

Candidiasis, esophageal or pulmonary

Coccidioidomycosis

Cryptococcosis

Cryptosporidiosis

Cytomegalovirus disease

Encephalopathy

HSV infection

Histoplasmosis

Kaposi's sarcoma

Lymphoma, primary, in brain

Lymphoma

Mycobacterium tuberculosis

Mycobacterium, other species or unidentified species

Mycobacterium avium complex or *M. kansasii*

Pneumocystis carini pneumonia

Progressive multifocal leukoencephalopathy

Salmonella

Toxoplasmosis of the brain with onset >1 month of age

Wasting syndrome

Adapted from centers for Disease Control and Prevention Revised classification system for human immunodeficiency virus infection in children less than 13 years of age MMWR 1994;43:1.

therapy for OIs, and determine antiretroviral therapeutic strategies for primary HIV-1 infection. Once HIV-1 infection is confirmed by anti-HIV-1 antibody testing (ELISA) (with a confirmatory Western blot in adults), a complete

TABLE 44-5 -- CDC PEDIATRIC HUMAN IMMUNODEFICIENCY VIRUS CLASSIFICATION (1994)

Immunologic Categories	Age of Child		
	> 12 Months Cells/mm ³ (Percent)	1 to 5 Years Cells/mm ³ (Percent)	6 to 12 Years Cells/mm ³ (Percent)
No evidence of suppression	1500 (25)	1000 (225)	>500 (25)
Evidence of moderate suppression	750 to 1499 (15 to 24)	500 to 999 (15 to 24)	200 to 499 (15 to 24)
Severe suppression	<750 (<15)	<500 (<15)	<200 (<15)

history should be obtained including a review of risk factors for HIV-1 exposure, drug and alcohol history, sexual history, travel history, and medical history. A complete baseline physical examination should be performed. Focused follow-up examinations are then recommended with attention directed to findings that indicate disease progression such as general appearance and weight loss, dermatological conditions (seborrheic dermatitis, folliculitis, dermatophytosis, Kaposi's sarcoma, bacillary angiomatosis), oral lesions (candidiasis, hairy leukoplakia, aphthous ulcers, periodontal disease), localized lymphadenopathy, splenomegaly and signs or symptoms of neurological/neuropsychiatric involvement (mood or affective disorders, psychomotor slowing, abnormal eye movements, hyperreflexia, change of gait).

Initial laboratory studies should include CD4+/CD8+ counts (absolute cell counts and percentages) and, if possible, HIV-1 RNA levels. CBC with differential count, electrolyte and liver function panel, hepatitis screen, reactive protein reagin (RPR) or VDRL, anti-toxoplasma IgG antibodies; purified protein derivative (PPD) with anergy panel, and chest x-ray should also be obtained. Ophthalmological, dental, and gynecological examinations (including a PAP smear, chlamydia and gonorrhea studies) should be pursued. The stage of HIV-1 infection will then determine follow-up, prophylaxis, and therapeutic strategies.

In addition to declining CD4+ cell counts and CD4+/CD8+ lymphocyte ratios, other immunological markers of disease progression include elevated levels of serum beta-2 microglobulin, neopterin, serum acid labile interferon, and decreased or absent levels of anti-p24 antibody. Virological indicators of disease progression are p24 antigenemia, HIV culture, quantitative polymerase chain reaction (PCR) of proviral DNA in cells or RNA in serum, the presence of syncytium-inducing strains of virus. Elevated erythrocyte sedimentation rate and decreased hematocrit values serve as nonspecific markers.

Newborns and young infants (up to 18 months of age) present special diagnostic challenges. Although the detection of anti-HIV-1-specific IgG antibody in peripheral blood in older children and adults is taken as proof of HIV-1 infection, a positive antibody test in a well infant or young child is uninterpretable, as maternal IgG crosses the placenta and may persist for up to 18 months. Thus, a positive IgG antibody test only confirms the seropositivity of the mother. Direct evidence for HIV-1 infection may be sought by HIV-1 culture, PCR studies, HIV-1 RNA levels, and assays of circulating p24 in the peripheral blood. If the results of these studies are negative in the neonatal period, they should be repeated when the infant is 3 to 6 months of age. If they are again negative, an ELISA should be performed when the child is 15 to 18 months of age to document infection status.

The initial laboratory evaluations of children over age 18 months suspected of having HIV-1 infection should include HIV-1 serological testing (ELISA/Western blot), a complete blood count, and lymphocyte subsets (CD3, CD4, CD8 [and CD4:CD8 ratio]) enumeration. Other routine diagnostic tests, such as chest x-ray study, urine analysis, appropriate cultures for pathogens, a chemistry panel, and IgA, IgM, IgG levels may also be warranted.

Management. Early recognition and diagnosis of HIV-1 infection is important to institute appropriate counseling, prevent further spread of the virus, limit the number of additional clinical and laboratory evaluations, to exclude possible other disorders. Thereafter, the mainstays of management of HIV-1 infection include antiretroviral therapy for primary HIV-1 infection and prophylaxis and treatment of OIs. [73] Drugs that treat HIV-1 infection attempt to interfere with the replication of HIV. Targeted points in the growth cycle of the virus include (1) blockage of viral entry (soluble CD4+ preparations); (2) prevention of transcription of RNA to DNA (reverse transcriptase inhibitors); (3) interference with translation (drugs acting on regulatory genes or their proteins); (4) inhibition of assembly (protease inhibitors); and (5) interruption of the release of virus (interferon) (see Fig. 44-5 (Figure Not Available)).

At present there are nine antiretroviral agents licensed in the United States: zidovudine (ZDV, AZT), Retrovir; didanosine (ddl), Videx; dideoxycytidine (ddC), Hivid; stavudine (d4T), Zerit; and lamivudine (3TC), Epivir. These agents are nucleoside analogues that inhibit reverse transcriptase. Protease inhibitors include saquinavir, Invirase; indinavir, Crixivan; ritonavir, Norvir; and agouron, Nelfinavir, Viracept. Non-nucleoside reverse transcriptase inhibitors have also recently been introduced and include delavirdine and nevirapine. The primary goal of antiretroviral therapy is to maintain viral suppression for as long as possible. [74] Antiretroviral clinical trials show promising beneficial results. Effective treatment reduces plasma HIV RNA levels and increases CD4+ cell counts. Treatments offer the potential to delay onset of AIDS, prolong survival, and interrupt transmission. [74] Unfortunately, limitations have also been observed. Antiretrovirals do not completely inhibit viral replication, and HIV-1 disease progresses despite therapy. Studies show that treatment with antiretroviral drugs favors the fall of HIV RNA titers, the rise of CD4+ cell counts, the

prolongation of time until HIV-1 related symptoms begin, and prolongation of survival. When to initiate primary HIV-1 therapy to an individual patient, however, remains unclear.

Recommendations for institution of antiretroviral therapy are guided by evaluation of the individual's clinical status and use of surrogate markers, such as CD4+ cell counts and plasma HIV-1 RNA levels.^[74] Some investigators

Figure 44-5 (Figure Not Available) Potential locations for treatment intervention in the life cycle of the HIV. The boxes depict the cellular signaling pathways used for replication by HIV. The first box indicates the cellular surface receptors; the second depicts the intracellular signals that transmit the first signal; the third pathway is assembled in response to second messenger signaling and includes protein-DNA and protein-RNA interactions. (Reproduced with permission from Folks TM, Hart CE: The life cycle of human immunodeficiency virus type 1. In DeVita VT, Hellman S, Rosenberg SA [eds]: AIDS: Biology, Diagnosis, Treatment and Prevention, 4th ed. Philadelphia, Lippincott-Raven, 1997, pp 29-43.)

suggest treatment before the onset of HIV-related symptoms when the CD4+ cell count falls to or below 500/mm³; HIV RNA titer is 30,000 to 50,000 copies/ml; or CD4+ cell count is rapidly declining. Treatment may also be considered if the HIV RNA titer is greater than 5000 copies/mm³ in those individuals whose CD4+ cell count is less than 500/mm³.

It is not certain which initial antiretroviral agent or combination of agents should be used. The specific initial antiretroviral treatment should be based on an assessment of the potency, expected duration of benefit, resistance, toxicity, potential interactions with other medications, ease of use, and cost.^[74] These medications are extraordinarily expensive and have certain common and distinct side effects (Table 44-6). Because this information is rapidly changing, clinicians should review yearly updates on therapy

TABLE 44-6 -- COMPLICATIONS OF TREATMENT WITH SPECIFIC ANTIRETROVIRAL AGENTS

Zidovudine	Anemia, neutropenia, nausea, anorexia, fatigue, insomnia, headache, myalgia, myopathy
ddl	Pancreatitis, peripheral neuropathy, hyperamylasemia, hyperuricemia, transaminase elevations
ddC	Peripheral neuropathy (dose-dependent), pancreatitis, rash, stomatitis, gastrointestinal disturbances
Stavudine (d4T)	Peripheral neuropathy, arthralgia, myalgia, anemia, asthenia, gastrointestinal complaints, headache, insomnia
Lamivudine (3TC)	Pancreatitis, paresthesias, peripheral neuropathy, rash, cough, headache, dizziness, fatigue, hair loss, insomnia

recommendations. It is recommended that initial therapy for antiretroviral-naïve patients consist of two nucleoside analogues that act on the transcription of viral RNA to DNA. Such combinations include ZDV/ddI, ZDV/zalcitabine and ZDV/lamivudine, as clinical trials indicate that combination therapy is more effective than monotherapy with ZDV. Monotherapy with ddI or stavudine is also an option for those patients who cannot tolerate or refuse ZDV. Stavudine (d4T) is another alternative, as is stavudine combined with ddI. In vitro studies show that resistance can develop to all these agents within 6 to 12 months of use. The clinical significance is uncertain. It should be remembered that nucleoside analogues are active against replicating HIV, and not latent provirus.

The development of the protease inhibitor class of therapy, aimed at inhibiting the assembly of active viral products, has provided further treatment options, including their use with double nucleoside therapy as discussed above.^[75] Efficacy and toxicity data are still limited. In choosing this regimen, consideration must be given to side effects and cross-resistance among drugs. In addition, these agents must also be administered at optimal dosages, because a reduction in dosage may lead to the development of resistance. Protease inhibitors (ritonavir, indinavir, and saquinavir) are all metabolized in the liver by the cytochrome p450 oxidase enzymes. Therefore, competition and interaction with other drugs metabolized by the cytochrome p450 system must be taken into consideration. Non-nucleoside reverse transcriptase inhibitors combined with other regimens are currently under clinical investigations and data are limited.

The goal of antiretroviral therapy is to maintain viral suppression as long as possible. Unfortunately, clinical experience has shown that over time therapy has a diminished

benefit. The optimum choice of secondary treatment is often a major dilemma. Many factors must be taken into consideration, for example, the patient's previous antiretroviral regimen, length of time the antiretroviral was taken, toxicities encountered, as well as side effects or toxicities of the new agent. Development of resistance to antiretroviral agents is a major problem, especially when protease inhibitors are administered as monotherapy or when not taken by the patient as directed. Skipped doses, drug holidays, and irregular dosing rapidly leads to the development of resistance.

There is still relatively limited published data concerning antiretroviral therapy for children with HIV-1 infection. In clinical trials, children treated with ZDV had improvement in weight gain and growth, stabilization of CD4 counts, a reduction in serum and CSF p24 antigen levels, decrease in immunoglobulin levels, and improvement or stabilization of cognitive function. At the time of this writing, the number of therapeutic agents available for the treatment of HIV-1 infection and its complications is limited. ZDV and ddI are the only antiretroviral agents approved by the FDA for treatment of HIV infection in children under age 13. The agents listed above for adult use are available at the present time for investigational use in pediatric patients. Protease inhibitors are also under investigation in pediatric clinical trials, as are protease inhibitors in combination with other antiviral agents. The optimal time to initiate antiretroviral therapy in children is unknown. At present, antiretroviral therapy is recommended for children who either have evidence of significant immunodeficiency or defined HIV-associated symptoms. It is recommended that initial therapy should begin with ddI or ddI in combination with ZDV with the caveat that combination therapy may carry a greater risk of toxicity.

HIV-RELATED CENTRAL NERVOUS SYSTEM DISORDERS

Aseptic Meningitis

Retrospective studies have suggested that up to 10 percent of patients with HIV-1 infection and AIDS develop clinically apparent aseptic meningitis during the course of their illness. Additionally, HIV has been isolated in blood and CSF of patients with an acute self-limited aseptic meningitis at the time of HIV seroconversion. The clinical features in these cases are similar to those present in patients with aseptic meningitis owing to other viruses, outside of the setting of HIV infection. Patients may have fever, meningeal signs, and headache that can be mild or severe with a dull or throbbing quality. These features may be accompanied by other constitutional signs that are characteristic of a viral syndrome including fatigue, malaise, myalgias, nausea, chills, and minor vomiting. Some individuals may have associated arthralgias, lymphadenopathy, and a maculopapular rash. This rash is erythematous, nonpruritic and typically involves the face or trunk. At times, cranial neuropathies may be a concomitant finding, most often affecting the trigeminal, facial, or vestibulocochlear nerves.

The differential diagnosis of this clinical presentation includes other causes of aseptic meningitis (enteroviruses, varicella zoster), bacterial meningitis, intracranial mass (abscess), subarachnoid hemorrhage, and other causes of headache (migraine). In HIV-related aseptic meningitis, the CSF will reveal a mononuclear pleocytosis ranging from 20 to a few hundred cell/mm³ in the association of an elevated protein. The diagnosis will be made by the demonstration of HIV-1 infection, which may require repeat testing after the resolution of the acute presentation.

The treatment of aseptic meningitis is supportive in nature and includes symptomatic treatment. In association with fluids and bed rest, acetaminophen, aspirin, and nonsteroidal anti-inflammatory agents may be utilized to reduce fever and lessen headache.

HIV-Associated Cognitive Impairment--Adults

Over the past two decades, various terms have been used to describe the cognitive features, including mental slowness, diminished concentration, and a decline in memory in the setting of HIV infection. These cognitive changes are variably associated with changes in behavior (lethargy, apathy, and diminished emotional responses) and motor symptoms (clumsiness, gait abnormalities, tremor, and reduced motor control). The term HIV-associated dementia or HIV dementia incorporates the cognitive changes seen in HIV-1 infection as well as those occurring in the setting of AIDS, previously termed "AIDS dementia complex" (*complex* was used to indicate the added presence of central nervous system--based motor deficits, often myelopathy and behavioral changes, including psychosis). As such, the term HIV dementia is considered to be synonymous with AIDS dementia complex, HIV encephalopathy, and HIV-associated dementia complex. A separate term, HIV-associated minor cognitive/motor disorder, has been used to denote minor degrees of cognitive and motor impairment that are not sufficient for the diagnosis of dementia. According to the American Academy of Neurology AIDS Task Force,^[51] this term is appropriate because it is unclear whether this degree of impairment uniformly progresses to overt dementia. The term HIV-associated delirium should be used in the setting of an alteration in consciousness with a rapid worsening of cognitive function in at least two domains. With these terms, three general categories can be used to classify HIV-associated cognitive dysfunction ([Table 44-7](#)). The terms HIV encephalitis, HIV-associated diffuse poliodystrophy, and HIV leukoencephalopathy are pathological findings that may be seen at autopsy in patients with HIV dementia and should not be used to denote clinical syndromes.

Pathogenesis and Pathophysiology. Much has been learned about the biology of HIV-1, the cells it infects, and the mechanisms by which viral entry into cells occurs. However, just how HIV-1 exerts its effects on the central nervous system remains uncertain and continues to be the focus of ongoing research. Gross examination of the HIV- infected individuals' brain who had cognitive impairment shows cerebral atrophy of variable degrees. There is ventricular

TABLE 44-7 -- CLASSIFICATION OF HIV-ASSOCIATED COGNITIVE DYSFUNCTION

Category 1 (HIV-associated, minor)	0.5 SD below normal on standardized neuropsychological tests Decline in work or other activities of daily living (ADLs) Symptoms for 1 month Criteria for HIV-I-associated dementia or delirium is absent No other etiology
Category 2 (HIV-associated dementia)	Marked impairment in at least two ability domains Significant impairment in work and other ADLs Symptoms for 1 month No other etiology Free of delirium for a period sufficient to establish the presence of dementia
Category 3 (HIV-associated delirium)	Clouding of consciousness Marked, rapid worsening of cognitive function in 2 domains

SD = Standard deviation.

enlargement, particularly in the frontal and temporal lobes, widening of sulci, and attenuation of deep cerebral white matter with, at times, softening of the centrum semiovale.^{[76], [77]} A spectrum of characteristic gross and microscopic changes has been described and categorized by an international working group consensus in 1991 as follows ([Table 44-8](#)). HIV-1 encephalitis is characterized by foci of inflammatory cells, microglia, macrophages, and multinucleated giant cells (Fig. 44-6 (Figure Not Available)). Location tends to be perivascular with predominance in the basal ganglia and subcortical white matter, although to a lesser degree the cortical gray matter may also be affected in some cases. In adult series, HIV encephalitis is reported in up to 90 percent (15 to 90 percent) of AIDS cases studied. Although HIV encephalitis is one of the most impressive postmortem findings, the degree of severity appears to be greater in adults than infants and young children.^[78] HIV-1 leukoencephalopathy is characterized by diffuse myelin pallor. There is diffuse damage to white matter with myelin loss. Associated findings such as reactive astrogliosis, the presence of macrophages, and multinucleated giant cells may also be present. Symmetrical white matter pallor can be

MGC, Multinucleated giant cells.

seen in the hemispheres (Fig. 44-7) and less often in the cerebellum. Leukoencephalitis was reported in one third of patients clinically diagnosed with HIV dementia^[79] and in 38 percent of autopsy series cases.^[80] A diffuse poliodystrophy has also been described in approximately 50 percent of cases. More recently, neuronal loss, dendritic changes, and reduced levels of synaptophysin have also been demonstrated by quantitative methods. A frontal and parieto-occipital predominance is noted.^[81], ^[82]

HIV-1 is most frequently localized in cells of bone marrow lineage (blood-derived macrophages), intrinsic microglia (the resident mononuclear phagocytic system of the brain), and multinucleated giant cells (formed by the fusion of these cell types). It is these cells that support productive infection.^[14], ^[15], ^[83] By immunocytochemistry, HIV-1 antigen is localized most often in the basal ganglia, subthalamic nucleus, substantia nigra, dentate nucleus, and white matter.^[84] PCR studies, though, show HIV to be more abundant in subcortical white matter than basal ganglia, deep white matter, or cortex.^[85] With more sensitive and specific techniques of viral detection, both a greater number of infected cells and cell types infected have recently been demonstrated. These include endothelial cells,^[86] astrocytes,^[87], ^[88] and neurons,^[89] although this may be restricted infection.

The clinicopathological correlates of HIV-1-associated CNS disease are not clearly delineated, nor is the exact role of the virus defined. Although studies have confirmed direct HIV-1 CNS infection early in the disease, the development of clinical HIV-1-associated CNS disease does not occur until the late stage of HIV-1 infection when the patient is immunosuppressed. Moreover, the pathological changes seen at autopsy in some cases do not always correlate with the clinical course. Some patients with clinically severe neurological disease may have relatively mild neuropathological findings. Even in those cases with more marked pathological findings, there may be a relatively small proportion of infected cells and those actively replicating. Indeed, one recent prospective study found 50 percent of patients with clinically diagnosed dementia had neither the hallmark features of HIV encephalitis nor white matter pallor, and only 25 percent of dementia cases had multinucleated giant cells.^[79] These discrepancies have suggested that other factors besides direct cellular damage by HIV-1 may be important in pathogenesis.^[90] Both virological and neuroimmunological processes have been implicated (Table 44-9). Many questions remain unanswered concerning the role of the virus, CNS viral load, evolution of

..

estimate. First, persons with HIV infection who came to medical attention in the early years of the epidemic were generally in more advanced stages of the disease. Early reports were thus probably biased toward a higher frequency rate of dementia. Second, terminology, study design, and methodology differed among studies, particularly with regard to the classification schemes used to categorize levels of HIV-1-related neurocognitive impairment. Thus, initial clinical reports described characteristics of a disorder with cognitive, motor, and behavioral manifestations, which was described in unitary terms as a single diagnostic entity, "AIDS dementia complex" (ADC).^[9] Delineation of clinical stages and precise definitions of clinical characteristics were not uniformly used across different studies. This lack of precise definition led to considerable variation in estimates of dementia in HIV-infected persons.^[92]

Current figures suggest that dementia develops in 10 to 20 percent of patients with AIDS, occurring at approximately a 7 percent annual incidence after AIDS onset.^[17] HIV dementia occurs as a late complication of HIV-1 infection when patients are immunosuppressed. It develops as the first AIDS-defining illness in only 3 percent of

adults. More generally, persons at risk for dementia are those who are farther along in the disease process and who have experienced moderate to severe immunosuppression, constitutional symptoms (e.g., anemia, weight loss, and poor nutrition), and systemic opportunistic processes.^{[93][94][95]} Education and premorbid capacities are factors as well: individuals with lower levels of education and premorbid function show more frequent cognitive deficits, whereas those with higher levels of education appear to benefit from the protective effects of "cognitive reserve" despite the impact of the virus on the CNS.^[96] Concurrent with the widespread use of antiretrovirals, there were early reports of a decline in the frequency of HIV dementia.^[97] More recent studies, however, have indicated neither a significant decline in incidence rates over the past several years nor increased survival following diagnosis of dementia.^[98]

Using the latest classification scheme, estimates of HIV dementia suggest its prevalence ranges from approximately 5 percent to approximately 14 percent.^[99] Unfortunately, there are no clear estimates at present of the rates of either HIV-associated minor cognitive/motor disorder or HIV-associated delirium. Most investigators believe that symptomatic HIV-1 infection presents at least some risk of neurocognitive impairment, but estimates of the rate of impairment vary. Neurocognitive findings on asymptomatic individuals have varied considerably as well. An early report^[100] suggested an increased incidence of impairment among asymptomatic patients. However, subsequent studies^{[101][102]} indicated no significant differences between asymptomatic HIV-positive patients and controls on selected cognitive measures. Still other concurrent efforts have again indicated mild deficits in asymptomatic individuals relative to control subjects.^{[103][104][105]} Among studies that have shown impairment in HIV-infected asymptomatic individuals, estimates of rates of impairment range from 9.1 percent to 30.5 percent.

Clinical Features and Associated Disorders. Initial clinical features of HIV-related cognitive impairment vary considerably in terms of time of presentation and severity. Symptoms are often sufficiently subtle that they may be overlooked or mistaken for psychiatric problems. Neuropsychological findings have not been completely consistent across the literature, particularly with regard to asymptomatic individuals and persons with a mild disorder. In part, this is due to the varying measures that have been used with subjects, as well as the variety of parameters used to define subject groups. It is also likely due simply to the fact that presentation varies from individual to individual. There are indications^{[103][105]} that a subgroup of seropositive, asymptomatic individuals may show deficits, particularly in memory and executive functioning. These deficits may be related to declines in CD4+ lymphocyte counts and may precede clinical evidence of AIDS.

HIV dementia has been termed subcortical in nature, at least with respect to initial presentation, whereas subsequent deterioration is more global in nature. Typical symptoms include forgetfulness, difficulty with sustained concentration, psychomotor slowing, apathy, inertia, and mild depressive symptoms. Manifestation of these problems in daily life may include problems in keeping track of appointments, telephone numbers, or medications; misplacement of personal items; difficulty following the direction of conversations or the plots of films or books; slow and clumsy handwriting, and other fine-motor problems; insecure balance and impaired gait; withdrawal from usual activities; and mild irritability and dysphoria.

Initial neuropsychological findings are also consistent with a subcortical picture. These patients may have memory loss with particular difficulty in retrieval of newly learned information, impaired manipulation of known material, or slowed psychomotor and information processing speed. Simple attention and language skills are not typically affected during the initial stages of HIV-related cognitive impairment. These may also deteriorate (though to a lesser degree) as the disease progresses.

HIV dementia in the setting of AIDS occurs along with increasing constitutional symptoms, immunosuppression, and opportunistic processes. The most pronounced neurocognitive deficits remain in the areas of retrieval of new information and psychomotor function, although deficits in executive function, language, attention, and new learning become more pronounced as well. Neurological examination is notable for diffuse signs of CNS dysfunction, e.g., slowed and erroneous motor programming, hyperreflexia, hypertonia, and frontal release signs. With advancing dementia, the patient is likely to manifest global cognitive deterioration, mutism, and abulia. There may be euphoria and denial of deficit, lack of insight/awareness, and hallucinations. Motor function and posture may be notable for marked psychomotor retardation, spasticity and weakness, ataxia, and ultimately, decorticate posturing. Although myoclonus is not consistently a feature of late dementia, generalized seizures may occur.

Progression of the dementia varies widely from individual to individual. In some, it may occur rapidly over the course of 3 to 6 months, whereas others may show relatively mild and stable dementia up until death. The reason for this difference between rapid progressors and slow progressors is not known. It is interesting to note that despite the widespread use of antiretrovirals, survival after diagnosis of HIV dementia has not improved significantly in recent years.

...

Differential Diagnosis. The differential diagnosis of HIV dementia is often problematic, particularly in the early period. Initial symptoms overlap with and can be mistaken for adjustment and mood disorders, alcohol and other substance abuse, medication effects, metabolic encephalopathy, and other brain disorders.^[106] It is important to pursue information from those close to the patient regarding the individual's history and current behavior, in order to rule out psychiatric or substance abuse complications as causes of an apparent dementia. Metabolic derangements (e.g., hypoxia and sepsis) must be considered. Other CNS processes, such as CMV encephalitis, toxoplasmosis, primary lymphoma, progressive multifocal leukoencephalopathy (PML), and cryptococcus can complicate the diagnostic process and must be excluded as causes of cognitive deterioration. Time course, level of consciousness, presence of fever and headache, and focal signs and symptoms on neurological examination may help differentiate these conditions. Of these disorders, CMV encephalitis is probably the most frequent and problematic differential diagnosis. In approximately 10 percent of all patients with AIDS, it presents as a rapidly developing encephalopathy. CMV encephalitis can be distinguished from HIV dementia by the presence of co-existing CMV infection, electrolyte abnormalities, and periventricular abnormalities.

Depression frequently complicates cognitive function in HIV infection. HIV-infected individuals are known to have higher rates of major depression than are seen in the general population, and it is thought that in most cases depression predates HIV infection.^[106] It appears that a substantial number of HIV-positive individuals can experience depression in concert with neurocognitive impairment, whereas others may show significant deficits without depressed mood, suggesting that although depression is a frequent concomitant of cognitive impairment in HIV infection, it does not play an etiologic role in such impairment.^[107]

Evaluation. A thorough neurological examination and history are essential. In the early stage, there may only be mild abnormalities of rapid eye and limb movements, as well as diffuse hyperreflexia. Increased tone, especially in the lower extremities; hyperreflexia; clonus; frontal release signs; and tremor are seen with progression disease. Focal neurological signs are suggestive of another CNS process (OIs, neoplasm, vascular). Neuropsychological assessment is also useful for characterizing the dementia and for tracking its progress, as well as the patient's response to antiretrovirals and other medications. Critical domains and specific assessment tools are listed in [Table 44-10](#) and are reviewed in Chapter 27.

Particularly important are tests of both explicit and implicit learning and memory, complex attention, information processing speed, and psychomotor speed. These areas are most likely to appear abnormal during early stages of HIV dementia and to demonstrate deterioration as the dementia progresses. Although neuropsychological assessment can be helpful with respect to the objective quantification of the nature and severity of cognitive impairment and the tracking of such impairment over time, it should be noted that neuropsychological testing in the case of HIV infection tends to be sensitive rather than specific, and numerous

disease processes may present with a similar neurocognitive picture. Consideration of this issue is particularly important because HIV-infected individuals quite often present with histories that include other problems (e.g., alcohol/drug abuse, depression and other psychiatric disorders, learning disabilities, head injury). In addition, concurrent CNS processes such as metabolic encephalopathy and OIs can also overlap with respect to cognitive deficits.

In addition to mental changes, central nervous system- based motor complications are also frequently seen in association with HIV dementia, especially myelopathies. Myopathies (see later discussion) and neuropathies (see later

discussion) can also occur but are considered as additional complications within the realm of ADC. Cerebrospinal fluid in HIV dementia is typically remarkable for elevated beta-2 microglobulin, as well as elevated total protein and increased total IgG fraction. Of these, elevated beta-2 microglobulin has the greatest diagnostic value, particularly in cases of mild dementia. The latter two findings are not specific to HIV dementia and may be seen in normal HIV carriers. Work by Martin and colleagues^[104] has also suggested that elevated CSF quinolinic acid concentrations in HIV-infected individuals are associated with deficits in motor learning and reaction time.

Imaging studies may not show abnormalities in persons with HIV-associated minor cognitive and motor disorder, despite positive neuropsychological findings. In mild HIV dementia, neuroimaging suggests subcortical and cortical atrophy with MRI abnormalities seen in deep white matter. White matter abnormalities, which may represent disruptions of the blood-brain barrier, progress and are more diffuse with increasing severity of dementia.^[108] There appears to be a positive relationship between MRI findings and neuropsychological impairment,^[100] and the diffuse, ill- defined nature of the MRI lesions also serves to differentiate HIV dementia from other CNS processes. Volumetric MRI indicates caudate atrophy as well as decreased gray matter.^[109] ^[110] PET studies have suggested that subcortical hypermetabolism occurs during early HIV dementia, particularly in the basal ganglia and thalamus. This hyper- metabolism later appears to progress to subcortical and cortical hypometabolism.^[111] ^[112] SPECT indicates abnormalities in cerebral blood flow in both neurologically normal HIV carriers and in demented patients. However, cocaine ingestion may also produce similar PET and SPECT patterns and should be ruled out.

EEG abnormalities have been reported in some asymptomatic seropositive patients,^[113] but this is not the experience of all investigators.^[114] Early dementia may be associated with EEG abnormalities, but up to 50 percent of these patients may be normal.^[94] As dementia becomes severe, diffuse slowing is frequently noted, consistent with widespread dysfunction.^[9]

Management. It is unclear if antiretroviral drug therapy initiated before the development of AIDS can prevent (or delay) the onset of HIV dementia. Portegies and associates reported a decline in the number of new cases with HIV dementia after the introduction of zidovudine therapy in 1987.^[97] The dose was 1000 to 1200 mg/d, and other groups reported a decrease in the number of patients developing new HIV-1 dementia when treated with zidovudine 1200 mg/d compared with patients taking lower doses.^[115] However, these reports should be viewed with caution because long-term, large cohort studies are limited. Moreover, other studies have shown no significant decline in incidence rates in the past several years.^[98] ^[99]

Antiretroviral therapy is recommended as the first-line treatment. The optimal dose has not been determined. Zidovudine regimens of 1000 to 1500 mg daily were used in the early clinical trials and were reduced to 600 mg daily, because the lower dose was found to have equivalent efficacy as the higher dose in preventing systemic infections. Results from the only U.S. placebo-controlled trial of this antiretroviral in HIV dementia suggested that neurocognitive improvement might be seen with high doses of ZDV. For patients with dementia and no prior treatment with ZDV, current recommendations include ZDV daily and regular blood count monitoring. If anemia or neutropenia develops, a dose reduction or treatment with erythropoietin or granulocyte colony stimulating factor (G-CSF) can be instituted. In most cases, however, HIV dementia patients will have been treated with ZDV already, and in these patients, or those who are ZDV intolerant, ddl in a dose of 200 mg bid or d4T 40 mg twice a day may be tried.

It is as yet unclear why some demented patients respond whereas others do not. In one study, neurological improvement was noted in patients with mild neurological

abnormalities, but no relationship could be found between treatment response and cumulative antiretroviral dose or CSF concentrations of antiretroviral or HIV levels. There is still very limited information about the therapeutic effects of ddI, d4T, ddC, or the protease inhibitors for the treatment of dementia. In addition to antiretroviral agents, other therapies (inflammatory, platelet activating factor, and *N*-methyl-D-aspartate (NMDA) antagonists) are currently or will be in clinical trials.

HIV-Associated Central Nervous System Disorders--Children

Neurological involvement was reported as a frequent complication of pediatric AIDS in the early years of the epidemic. A devastating progressive encephalopathy (PE) was described,^[116] as was more stable neurological impairment.^[117] It was observed that by the time HIV-1 infection had advanced to full-blown AIDS, cognitive and motor impairment of varying duration, progression, and severity were extremely common. In the majority of cases, neuropathological studies revealed no evidence of CNS opportunistic infections or neoplasms.^[13], ^[117], ^[118], ^[119] The clinical syndrome of progressive encephalopathy in children (variously termed AIDS encephalopathy, HIV-1 encephalopathy, PE, subacute PE, HIV-1-associated CNS disease, HIV-1-associated PE of childhood) is now recognized to be similar to the adult counterpart, HIV dementia (AIDS dementia complex),^[16] and is directly related to HIV-1 brain infection.

Pathogenesis and Pathophysiology. In adults, the pathophysiological mechanisms underlying HIV-1-associated CNS disease are not yet clearly defined. In infants and children, the study of neuropathophysiological mechanisms and their clinicopathological correlates is even more complex because developmental-maturational issues must also be considered.^[120] Adult HIV-1 CNS infection and disease occurs in mature, fully developed and completely myelinated nervous systems. The immune system and CNS elements of the mononuclear phagocyte system (intrinsic microglia) are also fully developed. Vertically transmitted HIV-1 infection occurs in an immature evolving organism. It is believed that HIV-1 invades the CNS early in the course of infection. Maternal-infant transmission may occur during gestation in some patients, whereas in others, the infection may occur during the perinatal period. The time of infection (gestation versus perinatal, and if gestation, in which trimester) is likely to be an important factor. The

developmental stage of the nervous and immune system when exposed to the direct and indirect effects of the virus, must be considered. Innumerable dynamic interactions occur between these two systems during development, and these undoubtedly interact in complex ways with HIV-1 variables. The maturational stage of CNS development when exposed to the effects of the virus is likely to manifest as different patterns of HIV-1 CNS disease.^[120], ^[121], ^[122]

The nervous system may also be affected secondarily by complications related to the immunodeficiency including CNS neoplasms, infections with pathogens other than HIV-1, and strokes. The nervous system may also be affected by systemic AIDS-related conditions (neurological complications of systemic illness), nutritional deficiencies, endocrinological and metabolic derangements and by toxic/metabolic complications that arise as a consequence of therapy. These conditions are not mutually exclusive, and co-existing conditions are common.^[120], ^[121], ^[122], ^[123], ^[124]

In addition, the developing nervous system in HIV-1-infected infants (as in non-HIV-1-infected infants) may be adversely affected by maternal conditions during pregnancy such as substance abuse, inadequate nutrition, deficient prenatal care, and AIDS-associated illnesses (e.g., infections with pathogens other than HIV-1).^[120], ^[121] Premature delivery is associated with some of these high-risk maternal conditions. The prematurely born HIV-1-infected infant, like any premature infant, is, in turn, at risk for developing perinatal CNS complications--intraventricular hemorrhages, periventricular leukomalacia, hypoxic encephalopathy--that carry the risk of neurological sequelae.

Epidemiology and Risk Factors. The true incidence of pediatric HIV-1-associated CNS disease is not yet known. A review of the published literature is difficult to interpret because of differences in terminology, definitions, study populations, and study designs. An incidence of 13 to 28 percent is reported from prospective studies of children followed from birth to early childhood.^[52], ^[66], ^[123], ^[125], ^[126] A 23.8 percent rate was reported by Tovo and co-workers in their cohort of 433 HIV-1 perinatally infected children in Italy.^[123] Blanche and colleagues reported a 15 to 20 percent incidence of HIV-1 encephalopathy by age 3 years in their patients followed prospectively from birth and a 10 percent incidence per year thereafter.^[52] In contrast, cohort studies of infants and children, who had already developed AIDS-related complex or AIDS, show a higher prevalence rate. A still higher rate (31 to 75 percent) is reported from cohorts of children who already developed AIDS.^[68], ^[125], ^[127] The frequency with which HIV-1-associated PE is reported as the initial AIDS-defining illness in children ranges from 12 to 16 percent.^[125] This is in contrast to the much lower percentage (0.8 percent to 2.2 percent) reported for adults.^[22], ^[39]

Extrapolating from the experiences of many investigators, it appears that in general HIV-1-associated CNS disease in children parallels progression and severity of immunodeficiency and systemic disease. The more fulminant form of PE is more common in infancy. In a subset of infants and young children, HIV-1-associated CNS disease thus is the first AIDS-indicator disease.^[52], ^[66], ^[128], ^[129]

Clinical Features and Associated Disorders. HIV-1-infected newborns are usually well at birth, and clinically recognizable neurological features of HIV-1-associated CNS disease are exceedingly rare. However, some HIV-1-infected neonates do have neurological problems owing to co-morbid conditions. Observations in both clinical care settings and longitudinal research studies show the rate and pattern of disease progression to have considerable clinical diversity.^[92], ^[120], ^[121] Neurological deterioration in some infants and young children is rapidly progressive. In some children, however, neurological deterioration occurs over a period of weeks to months, followed by a relatively stable period and then by further deterioration. Other children develop progressive and disabling motor deficits yet maintain relatively stable cognitive and socially adaptive skills. In contrast, some children have more impaired cognitive than motor function. Finally, there is a subset of children who have relatively minor and stable, motor and cognitive findings. In an effort to delineate further the clinical characteristics of HIV-1-associated CNS disease syndromes in children, a classification scheme was adopted based on: (1) age of onset of clinically apparent disease; (2) rate and pattern of disease progression; and (3) domains of function most affected.^[122], ^[127]

The most severe, devastating, and clearly recognized syndrome is HIV-1-associated progressive encephalopathy of childhood.^[51] Age of onset is usually in the first year of life (3 to 8 months of age) but may begin later. Neurological deterioration results in spastic quadriplegia and mental deficiency. Characteristic features are progressive corticospinal tract (CST) signs and loss of previously acquired motor milestones, acquired microcephaly, and marked delays in mental development. Opisthotonic posturing and rigidity may develop and are usually superimposed on spasticity. Pseudobulbar signs may also develop and feeding difficulties are frequent. The children develop a characteristic masklike facial appearance. They appear alert and wide eyed but have a paucity of spontaneous facial expression (manifestations of the basal ganglia and subcortical pathology).^[120] Despite these features, there is little facial weakness evidenced by full movement when crying. The child is hypophonic and has decreased spontaneous and responsive vocalizations. Play deteriorates and previously acquired language skills or adaptive skills are lost. Psychometric measures document a decline in the composite cognitive score. In endstages, the child is apathetic, withdrawn, and quadriparetic with markedly impaired higher cortical function.^[9], ^[131]

A less severe neurological syndrome also occurs in the first 2 years of life,^[120], ^[122], ^[128], ^[131] and most of these infants are hypotonic and have marked delays in attaining motor milestones. Cognitive impairment of a variable degree and expressive language problems are common.^[120], ^[124], ^[127], ^[130] Poor brain growth as determined by serial head circumference measurements may be present.^[12], ^[120], ^[121], ^[122], ^[128], ^[131] In early childhood, some of the children develop a diparesis-type syndrome,^[120], ^[122], ^[127] whereas others fortunately remain stable and continue to acquire mental, motor, and adaptive skills. A change in gait is often the first sign of HIV-1 motor involvement in early childhood, as the child begins to toe walk. These individuals become hyperreflexic and have increased tone in the lower extremities.^[120], ^[122], ^[127] The rate of progression and the severity of deficits vary. Some children

* See references 117, 121, 122, 124, 127, 128 and 130.

maintain independent ambulation for years, although they have a mildly spastic gait and are clumsy.^[120], ^[121], ^[128] Impairment of fine motor ability is frequent. Progression and severity in other children may be more rapid and marked. Some require orthotics for ambulation, whereas others become wheelchair-bound within months.^[117], ^[122], ^[127] Cognitive impairment is frequent but not invariable. In a subset of children, cognitive function is not affected, and composite IQ scores remain within the normal range. For most, the degree of impairment ranges from borderline intelligence to mild or moderate retardation.^[9], ^[117]

A subset of the children, who had a prolonged stable course, ultimately develop further neurological deterioration, formerly referred to as "plateau followed by further deterioration." The course then becomes similar to that of subacute PE.^[117] Progressive atrophy and white matter changes are invariably seen. In contrast, other children show improvement and steadily acquire additional developmental skills. Their rate of acquisition of new skills accelerates compared with their previous plateau performance.^[117], ^[122]

Cognitive decline, loss of interest in school performance, social withdrawal, emotional lability, decreased attention, and psychomotor slowing are reported as signs of HIV-1-associated PE in school-age children.^[9],^[117],^[122],^[127],^[132] With advancing disease, psychometric tests show a decline in the composite IQ score. Motor involvement of varying severity is common. There is usually hyperreflexia, with or without increased lower extremity extensor tone. Clumsy and poor fine-motor ability and coordination are often noted. Progressive long tract signs, movement disorders, cerebellar signs, and myelopathy may also develop. In the advanced stages of CNS disease the child has cognitive impairment and at endstage is apathetic and abulic.^[128],^[132]

Children, who in infancy and early childhood had marked delays in motor and mental development and were followed from birth in prospective studies, continued to acquire milestones and skills, although the rate and quality deviated from the norm.^[122],^[127] This suggests that HIV-1 may compromise the normal developmental process and result in a stable or static encephalopathy.

It is as yet unknown whether HIV-1-associated CNS disease manifestations in adolescents differs in early signs and progression from that of adults or of children, although it is anticipated that manifestations will be similar to adults.

Differential Diagnosis. The differential diagnosis includes other neurodegenerative disorders, infectious etiologies, and psychiatric conditions.

Evaluation. The evaluation of the HIV-1-infected child with neurological involvement requires the clinical skills and major diagnostic tools of the neurologist.^[128] The approach to the diagnosis of HIV-1-associated CNS disease, including differential diagnosis (secondary complications co-morbid complications), involves a careful medical and developmental history, HIV-1 systemic disease history, current immunological status, neurological examination, psychological assessment, and neuroimaging studies.^[121],^[128] The diagnosis of HIV-1-associated PE is relatively straightforward, if the patient has been followed prospectively. Longitudinal assessments of the infant or child reveal progressive involvement. The diagnosis is also fairly straightforward if the child on initial examination is found to have motor deficits (spasticity, ataxia, weakness, abnormalities of tone, change in gait, etc.), and by a careful history, either the new onset or progression of motor impairment can be documented (again, when other causes for progressive motor dysfunction have been excluded). Confirmation of progression can at times be obtained by review of family photographs of the child.

However, diagnostic difficulties arise when an HIV-1-infected youngster, who was not followed from birth or infancy by the examiner, is found at the initial neurological evaluation to have deficits or delays. Because the frequency of neurological and developmental impairment in this population is high, it is often impossible for the clinician to ascribe these findings to HIV-1-associated CNS disease rather than to possible co-morbid conditions. A careful history is paramount. If there are no other risk factors the diagnosis is likely. The child should have a formal psychological assessment and be re-evaluated by the neurologist and psychologist in 2 to 4 months.

Neuroimaging studies are extremely helpful and in fact are critical. If calcification of basal ganglia, with or without mineralization of the frontal white matter, is present, it is probable that the child has HIV-1-associated CNS disease. If cerebral atrophy is present in the absence of documented perinatal complications, steroid use, or other known causes of atrophy, the diagnosis becomes extremely likely. Follow-up neuroimaging studies should be requested in addition to the above-mentioned serial neurological and psychological evaluations.

Head circumference measurements are very helpful. It has been our experience that a careful review of medical records will document at least one or two past head circumference measurements. This allows the examiner to plot serial measurements. The pattern of downward deviation and "crossing percentiles" makes the diagnosis of HIV-1-associated CNS disease likely. This is especially true if acquired microcephaly is documented. Thus, neuroimaging evidence of atrophy accompanied by acquired microcephaly clearly strengthens the diagnosis.

HIV-Associated Myelopathies

Spinal cord involvement associated with HIV-1 infection has diverse causes. As with other neurological disorders associated with HIV-1 infection, different conditions occur with increased prevalence during different stages of HIV-1 infection. Some conditions are related to HIV-1 itself, whereas others are associated with other infectious, neoplastic, vascular, or nutritional and metabolic etiologies (B₁₂ deficiency).^[21],^[133],^[134],^[135] A self-limiting myelitis at the time of seroconversion and a vacuolar myelopathy that occurs during more advanced HIV-1 disease stages are related to primary HIV-1 infection.^[21],^[95] Other infectious agents reported include the herpesviruses (VZV, HSV, CMV), HTLV-1, *Treponema pallidum*, *Mycobacterium tuberculosis*, and other bacterial pathogens. Compressive lesions may be caused by neoplasms,^[9] of which lymphoma is most common. Epidural abscesses due to bacteria, fungi, or mycobacteria should also be considered. Intramedullary lesions due to infectious agents have also been described.

Vacuolar myelopathy, the most common myelopathy associated with HIV-1 infection, complicates the clinical course of infection in 5 to 27 percent of patients. It is reported in up to 55 percent of autopsy series and in one recent clinicopathologic series in 47 percent of adult AIDS patients.^[39],^[94],^[135],^[136] Myelopathy occurs in the immunosuppressed patient, although it may be the initial presentation of AIDS, but this is not usual. Autopsy cases of vacuolar myelopathy had a high frequency of PCP and MAI infection and a large number of OIs as compared with patients without vacuolar myelopathy. Clinical signs include a progressive paraparesis, sensory ataxia, and sphincter impairment. There is lower extremity hyperreflexia and spasticity with impairment of joint position sense.^[109] Distal sensory neuropathy may co-exist as may HIV dementia. Pathological findings include a spongy degeneration and intramyelin vacuolation of the dorsal and lateral columns with predominant involvement of the gracile tract. There eventually is macrophage infiltration with evidence of immune activation, cytokine elaboration, and finally necrosis and astrocytosis. The presence of HIV-1, when found, is confined to macrophages. The pathogenesis of vacuolar myelopathy is unclear, and whether or not HIV infection of the spinal cord is important to the pathogenesis is unknown.

In evaluating patients with a myelopathy, human T-cell lymphoma virus (HTLV) infection, abscess, infectious myelitis, and B₁₂ deficiency should be considered. In appropriate settings, an MRI study may be useful. Cerebrospinal fluid findings in the setting of vacuolar myelopathy are generally nonspecific. Antispasticity agents (baclofen, benzodiazepines) may improve spasms, but typically antiretrovirals agents are not useful.

HIV-RELATED PERIPHERAL NERVOUS SYSTEM DISORDERS

HIV-Associated Neuropathies

Peripheral neuropathies are a frequent complication of HIV-1 infection and in the setting of AIDS. A wide range of disorders has been described, and their causes are diverse. Some neuropathies are related to HIV-1 itself, or HIV-induced immune mediated mechanisms, and in other cases, it may be related to toxic complications of therapy, complications of systemic HIV-1 illness, nutritional deficiencies, metabolic derangements, opportunistic infections, or neoplasms (Table 44-11). The four major HIV-1- associated peripheral neuropathy syndromes have well-defined clinical characteristics (Table 44-12). Distinguishing clinical features that aid in the diagnosis, management, and, at times, prognosis of patients are stage of HIV-1 disease and CD4+ lymphocyte count, rate of symptom progression, degree of weakness relative to sensory loss, and characteristic electrophysiological findings.

Different neuropathic syndromes occur with increased prevalence at particular stages of HIV-1 disease. Some syndromes are encountered frequently whereas others are rare. In general, the overall incidence of peripheral neuropathies increases with advancing systemic disease, progressive immunodeficiency, and declining CD4+ counts.^[137] By

the time patients develop AIDS, clinical and electrophysiological evidence of neuropathy is present in up to one third of patients ^[137] and an even higher rate of nerve pathology is reported from autopsy studies. Data from the Multicenter AIDS Cohort Study indicate that the frequency of neuropathy in AIDS increased between 1985 and 1992.^[98]

Acute demyelinating polyneuropathy, brachial plexopathy, and mononeuritis may occur at the time of acute infection or seroconversion. Acute inflammatory demyelinating polyneuropathy (AIDP) and chronic inflammatory demyelinating neuropathy (CIDP), although rare, are the most common form of peripheral neuropathy during the latent, asymptomatic, or mildly symptomatic stage of HIV- 1 disease when CD4+ cell counts are greater than or equal to 500 cells/mm³.³ As immunodeficiency progresses and as CD4+ cell counts decline to the 200 to 500 cells/ mm³ range, the most frequent neuropathies encountered are mononeuritis multiplex and herpes zoster neuropathy. With HIV-1 disease progression (CD4+ cell counts are less than 200 cells/mm³), the occurrence of distal symmetrical polyneuropathy increases, as does the prevalence of other types of neuropathies such as autonomic neuropathy, mononeuritis multiplex, cranial mononeuropathies, mononeuropathies-radiculopathies associated with neoplasms, and toxic neuropathies. Progressive polyradiculopathy occurs in advanced HIV-1 disease when the patient is severely immunosuppressed (CD4+ counts less than 50 cells/mm³).

INFLAMMATORY DEMYELINATING POLYNEUROPATHIES

Although they are relatively uncommon, both acute AIDP and chronic CIDP are well-recognized complications of HIV-1 infection.^[138] Unlike other HIV-associated neuropathies, the inflammatory neuropathies occur primarily in patients early in the course of the illness before AIDS develops. Acute inflammatory demyelinating polyneuropathy, in particular, may occur coincidentally with seroconversion.^[139] This syndrome may uncommonly occur in the early stages of the disease when CD4+ cell counts are high.

TABLE 44-12 -- HIV-1-ASSOCIATED PERIPHERAL NEUROPATHIES: CLINICAL FEATURES

Neuropathy	HIV Disease Stage (CD4+ cells/mm ³)	Onset	Symptoms	Signs	Diagnostic Studies	Comments
INFLAMMATORY DEMYELINATING POLYNEUROPATHY (AIDP OR CIDP)	AIDP: early (pre-AIDS) CIDP: early > late (variable)	Subacute	Progressive symmetric weakness paresthesias	Moderate to severe weakness ± mild sensory loss areflexia	EMG: demyelination CSF: Protein WBC	Indistinguishable clinically from AIDP and CIDP in non-HIV-infected states
DISTAL SYMMETRIC POLYNEUROPATHY	Late (variable <200/400)	Subacute	Pain is predominantly symmetric distal dysesthesias/paresthesias numbness burning pain	Stocking-glove sensory loss (symmetric length-dependent) ankle DTRs	EMG: distal axonopathy	Most common HIV-1-related form of neuropathy
PROGRESSIVE POLYNEUROPATHY	Late (<200)	Acute	Prominent lower extremity syndrome back pain radicular pain paresthesias lower extremity weakness urinary incontinence	Bilateral lower extremity weakness flaccid paraparesis saddle anesthesia bowel and bladder dysfunction ankle and knee DTRs	EMG polyradiculopathy CSF: WBC + CMV culture	Prominent lower extremity syndrome resembling spinal cord compression
MONONEURITIS MULTIPLEX	Early: limited Late: extensive progressive (variable)	Acute or subacute	Facial weakness wrist drop foot drop Focal deep aching pain	Asymmetric multifocal cranial and peripheral neuropathy	EMG: multifocal axonal neuropathy Nerve Bx: inflammation vasculitis ± CMV	Laryngeal nerve involvement can occur and lead to hoarseness with vocal cord paralysis

Modified from So YT Holtzman DM Abrams DI Olney RK Peripheral neuropathy associated with acquired immunodeficiency syndrome; prevalence and clinical features from a population-based survey Arch Neurol 1988;45:945-948. AIDP Acute inflammatory demyelinating polyneuropathy; CIDP, chronic inflammatory demyelinating polyneuropathy; Bx, biopsy.

Clinical features of AIDP are similar to that of patients without HIV-1 infection (see [Chapter 49](#)). Patients present with progressive, symmetrical weakness of the upper and lower extremities. Although sensory symptoms may be present, the examination commonly shows sensory deficits that are mild in comparison to degree of weakness. The CSF protein may be elevated, and a majority of patients have a lymphocytic pleocytosis of up to 50 cells/mm³. As in non-HIV-1-infected patients with AIDP, the pathophysiological mechanism is thought to be on an immune-mediated basis ("autoimmune"). AIDP is a monophasic illness which responds well to treatment but can also remit without therapy. At present, plasmapheresis is the treatment of choice. The natural history of HIV-1-associated CIDP is unknown. As in treatment of CIDP in non-HIV-1 patients, prednisone or plasmapheresis are reported to be efficacious (see [Chapter 49](#)).

DISTAL SYMMETRICAL POLYNEUROPATHY

Pathophysiological mechanisms of this form of HIV-associated polyneuropathy remain unclear. Several hypotheses have been proposed: (1) direct effects of HIV-1^[7],^[140]^[141]^[142]; (2) HIV-1-mediated effects of activated macrophages and the production of cytokines (tumor necrosis factor (TNF)-alpha, interleukin-1 (IL-1) and (IL-6)^[143]; (3) nutritional deficiencies; and (4) toxins. Further studies are needed to clarify the role of these agents in the pathogenesis of distal symmetrical polyneuropathy (DSP) in AIDS. Infectious etiologies (mainly CMV) have also been implicated; however, some investigators believe that infection-related distal symmetrical polyneuropathy should be considered as a separate and distinct category.^[39]

Pathological examination of nerve biopsies shows degeneration of myelinated and unmyelinated axons,^[141]^[144] with mild epineurial and endoneurial perivascular mononuclear inflammation. The inflammatory cells are characterized as T lymphocytes and activated macrophages. In the endoneurium, suppressor/cytotoxic cells (CD8+) predominate over helper/inducer (CD4+) cells. A more equal ratio is seen in the epineurium and perineurium. Immunoglobulin, complement, or fibrin is not seen. Associated demyelination^[141] may be present but does not appear to be macrophage mediated or segmental.^[141] Distal axonal degeneration is noted in both central and peripheral projections of dorsal root ganglion cells and is a frequent autopsy finding in AIDS patients. Gracile tract degeneration in the upper thoracic and cervical segments may also be seen.^[142] Loss of dorsal root ganglion cells and mononuclear infiltration is usually mild in comparison with the degree of axonal degeneration and inflammation of distal nerves.

Characteristically, sensory symptoms in the form of neuropathic pain far exceed motor dysfunction in DSP. Typical symptoms are burning pain, numbness, or tingling of the toes or over the soles. Some patients develop contact hyperalgesia. Upper extremity involvement occurs somewhat later in the course of the neuropathy. Muscle weakness is not a prominent symptom. The most common signs are those typical of a predominantly sensory length-dependent neuropathy with depressed or absent ankle tendon reflexes, elevated sensory threshold, increased vibratory thresholds, decreased pinprick and temperature, in a stocking-and-glove distribution. Joint position sensation is relatively normal.^[145]^[146] If present, weakness is minimal and is generally restricted to intrinsic foot muscles.^[135]^[138]

DSP is the most frequent type of HIV-associated neuropathy. A 2.81 percent overall incidence is estimated in HIV-1-infected persons; however, it can be detected clinically in 10 to 35 percent of patients with AIDS.^[138]^[147]^[148]

Differential diagnosis of HIV-1-associated DSP includes toxic neuropathies attributable to chemotherapeutic agents (e.g., vincristine, isoniazid 2

,3

-dideoxycytidine [ddC], and 2

,3

-dideoxyinosine [ddI], d4T [stavudine]^[149]^[150] and tarsal tunnel syndrome. Electrodiagnostic studies do not differentiate between toxic neuropathies and other causes of DSP. The diagnosis of toxic neuropathy is based on the temporal association of the peripheral neuropathy with drug treatment and improvement after the suspected agent is removed. Co-morbid conditions such as diabetes or excessive alcohol intake may exacerbate, unmask, or predispose HIV-1 patients to develop this neuropathy sooner than expected.

The electrodiagnostic features of DSP in AIDS are consistent with distal and symmetrical degeneration of sensory and motor axons, in a pattern similar to other forms of DSP (absent or low-amplitude sural nerve action potentials).^[138] Nerve conduction velocities are usually in the low range of normal or mildly reduced.^[138] Late responses are also delayed in a pattern consistent with axonal neuropathy. Reduction in the amplitudes of the peroneal or tibial compound muscle action potential is less common. Electromyography (EMG) may demonstrate signs of active or chronic partial denervation with re-innervation in distal leg muscles.^[138]^[145] Serum vitamin B₁₂ levels, folate, erythrocyte sedimentation rate, antinuclear antibodies, fasting blood glucose, liver enzymes, creatinine, thyroid function tests, and serum protein electrophoresis are usually normal.^[138] Cerebrospinal fluid examination is nonspecific and often shows mild abnormalities in cell count and protein level (as is common in HIV-1-infected patients).^[151]

DSP is often a disabling condition owing to severe pain. The main treatment is symptomatic and includes those agents used in the treatment of painful non-AIDS peripheral neuropathies (analgesics, tricyclic, antidepressants, and membrane stabilizing drugs) (see [Chapter 20](#)).

MONONEURITIS MULTIPLEX

Two forms of mononeuritis multiplex (MM), both relatively rare, have been recognized as a complication of HIV-1 infection and AIDS. The first form affects patients in early stages of HIV-1 infection (CD4+ cell counts greater than 200 cell/mm³), and the second affects those individuals with advanced disease.^[144]^[152] Patients in early HIV-1 stages have a more benign disease, the extent of nerve involvement is more restricted, and the course is self-limited. Motor and sensory deficits have an asymmetrical pattern in the distribution of discrete peripheral nerves that usually develops over the course of a few weeks. As in non-AIDS mononeuritis multiplex, an autoimmune vasculitis is proposed (see [Chapter 50](#)). This form of mononeuritis neuropathy should be differentiated from compressive neuropathies of the ulna or peroneal nerves seen particularly in patients who are bed-bound with profound weight loss.

In contrast, more widespread, multifocal weakness is characteristic of the second type, which affects patients with low CD4+ counts. The clinical presentation is typically subacute with progression over several weeks or a few months. Asymmetrical, multifocal sensory and motor deficits in the distribution of several major peripheral nerves or spinal roots are characteristic of this neuropathy. Significant motor deficits are present, and deep tendon reflexes mediated by the affected nerves are diminished or absent. Cranial neuropathy is common, and^[144] some patients have hypophonia, hoarseness, and vocal cord paresis. The asymmetric weakness in discrete distributions of peripheral nerves and occasional laryngeal nerve involvement help distinguish these patients from those with the more frequently encountered CIDP.

Electrodiagnostic studies show multifocal neuropathy with mixed demyelination and axonal loss. Compressive or entrapment neuropathies are excluded by these studies. Early disease stage HIV-1-associated MM, as is non-HIV-1-related MM, is thought to be due to a vasculitis.^[153]^[154] Pathological specimens from patients with advanced AIDS show polymorphonuclear infiltrates, with mixed axonal and demyelinating lesions as well as evidence of CMV.^[153]^[154]

PROGRESSIVE POLYNEUROPATHY/RADICULITIS

This syndrome develops primarily in patients with very low CD4+ counts and advanced HIV-1 disease. It is generally considered to be due to secondary viral, infectious, or tumorous processes in the immune-compromised host and not directly related to HIV infection. Presenting features of progressive lumbar polyneuropathy include an acute cauda equina syndrome with rapid progression of bilateral leg weakness and urinary/fecal incontinence. Back pain is a prominent feature in some patients. Initially, weakness is restricted to the lower extremities as is areflexia. Paresthesias are common, but sensory deficits are rarely marked. Perineal or perianal sensory changes are characteristic but not always present. Areflexia and sensory disturbance (albeit mild) help differentiate this syndrome from weakness due to myopathy or the wasting syndrome (see later). Sphincteric disturbances and sparing of the upper extremities separate this disorder from AIDP,

CIDP, and mononeuritis multiplex. Electromyography demonstrates denervation in clinically weak muscles. Nerve conduction velocity abnormalities may be present in up to one third of patients and indicates a co-existing polyneuropathy. Cerebrospinal fluid examination is the most important confirmatory study. Elevated protein content and hypoglycorrhachia are common. About half of patients have a marked pleocytosis, with cell counts in excess of 500 cells/mm³. The other half have a less striking mononuclear cell count.

CMV infection is the most important infectious cause of this syndrome^[155] and may be detected by CSF culture and the use of CMV PCR testing. This disorder should be treated with ganciclovir and foscarnet (see [Chapter 41](#)). A polyradiculopathy syndrome may also be caused by pathogens other than CMV (e.g., herpes zoster infections, *Treponema pallidum*, *Mycobacterium tuberculosis*, toxoplasmosis of the conus medullaris and by leptomenigeal lymphoma).^[156] Therefore, CSF studies should include viral cultures, VDRL titer, and cytological studies. A lumbar sacral spine MRI excludes a compressive or mass lesion and may show enhancement of nerve roots. When herpes zoster radiculitis is present, lesions are improved and the incidence of neuralgia reduced by acyclovir. Parenteral acyclovir (30 mg/kg/d) should be used when cervical or lumbar dermatomes are involved in an attempt to prevent a severe myeloradiculitis. Amitriptyline, carbamazepine, and capsaicin can be used in the setting of postherpetic neuralgia.

HIV-1-Related Myopathies

Muscle disorders related to HIV-1 infection include HIV-1-associated polymyositis, ZDV toxic myopathy, pyomyositis or infectious myopathy, cardiomyopathy, and the so-called wasting syndrome myopathy. Of these conditions, HIV-1-associated polymyositis and toxic myopathy related to ZDV are the most common. Distinguishing between these two forms of myopathy at times may be difficult.

Pathogenesis and Pathophysiology. The pathophysiological mechanisms underlying HIV-related myopathy are uncertain. A wide spectrum of histopathological findings has been described including inflammatory infiltrates^[157],^[158],^[159] noninflammatory myofiber degeneration,^[158] nemaline rod bodies,^[157],^[158] cytoplasmic bodies, and mitochondrial abnormalities.^[160] Muscle biopsy examination usually shows characteristic myopathic features such as variation in fiber size or degenerating muscle fibers. Features of polymyositis (necrotic fibers and lymphocytic infiltrates in the perimysium and perivascular space) are also noted in some patients, although the degree of these changes is variable.^[161] In a subset of patients, gomori trichrome-stained sections of muscle show prominent abnormalities of mitochondria giving the appearance of ragged-red fibers.^[162],^[163],^[164] In other subsets of patients, electron microscopy examination shows granular material that appears as electron-dense rod bodies.^[158] Variable amounts of inflammatory infiltrates have been described in both of these types.

Before the widespread use of ZDV, overt myopathy or a polymyositis-like syndrome was reported but not frequently. With increasing use of ZDV, and especially at the initially high 1200 mg/d dosage, reports of myopathy in ZDV-treated patients and those who improved following ZDV withdrawal appeared in the literature.^[164],^[165],^[166] Studies showed ZDV to be an inhibitor of the gamma-polymerase of the mitochondrial matrix,^[167] and ZDV toxicity in skeletal muscle mitochondria was demonstrated in some^[160],^[163],^[165],^[168],^[169],^[170] but not all studies.^[169],^[170]

Investigators have suggested that muscle changes may be due to the virus, the length of time of the patient's infection, and length of time taking ZDV. Whether there are pathological features that distinguish between HIV-1- and ZDV-related myopathies remains uncertain.^[162],^[163],^[166],^[171] One clinical study of HIV-related myopathy conducted in unselected patients of all disease stages found that none of the patients taking ZDV had symptomatic myopathy thought to be related to ZDV. However, some patients had characteristic ZDV morphological changes on muscle biopsy.^[171] The clinical relevance of the structural changes

..

described earlier, the causal role of ZDV, and thus, the pathogenesis of HIV-related myopathy remain unclear and the subject of controversy.

HIV-1 has been localized in infiltrating monocyte/macrophage cells by immunocytochemistry.^[172] Myofibers do not appear to be directly infected.^[158] This suggests that it is unlikely that HIV-1 has a direct role in myopathy. As in other forms of polymyositis (see [Chapter 50](#)), immunemediated mechanisms are proposed. It is postulated that activated macrophages secrete toxic factors (cytokine hypothesis) that mediate myofiber damage. Tumor necrosis factor, which causes cachexia in laboratory animals, produced mainly by monocytes is also implicated as is interleukin-1 alpha (shown to accumulate in muscle fibers of HIV- infected patients).^[173] HIV-1-infected CD8+ cells produce cytokines that expose muscle fiber antigens against which there is no self-tolerance. It has also been suggested that homology between viral GAG protein and muscle ribonucleoproteins triggers an autoimmune process leading to cellular infiltration and myofiber damage.^[174]

Epidemiology and Risk Factors. Risk factors are not yet clearly defined. One study of 50 unselected patients in all stages of HIV-1 infection found that 26 percent of patients had myopathy. An autopsy series reported myopathic changes in 26 percent of AIDS cases.^[159] A retrospective analysis of patients enrolled in an antiretroviral clinical trial showed a 0.4 percent incidence of myopathy in patients not treated with ZDV (placebo group), which rose to 3 percent in ZDV-treated patients (D. Simpson, personal communication). HIV-associated myopathy may develop in patients in all stages of HIV-1 infection and does not appear to be associated with degree of immunosuppression.^[158]

Clinical Features and Associated Disorders. Muscle weakness is the predominant sign and symptom.^[158],^[162] Patients present with slowly progressive symmetrical and predominantly proximal weakness of the upper and lower limbs. Patients have difficulty arising from a chair or climbing stairs. Myalgia is present in 25 to 50 percent of affected patients. Neurological examinations reveal symmetrical weakness of proximal muscle groups with prominent involvement of neck and hip flexors. HIV-1-associated polymyositis can occur at any stage of HIV-1 infection. Presentation is similar to sporadic polymyositis with proximal muscle weakness, myalgias, and elevated CK.

There are no clinical features that differentiate HIV from ZDV myopathy. ZDV myopathy usually occurs after at least several months of therapy and there appears to be a dose and duration effect. Although some patients may improve after ZDV withdrawal (resolution of muscle pain and a slower recovery of strength),^[164],^[165] others do not.^[162] To add further confusion, ZDV rechallenge in some patients does not cause a relapse.^[166]

Differential Diagnosis. Other myopathic complications of HIV-1 infection include wasting syndrome and infectious myopathies. Patients with advanced HIV-1 disease frequently develop a wasting syndrome (Slim's disease) consisting of fatigue, profound involuntary weight loss, and diffuse weakness. Affected individuals are cachectic, weak, and have a general loss of muscle bulk. The frequent finding of the wasting syndrome in persons with severe HIV-1 infection makes it difficult to delineate a myopathic component. Although a myopathy can also cause a wasting syndrome characterized by involuntary weight loss and chronic muscle weakness,^[175] at times it is difficult to distinguish between the two. HIV-1-associated myopathy can occur at any stage of HIV-1 infection. Thus, if myopathy develops in early HIV-1 infection before other AIDS-defining illnesses and immunosuppression, the diagnosis of HIV-related myopathy is likely if systemic or nutritional factors have been excluded and criteria for a diagnosis of myopathy are met. The importance of determining a specific diagnosis of myopathy in patients is evidenced by some patients' improvement with prednisone therapy.^[175]

Infectious causes of myopathy in patients with AIDS, although infrequent, should be considered in the differential diagnosis. Pathogens reported in muscles of AIDS patients include *Toxoplasma gondii*,^[176] CMV, *Microsporidia*, *Cryptococcus neoformans*, *Mycobacterium avium-intracellulare*, and *Staphylococcus aureus*.^[159]

HIV-infected individuals may present with acute rhabdomyolysis characterized by a myopathic syndrome (myalgia, muscle weakness) associated with serum CK levels greater than 1,500 IU/L. The cause of acute rhabdomyolysis in HIV-1 disease is unknown, although investigators have suggested several etiologies including HIV-1 itself, drug toxicity (e.g., ddl, sulfadiazine, pentamidine), and opportunistic infections.^[177]

Evaluation. The diagnosis of myopathy is made by the presence of limb weakness with CK elevation, supportive electrodiagnostic and muscle biopsy studies. As in the diagnosis of polymyositis (non-HIV-1 related), if three of four features are present, the diagnosis is considered probable, and if two of four features are present, the diagnosis is possible (see [Chapter 50](#)). Electrophysiological studies show typical myopathic EMG features (small, brief, and polyphasic motor unit potentials that recruit with full interference patterns and fibrillation potentials).^[162] Some patients also have NCV abnormalities indicative of coincident DSP.^[158]

In HIV myopathy, CK levels are usually elevated to a moderate degree, with a median level of approximately 500 IU/L.^[158],^[163],^[164],^[165] The CK elevation parallels the degree of myonecrosis observed in coincident muscle biopsies but does not seem to correlate with weakness and is not a specific marker of HIV myopathy (patients may have elevated CK without clinical features of myopathy).

Muscle biopsy is useful in the evaluation and management of patients. Some investigators propose that the histological finding of ragged-red fibers supports the diagnosis ZDV myopathy.^[163],^[165] However, not all ZDV patients with myopathy have ragged-red fibers on biopsy; thus, the absence of the finding does not exclude a

toxic myopathy.

Management. Because it is often difficult to distinguish patients with ZDV-related myopathy from those without, the initial management of patients with significant limb weakness and objective evidence of myopathy includes ZDV withdrawal. An 18 to 100 percent rate of improvement in muscle strength is reported from different series.^{[162], [164], [171]} Some patients show further deterioration or no improvement after cessation of ZDV but do respond to treatment with corticosteroids. Thus, if signs and symptoms persist after ZDV withdrawal (about 1 month), a muscle biopsy should be considered. If there are signs of inflammation,

90

a trial of steroids is warranted. Prednisone may be effective in treatment of polymyositis or rod-body myopathy.^{[157], [162]}

HIV-ASSOCIATED NEOPLASMS

Primary central nervous system lymphoma (PCNSL), non-Hodgkin's lymphoma metastatic to the CNS and Kaposi's sarcoma are the principal brain neoplasms associated with HIV/AIDS. Of these neoplasms, PCNSL is the most common in both adults and children and is designated as an AIDS-defining condition. Neurological involvement associated with Kaposi's sarcoma is rare. Metastatic CNS lesions are found at the gray-white junction, and they enhance with contrast material. They are vascular tumors and can hemorrhage.

Primary Central Nervous System Lymphoma

PCNSL (see [Chapter 46](#)) develops in approximately 5 percent of patients with AIDS and is found at autopsy in up to 10 percent of cases. It is the initial AIDS-defining illness in 0.6 percent of adults. Primary CNS lymphoma develops in patients with advanced HIV-1 disease who are severely immunosuppressed. The incidence of PCNSL in the AIDS population may be increasing as longevity is extended by medical management and antiretroviral agents. Lymphomas are usually of the diffuse immunoblastic, or diffuse large cell, or small-cell noncleaved B-cell type ^[178] with a predilection for the deep cerebral gray matter, corpus callosum, periventricular white matter, and cerebellar vermis. A relationship to EBV is strongly suggested. EBV is frequently detected in the tumor tissue and detection of EBV DNA by PCR in CSF is sensitive and specific for establishing a diagnosis in the appropriate clinical setting.

Clinical presentation includes headache, mental status changes (confusion, lethargy, memory problems), seizures, cranial nerve palsies, and focal neurological deficits. ^[12], ^[178] In children, neurological deterioration at times may be rapidly progressive and fulminant. ^[13]

Computed tomography and MR characteristics of lymphoma include: (1) hyperdense or isodense mass lesions with variable contrast enhancement; (2) diffusely infiltrating contrast-enhancing lesions; and (3) periventricular contrasting lesions. Surrounding edema is variable, and a large solitary mass may be seen as well as multiple lesions. PCNSL is the most common mass lesion in children and the second most common mass lesion in adults (after toxoplasmosis). The differential diagnosis of intracranial lesions in AIDS patients includes a variety of infectious, neoplastic, and cerebrovascular processes. In adults, the most common mass lesion is toxoplasmosis. Unlike toxoplasma encephalitis, PCNSL lesions may cross the midline in the corpus callosum and be associated with patchy nodular ventricular enhancement. Thallium-201 SPECT scanning (or PET scanning) may be able to distinguish between lymphoma and CNS infections.

Recommendations for the management of intracranial mass lesions in AIDS patients have recently been published. Large lesions with mass effect and threatening impending herniation require open biopsy with decompression. SPECT should be performed when available, because it appears to be highly specific for PCNSL. If the results are positive, stereotactic brain biopsy is warranted for tissue diagnosis. In adults, empiric treatment for toxoplasmosis should be instituted in all other cases except when a single intracranial mass lesion accompanies negative serology for toxoplasmosis. The concomitance of negative toxoplasmosis serology and a single lesion on neuroimaging is deemed sufficient to warrant the performance of a stereotactic biopsy. In children, proceeding directly to stereotactic biopsy may be a consideration to eliminate diagnoses other than OIs.

PCNSL are radiosensitive tumors, but prognosis is extremely poor. ^[179], ^[180] Reduction in tumor size has been noted in patients following whole brain radiation therapy and steroids (400 rad administered over 3 weeks). ^[180], ^[181] A 2- to 4-month survival after diagnosis is reported. In general, chemotherapy regimens have not significantly altered long-term survival rates. Prognosis for long-term survival is grim, with death resulting from concurrent illness and OIs rather than lymphoma. Absence of OIs at the time of diagnosis is associated with a longer median survival. Selected patients may be candidates for combined chemotherapy and radiation therapy. ^[182]

Metastatic Non-Hodgkin's Lymphoma

Non-Hodgkin's lymphoma occurs in 5 percent of AIDS patients. This malignancy develops in patients who are

severely immunosuppressed, and like PCNSL, is linked etiopathologically to Epstein-Barr virus. Non-Hodgkin's lymphoma often presents as an aggressive tumor, and there is a propensity for CNS metastasis. Approximately one third to one half of patients with non-Hodgkin's lymphoma develop metastatic CNS disease. Leptomeningeal involvement is common, with extension along the Virchow-Robins spaces, the cranial and spinal nerve sheaths, and the CSF pathways. Clinical features include mental status changes, seizures, cranial neuropathies and radiculopathies, and paraspinal masses. ^[83] Neuroimaging studies often reveal hydrocephalus with basilar meningeal enhancement. Diffuse leptomeningeal and cortical enhancement may also occur. CSF studies show depressed glucose levels. Lymphoma cells may be seen on cytological studies. Combination chemotherapy regimens have not been as successful in prolonging life in patients with AIDS-associated non- Hodgkin's lymphoma as they have in non-AIDS-non- Hodgkin's lymphoma patients. The poor response and short survival may be due to severe immunosuppression and the occurrence of OIs.

OPPORTUNISTIC INFECTIONS IN AIDS

A variety of opportunistic infections occur in the setting of AIDS and may affect the CNS ([Table 44-13](#)). The susceptibility of individuals with HIV to opportunistic infections is related to the degree of immunosuppression, and correlates to the peripheral blood CD4+ lymphocyte count ([Table 44-14](#)). A full discussion of the clinical features, evaluation, and management of infection with these organisms is detailed in the preceding chapters on viral (see [Chapter 41](#)) and nonviral ([Chapter 42](#)) infections.

HISTORICAL BACKGROUND

During the seventeenth and eighteenth centuries, physicians and morphologists (Wepfer, Willis, Morgagni, Cheyne, and others) recognized that the brains of patients who died of apoplexy often contained hemorrhages and softenings and that brain damage could result from either bleeding or deprivation of the vital blood supply. [1], [2] During the nineteenth and early twentieth centuries, physicians became interested in correlating the neurological symptoms and signs found in stroke patients during life with the anatomical region of damage in the brain found after death. Various eponymic syndromes such as those of Wallenberg, Babinski-Nageotte, Weber, Millard Gubler, among others, described the neurological findings in patients with lesions at various brain stem sites. Anatomical-clinical correlations culminated in the work of Charles Foix and his Paris colleagues who, in the mid-1920s, defined the territories of supply of the various vessels within the anterior and posterior brain circulations and noted the findings in patients with infarcts in the territories of the various arteries. [3]

During the middle years of the twentieth century, clinicians became interested in the clinical findings in patients with brain hemorrhages and infarcts. In 1935, Aring and Merritt analyzed the clinical findings in patients who died at the Boston City Hospital from large strokes and tried to separate the signs of embolism, thrombosis, and brain hemorrhage. [4] Kubik and Adams, in 1946, reported the first detailed clinicopathological analysis of a stroke syndrome--occlusion of the basilar artery. [5] In 1951, Miller Fisher described the clinical findings in patients who had internal carotid artery occlusions in the neck. [6] Fisher emphasized that warning spells, which he dubbed transient ischemic attacks (TIAs), often preceded strokes in his patients and that the causative vascular disease was located in the neck, where it could theoretically be repaired by surgeons, rather than intracranially in the middle cerebral arteries (MCAs), where most of the prior literature had indicated that the usual vascular lesions were located. Shortly thereafter, Hutchinson and Yates showed that patients with posterior circulation infarcts and TIAs also often had occlusive disease in the neck, [7] at the origins of the extracranial vertebral arteries, rather than in the head. Wallenberg and Kubik and Adams had identified the vascular pathology. In 1961, Miller Fisher described the clinical findings in patients with large fatal brain hemorrhages located in the putamen, thalamus, pons, and cerebellum. [8]

Stimulated by these seminal reports and their own clinical experiences, physicians became more interested in the clinical features of stroke, brain ischemia, and cerebrovascular disease. Unfortunately, during the third quarter of the twentieth century (1951-1975), few neurologists had much interest in stroke, and most patients were cared for by non-neurologists. Furthermore, few investigations were available that could be performed safely during life and could also clarify the nature, location, and extent of stroke-related brain damage or the causative cardiac and cerebrovascular lesions. Physicians during this era turned to classifications based solely on the temporal features of symptoms. The terms TIAs, reversible ischemic neurological deficit (RIND), stroke-in-evolution, progressing stroke, and completed stroke became popular and were used as a basis for treatment. These terms were arbitrarily and variously defined and proved unpredictable of the presence of

brain infarction, prognosis, and stroke mechanism; they are now obsolete and of historical interest only. [9], [10] TIA is the only term that remains useful, mainly for ease in communication but not as a guide to diagnosis or treatment.

During the last quarter of the twentieth century, an explosion of technical advances in brain imaging (computed tomography [CT] and later magnetic resonance imaging [MRI]) and technology occurred that could give information about the cervicocranial arteries (subtraction angiography, magnetic resonance angiography [MRA], computed tomography angiography [CTA], and extracranial and transcranial ultrasound). Knowledge of the role of blood cells and coagulation factors in causing or contributing to thromboembolism also advanced. During this time, potential treatments also proliferated; these included agents that modify platelet functions; standard anticoagulants including heparin, heparinoids, low-molecular-weight heparins, and warfarin (Coumadin); endarterectomy and surgical bypass of stenotic or occluded arteries; thrombolytic treatment; angioplasty; and neuroprotective drugs aimed at increasing the brain's tolerance of ischemia. Treatment should now be based mainly on the nature, location, and severity of the causative cardiac, vascular, and hematological disorder; the pathogenesis of the stroke; and the state of the brain (normal, stunned, infarcted, or containing a hematoma). The newer available diagnostic technologies now make it possible to collect these data safely and quickly in most stroke patients.

OVERVIEW OF STROKES

Ischemia

Brain ischemia results from the occlusion of cervicocranial vessels or hypoperfusion to the brain caused by various processes: atherothrombosis, embolism, or hemodynamic abnormalities.

ATHEROTHROMBOSIS

Atherothrombosis occurs in the large cervicocranial arteries in the neck and head and small penetrating arteries. In this condition, a localized thrombus is formed in situ on an atherosclerotic arterial narrowing; it impedes distal blood flow and causes ischemia and ensuing infarction of the brain tissue supplied by the artery. The neurological symptoms and signs depend on the location of the brain vessel affected.

EMBOLISM

In brain embolism, a brain artery is suddenly blocked by embolic material, which is usually a thrombus that developed more proximally in the heart (cardiogenic), aorta, proximal arteries (intra-arterial), or venous system (paradoxical). These donor sites give rise to various types of particulate matter (white platelet-fibrin and red erythrocyte-fibrin thrombi, cholesterol crystals, fragments of atherosclerotic plaques, calcific fragments of valves and plaques, air, fat, myxomatous tumor fragments, bacterial vegetations), which then travel within the cervicocranial arteries to reach a recipient site. If the embolic material lodges for very long at a recipient site, the resulting hypoperfusion causes an infarct that often becomes hemorrhagic when the embolus moves or fragments and reperfusion occurs. The clinical findings depend on the location of the recipient brain artery affected.

SYSTEMIC HYPOPERFUSION

Critically lowered blood flow to the brain (too severe to be compensated by cerebral autoregulation mechanisms) caused by cardiac pump failure or hypovolemia causes a global decrease in cerebral blood flow. During such episodes, most patients are hypotensive. This condition causes infarction in the border zones between the major cerebral arteries (so-called watershed infarction) as well as widespread bilateral cerebral dysfunction. The major zones of damage are between the anterior and middle cerebral arteries, and between the middle and posterior cerebral arteries in the parieto-occipital regions of the cerebral hemispheres (Fig. 45-1 (Figure Not Available)). Loss of vision, decreased alertness, and weakness affecting predominantly the shoulder, hand, and thigh result.

Figure 45-1 (Figure Not Available) In heart (pump) failure and watershed infarction, (A) normal pump and arterial circulation do not occur; instead, due to (B) low pump pressure and border-zone ischemia, water goes to the center of hoses (arteries) and stippled areas show poor flow. In contrast, with (C) "blocked hose" and middle cerebral artery infarction, water flow is deficient in the center of si(stippled area). (Adapted from Caplan LR: Stroke. Clinical Approach. Boston, Butterworth-Heinemann, 1993.)

Hemorrhage

Rupture of a brain vessel causes leakage of blood into the brain parenchyma, cerebrospinal fluid (CSF) spaces around the brain, or both. Bleeding injures the neighboring tissues by interrupting and cutting vital brain pathways, by exerting local pressure on the surrounding brain structures, and by causing ischemia of tissues adjacent to the hematoma. Further increase in intracranial pressure (ICP) causes shifts and herniations of brain tissues and may compress the brain stem. There are two large subcategories of spontaneous intracranial hemorrhages. Intracerebral hemorrhage (ICH) is bleeding in the brain parenchyma itself, and subarachnoid hemorrhage (SAH) refers to bleeding around the brain into the subarachnoid spaces and CSF. These two types of hemorrhages have different etiologies, clinical courses, and outcomes and thus require different management strategies.

The differential diagnosis of stroke is depicted in [Figure 45-2](#) .

Stroke Incidence and Prevalence

Stroke is a major public health problem, ranking among the top three causes of death in most countries. It affects the brains of almost a half million people every year, causing 150,000 deaths, and there are now approximately 3 million stroke survivors in the United States. Overall, age-adjusted incidence rates range between 100 and 300 per 100,000 population per year. Stroke is the major cause of serious disability in adults and is responsible for \$20 billion in annual costs per year in lost wages in the United States. Stroke incidence rates declined during the 1950s and 1960s but increased during the 1980s. This increase may be due to increased recognition related to advances in neuroimaging technology, increased survival of patients with ischemic heart disease, better detection of milder cases of stroke, and other undefined factors during the past 10 years.^[11] , ^[12]

Stroke accounts for about 10 percent of all deaths in most industrialized countries, and the great majority of deaths are among persons over age 65. The average age-adjusted mortality rate is 50 to 100 per 100,000 population

Figure 45-2 Differential diagnosis of stroke.

per year in the United States. Stroke mortality rises exponentially with age, virtually doubling every 5 years. Stroke death rates are higher among blacks. The stroke mortality rate has steadily declined in the United States since 1915; the decline in black mortality rates has exceeded that of whites and spans all age groups. Improved survival after stroke contributes to this trend most significantly.

Ischemic stroke accounts for more than 80 percent of all strokes. ICH usually accounts for 10 to 30 percent of cases depending on the origin of the patient, with greater relative frequencies reported in Asians and blacks. Frequency of SAH is usually a third to a half of that of ICH. Among patients with brain ischemia, cardioembolism accounts for 20 to 30 percent of cases, atherothrombotic infarction accounts for 14 to 40 percent, and small deep infarcts due to penetrating artery disease (lacunes) account for 15 to 30 percent of cases.^[13]

There are major sex and racial differences in the distribution of occlusive cerebrovascular lesions. Extracranial occlusive diseases usually affect white men, are located at the origins of the internal carotid and vertebral arteries in the neck, occur twice as often in men, and are strongly associated with coronary and peripheral vascular occlusive disease, systolic hypertension, and hyperlipidemia. Compared with white men, blacks, persons of Asian origin, and women have more severe diseases of the intracranial arteries and their perforating branches. Intracranial stenosis is usually less frequently associated with coronary and peripheral vascular disease. [Figure 45-2](#) shows the major differential diagnostic stroke categories.

Risk Factors for Stroke

Knowledge of stroke risk factors has advanced substantially during the past several decades and exceeds that of many other major neurological diseases. Important stroke risk factors include advanced age, systolic hypertension, diabetes mellitus, hypercholesterolemia, carotid artery stenosis, TIAs, cigarette smoking, lack of exercise, cardiovascular disease, atrial fibrillation, and left ventricular hypertrophy (LVH) on electrocardiography (ECG).^[14] , ^[15] Based on epidemiological data, a risk profile table can be used to estimate a person's 10-year probability of stroke occurrence.^[14] Stroke rates increase dramatically with age. About two thirds of all strokes occur after the age of 65. In the Framingham study the mean age of stroke patients was 65.4 years for men and 66.1 years for women.^[14] As the population ages, the burden of stroke becomes greater.

Hypertension is the most significant modifiable risk factor for stroke, and stroke incidence is proportional to the level of the blood pressure.^[16] This is particularly true in blacks because of higher prevalence, earlier onset, greater severity, and poorer control of hypertension in this population. Decreasing systolic blood pressure by about 10 mm Hg reduces the relative risk of stroke by 35 to 40 percent.^[16] Improved control of hypertension has resulted in a recent dramatic decline in stroke frequency, most notably in black women. The combination of hypertension, diabetes, and cigarette smoking is particularly risky and requires aggressive interventions.

risk factor and is present in about 10 percent of stroke patients.^[14] It is common among blacks and particularly contributes to the development of intracranial atherosclerosis.

Cigarette smoking is a very important preventable cause of stroke, and about 30 percent of stroke patients do smoke.^[14] Heavy cigarette smoking (more than a pack per day) carries 11 times the ischemic stroke risk and four times the SAH risk of people who do not smoke.^[17] Smoking has an especially toxic effect on women taking oral contraceptives, in whom it carries 22 times the risk of developing stroke than occurs in nonsmoking women who use other forms of birth control. With cessation of cigarette smoking, the risk of stroke declines after 2 to 5 years. A J-shaped relationship exists between alcohol and stroke. The relative risk of stroke increases with moderate to heavy alcohol consumption and decreases with light drinking compared with nondrinkers.^[14] Heart diseases are clearly associated with increased risk of ischemic stroke, particularly atrial fibrillation, valvular heart disease, myocardial infarction, coronary artery disease, congestive heart failure, LVH on ECG, and mitral valve prolapse. Atrial fibrillation, which alone carries a fivefold increased risk of stroke,^[18] is particularly important in the elderly and among those with coronary heart disease or heart failure or valvular heart disease. Ascending aorta and aortic arch atheromas are an important independent risk factor for brain infarction.^[19] Abnormal serum lipid levels are regarded as risk factors, more for coronary artery disease than stroke, and are more closely related to the progression of carotid stenosis. Sex also has an influence on stroke incidence; the stroke incidence rate is greater in men than in women.

Transient Ischemic Attacks and Strokes

Miller Fisher first described the phenomenology of TIAs as "prodromal fleeting attacks of paralysis, numbness, tingling, speechlessness, unilateral blindness or dizziness," which nearly always preceded cerebral infarction in patients with occlusion of the internal carotid artery (ICA).^[4] TIA is a strong indicator of a subsequent stroke. The first year after a TIA carries the greatest stroke risk (5 percent).^[13] TIA is arbitrarily defined as a focal neurological deficit lasting less than 24 hours, but attacks are usually shorter, most episodes clearing within 1 hour.^[9] If neurological deficits last 4 hours or longer, patients often have infarcts in the locations corresponding to the transient symptoms.^[9] The clinical features of TIAs are usually similar to those of infarctions located in the arteries affected except for the transient nature of the clinical episodes.

Because TIAs are a manifestation of underlying cardiovascular or blood diseases, the underlying cardiac, hematological, and cerebrovascular diseases that potentially cause TIAs should be thoroughly investigated to manage the patients optimally.^[9] For accurate diagnosis and management, detailed clinical information is essential and helps to predict the underlying cause. Data should include the duration of the neurological deficit, heterogeneity or stereotypy, time from first TIA and from last TIA, number of spells, and nature of symptoms (motor, sensory, visual, motor and sensory, distribution on the body). There are many laboratory tests that are helpful in defining the most probable causative mechanisms of TIAs, but they should be selected and ordered on the basis of judicious interpretation of clinical data.

Management of patients with TIAs should be directed toward specific vascular lesions and underlying causative diseases.^[9] Further details are discussed later in relation to the individual disease entities.

Diagnosis

To determine the stroke mechanism or mechanisms, the following clinical bedside data should be obtained through careful history taking: (1) ecology--past and present personal and family illnesses; (2) the presence and nature of past strokes and TIAs; (3) the time of onset of the symptoms; (4) activity at onset; (5) the temporal course and progression of the findings; and (6) accompanying symptoms. A general physical examination should then be done to add more data that can be used for diagnosis of the stroke mechanism. Elevated blood pressure, cardiac enlargement or murmurs, bruits in the carotid and supraclavicular region, and symmetry of blood pressure and pulses in the arms are important check points during physical examination of stroke patients^[4] (see [Chapter 22](#)).

The presence of some findings, such as headache, vomiting, loss of consciousness, and seizures, is helpful in diagnosing subtypes of strokes. Headache at onset is an invariable feature of SAH and is also common in patients with large ICHs and large cerebral infarcts due to large artery occlusive disease and brain embolism. Headache unusual for the patient is rare in patients with lacunar infarction due to penetrating artery disease. Some patients with large artery occlusive disease and those with severe hypertension often have unaccustomed headaches in the days and weeks preceding a stroke or TIA.

Vomiting is very common in patients with SAH and ICH and in those with brain stem and cerebellar infarcts. Vomiting is very rare in patients with hemispherical brain infarction due to large artery occlusive disease or embolism. Seizures at or shortly after the onset of the stroke are relatively common in patients with lobar hemorrhages and those with brain embolism, but do not occur in patients with lacunar infarcts. Loss of consciousness at onset is common in patients with large SAHs and in those with embolism to the basilar artery but is rare in strokes due to other mechanisms. Patients with large ICHs often have headache, vomiting, and progressive loss of alertness as the hematoma enlarges and intracranial pressure rises.

Neuroimaging studies include CT scan, MRI, single-photon emission computed tomography (SPECT), and positron emission tomography (PET). CT and MRI scans image brain structure. CT scans are best for differentiating ischemic stroke from hemorrhagic stroke. MRI can detect an acute ischemic stroke earlier than CT and is the preferred technique for identifying brain stem and cerebellar infarctions. SPECT and PET scans image the perfusion and metabolic state of the brain and can quantify cerebrovascular reserve capacity.^[22]

Vascular imaging can be divided into noninvasive and invasive studies. Four commonly used noninvasive tests are Duplex scans (B-mode and Doppler combined), transcranial Doppler ultrasonography (TCD), MRA, and CTA. Duplex scans show an accurate image of the extracranial carotid and subclavian arteries. TCD is useful for the evaluation of the intracranial cerebral arteries by measuring flow velocities and directions. MRA and CTA are also noninvasive methods for the evaluation of intracranial and extracranial large arteries. Combined use of these noninvasive tests is usually adequate for evaluation of most stroke patients. MR venography is now a very useful diagnostic tool for showing cerebral venous sinus thrombosis and has largely replaced invasive conventional cerebral angiography. When there is any suspicion of significant vascular lesions such as severe intra- or extracranial stenosis, aneurysm, arteriovenous malformation (AVM), or vasculitides, standard femoral artery catheterization and angiography are usually done to further define and characterize the

Figure 45-3 (Figure Not Available) Internal carotid artery atherosclerotic lesions: (a) plaque; (b) plaque with platelet-fibrin emboli; (c) plaque with occlusive thrombus; (d) recent ischemic cerebral infarct due to internal carotid artery α (Adapted from Caplan LR: *Stroke. lesions and, when possible, to intervene to treat vascular lesions at the same time. ^[22] Important laboratory tests for stroke patients are listed in [Table 45-1](#).

[PreviousNext](#)

DISEASES THAT CAUSE BRAIN ISCHEMIA

Atherothrombotic Disease

Pathogenesis and Pathophysiology. Atherothrombosis implies a reduction or occlusion of blood flow caused by a localized thrombotic process in one or more atherosclerotic cervicocranial arteries. Branching points of arteries are the predilection sites of development of atherosclerosis (Fig. 45-3 (Figure Not Available)). In atherosclerosis, fibrous and muscular tissues of the vessel wall overgrow in the subintima, and fatty materials form plaques that can encroach on the lumen. Platelets adhere to the crevices in the plaques and form clumps that serve as *nidi* for the deposition of fibrin, thrombin, and clot. Plaques and ulcers are associated with denudation of the endothelium and decreased release of endothelium-releasing factors including nitric oxide. Endothelins can promote platelet activation and thrombus formation. Intraluminal thrombi are of different types: so-called "white clots," which are mainly composed of platelets and fibrin, and "red thrombi," which are red blood cells enmeshed in fibrin. White platelet clumps form most often in fast-moving streams, adhering to crevices and irregularities along the intimal surface. Fibrin-dependent red thrombi develop in slow-moving streams, for example, arteries with severe luminal narrowing. Narrowing of arteries decreases blood flow, leading to stagnation of the blood column and activation of clotting factors. Clot and fibrin-platelet clumps form and break off, blocking distal arteries and further impeding flow in the affected parent artery (see Fig. 45-3 (Figure Not Available)).^[1]

Epidemiology and Risk Factors. Atherosclerosis affects chiefly the large extracranial and intracranial arteries (Fig. 45-4), but there are important sex and racial differences in the distribution and incidence of lesions at these sites. White men have more severe disease of the extracranial arteries, whereas in blacks, persons of Asian origin, and women there is a predilection for narrowing of the intracranial arteries.^[23]

Patients with extracranial large artery disease also have a high incidence of coronary artery disease (angina pectoris

92

Figure 45-4 Sites of predilection for atherosclerotic narrowing; black areas represent plaque (Adapted from Caplan LR: *Stroke. Clinical Approach*. Boston, Butterworth-Heinemann, 1993.)

and myocardial infarction), peripheral vascular occlusive disease (claudication), hypertension, and hypercholesterolemia. Death is more often due to fatal coronary artery disease than stroke.

Clinical Features and Associated Disorders. Development of neurological deficits preceded by brief, frequent shotgun-like TIAs in the same vascular territory usually suggests atherothrombosis as the vascular mechanism. Stroke caused by a thrombotic process often develops during or just after sleep. Atherothrombotic infarctions are usually characterized by postural sensitivity of symptoms, occlusion or severe stenosis of a large artery, absence of distal embolus by angiography, infarct on CT or MRI near the border zone territory of the affected artery, and the presence of risk factors for atherosclerosis such as hypertension, diabetes mellitus, and smoking. The neurological symptoms and signs depend on the vessels involved and the regions of brain ischemia.

Differential Diagnosis and Evaluation. The diagnosis of large artery occlusive disease is based on the demographic and epidemiological situation of the patient, analysis of the time course of the brain ischemia, physical examination of the heart and neck vessels, and tests that define the anatomy and function of the cervicocranial arteries. Brain imaging (by CT or MRI) is usually important to define the presence, location, and size of any infarction and may show unexpected ("silent") infarcts not predicted from the history and physical examination. Ultrasound has now become the cornerstone of noninvasive vascular diagnosis. Duplex scans of the carotid and vertebral artery origins combined with color-flow Doppler ultrasound can define and quantify most extracranial carotid and vertebral artery (VA) lesions. TCD can detect many intracranial occlusive lesions, especially those involving the MCAs, intracranial VAs, and the posterior cerebral arteries (PCAs). TCD also yields information about the impact of occlusive extracranial lesions on intracranial blood flow. MRA and CTA are also helpful in imaging the large extracranial and intracranial arteries. When ultrasound and MRA or CTA are concordant and define the occlusive vascular lesions, catheter angiography is usually not necessary.

Management. The very basic goal of management of ischemic stroke patients in the acute phase is protection of the so-called penumbra zone. This zone comprises the brain tissues at risk of irreversible ischemic damage. Brain tissues adjacent to the ischemic core are often impaired functionally ("stunned"), but ischemia is potentially reversible if the circulation is restored soon enough. To achieve this goal, several therapies can be used: (1) occluded vessels can be recanalized (thrombolytic therapy) if possible, (2) blood volume and cerebral blood flow can be maximized and blood viscosity can be reduced, (3) perfusion pressure must be maintained sufficiently (by careful control of blood pressure, reduction of cerebral edema, and lowering of intracranial pressure), and (4) the progression of occlusive processes should be blocked using anticoagulants and agents that alter platelet function in some instances. All these measures should be guided by the severity and reversibility of the lesion, the nature, location, and severity of the underlying stroke mechanism, and the viscosity and coagulability of the blood. Recanalization is usually performed by thrombolysis and will be discussed later in this chapter. Hemodilution therapy decreases blood viscosity by lowering the hematocrit level. Blood pressure should not be aggressively lowered during the acute phase, since this decreases pressure in the collateral channels and may extend the infarct. Various neuroprotective agents are presently under study.

For prevention of recurrence of ischemia in the future, prophylactic treatment should be guided by the mechanism of the stroke. Theoretically, red clots would respond more to warfarin anticoagulants and heparin, and white clots would be better prevented with platelet antiaggregants, such as aspirin. Surgery (endarterectomy), angioplasty, or warfarin may be indicated for patients with tight stenotic lesions and important tissue at risk for further ischemia. The choice of warfarin versus surgery or angioplasty depends on the accessibility of the lesions to treatment, the risk of surgery and angioplasty, the patient's wishes, the likelihood of the patient's compliance with anticoagulant usage, and any contraindication to the use of anticoagulants.^[24] Heparin may be used for as long as 2 to 3 weeks to prevent propagation and embolization of clot. Long-term warfarin use is usually not needed after the clot organizes and adheres to the vessel wall in atherothrombotic stroke (usually 3 to 4 weeks). Aspirin, 325 mg or more per day, can prevent platelet-fibrin emboli in patients with minor or moderate stenosis. An increase in the dose of aspirin (especially if an *in vitro* aspirin effect is not shown at the lower dose) or use of ticlopidine should be tried if symptoms recur. Ticlopidine hydrochloride, a thienopyridine derivative, is another effective antiplatelet agent that has been

93

recently introduced into clinical practice. The recommended dosage is 250 mg twice a day. Its side effects are gastrointestinal symptoms, skin rash, and leukopenia, which require careful monitoring of clinical findings and blood tests during the first 3 months. Neither warfarin nor surgery is recommended in patients with slight to moderate stenosis. If the patient has a primary coagulopathy, polycythemia, or thrombocytosis, these disorders should be treated more specifically.^[1]

Prognosis and Future Perspectives. In patients with large artery occlusions, the risk of infarction is maximal in the days after occlusion. After the first week, the likelihood of further infarction is much less. Prognosis depends on whether the initial thrombus propagates distally or embolizes to intracranial arteries and the extent of collateral circulation that develops. Optimization of blood pressure and blood volume during the time when the collateral circulation is developing helps to augment blood flow to the penumbral zones and thus limits the extent of infarction. Of course, patients with large artery atherosclerosis are at risk during the subsequent months and years of narrowing and occlusion of other arteries, so preventive measures instituted at the time of the initial symptoms may help in preventing or delaying further strokes. The effectiveness of surgery and angioplasty for various occlusive lesions is now under study in large trials. At times, thrombolysis and angioplasty may be used together because patients with thrombi superimposed on severe atherosclerotic occlusive disease often experience reocclusion of the artery after thrombolysis unless the atherosclerosis is repaired. The optimal thrombolytic agent, portal of delivery, dose, timing, and target population for thrombolysis are now being studied. Many trials now are trying to define the usefulness of a variety of neuroprotective agents.

Occlusive Disease of Small Penetrating Arteries

The small penetrating arteries deep within the brain parenchyma are the sites of various occlusive processes that are different from those of the larger arteries.

Pathogenesis and Pathophysiology. Lipohyalinosis, a destructive vasculopathy linked to severe hypertension, affects arteries 40 to 200 μm in diameter. The arterial lumen is compromised not by an intimal process but by thickening of the vessel wall itself. Subintimal lipid-laden foam cells and pink-staining fibrinoid material thicken the arterial walls, sometimes compressing the lumen. In places, the arteries are replaced by tangles and wisps of connective tissue that obliterate the usual vascular layers. The small, deep infarcts that result from occlusion of these arteries are usually called lacunes.^[1],^[24],^[25] Small, deep infarcts can also result from miniature

atheromas (microatheromas) that form at the origin of penetrating arteries, as well as by plaques within the parent arteries that obstruct or extend into the branches (junctional plaques). Rarely, they are occluded by microemboli (Fig. 45-5 (Figure Not Available)). Vascular lesions involving the mouths of penetrating arteries are called intracranial branch atheromatous disease.^[25]

A recently recognized entity named CADASIL (cerebral

Figure 45-5 (Figure Not Available) Branch atheromatous diseases of the basilar artery. (A) Plaque within parent artery blocking the branch artery orifice. (B) Plaque extends into the branch from the parent artery (junctional plaque). (C) Microatheroma originating in orifice of branch. (Adapted from Caplan LR: Intracranial branch atheromatous disease: A neglected, understudied, and underused concept. *Neurology* 1989;39:1246-1250; with permission.)

autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy) is a familial arterial disease of the brain that begins in early adult life. Its gene is mapped to chromosome 19. The CADASIL vasculopathy affects the media of leptomeningeal and perforating arteries of the brain. The media is thickened by an eosinophilic granular material of unknown origin. Clinically, patients present with recurrent subcortical infarcts, progressive or stepwise dementia, migraine with aura, and depression. Usually, there is no hypertension or other vascular risk factors. Prominent subcortical white matter and basal ganglia hyperintensities are noted on T2-weighted MRI. Vascular studies are usually not helpful diagnostically.^[26]

Epidemiology and Risk Factors. Hypertension is the most significant risk factor for small vessel occlusive diseases and is responsible for about 80 to 90 percent of lacunar infarctions. In addition to hypertension, diabetes mellitus and smoking are also significantly associated with small vessel occlusive disease, particularly with branch atheromatous disease. Blacks and Asians, races with a predilection for hypertension, also have a higher frequency of penetrating artery disease and lacunar infarction than whites.

Clinical Features and Associated Disorders. The arteries commonly affected are the lenticulostriate branches of the MCAs, the thalamogeniculate and thalamoperforant branches of the PCAs, and midline and paramedian penetrating branches of the vertebral and basilar arteries (Fig. 45-6). Infarcts do not involve the cerebral cortex but usually affect the subcortical structures such as the basal ganglia, thalamus, internal capsule, subcortical white matter, and brain stem. Clinical findings are characteristically less severe, neurological dysfunctions are restricted within a few systems, and cognitive and behavioral abnormalities

Figure 45-6 Penetrating arteries prone to lipohyalinosis and microaneurysms; the thalamogeniculate and lenticulostriate vessels and arteries to the (Adapted from Jones EF, Kalman JM, Calafiore P, et al: Proximal aortic atheroma. An independent risk factor for cerebral ischemia. *Stroke* 1995;26:218-224; with permission.)

are less common. Lacunar infarcts present diverse clinical syndromes.^[24]

Deep infarcts in some regions such as the caudate nucleus, anterior thalamus, and genu of the internal capsule can produce apathy, inertia, and reduced interest in the environment. Bilateral extensive lacunar infarcts are often associated with white matter damage and clinical dementia. Neurological deficits in patients with lacunar infarction can progress gradually or stepwise for 1 to 7 days.

Differential Diagnosis and Evaluation. The major differential diagnostic considerations are restricted cortical and brain stem infarcts due to large artery occlusive disease or embolism and small ICHs. The diagnosis of penetrating artery disease is based on (1) the presence of risk factors, especially present or past hypertension, and diabetes; (2) clinical neurological symptoms and signs typical for or compatible with occlusion of a single perforating artery; and (3) CT or MRI showing a lacunar cerebral infarct or a brain stem infarct in the territory of a single penetrator, or at least no cortical infarct. In uncertain cases, vascular and cardiac imaging may be needed to clarify the diagnosis of penetrating versus large artery occlusive disease.^[1]

Management. Treatment consists primarily of controlling the underlying causative process--hypertension. Antiplatelet agents have not been shown to be effective in this condition but are frequently prescribed. Heparin and warfarin anticoagulants are probably ineffective. No specific treatment is currently available for CADASIL.

Prognosis and Future Perspectives. Recovery from lacunar infarctions or branch atheromatous diseases is usually better than that from cortical infarctions. However, many patients develop recurrent lacunar infarcts and white matter ischemia. Dementia, pseudobulbar dysarthria and dysphagia, gait abnormalities, and parkinsonian-like stiffness are common features in patients with extensive brain damage caused by penetrating artery disease.

To date, there have been no controlled trials of patients with acute lacunar infarcts, but these are badly needed in the future. Also badly needed are studies of prevention of further brain damage in patients who already have lacunar infarcts and white matter damage.

Brain Embolism

Pathogenesis and Pathophysiology. There are three major types of embolism--cardiogenic, intra-arterial, and paradoxical (Fig. 45-7). Emboli from any source tend to be arrested in a recipient artery, depending on the location of branch points and the size of the embolic material. Once lodged, embolic matter often migrates distally within 48 hours, allowing reperfusion of the previously ischemic zone. This reperfusion frequently causes extravasation of blood through the disintegrated endothelial linings and hemorrhagic conversion of the ischemic lesions, so-called hemorrhagic infarction.

Recent advances in technology have improved the identification of previously unrecognized potential cardiogenic embolic sources and have documented the fact that a higher proportion of ischemic strokes than previously suspected are embolic in origin. Arrhythmias, especially atrial fibrillation and sick sinus syndrome, are important causes of brain embolism. Valvular disease--rheumatic, congenital, calcific, and bacterial and nonbacterial vegetations--is another very important donor source for embolism. Thrombi also form within the heart in patients with myocardial infarcts, myocardopathies, ventricular aneurysms, and other diseases that cause endocardial and myocardial damage.

Atherosclerotic stenosis of the ICA or VA causes intraarterial thromboembolism when the thrombus formed on the ulcerative plaque dislodges and travels up to a distal intracranial cerebral artery. Usually emboli are composed of clot, platelet clumps, or fragments of plaques. Embolism is especially apt to occur just after a clot is formed, before it becomes organized and adheres to the arterial wall. Cholesterol crystals, fat, tumor, and foreign body material, particularly talc and cornstarch injected by drug abusers,

are less frequent intra-arterial embolic materials. Another important source of intra-arterial embolism is atheromatous aortic plaques. Transesophageal echocardiographic studies have shown that protruding, often mobile and pedunculated, atheromas and clots can be found in the thoracic aorta and are a relatively common source of embolism.^[27] Angiography and cardiac surgery with clamping of the aorta promote embolism from aortic lesions.

A less common form of embolism, paradoxical embolism, occurs when the heart serves as a conduit for emboli arising from blood clots in the peripheral veins; these clots pass through septal defects, a patent foramen ovale (PFO), or pulmonary arteriovenous (AV) fistulas to reach the brain and systemic circulation (Fig. 45-8). Because PFOs usually open during exertion, stroke frequently occurs during Valsalva maneuvers, exertion, and sexual intercourse.

Epidemiology and Risk Factors. At least 30 percent of ischemic strokes are caused by cardiogenic embolism. The lesions with the highest risk are probably atrial fibrillation, acute myocardial infarction with mural thrombosis,

Figure 45-7 Examples of potential sources of embolism: (a) cardiac mural thrombus; (b) vegetation on heart valve; (c) emboli from carotid plaque. Also shown: (d) infarcted cortex in area supplied by terminal anterior cerebral artery due to (Adapted from Jones EF, Kalman JM, Calafiore P, et al: Proximal aortic atheroma. ventricular aneurysms, prosthetic heart valves, rheumatic heart disease with atrial enlargement, myocardiopathies, and bacterial and marantic endocarditis. Cardiac surgery now also poses an important risk of embolism from the heart and aorta.

Clinical Features and Associated Disorders. Brain embolism usually presents abruptly with clinical abnormalities. Fluctuations or worsening symptoms and sudden improvements are common during the first 24 to 48 hours, probably because of emboli passing distally. Usually embolic infarcts are large, and deficits are more severe in patients with emboli than with in situ occlusions. Single or infrequent but longer lasting TIAs may precede embolic infarctions. Embolic events often occur during activity or sudden straining, coughing, or sneezing. Infarcts may involve multiple vascular territories and are mixed in age. Early angiographic or TCD studies may show the presence of distal intra-arterial emboli. Hemorrhagic conversion of infarcted areas is commonly noted on CT and MRI scans. Infarcts are often wedge-shaped and involve the cerebral cortical surface.

Intra-arterial sources of cerebral embolism are usually atheromatous plaques at the carotid bifurcation, but occasionally responsible proximal vascular lesions are detected

at the originating sites of the common carotid arteries or vertebral arteries from the subclavian arteries or aorta. Cardiac sources of emboli are listed in [Table 45-2](#).

Differential Diagnosis and Evaluation. Embolic strokes are often difficult to separate from in situ thrombosis engrafted on stenotic lesions and intracerebral hemorrhage. Patients with brain hematomas more often develop signs gradually, whereas embolic strokes often begin instantly and in about 80 percent of patients reach their maximum intensity at or near onset. Decreased consciousness, headache, and vomiting are more common acutely in patients with hematomas than in those with embolic infarction. Still, CT is most often needed to differentiate hematomas from ischemia.

In patients with pre-existing arterial stenotic lesions and superimposed acute thrombosis, preceding TIAs are common and may occur several times over a period of weeks

TABLE 45-2 -- COMMON CARDIAC SOURCES OF EMBOLI

Coronary Artery Diseases

- Myocardial infarcts
- Ventricular aneurysms
- Mural thrombi
- Hypokinetic segments (focal and global)

Cardiomyopathies and Endocardiopathies

- Endocardial fibroclastosis
- Alcoholic cardiomyopathy
- Cocaine cardiomyopathy
- Myocarditis
- Sarcoidosis
- Amyloidosis

Valvular Diseases

- Mitral stenosis, rheumatic
- Aortic stenosis, rheumatic
- Bicuspid aortic valve
- Mitral annulus calcification (MAC)
- Calcific aortic stenosis
- Mitral valve prolapse (MVP)
- Bacterial endocarditis
- Nonbacterial thrombotic (marantic) endocarditis--systemic lupus erythematosus (SLE)
- Prosthetic valves

Arrhythmias

- Atrial fibrillation and flutter
- Sick sinus syndrome

Intracardiac Lesions, Defects, and Shunts

- Myxomas
- Fibroelastomas
- Malignant cardiac tumors
- Metastatic tumors
- Ball-valve thrombi

Cardiac Chamber Abnormalities

- Atrial and ventricular thrombi
- Spontaneous contrast on echocardiography

Septal Abnormalities for Paradoxical Embolism

- Atrial septal defects
- Patent foramen ovale
- Atrial septal aneurysms
- Pulmonary arteriovenous fistulas

Modified from Caplan LR: Stroke. A Clinical Approach, 2nd ed. Boston, Butterworth-Heinemann, 1993.

or months. The region of ischemia is also smaller than it is in patients with embolism, and the signs tend to accumulate over a longer period of time, producing frequent fluctuations and stepwise changes in neurological signs.

Angiography performed in the first 12 hours shows emboli in a high percentage of cases, but after 48 hours most emboli are no longer detectable. The most common recipient arteries are the MCAs and ACAs in the anterior circulation and the VAs, distal basilar artery (BA), and PCAs in the posterior circulation. The clinical signs

and imaging findings are the same as those described in the discussion of these vessels in the section on thrombotic stroke. In patients in whom brain embolism is suspected, the possible embolic sources should be evaluated to prevent further strokes. Evaluation of cardiac and aortic sources usually involves transesophageal echocardiography (TEE) and sometimes cardiac rhythm monitoring.^[27] Noninvasive vascular tests (ultrasound, MRA, CTA) can be used to evaluate arterial sources. TCD monitoring for embolic signals can help identify the presence of embolism and may suggest the source.

Management. Treatment of cerebral embolism consists of two major strategies: acute thrombolytic therapy to lyse the embolus and long-term prophylactic therapy to prevent recurrence of embolic stroke.

Thrombolytic therapy has usually been tried in patients with acute embolic stroke to recanalize the occluded artery, restore cerebral blood flow, reduce ischemia, and limit neurological disability. Recanalization may assist the recovery of reversibly ischemic tissue. Several thrombolytic agents have been tested in uncontrolled trials (urokinase, recombinant tissue plasminogen activator [rt-PA], streptokinase) using either intra-arterial^[28] or intravenous administration.^[29],^[30] So far the efficacy and safety of thrombolytic therapy have not been confirmed, but timely recanalization may benefit patients with acute thromboembolic stroke if it is started early enough. Two recent placebo-controlled studies using intravenous rt-PA have shown that thrombolytic therapy may be effective and relatively safe when it is started within 3 to 6 hours.^[29],^[30] The most feared complication of this therapy is severe intracranial hemorrhage.

After an acute stroke the goal of treatment is to prevent the next embolus, using anticoagulation or removal of embolic sources. Cardiac sources may be corrected surgically. Usually intravenous heparin is used, followed by oral warfarin. Because it has been generally accepted that hemorrhagic complications are common in patients with large infarctions, early anticoagulation should be carefully monitored in such patients.^[31]

If a tightly stenotic carotid artery is present, either surgery (if feasible) or longer-term warfarin is indicated. When stenosis is not as severe, antiplatelet agents such as aspirin or ticlopidine may be used. Warfarin is effective in preventing embolism in patients with nonrheumatic atrial fibrillation.^[32] Warfarin also decreases the incidence of embolism in patients with rheumatic mitral stenosis and in those with mechanical heart valves.^[33] When warfarin anticoagulation is used, it is advisable to keep the international normalized ratios at around 3.^[32],^[33] In older patients, long-term anticoagulation poses important risks and problems. Aspirin may be useful for prophylaxis in some patients with cardiac

lesions of low embolic potential and in patients with absolute or relative contraindications to warfarin use.

Carotid artery stenosis is a very common source of intra-arterial embolism. Carotid endarterectomy has been used as a method of stroke prophylaxis, but there has been controversy about its safety and efficacy.^[34] Recent studies suggest that symptomatic carotid stenosis of 70 percent or more^[35] and asymptomatic carotid stenosis of 60 percent or more may be indications for carotid endarterectomy.^[36]

Prognosis and Future Perspectives. Prognosis depends on the nature of the potential embolic sources and the effectiveness of prophylaxis. The advent of monitoring for emboli with TCD technology has opened new diagnostic possibilities. Further advances in this technology with the use of multiple concurrent channels (such as EEG) will allow better recognition of the source and of the nature and frequency of release of embolic material.

Systemic Hypotension (Border Zone Infarction)

Pathogenesis and Pathophysiology. Inadequate pumping of the heart results in a lack of blood flow to the brain. This occurs when there is too little blood in the system (shock, hypovolemia), when the pump itself fails (myocardial failure or severe arrhythmia), or when systemic hypotension is present. Collateral blood flow is affected first by a generalized lowering of blood pressure.^[37] In contrast to thromboembolic stroke, hypoperfusion is global and causes so-called border zone or watershed infarcts in the areas between the major regions of vascular supply (see Fig. 45-1 (Figure Not Available)). Infarcts are usually bilateral but may also occur unilaterally when there is severe stenosis of the ipsilateral proximal carotid or other large arteries.^[38] The most common area of border zone ischemia is in the temporoparietal region between the MCA and PCA supply regions.

Epidemiology and Risk Factors. Causes of stroke due to cerebral hypoperfusion include orthostatic hypotension (due to diabetic dysautonomia or antihypertensive therapy), orthostatic brain ischemia (without hypotension), perioperative complications (especially cardiac surgery), myocardial ischemia, cardiac arrhythmias, severe carotid stenosis or occlusion, or combinations of these.

Clinical Features and Associated Features. Faintness, pallor, dim vision, dim hearing and lightheadedness, dizziness, and lack of thought clarity are commonly noticed. The patient is worse when sitting or standing, and the blood pressure is low. Profuse sweating is common. Temporoparietal border zone ischemia most often causes visual abnormalities. Balint's syndrome is common and consists of asimultagnosia (difficulty in seeing multiple objects at one time), optic ataxia (abnormal hand-eye coordination in one or both visual hemifields), and apraxia of gaze (difficulty in directing the eyes where willed)^[2]. Ischemia in the anterior border zone between the anterior and middle cerebral arteries affects mostly the convexal surface of the precentral and postcentral gyri and causes arm and thigh weakness, usually with sparing of the face, feet, and often the hands. Occasionally patients have ischemia in the cerebellar border zones between the posteroinferior, anterior, and superior cerebellar arteries and have some gait and limb ataxia.^[2]

Differential Diagnosis and Evaluation. Frequently watershed infarction is diagnosed on the basis of one or more of the following: documented hypotension, a history of syncope or near-syncope preceding the event, and characteristic patterns of infarction on CT or MRI.

Orthostatic hypotension is defined as a persistent decline of greater than 20 mm Hg in systolic pressure from the supine to the standing position.^[39] Hypotension due to other causes is defined as systolic blood pressure of 90 mm Hg or less or at least a 25 percent drop from pre-existing levels. Symptoms of syncope, near-syncope, or cardiac arrhythmia should be sought. Laboratory tests include (1) systemic blood tests including CBC, blood urea nitrogen, and electrolytes; (2) cardiac studies--ECG, echocardiography, and Holter monitoring; and (3) neuroimaging--CT, MRI, and SPECT.

Management. Correction of underlying disorders is essential. Care should be taken when performing interventional procedures such as carotid endarterectomy or cardiac surgery. Excessive use of antihypertensive drugs should be avoided. Recurrences are common and, if not treated early, the outlook is poor. The mortality rate is around 10 percent, and there is a high incidence of myocardial infarction.

Selected Nonatherosclerotic Occlusive Diseases

NONINFLAMMATORY VASCULAR DISEASES

Fibromuscular dysplasia (FMD) is a rare condition that affects any or all of the three layers in the arterial walls of both extracranial and intracranial arteries, particularly those of the bilateral ICAs. FMD causes fibrous dysplastic tissue and proliferating smooth muscle cells in the media, presenting as constricting bands and a string-of-beads appearance on arteriography.^[1],^[40]

FMD is commonly found in middle-aged women and is most often asymptomatic. Because of its frequent association with cerebral aneurysms, FMD is often found during the evaluation of SAH.^[41] FMD also causes arterial dissections, producing ischemic stroke syndromes, but it may present as a TIA or stroke without any evident compromise of the vascular lumen, possibly due to functional constriction. The stroke recurrence rate is quite low, even with no therapy. If the patient is hypertensive, the renal arteries should be studied.

Moyamoya disease is defined as progressive occlusion of the intracranial ICAs at their intracranial bifurcations and formation of collateral channels through the basal penetrating branches of the cerebral arteries. Pathologically, this condition is characterized by endothelial hyperplasia and fibrosis with intimal thickening and abnormalities of the internal elastic laminae and arterial walls of the perforating arteries, probably due to greatly increased flow through these small vessels. Inflammatory changes are absent. Moyamoya vessels are also found in patients with sickle cell disease, neurofibromatosis, and FMD, and in young

women (especially those who smoke cigarettes and take oral contraceptives).^[1]

Although the disease was first described in young Asians, it has subsequently been found to be widespread and is not limited to Asians. Clinically, children under 15 years of age usually present with transient episodes of hemiparesis, headache, seizures, or other focal neurological deficits, often precipitated by physical exercise or hyperventilation. In contrast, adults usually present with brain hemorrhages--usually in the thalamus, basal ganglia, or deep white matter. Occasionally the hemorrhages are SAH.^[42]

Cerebral angiography, the standard method of diagnosis, shows progressive abnormalities in the intracranial ICAs bilaterally.^[42] MCA and ACA branches are also frequently involved. Collateral vessels appear as a cloud of smoke. Recently, MRA has been used as a noninvasive alternative to conventional angiography in typical moyamoya disease.^[43]

Some patients with moyamoya disease stabilize clinically, often after they have developed disabilities. The best treatment is not known. A variety of surgical revascularization procedures called encephaloduro-arteriosynangiosis (EDAS) have been used, but whether they improve the outcome is now uncertain.

CEREBROVASCULAR DISEASES ESPECIALLY RELATED TO PREGNANCY

Oral contraceptive pills can be associated with stroke. Although the incidence of ischemic stroke is not much increased during pregnancy and the early puerperium, pregnancy does increase the risk of cerebral hemorrhage. The incidence rates for ischemic stroke associated with pregnancy vary from 5 to 210 per 100,000 deliveries. Ischemic strokes seem to be most common in the puerperal period and third trimester, with few cases occurring in the first trimester. Hypertension contributes independently to the risk of pregnancy-related stroke, especially in older women with chronic hypertension.^[44] Eclampsia is the main cause of both ischemic and hemorrhagic stroke. Eclampsia accounts for about half of ischemic strokes, and eclampsia-related ICH carries a poor prognosis.^[45] Stroke was responsible for 4.3 percent of maternal deaths in one major American study.^[46] Up to one third of pregnancy-related brain infarcts may be due to intracranial venous thrombosis. This condition is more frequent in the early postpartum period and in the third trimester. Dehydration, infection, and sepsis may contribute to venous thrombosis.^[2]

Patients with eclampsia present with focal neurological deficits of sudden onset in addition to headaches, seizures, or altered consciousness. These symptoms and signs usually resolve in several days. The precise pathogenesis of these short-lasting focal deficits associated with eclampsia is still poorly understood. Premature atheroma is causative in a quarter of strokes in pregnancy, but there are many other uncommon causes of ischemic stroke during pregnancy: amniotic embolism, choriocarcinoma, reversible postpartum cerebral angiopathy, arterial dissection, postpartum cardiomyopathy, paradoxical embolism, border zone infarction, use of ergot, pregnancy-related cardiac diseases, hematological disorders, antiphospholipid antibody syndrome, and homocystinuria. MRI and CT can confirm the location and nature of the brain lesions. For vascular imaging, MRA or ultrasound techniques are recommended. Prognosis is worse than in nonpregnant women or men of the same age.^[46]

Cerebral venous sinus thrombi are rich in red blood cells and fibrin but poor in platelets ("red thrombus") and are then replaced by fibrous tissue with time. Occlusion of a dural sinus often results in severe brain edema, venous infarction in the cortex, and adjacent white matter, while deep cerebral vein thrombosis causes venous infarcts in the basal ganglia, thalamus, or both.^[2], ^[47] The venous hypertension caused by blockage of blood draining from the skull can also lead to brain hemorrhages. Brain edema, ischemia, and hemorrhages result from extensive thromboses. The sagittal sinus is involved most often, followed by the lateral sinuses and the cavernous sinus.

Cerebral venous thrombosis (CVT) is an uncommon condition. Basic mechanisms of CVT include venous stasis, increased clotting tendency, and traumatic or infective changes in the venous walls. Various endocrine, hematological, immunological, vasculitic, infective, and neoplastic diseases may be associated with CVT.^[47] In neonates and children, regional infections (otitis media and mastoiditis), neonatal asphyxia, severe dehydrations, and congenital heart diseases are common associated diseases. In young women, pregnancy, puerperium, oral contraceptive pills, and various connective tissue diseases like systemic lupus erythematosus are the major causes. Other causes include malignancies, antithrombin III protein C and protein S deficiencies, and Behçet's disease.^[2], ^[47]

CVT has a variable mode of onset and usually has a favorable outcome. The most common symptom is headache. Head pain can be severe and persistent and is often due to increased intracranial pressure. Vomiting also results from increased pressure. Seizures and focal neurological symptoms and signs result from brain ischemia, edema, or hemorrhage. Clinical patterns include (1) isolated intracranial hypertension mimicking pseudotumor cerebri and presenting with headache, papilledema, and sixth nerve palsy; (2) focal neurological signs simulating arterial strokes or seizure attacks; and (3) a cavernous sinus syndrome. These syndromes usually resolve spontaneously. The dural venous sinuses may become recanalized after antithrombotic therapy. Poor prognostic factors include rapid evolution of thrombosis, coma, infancy or old age, involvement of deep veins and cerebellar veins, and septic thrombi.

Differential diagnoses include benign intracranial hypertension ("pseudotumor cerebri"), migraine, meningitis, encephalitis, cerebral infarction (arterial), ICH, brain abscess, brain tumor, and eclampsia. Diagnosis is based on clinical data, CT or MRI, and conventional and MRI venographic findings. Venous infarcts appear as unilateral or bilateral or single or multifocal on CT or MRI. Hemorrhagic infarction and small hematoma are commonly found because of the increased pressure in draining veins.

Management of patients with CVT includes reducing ICP and administering anticoagulant therapy, thrombolytic therapy, and antibiotics in case of an infected thrombus. Intravenous heparin followed by warfarin is indicated. Steroids and osmotic diuretics are used in patients with brain edema or increased intracranial pressure. Anticonvulsants are given for seizures due to venous infarcts. Review of the published experience of patients with dural sinus thrombosis

..

shows a clear and definite improvement in outcome in patients treated with anticoagulants.^[2], ^[48] Even in patients who had hemorrhagic infarction of hematomas before treatment, anticoagulation led to fewer new hemorrhages and better outcomes than occurred in patients not given anticoagulant treatment. Thrombolytic treatment given by inserting a catheter into or adjacent to the occluded sinus has also been successful, but often high doses are needed for a prolonged period of time.^[2]

If left untreated, CVT is potentially life-threatening. Recent reports attributed better outcomes to greater awareness of CVT, noninvasive imaging techniques, and a relative decline of infective etiologies. Among survivors only a minority develop a permanent deficit such as focal limb weakness, epilepsy, or optic atrophy.

Arterial dissection, especially spontaneous dissection of the cervicocranial arteries, is an important cause of ischemic strokes, especially in young people. The pharyngeal portion of the extracranial ICA and the first and third segments of the VA are more mobile and thus more vulnerable to trauma and mechanical stress.^[1], ^[2], ^[49], ^[50] Congenital changes in the media or elastic layer of the arteries and edema of the arterial wall also promote dissection.

A tear within the arterial wall leads to bleeding, which dissects along the longitudinal course of the artery. The dissection can also produce an intimal tear, allowing the blood clot within the media to reenter the lumen. The expanded arterial wall encroaches on the lumen. Clot formed in the lumen is usually loosely adherent to the intima and can readily embolize distally and cause brain infarction. The intraluminal clot is absorbed within several weeks, and the lumen usually returns to its normal size. Aneurysmal pouches may remain as a mark of the healed lesion. When dissections extend between the media and the adventitia, both aneurysms and tears through the adventitia may lead to SAH or aneurysmal masses, presenting as space-occupying lesions that compress adjacent cranial nerves or brain parenchyma.

Dissections usually occur in young people, although they can develop at any age. Individuals with inherited disorders of connective tissue such as Marfan's disease, Ehlers-Danlos syndrome, and pseudoxanthoma elasticum are susceptible. Migraine and fibromuscular dysplasia also make the vascular walls more susceptible to tearing. Chiropractic manipulation of the neck and sports and other activities that involve sudden neck stretching or, alternatively, prolonged holding of the neck in an eccentric position promote dissections.

Carotid dissection usually causes ipsilateral throbbing headache; local sharp pain in the neck, jaw, pharynx, or face; or an ipsilateral Horner's syndrome. TIAs are common and are probably due to luminal compromise with distal hypoperfusion, but most patients with severe strokes have evidence of embolization of blood clot to the MCA from thrombus at the site of dissection. In carotid dissections, strokes usually occur within the first few days after the ICA dissection.^[51] At times, both carotid arteries and even the VAs are dissected at the same time. Recurrent dissection is rare.

Pain in the neck and head are important symptoms in patients with dissections that help to separate this entity from other causes of brain ischemia. Subarachnoid hemorrhage also is a consideration in some patients.

CT and MRI can directly visualize the intramural bleeding and expansion, confirming the diagnosis. Conventional angiography, MRA, and ultrasound testing are reliable noninvasive diagnostic and monitoring tools for the detection of arterial dissections. ^[2], ^[52], ^[53] MRA is a reliable noninvasive method for use in diagnosis and follow-up of extracranial ICA dissections, but conventional angiography is more useful for VA dissections. Angiography may show regions of severe narrowing ("string sign"), or the ICA may be totally occluded, beginning more than 2 cm distal to the ICA origin, sparing the siphon, and having a gradually tapering segment. Localized aneurysmal sacs or outpouchings may be seen. B-mode ultrasound testing can show tapering of the ICA lumen, an irregular membrane crossing the lumen, and true and false lumens. Duplex scans of the VAs in the neck can show increased arterial diameter, decreased pulsatility, intravascular abnormal echoes, and hemodynamic evidence of decreased flow. TCD demonstrates the effect of the neck pathology on the poststenotic intracranial circulation, including collateral blood flow. TCD may show diminished intracranial velocities in the ICA siphon and the MCAs or the ICVAs. When this occurs in young patients without risk factors for atherosclerosis or embolism who have normal ICA bifurcations in the neck, the diagnosis of dissection is quite likely.

Most extracranial dissections heal spontaneously with time. Their location high in the neck usually makes surgical repair difficult or impossible. When complete occlusion has occurred, the arteries often do not recanalize, and they remain occluded. Arteries that retain some residual lumen invariably heal and become normal. Intracranial dissections can be repaired surgically in those patients with SAH. Although there have been no controlled trials of medical therapy, prevention of embolization of clot at or shortly after the dissection should prevent stroke. Anticoagulants do not seem to increase the extent of the dissection. Because the risk of embolization exists only during the acute period, intravenous administration of heparin followed by warfarin may be effective and is continued until the lumen is not severely compromised.

Most patients with dissections who will develop strokes do so shortly after the onset of symptoms. Late strokes are unusual. Recurrence is also rare, occurring in only about 7 percent of patients with dissection. Most research on vascular disease has concerned intimal and endothelial abnormalities such as atherosclerosis, and the media of vessels has been given very scanty attention. Subtle abnormalities of connective tissue including smooth muscle, elastic tissue, and collagen may predispose to dissection. Further research on vascular connective tissue and muscle will help in gaining a better understanding of arterial dissections and fibromuscular dysplasia, two conditions that sometimes coexist.

INFLAMMATORY VASCULAR DISORDERS

This subject is discussed in depth in [Chapter 50](#). [Table 45-3](#) outlines some of the important vasculitides and their key features. ^[54]

TABLE 45-3 -- SOME IMPORTANT VASCULITIDES

Condition	Demography	Pathology Vessel Type	Clinical Environment	Other Features
Polyarteritis nodosa	1:2.5 f/m ratio; 30 to 50 years old	Necrotizing, small-medium muscular arteries	Strokes; kidney, peripheral nerves	Fever, hypertension, circulating immune
Churg-Strauss syndrome	1:1.4 f/m ratio; 10 to 50 years old	Fibrinoid necrosis with eosinophils; small-medium arteries, veins, capillaries	Asthma; skin, kidney, encephalopathy, peripheral nerves	Eosinophilia, fever, rheumatoid factor
Hypersensitivity vasculitis	Any age and sex	Leukocytoclastic vasculitis, postcapillary venules	Peripheral nerves and plexus, encephalopathy, palpable purpura	Drug-induced cryoglobulins, circulating immune complexes
Wegener's granulomatosis	1:1.2 f/m ratio; any age	Granulomas in organs, necrotizing arteritis	Sinuses, respiratory tract, kidneys, cranial and peripheral nerves	cANCA-positive; upper and lower respiratory tract involvement
Sarcoidosis	20 to 30 years old; no sex predilection, blacks > whites	Perivenous, granulomas	Peripheral nerves, muscle, eyes, lungs, skin, lymph nodes, brain granulomas	Granulomas in skin, muscle, liver, nodes
Temporal arteritis	1:2 to 1:3 f/m ratio; >50 years	Segmental granulomatous, external carotid, and aortic branches	Eyes, peripheral nerves, occasional strokes	High ESR, jaw claudication, scalp tender
Isolated CNS angiitis	1:2 f/m ratio any age	Mononuclear perivascular cell, granulomas	Brain only, seizures, confusion	High CSF protein, no systemic symptoms
Takayasu's arteritis	9:1 f/m ratio; Asians; age range 15-40 yr	Acute inflammatory giant cell; large arteries of aortic arch	Syncope, light-headedness, headache, absent arm pulses (strokes rare)	Systemic symptoms, hypertension
Behcets disease	1:9 f/m ratio; Japan and Mediterranean heritage	Perivascular cell loss and demyelination, perivascular plasma cells and lymphocytes	Aphthous oral ulcers, genital ulcers, eye inflammation, meningitis, brain stem lesions	Strokes and meningoencephalitis with focal brain stem lesions
Cogan's disease	Young adults	Arteritis of small and medium-sized arteries	Interstitial keratitis of eye, uveitis, ear involvement	Vertigo, tinnitus, decreased hearing, cornea opacification
Eales' disease	Mostly young men, aged 20 to 30 years old; middle East and Indian heritage	Inflammation of retinal arteries and veins	Retinal and vitreous hemorrhages, meningitis, occasional brain and spinal cord infarcts	Characteristic sheathing of retinal arteries and veins and vitreous hemorrhages
Microangiopathy of the brain, retina, ear	Almost always women, 15 to 30 years old	Obliterative, noninflammatory arteries and arterioles	Retina, ear, brain	High CSF protein
Kohlmeier-Degos syndrome	Young adults 15 to 30 years old	Fibrous vascular proliferation, rare inflammation	Small yellow-raised skin lesions, GI tract, brain infarcts	Skin, GI, and brain infarcts
Sneddon's disease	Females > males; age 30 to 50	Proliferative thrombo-occlusive disease of skin and brain and small arteries and arterioles	Livedo reticularis of skin and brain infarcts	Antiphospholipid antibodies common

cANCA, Classic antineutrophil cytoplasmic antibody; CSF, cerebrospinal fluid; ESR, erythrocyte sedimentation rate; f/m, female-to-male; GI, gastrointestinal.

DRUG-RELATED VASCULOPATHIES

Illicit drug use and abuse has unfortunately become an important cause of stroke, especially in young individuals. This topic is discussed in [Chapter 39](#). [Table 45-4](#) outlines the common drugs implicated and some features of the strokes that they cause.

MIGRAINE-RELATED STROKE

Stroke is a rare but potentially devastating complication of migraine. ^[2], ^[55], ^[56], ^[57] Infarction is thought to be due to prolonged intense vasospasm associated with migraines. Intense vasospasm can impede flow, promoting thrombosis. Platelets are activated during migraine and the vasoconstrictive process itself may stimulate the endothelium to release factors that promote thrombosis. Severe vasoconstriction and thrombi have been demonstrated in patients with migraine who have PCA

and basilar artery territory infarcts. ^[2], ^[57]

To complicate matters, atherosclerotic lesions in the coronary arteries of humans--and in the extracranial and retinal arteries of experimental animals--seem to predispose them to superimposed vasoconstriction. Thus, vasoconstriction can complicate atherostenosis. TCD shows promise of identifying vasoconstriction by showing high velocities that change with time and with various pharmacological treatments.

Hemorrhage can occasionally complicate a severe migraine attack. Intense vasoconstriction leads to ischemia of a local brain region, accompanied by edema and ischemia of the small vessels perfused by the constricted artery. Then, when vasoconstriction abates, blood flow to the region is augmented, and the reperfusion can cause hemorrhage from the damaged arteries and arterioles. ^[58] The mechanism is the same as that found in hemorrhage after carotid endarterectomy and in reperfusion after brain embolization.

TABLE 45-4 -- DRUG ABUSE AND STROKES

Drug	Route	Ischemia	Hemorrhage	Other Features
Heroin	IV	Strokes--brain and spinal cord	No	Increased gamma globulins
Amphetamines	Oral, IV	No ischemic strokes	SAH, ICH; aneurysms and AVMs rare	Hypertension
Cocaine HCl	Nasal, IV	Ischemic strokes	SAH and ICH; aneurysms and AVMs common	Hypertension
Crack cocaine	Nasal, IV	Ischemic strokes very common	SAH and ICH; aneurysms and AVMs common	Hypertension
Mashed pills	IV	Ischemic strokes	No	Tale particles in eyes and lungs

SAH, Subarachnoid hemorrhage; ICH, intracerebral hemorrhage; AVM, arteriovenous malformation.

Prophylactic agents (most often calcium channel blockers, cyproheptadine, or methysergide) should be maintained as well as agents that modify platelet function and coagulation. Aspirin may be prescribed, but warfarin can be used in patients with prior infarcts.

Coagulation Disorders

Brain ischemia and hemorrhage often result from hematological disorders.

Changes in the formed cellular constituents of the blood may be quantitative or qualitative. Polycythemia increases blood viscosity, decreases cerebral blood flow, and increases the risk of thrombosis. Sick-cell disease and sickle-cell hemoglobin-C disease are examples of qualitative red blood cell abnormalities that affect blood flow. Sickle-cell disease causes occlusive changes in large intracranial arteries and small penetrating vessels. Subcortical, cortical, and borderzone infarcts are often found on CT and MRI.

Increased platelet counts, especially those over 1 million, are associated with hypercoagulability. Thrombocytosis can be primary (so-called essential thrombocythemia), can be associated with other myeloproliferation, or less often, can be secondary to systemic disease. Essential thrombocythemia is associated with strokes and digital arterial occlusions. There are also qualitative abnormalities of platelet function. In some patients, increased coagulability has been attributed to increased adhesion and aggregation of platelets (so-called sticky platelets) in the absence of thrombocytosis.

Leukemia is complicated occasionally by brain hemorrhages and microinfarcts. When the white blood cell count is very high (increased leukocrit), the white blood cells can pack capillaries, leading to microinfarcts and vascular rupture with small hemorrhages in the brain. Larger intraparenchymatous hemorrhages and SAHs are most often related to thrombocytopenia, due to replacement of the bone marrow with leukocyte precursors.

Abnormalities of the coagulation cascade can also cause hypercoagulability and lead to venous and arterial occlusions and brain infarction. ^[59] Table 45-5 lists some of the most common abnormalities.

Immunological Abnormalities

Circulating antibodies, like lupus anticoagulant (LA) and anticardiolipin antibodies, may be related to stroke. The LA is a phospholipid antibody that interferes with the formation of the prothrombin activator. In the laboratory, there is a prolonged activated partial thromboplastin time (PTT). Some patients with LA have SLE, but most do not. When antiphospholipids of the IgG, IgM, or IgA classes are found in the absence of a known systemic illness, and patients present with an increased incidence of spontaneous abortions, thrombophlebitis, pulmonary embolism, and large- and small-artery occlusions, the disorder is now referred to as primary antiphospholipid lupus anticoagulant (APLA) syndrome. The APLA-associated stroke syndrome is characterized by its younger age at onset, predominance in women, and high risk of recurrent thrombo-occlusive events. Some patients have mitral and aortic valve vegetations and ocular ischemia. In addition to the presence of LA or anticardiolipins, or both, laboratory abnormalities include false-positive Venereal Disease Research Laboratory (VDRL), thrombocytopenia, antinuclear antibodies, and prolonged activated PTT. The risk of recurrent thrombosis in patients with the antiphospholipid-antibody syndrome is high. More than one-half of the patients have at least one recurrent thrombo-occlusive stroke, most occurring within the first year. ^[60] Long-term anticoagulation therapy is recommended, maintaining the international normalized ratio at or above 3. ^[61]

Disseminated intravascular coagulation occurs when a primary disorder leads to local or diffuse clotting and the coagulation cascade is activated, with generation of excess intravascular thrombin. The coagulation system then is activated further, fibrin is deposited into the microcirculation, hemostatic elements have a shortened survival, and the fibrinolytic system is activated. The most common disorders inciting disseminated intravascular coagulation

TABLE 45-5 -- SOME COMMON COAGULATION DISORDERS CAUSING HYPERCOAGULABILITY

1. Deficiencies of natural coagulation inhibitors
Antithrombin III
Protein C
Protein S
2. Resistance to activated protein C
3. Increased levels of serine protein coagulation factors (can occur in patients with inflammatory diseases), factors V, VII, and VIII
4. Cancer, especially mucinous adenocarcinomas
5. Abnormalities of the normal fibrinolytic system
Tissue plasminogen activator (t-PA)
Plasminogen activator inhibitor (PAI)
6. Dysfibrinogenemias including increased levels of fibrinogen

are infections, obstetric and vascular emergencies, cancer, nonbacterial thrombotic endocarditis, head trauma, SAH, brain tumors, and vascular malformations. The laboratory findings usually include thrombocytopenia, reduced fibrinogen levels, prolongation of prothrombin time (PT) and PTT, and increased levels of fibrin split products. Neurological findings are frequent and include an encephalopathy with multifocal signs and frank thrombotic and embolic infarcts. Bleeding can also

occur.^[62], ^[63]

Whole blood viscosity is one of the major determinants of cerebral blood flow, especially in the microcirculation. Whole blood viscosity is very dependent on the hematocrit and fibrinogen levels, and these are often elevated in patients with stroke.^[64] Hyperviscosity also is probably pathogenetically related to Binswanger's disease (subcortical arteriosclerotic encephalopathy).^[65] Less often, viscosity is increased by high levels of globulins as in Waldenstrom's macroglobulinemia or in other disorders with abnormal proteins or cryoglobulins, such as multiple myeloma, or by very high levels of serum lipids, especially chylomicron.

Thrombotic thrombocytopenic purpura is characterized clinically by fever, renal failure, thrombocytopenia, and microangiopathic hemolytic anemia. Transient focal neurological signs and a more diffuse encephalopathy are common, but occasionally, persistent neurological deficits due to occlusion of medium-sized arteries or brain hemorrhages occur.^[66] Plasma exchange can be an effective treatment.

HEMORRHAGIC CEREBROVASCULAR DISEASE

Primary Intracerebral Hemorrhage

Pathogenesis and Pathophysiology. Chronic hypertension causes fibrinoid necrosis in the penetrating and subcortical arteries, weakening of the arterial walls, and formation of small aneurysmal outpouchings, so-called Charcot-Bouchard microaneurysms, that predispose the patient to spontaneous ICH. Bleeding usually arises from the deep penetrating arteries of the circle of Willis, including the lenticulostriate, thalamogeniculate, and thalamoperforating arteries and perforators of the basilar artery. Acute rises in blood pressure and blood flow can also precipitate ICH even in the absence of preexisting severe hypertension. A ruptured vascular malformation is the second most common cause of ICH.

Bleeding is limited by the resistance of tissue pressure in the surrounding brain structures. If a hematoma is large, distortion of structures and increased intracranial pressure (ICP) cause headache, vomiting, and decreased alertness. Because the cranial cavity is a closed system, enlargement of hematoma or development of severe edema may shift brain tissues into another compartment, so-called herniation, and cause deterioration in the clinical condition.

Epidemiology and Risk Factors. ICH is a major cause of morbidity and death and accounts for 10 to 15 percent of all strokes in whites and about 30 percent in blacks and individuals of Asian origin. Pregnancy may increase the risk of ICH. Eclampsia accounts for more than 40 percent of ICHs in pregnancy and is a common cause of death from eclampsia. Locations of hypertensive ICHs are putamen (40 percent), lobar (22 percent), thalamus (15 percent), pons (8 percent), cerebellum (8 percent), and caudate (7 percent) ([Fig. 45-9](#)).

Spontaneous ICH can also occur in association with bleeding diatheses, especially the prescription of anticoagulants, primary or metastatic brain tumors or granulomas, and use of sympathicomimetic drugs. Aneurysms rarely bleed only into the brain, causing a local hematoma near the brain surface.

Clinical Features and Associated Disorders. Hematomas are often classified as putaminal, thalamic, caudate, lobar, pontine, or cerebellar, and each has its specific neurological features in addition to the symptoms and signs of sudden increased ICP. ^[67] Even hematomas arising in the same anatomical location may present different clinical features and prognosis because they differ in size, intraregional location, direction of intraparenchymal extensions, and presence of ventricular hemorrhage. ^[67]

The earliest signs relate to blood issuing into parenchymatous structures. For example, a hematoma in the left putamen and internal capsule would first cause weakness of the right limbs while a cerebellar hematoma would cause

Figure 45-9 Horizontal cerebral section(top) and sagittal brain stem section(bottom), showing commonest sites of intracerebral hemorrhage(Adapted from Jones EF, Kalman JM, Calafiore P, et al: Proximal aortic atheroma. An independent risk factor for cerebral ischemia. Stroke 1995;26:218-224; with permission.)

gait ataxia. As the hematomas enlarge the focal symptoms increase. If the hematoma becomes large enough to raise intracranial pressure, then headache, vomiting, and decreased alertness develop. Some hematomas remain small and the only symptoms relate to the focal collection of blood. ^[67] [Table 45-6](#) notes the most important features of hematomas at the most common sites. This material is discussed in detail elsewhere ^[67] and in another section of this book.

Differential Diagnosis and Evaluation. Diagnostic considerations include infarcts in similar regions and subdural and epidural hematomas. Rarely, brain tumors and abscesses can have a rapid onset mimicking ICH.

It is very important to identify the cause of the hemorrhage. Hypertension, bleeding diatheses (especially as a result of iatrogenic prescription of coumadin), trauma, and amyloid angiopathy are the most frequent causes. In young normotensive patients, especially those with lobar and intraventricular hemorrhages, vascular malformations are the most likely source of bleeding. Aneurysms can also rarely bleed directly into brain parenchyma. Some primary and metastatic brain tumors, especially renal carcinoma and choriocarcinoma, have a propensity to develop hemorrhages within the tumor, thus causing an abrupt onset or worsening of neurological symptoms. ^[67]

During the initial evaluation, blood samples for basic laboratory studies including CBC, chemistries, coagulation studies (prothrombin time, PTT, bleeding time, and platelet count), arterial blood gas analysis, toxicology screen, and arterial blood gases are obtained.

The CT scan is an essential tool for diagnosis, management, and follow-up of ICH. It accurately documents the size and location of the hematoma, the presence and extent of any mass effect, and the presence of hydrocephalus and intraventricular hemorrhage. CT scans should be performed immediately in patients suspected of having an ICH. Follow-up CT scans are requested when there is a change in clinical signs or state of alertness in order to monitor changes in the size of the lesion and ventricular system and to detect important pressure shifts. If the clinical syndrome and CT findings are typical of hypertensive

TABLE 45-6 -- SIGNS IN PATIENTS WITH INTRACEREBRAL HEMORRHAGES AT VARIOUS SITES

Location	Motor/Sensory	Eye Movements	Pupils	Other Signs
Putamen or internal capsule	Contralateral hemiparesis and hemisensory loss	Ipsilateral conjugate deviation	Normal	Left: aphasia Right: left-sided neglect
Thalamus	Contralateral hemisensory loss	Down and in upgaze palsy	Small, react poorly	Somnolence, decreased alertness; left: aphasia
Lobar				
Frontal	Contralateral limb weakness	Ipsilateral conjugate gaze	Normal	Abulia
Temporal	None	None		Hemianopia Left: aphasia
Occipital	None	None		Hemianopia
Parietal	Slight contralateral hemiparesis and hemisensory loss			Hemianopia; left: aphasia; right: left neglect; poor drawing and copying
Caudate	None or slight contralateral hemiparesis	None	Normal	Abulia, agitation, poor memory
Pons	Quadriparesis	Bilateral horizontal gaze paresis,	Small; reactive ocular bobbing	Coma
Cerebellar	Gait ataxia, ipsilateral limb hypotonia	Ipsilateral gaze or sixth nerve paresis	Small	Vomiting, inability to walk, tilt when sitting

hemorrhage in the basal ganglia, caudate nucleus, thalamus, pons, or cerebellum, angiography is usually not necessary. If the hemorrhage is in an atypical location or the patient is young and not hypertensive, angiography is indicated to exclude an AVM, aneurysm, vasculitis, or tumor. Patients who have ICH after cocaine use have a high likelihood of vascular malformations and aneurysms and need angiography.

Management. Prompt and careful management of patients with ICH may be life saving and is important even in those who will later undergo surgical intervention. Adequate airway and respiratory support should be established. Blood gases should be measured in patients with reduced alertness. Endotracheal intubation is performed for patients presenting in coma, for those who are unable to protect their airway, and for those who have respiratory failure. Wide swings in blood pressure, especially hypertension, are common in the initial period following hemorrhage. Intravenous labetalol or sodium nitroprusside with concomitant intra-arterial pressure

monitoring is an effective method of controlling such elevations. Continuous cardiac monitoring for arrhythmias is important. Hypotension, however, from cardiac or other etiologies can be devastating due to the impact on cerebral perfusion pressure. Control of local tissue pressure and intracranial pressure (ICP) is also important to guarantee adequate cerebral perfusion pressure. The available medical and surgical treatment modalities are outlined in [Table 45-7](#). They are not competitive, but a combined approach utilizing both medical and surgical modalities will often yield satisfactory results. ^[67], ^[68]

Emergency surgical treatments have been tried for several decades. Early studies showed that there was no value in surgical removal of hematomas over standard medical management. More recent studies of hematoma removal have shown promise for open surgical decompression, but only if it is accomplished early after the onset of symptoms. The best candidates for surgery may be patients with moderate to large hematomas who are still awake. Recent advances in neuroimaging techniques have made it possible to drain hematomas percutaneously, using stereotactic surgery.

TABLE 45-7 -- TREATMENT OF INTRACEREBRAL HEMORRHAGE

Medical

- Medical decompression for increased intracranial pressure
- Intubation and mechanical hyperventilation
- Dexamethasone (Decadron), 4 mg every 6 hours
- Mannitol, 0.5 to 1 g/kg every 4 hours intravenously (IV)
- Glycerol, 1 to 1.5 ounces orally every 6 hours
- Furosemide (Lasix), 40 mg (4 mg/min) IV*
- Control of hypertension
- Labetalol, 10 mg IV, followed by 10-mg doses as needed
- Trimethaphan camsylate (Arfonad), 0.5 to 1 mg/min IV by drip
- Nitroprusside sodium, 15 to 200 mug/min
- Hydralazine hydrochloride (Apresoline), 50 to 100 mg twice daily orally
- Reversal of bleeding diathesis
- Fresh frozen plasma
- Antihemophilic factor
- Phytonadione (vitamin K, AquaMEPHYTON) 20 to 40 mg IV
- Platelet transfusion
- Fresh blood transfusion

Surgical

- Drainage of hematoma--stereotactic drainage or surgical evacuation
- Ventricular drainage or shunt
- Removal of bleeding arteriovenous malformation or tumor
- Repair of aneurysm

*FDA approved for this indication.

Modified from Chung C-S, Caplan LR: Parenchymatous brain hemorrhage. *In* Rakel RE (ed): *Conn's Current Therapy Philadelphia*, WB Saunders. 1995, p 794.

A burr hole is made, and the drainage instrument is guided stereotactically, using CT, to the core of the hematoma, which is then evacuated. Fibrinolytic agents also can be instilled to soften and lyse coagulated hematomas. As yet, there is too little experience to allow comparison of open versus stereotactic drainage of hematomas although stereotactic surgical aspiration of ICH is probably safe and is promising. ^[67], ^[68]

Prognosis and Future Perspectives. Survival depends on the size and rapidity of development of the hematoma. ICHs are at first soft and dissect along white matter fiber tracts. If the patient survives the initial changes in ICP, blood is absorbed and a cavity or slit forms that may disconnect brain pathways. Patients with small hematomas located deep and near midline structures often suffer from secondary herniation and mass effect, and these patients have a high mortality rate. Survivors invariably have severe neurological deficits. In patients with medium-sized hematomas, the deficit varies with the location and size of the hematomas. Most patients survive with some residual neurological signs.

Recent studies show that ischemic pressure damage develops around the hematomas in ICH. This finding implies the necessity of new treatment strategies in the future. The recent development of stereotactic surgical aspiration is promising.

Subarachnoid Hemorrhage (SAH)

SAH is a common and often devastating condition. Despite considerable advances in diagnostic, surgical, and anesthetic techniques and perioperative management, the outcome for patients with SAH remains poor.

Pathogenesis and Pathophysiology. SAH is most often caused by leakage of blood from abnormal blood vessels on the surface of the brain resulting in aneurysms and vascular malformations. Aneurysms, often referred to as berry or congenital, are outpouchings on arteries probably caused by a combination of congenital defects in the vascular wall and degenerative changes. Aneurysms usually occur at branching sites on the large arteries of the circle of Willis at the base of the brain ([Fig. 45-10](#)). When an aneurysm ruptures, blood is released under arterial pressure into the subarachnoid space and quickly spreads through the CSF around the brain and spinal cord. Aneurysms are less often caused by arterial dissection through the adventitia of arterial walls, embolism of infected or myxomatous material to the vasa vasorum of distal cerebral arteries (mycotic aneurysms), and degenerative elongation and tortuosity of arteries (dolichoectasia).

Vascular malformations (AVMs) are the second most common identifiable cause of nontraumatic SAH, accounting for approximately 10 percent of SAHs. Rupture of AVMs often causes ICH and SAH. Bleeding of AVMs is usually less vigorous and under less pressure than aneurysmal bleeding. Other less frequent causes of SAH include bleeding diatheses, trauma, bleeding into meningeal tumors, and the use of sympathomimetic drugs such as methamphetamine and cocaine. Amyloid angiopathy is an important cause of SAH during the geriatric years.

Epidemiology and Risk Factors. SAH is a significant cause of worldwide morbidity and mortality, predominantly among young adults of both sexes. Population-based incidence rates for SAH vary from 6 to 16 per 100,000, with the highest rates reported in Finland and Japan. The annual prevalence of aneurysmal SAH in the United States probably exceeds 30,000 persons. Unlike other stroke types, the incidence of SAH has not declined over time.

Figure 45-10 Commonest sites of intracranial aneurysms: (a) posterior inferior cerebellar artery, (b) basilar artery, (c) posterior communicating artery (PCA), (d) internal carotid artery (ICA), (e) anterior communicating artery (ACA), and (f) bifurcation of the middle cerebral artery (MCA). (Adapted from Jones EF, Kalman JM, Calafiore P, et al: Proximal aortic atheroma. An independent risk factor for cerebral ischemia. *Stroke* 1995;26:218-224; with permission.)

The incidence of SAH increases with age (mean age of approximately 50 years) and is higher in women than in men. Blacks are at higher risk than whites. Population-based mortality rates for SAH have progressively declined, and the survival rate after SAH has improved since the 1970s. The risk of SAH is increased during the third trimester of pregnancy. SAH due to aneurysm rupture is a leading cause of maternal mortality, contributing to between 6 and 25 percent of maternal deaths.^[69] Significant risk factors for SAH include smoking, hypertension, and heavy alcohol use. Use of oral contraceptives, hormone replacement therapy, hypercholesterolemia, and physical activity are not significantly related. During pregnancy, there is also a greater risk of AVM rupture.^{[45], [47]}

Clinical Features and Associated Disorders. A sudden increase in ICP and meningeal irritation cause sudden severe headache, cessation of physical and intellectual activity, vomiting, and alteration of consciousness. Drowsiness, restlessness, and agitation are especially common. Severe focal neurological signs such as hemiplegia and hemianopia are absent at onset unless the aneurysm also bleeds into the brain. Expanding aneurysms or focal surrounding collections of blood within the cisterns and sub-arachnoid space can affect the cranial nerves and adjacent brain structures, causing characteristic focal features that depend on the location of the aneurysm. [Table 45-8](#) lists these common focal signs. SAH commonly causes various complications, which are discussed later in association with the management of patients with SAH.

Patients with fibromuscular dysplasia, polycystic kidney disease, and connective tissue diseases have a higher incidence of aneurysms. Embolization of bacteria, fungi, and tumor tissue to the adventitia of cranial arteries can cause mycotic aneurysms. Endocarditis and cardiac myxomas are the usual causes. About one fifth of patients with aneurysms have more than one vascular anomaly or other aneurysms.

Differential Diagnosis and Evaluation. Severe migraine and meningitis are the major differential diagnostic considerations. Sometimes only lumbar puncture can settle separation of these three disorders.

History taking and neurological examination are the essential core of the diagnosis of SAH and of grading the clinical status. A CT scan that is performed within the first 24 hours shows approximately 95 percent of all SAH cases

TABLE 45-8 -- FOCAL SIGNS IN PATIENTS WITH ANEURYSMS AT VARIOUS SITES

Site of Aneurysms	Clinical Finding
Internal carotid--post communicating	Third nerve palsy
Middle cerebral artery	Contralateral face or hand paresis Aphasia (left side) Contralateral visual neglect (right side)
Anterior communicating	Bilateral leg paresis Bilateral Babinski's signs
Basilar artery apex	Vertical gaze paresis Coma
Intracranial vertebral artery/posterior inferior cerebellar artery	Vertigo Elements of lateral medullary syndrome

and is also useful in detecting increased intracerebral density in large AVMs. When the diagnosis of SAH is highly likely clinically but the CT scan is normal, a lumbar puncture to detect blood in the CSF is necessary. After the diagnosis of SAH has been made, cerebral angiography is performed to define and localize aneurysm(s).^[69]

Management. Management of patients with SAH is directed to prevent and manage relatively common complications of SAH, such as rebleeding, vasospasm, hydrocephalus, hyponatremia, and seizures.

Rebleeding may be related to variations or changes in blood pressure rather than to absolute blood pressure. Bed rest, analgesics to relieve headache, and stable maintenance of blood pressure using antihypertensive medications in hypertensive patients are generally recommended. Because antifibrinolytic therapy has been found to be associated with a higher risk of brain ischemia and no benefits in overall outcome, use of antifibrinolytic agents is usually recommended only in certain clinical situations, for example, patients with low risk of vasospasm or a beneficial effect of delaying surgery. Early surgical clipping of the aneurysm is the method of choice, but interventional endovascular occlusive procedures are occasionally used for surgically unclippable aneurysms.^[69]

Cerebral vasospasm is the delayed narrowing of large capacitance arteries at the base of the brain after SAH, which is often associated with radiographic or cerebral blood flow evidence of diminished brain perfusion in the territory of the constricted arteries. About one half of patients with SAH have vasospasm, which may resolve or progress to cerebral infarction, and 15 to 20 percent of such patients die from vasospasm despite maximal therapy.^[70] Angiographic vasospasm has a typical temporal course: onset between 3 to 5 days after hemorrhage, maximal narrowing at 5 to 14 days, and gradual resolution over 2 to 4 weeks.^[71] Oral nimodipine is recommended to reduce poor outcome related to vasospasm. Other calcium antagonists administered orally or intravenously are of uncertain value. So-called triple H therapy composed of hypertension, hypervolemia, and hemodilution is recommended. Aneurysms should be clipped when possible, and patients receiving this therapy should be closely monitored in an intensive care setting for hemodynamic function using TCD. The value of intracisternal fibrinolysis and antioxidant and anti-inflammatory agents are uncertain. Transluminal angioplasty is recommended for treatment of vasospasm in patients in whom conventional therapy has failed.

Acute obstructive hydrocephalus after SAH complicates about 20 percent of cases. Ventriculostomy is recommended in severe cases, although there may be associated increased rebleeding and infection. Chronic communicating hydrocephalus also occurs frequently. Temporary or permanent CSF diversion is recommended in symptomatic patients. In many patients, hydrocephalus and increased subarachnoid fluid can be managed by repeated lumbar punctures.

Hyponatremia occurs in 10 to 34 percent of cases after SAH. Hypotonic fluids should be avoided, and fluid restriction should not be instituted to treat hyponatremia. Volume should be maintained using isotonic solutions.

Seizure-like episodes occur in 25 percent of patients after SAH. Because of the potential risk of rebleeding,

some recommend the administration of prophylactic anticonvulsants. The long-term use of anticonvulsants is not routinely recommended for patients with no seizure episodes and should be considered only for patients with risk factors such as prior seizure, hematoma, infarcts, or middle cerebral artery aneurysms.

During pregnancy, the management options after SAH are early clipping or delivery (spontaneous or by cesarean section), with a possible risk of rebleeding during delivery when aneurysms are unclipped. Cesarean section may be appropriate for patients with an acute hemorrhage who are near term, but management is otherwise similar to nonpregnant patients. Craniotomy and clipping have been successfully archived at all stages of pregnancy. No difference is present in prognosis between pregnant and nonpregnant patients with SAH.

Reduction of exposure to the risk factors for SAH might result in a decreased incidence of SAH. Treatment of hypertension with antihypertensive medication, cessation of smoking, and moderation of alcohol use reduces the risk of SAH. Screening of certain high-risk populations for unruptured aneurysms is of uncertain value. Advances in MRA may facilitate screening in the future. In patients with acceptable surgical risk, clipping of unruptured aneurysms larger than 5 to 7 mm is often recommended.^[69]

Prognosis and Future Perspectives. At times, the initial bleeding is so severe that death or irreversible brain damage occurs. If the bleeding is limited, the patient

survives but is at risk for rebleeding in the days and weeks after the initial SAH. For untreated, ruptured aneurysms, there is a 3- to 4-percent risk of rebleeding in the first 24 hours, 1- to 2-percent per day risk in the first month, and a long-term risk of 3 percent per year after 3 months. Urgent evaluation and treatment of patients with suspected SAH is strongly recommended.^[69]

Many recent advances in endovascular treatment of aneurysms and AVMs may improve the outcome in patients with lesions that are inaccessible to surgery. The major problem is early recognition and referral to neurological centers for early definitive treatment.

Arteriovenous Malformations

Pathogenesis and Pathophysiology. Vascular malformations are congenital in origin. They are classified into several subtypes according to the predominant vasculature. The most common type is venous angiomas, which are composed of anomalous veins without any direct feeding artery. The next most common is telangiectasia, usually found deep within the brain, particularly in the brain stem. It is composed of vessels morphologically resembling capillaries but slightly larger and often found at necropsy. Another less common vascular abnormality, which also rarely causes symptoms, is the venous varix. Two other common symptomatic angiomas are AVMs and cavernous angiomas.^[2], ^[67], ^[72] AVMs are composed of clusters of abnormal arteries and veins of varying size, without intervening capillaries.

Epidemiology and Risk Factors. Vascular malformations are the second most common cause of nontraumatic SAH and ICH. Vascular malformations are one tenth as common as aneurysms; an estimated 1000 new cases are identified in the United States each year. They rupture most commonly during the second and third decades of life. Hemorrhage from malformation is most common during early pregnancy or delivery.

Clinical Features and Associated Disorders. As AVMs enlarge, symptoms are related to a number of mechanisms. They can cause bleeding, seizures, vascular headache, and chronic ischemia. Bleeding is most likely due to fragility of the abnormal vessels. The angiomas that most frequently rupture are of the AV type. Symptoms and signs depend on the location of hemorrhage. There are usually signs of meningeal irritation due to bleeding into the CSF. Not all ruptures are symptomatic but evidence of previous bleeding is often observed at necropsy. About one half of the patients present with epilepsy. Progressive neurological signs may develop secondary to a mechanism called intracerebral steal or compression of adjacent brain tissue by the pulsating blood vessels. Chronic migrainous headaches are also a frequent complaint in patients with vascular malformations. Patients with unruptured AVMs may present with increased ICP and papilledema. Angiomas in the brain stem may cause serious bleeding or progressive neurological deficits, which may be fluctuating in clinical course and may simulate multiple sclerosis. Rarely, angiomas, particularly aneurysms of the vein of Galen, present with hydrocephalus by disrupting the normal flow of CSF. Bruits may be audible either to the patient or to the examiner. If there is enough shunting through a large AVM, high-output congestive heart failure may develop, especially in children. In spinal AVMs, the patients may present with back pain, myelopathic symptoms, and root dysfunction. However, headache often accompanies spinal AVM rupture, mimicking aneurysmal SAH. A number of patients with spinal AVMs have intracranial symptoms, including headache, mental status changes, loss of consciousness, papilledema, decreased vision, nystagmus, diplopia, seizures, sixth nerve palsy, and oculomotor paresis.^[1]

Some cavernous angiomas are familial. Patients with hereditary hemorrhagic telangiectasias (Osler-Weber-Rendu syndrome) have a higher than normal incidence of vascular malformations.

Differential Diagnosis and Evaluation. Diagnostic considerations include aneurysms and brain infarcts and tumors. Diagnosis of AVMs can be suspected clinically when young patients present with intracerebral hemorrhage, seizures, or frequent unilateral headaches. CT scan, MRI, MRA, and transcranial Doppler ultrasonography are helpful noninvasive tests. However, a confirmative diagnosis is made using angiography, through which therapeutic embolization can sometimes be performed at the same time. On angiography, a typical AVM shows large feeding arteries; a central tangle of vessels; enlarged, tortuous draining veins; and rapid arterial-to-venous shunting of blood.

Management. Direct surgical excision of AVMs has been improved with the use of the operating microscope and often can be carried out with low rates of morbidity and mortality. The major complications of surgical excision are loss of normal brain tissue, with additional loss of neurological function, and the so-called breakthrough phenomenon. This term describes massive brain swelling and

ICH occurring postoperatively, which is caused by redirection of the large volume of blood into small vessels that are unable to handle the large volume of blood that previously flowed into the AVM.^[73]

Endovascular treatment of AVMs using embolization techniques can be used alone, before surgery, or at the time of surgery. It is particularly useful in treating lesions that are not surgically accessible and as an adjunct to surgical removal.^[74] Complications include hemorrhage, ischemic stroke, and angionecrosis due to toxicity of the embolic materials.

Radiotherapy of AVMs with high energy x-rays, gamma rays, and protons induces subendothelial deposition of collagen and hyaline substances, which narrow the lumen of small vessels and shrink the nidus of the malformations by progressive occlusion of vessels during the months after treatment. Recent techniques focus the radiation beam on small regions. An example is the so-called gamma knife, a system that uses a cobalt source to generate highly collimated gamma rays that converge on a focal point. Modified linear accelerators can now deliver radiation to a defined volume of tissue with very good accuracy. Complications include radionecrosis of normal brain, bleeding, hydrocephalus, immediate post-therapy seizures, loss of body temperature regulation, and possibly long-term cognitive function deficits.^[75]

Forms of medical management include strict control of blood pressure and avoidance of anticoagulants and antiplatelet drugs. Because pregnancy increases risk of bleeding, appropriate contraception may be recommended in fertile women with an AVM.

Prognosis and Future Perspectives. In the short term, the prognosis of ruptured AVMs and cavernous angiomas is better than that of aneurysms. The rebleeding rate is low during the first few months. Only 6 percent of patients rebleed during the first year, and vasospasm occurs only rarely. Mortality from the first hemorrhage is low, only about 10 percent. However, in the long term, the prognosis of AVMs is not as good. With subsequent hemorrhages, the mortality rate is higher, about 20 percent. With each recurrence, the chances of additional bleeding increase.

Improved noninvasive diagnosis using MRI and MRA and improved methods of treatment (endovascular and radiotherapy) promise to help reduce the rates of morbidity and mortality of this serious vascular condition.

TRAUMATIC NEUROVASCULAR DISEASES

Carotid-Cavernous Sinus Fistulas

A carotid-cavernous sinus fistula (CCF) is an abnormal communication between the cavernous sinus and the carotid arterial system. CCFs usually develop after head trauma but can occur spontaneously. CCFs are classified into direct and dural types.^[76] The most common type is the direct type (70 to 90 percent) in which there is a direct connection between the intracavernous portion of the ICA and the cavernous sinus. This is a high-flow type often caused by a traumatic tear of the arterial wall. The other dural types are communications between the cavernous sinus and meningeal arterial branches of the ICA, of the external carotid artery, or of both. They develop spontaneously or in the setting of atherosclerosis, systemic hypertension, collagen vascular disease, and during and after childbirth. These fistulas usually are of the low-flow type and almost always produce symptoms and signs spontaneously without antecedent trauma.^[77]

Patients with a direct CCF may develop monocular visual loss and abnormalities of the oculomotor nerves (III, IV, VI) ipsilaterally or bilaterally. Ocular manifestations include diplopia, proptosis, ocular bruit, chemosis, ocular pulsation, dilatation of retinal veins, optic disc swelling, visual loss, and potentially glaucoma. There are often signs of intracranial hypertension. Trigeminal nerve dysfunction is the most common cranial nerve abnormality. Dural types usually occur in middle-aged or elderly women. They present similar clinical symptoms and signs but are less severe than those of the direct type.

If a CCF is suspected, CT or MRI and ocular ultrasonography are performed and often show enlarged extraocular muscles, dilated superior ophthalmic veins, and an enlarged affected cavernous sinus. The ultimate diagnostic test is cerebral arteriography of both the bilateral internal and external carotid arteries.

Urgent treatment is indicated in patients who have rapidly deteriorating vision, hemorrhage, and intracranial hypertension. Surgical repair of the damaged portion of the intracavernous ICA is only rarely used these days. Endovascular occlusion using detachable balloons has a success rate of 90 to 100 percent with low complication rates (2 to 5 percent).^[78] The recurrence rate is 1 to 3.9 percent, and recurrence often responds to second balloon treatment. Early complications include migration of balloons and thromboembolism resulting in stroke; delayed complications are pseudoaneurysm formation and persistent ophthalmoplegias.^[77] If the condition is left untreated, almost all patients have progressive ocular problems, including increasing proptosis, chemosis, and visual loss. The most feared complications are central retinal vein occlusion and secondary glaucoma. Endovascular techniques have greatly improved the prognosis of CCFs. Most symptoms and signs usually disappear within days after treatment or at least improve with this procedure, but complete resolution may take weeks to months.^[77]

Subdural Hematomas

Pathogenesis and Pathophysiology. A subdural hematoma (SDH) results from venous bleeding after blunt head trauma, which causes brain motion within the skull, shearing off the bridging veins between the surface of the brain and adjacent dural venous sinuses. The blood leaks and collects slowly, forming a hematoma in the subdural space.^[79] An SDH may be absorbed spontaneously or may form an encapsulated and liquefied hematoma. After about 2 weeks, membranes form around the hematoma. The outer membrane is thicker and more vascular than the inner membrane. The center of the encapsulated SDH liquefies and may enlarge due to repeated bleeding from the vascular outer membrane, assuming a progressively larger biconvex lens shape.^[79]

Epidemiology and Risk Factors. Acute SDHs develop after severe head trauma and carry a poor prognosis. The mortality rate of a treated acute SDH is roughly 50 percent. A chronic SDH usually develops after minor trauma, typically in an elderly person under anticoagulation or in an alcoholic individual with some degree of brain atrophy. Because an atrophic brain cannot tamponade a beginning hematoma, bleeding frequently continues, causing headaches, behavioral changes, altered level of consciousness, or a focal neurological deficit such as hemiparesis.^[79] At times, subdural hematomas develop without a history of trauma. Patients treated with anticoagulants and those with bleeding disorders may develop spontaneous subdural bleeding. Occasionally, subdural collections develop after lumbar puncture. In other patients head trauma is forgotten or considered too inconsequential to mention. In many instances, a fall causes retrograde amnesia and the patient may not have been fully aware of the injury.

Clinical Features and Associated Disorders. The three most common findings in patients with subdural hematomas are headache, decreased level of alertness, and abnormalities of cortical function. Headache is usually ipsilateral to the hematoma and may be worse at night. Drowsiness and decreased alertness reflect an increase in intracranial pressure. There is often slight weakness, hyperreflexia, and Babinski sign contralateral to the hematoma. Slight aphasia may develop in patients with left-sided hematomas and neglect of the right side of space occurs in patients with right subdural hematomas. Usually, the neurological abnormalities are soft and seldom are as profound deficits as those that occur in patients with large hemisphere infarcts or intracerebral hematomas. Seizures may occur and probably indicate some contusion of the underlying brain tissue as the hematoma enlarges, headache worsens, and the level of consciousness often decreases. An ipsilateral Babinski sign or elements of an ipsilateral third nerve palsy, or both, may develop and indicate midbrain compression.

Differential Diagnosis and Evaluation. The diagnosis is usually obvious in patients with head injury. The insidious development of symptoms, especially in patients who provide no history of trauma can readily mimic brain tumor or abscess. Brain infarcts and hematomas usually present with more acute onset symptoms and signs and more severe focal deficits. Neuroimaging is now indispensable for accurate diagnosis. On a CT scan, an acute SDH appears as a sickle-shaped, hyperdense lesion over the outer surface of the brain lying against the inner surface of the skull and dura. A subacute SDH appears isodense in relation to the brain, making diagnosis difficult. During this acute period, a T1-weighted MRI is very helpful and shows a high signal intensity lesion in the subdural space. A chronic SDH appears hypodense on CT scans.^[79]

Management. If an SDH is not recognized and is left untreated, it may cause a severe neurological deficit or death. SDHs should be surgically evacuated. The prognosis is good and primarily related to the degree of associated brain injury.^[79] In older patients and in those with brain atrophy, re-expansion of the compressed brain may be delayed. Because subdural bleeding may recur, a drain must be left in for days and the patient must be watched carefully for continued bleeding.

Prognosis and Future Perspectives. Recovery is usually excellent in patients in whom subdural hematomas are recognized and treated. Small subdural hematomas probably are more common than recognized and may heal spontaneously without medical treatment. Because subdural hematomas represent a very treatable cause of mental abnormalities and neurological signs in elderly populations prone to falls, improved screening of these patients would be an important public health advance.

Epidural Hematomas

Pathogenesis and Pathophysiology. An epidural hematoma (EDH) develops when blood collects between the skull and the dura mater as the result of a severe head injury causing a fracture of the squamous portion of the temporal bone and producing a tear in the middle meningeal artery. Blood escaping under arterial pressure dissects the dura inward away from the bone and forms a hematoma. The most common location of EDH is along the lateral wall of the middle cranial fossa. The underlying brain is displaced inward, and brain herniation may follow.^[79] Occasionally, epidural hematomas can develop in patients with tumors involving those that have spread into the epidural space.

Epidemiology and Risk Factors. Epidural hematomas are rare when compared with subdural hematomas. They usually develop only in patients with severe head trauma. They may be an important cause of death in patients with severe head injury. Subdural, intracerebral, and subarachnoid hemorrhage often co-exists.

Clinical Features and Associated Disorders. Classically, the patient often has a lucid interval just after head trauma and then often has a progressive reduction in the level of consciousness as the hematoma enlarges. The lucid interval is explained as follows: The initial injury causes brain concussion and loss of consciousness from which the patient awakens and may have some headache but seems otherwise to have recovered. The acute development of epidural bleeding causes pressure on the ipsilateral cerebral hemisphere and headache, reduction in consciousness, and abnormalities of function of the ipsilateral hemisphere. Downward transtentorial herniation may develop rapidly, causing dilatation of the ipsilateral pupil due to third nerve compression and an ipsilateral hemiparesis due to compression of the contralateral cerebral peduncle of the midbrain against the contralateral tentorial edge.^[79]

Rarely, an EDH may be venous in origin due to laceration of the middle meningeal vein or a dural venous sinus. The time course is more protracted, evolving over several days. Altered mental status and hemiparesis develop before signs of brain herniation.^[79]

Differential Diagnosis and Evaluation. Diagnosis is made by CT. The hematoma typically appears as a biconvex lens-shaped hyperdense lesion. There is an underlying skull fracture. However, if the patient's condition is rapidly deteriorating, the diagnosis is better made by taking the patient directly to the operating room for a procedure that is both diagnostic and therapeutic.

Management. Epidural hematomas should be surgically

evacuated as soon as possible. There is no place for conservative management of epidural hematomas. Rapid drainage can be life saving.

Prognosis and Future Perspectives. The outcome is usually excellent when epidural hematomas are rapidly diagnosed and treated surgically. Death usually results from unrecognized epidural hematomas. After effective treatment, there are usually no residual neurological deficits.

Spinal Cord Strokes

Pathogenesis and Pathophysiology. Spinal cord infarcts are most often caused by interruption of the blood flow in one or more of the arteries that feed into the anterior spinal arterial system. A large anterior spinal artery runs in the ventral midline from the medullospinal junction rostrally to the conus medullaris and the filum terminale caudally. This anterior spinal artery system is supplied by five to 10 single radicular arteries. The cervical region is supplied by the anterior spinal artery branch of the intracranial vertebral artery and inferiorly by branches of the thyrocervical and costocervical branches of the subclavian arteries. The thoracic and lumbar spinal cord segments are fed by radicular arterial branches of the deep cervical and intercostal arteries and branches of the aorta. The lower thoracic cord is supplied by direct branches from the aorta, the largest of which is the artery of Adamkiewicz, which most often enters between T12 and L2. The sacral cord and cauda equina are supplied by branches of the hypogastric and obturator arteries. This anterior system is vulnerable to interruption of flow through any one of the feeding arteries. Resulting infarcts usually affect the anterior horns and the lateral and ventral white matter columns.

In contrast to the anterior spinal artery system, there are paired posterior spinal arteries, which are fed by small posterior radicular arteries and which enter along nerve roots at every level from both sides. The posterior spinal arteries form a rete of communicating vessels that supply the posterior columns and posterior gray horns of the spinal cord. Because of the multiple feeding channels, this system is very resistant to interruption of its blood supply.

Interruption of blood flow in anterior spinal branches is probably most often due to disease within the aorta. Aortic aneurysms, surgery on the aorta, aortic dissections, and emboli from atheromatous aortic plaques can result in obstruction to flow in feeding arteries. Disc cartilage can also fragment and enter spinal arteries and veins and lead to infarction.

AV fistulas are also an important cause of spinal cord infarction. These lesions are most common in older men. Direct communications develop between radicular arteries and veins outside the dura mater. This greatly increases pressure in the venous system, and large drainage veins develop on the surface of the spinal cord. At the same time, shunting of blood decreases flow to the spinal cord from the feeding artery. In order to maintain adequate spinal perfusion, the pressure of blood in the arterial system must exceed venous pressure. The spinal-dural AV fistula often creates a situation in which intermittently venous pressure exceeds arterial pressure, and ischemia develops. At first, ischemia can be intermittent, and spinal cord TIAs can result.

Spinal infarcts can also develop in relation to infections in the meninges and parasitic invasion of the spinal arteries. Syphilis, tuberculosis, and Lyme borreliosis can involve the spinal arteries. Adhesive arachnoiditis can also cause obliteration of spinal arteries and lead to cord ischemia, especially in the central portion of the spinal cord. Schistosomiasis can involve feeding spinal arteries. Hypoxic-ischemic injury to the spinal cord also develops in patients with severe systemic hypotension and shock. In these patients, brain damage usually is more severe than spinal injury and makes it difficult to identify the spinal pathology clinically.

Spinal cord hemorrhage most often results from trauma. Bleeding diathesis, especially anticoagulation, is another important cause. Aneurysms of intradural arteries and intradural AVMs and cavernous angiomas are other causes of spinal cord hemorrhages.

Epidemiology and Risk Factors. Spinal strokes are very rare in comparison to strokes that involve the brain. The rarity of spinal cord strokes and the inaccessibility of the spinal cord vascular system to imaging during life have greatly limited knowledge about the causes and pathophysiology of spinal strokes. In addition, the spinal cord and its vascular system are seldom examined in detail during postmortem examinations. The major risk factor for spinal strokes is disease of the aorta and aortic surgery. In older individuals, aortic disease and dural fistulas account for the bulk of cases. In younger persons, trauma, cartilaginous emboli, and congenital vascular malformations and bleeding diatheses account for most instances of spinal strokes.

Clinical Features and Associated Disorders. Spinal cord infarcts usually develop abruptly. Most spinal strokes are thoracic or lumbar, so that the lower extremities are selectively involved. The most common signs are motor and include both lower motor neuron and upper motor neuron abnormalities within the lower limbs. Paraplegia is usually symmetrical. There may be a pain and temperature level along the thorax. Sphincter function is most often lost. Posterior column functions (vibration and position sense) are usually spared. The findings are most often roughly symmetrical. When the lesion is asymmetrical or unilateral, sensory dissociation occurs, producing a Brown-Sequard-like pattern. In patients with spinal-dural AV fistulas, TIAs and steplike development of deficits are common.

Differential Diagnosis. Almost always, the symptoms and signs allow recognition that the lesion is spinal. Occasionally, medullary and pontine infarction can be a consideration. Tumors, abscesses, and syrinxes usually cause symptoms that develop gradually, but hemorrhage into a spinal cord tumor, most often an ependymoma, can be an important consideration. Spinal cord compression caused by cancer, epidural and subdural infections, and hematomas are other considerations.

Almost all compressive spinal cord lesions involve the vertebral column. Plain bone x-ray studies and CT, MRI, and bone scans can yield information about osseous lesions that could compress the spinal cord. MRI is the best method to visualize the spinal cord, dura mater, and overlying bony structures. MRI can show spinal hemorrhages and infarcts and can identify the presence of spinal cord compression. MRI is not very sensitive for the detection of

spinal-dural AV fistulas. Myelography may be needed to show the characteristic dilated veins that course on the surface of the spinal cord. Lumbar puncture is helpful in identifying spinal hemorrhage and infection. Spinal angiography is often necessary to characterize spinal vascular malformations and fistulas.

Management. There is little information about treatment of patients with spinal cord infarcts. Definitive treatment depends, as it does in the brain, on identification of the etiology in the individual patient. Hemorrhage, infection, and infarction can be separated by MRI and lumbar puncture. Identification of spinal-dural AV fistulas is very important because obliteration of the abnormalities can prevent further spinal cord damage. Rehabilitation and management of sphincter functions is similar to that pursued in other diseases of the spinal cord.

Prognosis and Future Perspectives. Outcome depends almost entirely on the cause of the spinal cord vascular damage. In the future, we need to develop more accurate ways to study the aortic blood supply to the spinal cord. Intravascular ultrasound is promising. Perhaps further development of MRA and venography will be helpful and obviate the need for spinal angiography, which can be hazardous. Basic research on spinal cord protection may help limit damage in patients with vascular spinal cord insults.

STROKES IN THE YOUNG

Strokes in children younger than 15 are often different from those found in adults. Brain infarcts tend to be limited more to the deeper regions of the cerebral hemispheres, especially the striatocapsular areas. Vascular occlusive lesions are more often intracranial and affect mostly the intracranial carotid and the middle cerebral and basilar arteries. Extracranial lesions are less common; when they occur, they usually involve the pharyngeal portions of the carotid and vertebral arteries rather than the arterial origins that are involved more commonly in adults. Vasoconstriction, dissection, fibromuscular dysplasia, trauma, and contiguous infection are the major diseases that affect the extracranial arteries of children. When the vascular occlusive process or embolism involves the middle cerebral artery, vascular compromise is maximal in the territory of the lenticulostriate branches. Because of the invariable absence of severe occlusive disease, collateral circulation over the convexities is abundant. This explains the striatocapsular localization of infarcts. Because atherosclerosis is very rare in youth, the types of vasculopathies that cause brain ischemia in children is much more diverse than in adults, and the differential diagnosis is very broad. Congenital cardiac disease is an important cause of stroke in children. [Table 45-9](#) lists the most important causes of brain ischemia in children younger than age 15 years.

Brain and subarachnoid hemorrhages, especially from aneurysms and vascular malformations, comprise a much higher percentage of strokes in children than they do in adults.^[9]

In young adults, premature atherosclerosis and stroke risk factors are much more important than in youths. Cardiac

TABLE 45-9 -- DIFFERENTIAL DIAGNOSIS OF PEDIATRIC BRAIN ISCHEMIA (1-15 YEARS)

Migraine

Trauma: Dissection and other vascular injuries; abuse including whiplash-shake injuries; oral foreign body trauma to the internal carotid artery

Cardiac: Congenital heart disease with right-to-left shunts; tetralogy of Fallot; transposition of great vessels; tricuspid atresia; atrial and ventricular septal defects; cardiomyopathies; endocarditis; pulmonary arteriovenous fistula

Drugs: Especially cocaine and heroin

Infections: Bacterial meningitis, especially *Hemophilus influenzae*, pneumococci, and streptococci; facial, otitic, and sinus infections; AIDS; dural sinus occlusion and infection; tuberculous meningitis

Genetic and metabolic: Neurofibromatosis; hereditary disorders of connective tissue (Marfan's and Ehlers-Danlos syndromes, pseudoxanthoma elasticum); homocystinuria; Menkes' kinky hair syndrome; hypophosphatidylproteinaemia; familial hyperlipidemias; methylmalonic aciduria; MELAS syndrome (mitochondrial myopathy, encephalopathy, lactic acidosis, strokes)

Hematological and neoplastic: Sick cell anemia; purpuras; leukemia; L-asparaginase and aminocaproic acid (Amicar) treatment; radiation vasculopathy; hypercoagulable states (e.g., caused by decrease in natural inhibitors such as antithrombin III)

Arteritis: Collagen vascular disease; local infections; Takayasu's disease; Behcet's disease

Venous sinus thrombosis: Head and neck infections; dehydration; coagulopathy; paroxysmal nocturnal hemoglobinuria; puerperal or pregnancy-related

Systemic disease: Rheumatic; gastrointestinal; renal; hepatic; pulmonary

Moyamoya disease

From Caplan LR, Estol CE: Strokes in youths. In Adams HP (ed): Cerebrovascular Disease. New York, Marcel Dekker, 1993, pp 233-254.

disease and hematological diseases and cancer provide a higher proportion of infarcts in young adults than during the geriatric years. [Table 45-10](#) lists the major differential considerations of brain ischemia in persons 15 to 40 years of age.

TABLE 45-10 -- DIFFERENTIAL DIAGNOSIS OF ISCHEMIA IN YOUNG ADULTS (15-40 YEARS)

Migraine

Arterial dissection

Drugs, especially cocaine and heroine

Premature atherosclerosis, hyperlipidemias, hypertension, diabetes, smoking, homocystinuria

Female hormone-related (oral contraceptives, pregnancy, puerperium): eclampsia; dural sinus occlusion; arterial and venous infarcts; peripartum cardiomyopathy

Hematological: Deficiency of antithrombin III, protein C, protein S; fibrinolytic system disorders; deficiency of plasminogen activator; antiphospholipid antibody syndrome; increased factor VIII; cancer; thrombocytosis; polycythemia; thrombotic thrombocytopenic purpura; disseminated intravascular coagulation

Rheumatic and inflammatory: Systemic lupus erythematosus; rheumatoid arthritis; sarcoidosis; Sjogrens syndrome; scleroderma; polyarteritis nodosa; cryoglobulinemia; Crohn's disease; ulcerative colitis

Cardiac: Interatrial septal defect; patent foramen ovale; mitral valve prolapse; mitral annulus calcification; myocardopathies; arrhythmias; endocarditis

Penetrating artery disease (lacunes); hypertension, diabetes

Others: Moyamoya disease; Behcet's disease; neurosyphilis; Takayasu's disease; Sneddon's disease; fibromuscular dysplasia; Fabry's disease; Cogan's disease

From Caplan LR, Estol CE: Strokes in youths. In Adams HP (ed): Cerebrovascular Disease. New York, Marcel Dekker, 1993, pp 233-254.

HISTORY

Primary malignant brain tumors have been a cause of increasing concern in the last several years. There has been a steady rise in the incidence of primary brain tumors, with an almost 25 percent increase during the last two decades, perhaps due to improved detection with neuroradiological imaging.^[1],^[2] Although the incidence of some tumors such as lung cancer has declined, and improvements in therapy have increased survival for other tumors such as breast cancer, the incidence of brain tumors continues to increase. Just as important as the rise in incidence is the fact that the need for treatment of these neoplasms is urgent because they afflict the young in disproportionate numbers, significantly affecting their chances of living productive lives.

According to statistics gathered by the American Cancer Society, 17,900 new cases of central nervous system (CNS) tumors were diagnosed in 1996, involving approximately 10,400 men and 7500 women ([Table 46-1](#)). More than half of these cases were malignant gliomas. In children, brain tumors are the most common solid tumor and are second only to leukemias in overall incidence. For comparison, during 1996 there were 185,700 cases of breast cancer and 27,600 cases of leukemia.

Early studies date back centuries to descriptions or drawings of lethal brain tumors discovered at autopsy. In 1828, John Ambercrombie published the first pathological descriptions of brain tumors in his monograph *Pathological and Practical Research on Disease of the Brain and Spinal Cord*. The first acknowledged resection of a brain tumor was performed in London in 1884, after Hughes Bennett provided sufficient clinical localization to permit Rickham Godlee to perform a craniotomy. Even then, doctors were quick to announce their findings in the lay press, and a report documenting the operation was published in *The London Times* a mere 21 days following the procedure. Formal reports of the operation were later published in the medical literature. The first monograph on brain tumors was prepared 4 years later by Sir Byron Bramwell.

Pathological criteria for the diagnosis of primary brain tumors remained under study and was controversial for almost a century. Even at the turn of the century, surgeons complained bitterly that a lack of precise pathological criteria hindered diagnosis. Fedor Krause, in his three-volume *Surgery of the Brain and Spinal Cord* (1912), described several successful tumor surgical procedures in which the neuropathologist was either unable or unwilling to venture a diagnosis. Bailey and Cushing published the first modern treatise on brain tumors and pathological description in 1932. Previously, they had histologically defined and coined the term medulloblastoma.^[3] Use of this term to refer to a blue cell tumor of the posterior fossa continues to spark debate.^[4]

In the first half of this century, Cushing continued to develop and refine the techniques of neurosurgical removal and localization, including angiography and pneumoencephalography. Greg Walter described the first use of electroencephalography for tumor localization in 1936. Improvements in radiotherapy and chemotherapy^[5] during the second half of this century marked the emergence of neuro-oncology as a truly multidisciplinary field. In the 21st century, analysis of the biological markers and genetic behavior of these tumors is expected to advance our ability to treat effectively this most difficult class of cancers.

TABLE 46-1 -- FREQUENCY OF PRIMARY CNS TUMORS

Children (0-14 Years)		Adults (215 Years)	
Type	Percentage	Type	Percentage
Glioblastoma	20	Glioblastoma	50
Astrocytoma	21	Astrocytoma	10

NEUROECTODERMAL TUMORS

Low-Grade Glioma, Astrocytoma, and Pilocytic Astrocytoma

Pathogenesis and Pathophysiology. The diagnosis of glioma remains one of the most difficult areas of neuro-oncology. As we learn more about the biological behavior and cellular markers of these tumors, the diagnostic criteria continue to change. Because of the popularity of stereotactic biopsy, resulting in small tissue samples that may not be representative of the entire tumor, pathological confirmation has become increasingly difficult. Previously determined diagnostic criteria have been found to be inconsistent; therefore, the results of clinical trials of radiotherapy and chemotherapy were unreliable because the patient populations for individual studies were not homogeneous. Finally, histological interpretation does not necessarily predict biological behavior in the individual patient.

Recent attempts to devise a grading system that provides ease of interpretation and interobserver consistency have had limited success. For example, the St. Anne-Mayo system proposed a modification of previous grading schemes that relied on histological criteria including nuclear atypia, mitosis, vascular endothelial proliferation, and necrosis as differentiating features. A point system was assigned to these histological variables, as follows: (1) grade 1 tumors had none of these features, (2) grade 2 tumors had one feature, (3) grade 3 had two features, and (4) grade 4 had three or more features. In the initial evaluation, these groups led to distinct median survival curves, but a subsequent review of 251 cases at the Massachusetts General Hospital found no statistical difference in survival between patients with grade 2 and 3 tumors. Even when the histological criteria are consistent, clinical features such as age or extent of resection alter the survival characteristics. For example, a patient with an astrocytoma at age 20 has a median survival of 5 to 10 years, whereas a patient at age 60 may have a survival similar to that characteristic of a malignant astrocytoma.

The modified Ringertz system remains the most reasonable grading scheme for astrocytic gliomas. It separates these tumors into three categories ([Table 46-2](#)): astrocytoma, anaplastic astrocytoma, and glioblastoma multiforme. This grading system appears to correlate best with survival. The recent World Health Organization classification incorporates the Ringertz system, assigning grades II to IV, respectively, to these histological categories and including a fourth category, pilocytic astrocytoma, as grade I ([Fig. 46-1](#)). Even with current research, necrosis remains the only significant histological predictor of survival.

Astrocytomas can infiltrate and invade vital neural systems and may prohibit complete surgical removal. They eventually lead to death because of this disruption of neural systems or because of increased intracranial pressure due to volume expansion. Histologically, they appear to be characterized by increased cell number and nuclear pleomorphism without necrosis. Mitotic figures should not be present. Microcystic changes separate these tumors from a glial reaction.

Pilocytic astrocytomas are commonly found in the cerebellum, brain stem, thalamus, and optic nerve tracts of preteen-age youths, but they can occur in individuals up to 30 or 40 years of age. They have a gelatinous appearance, are often well circumscribed, and, if in a favorable location, can be totally excised. Histologically, they have a highly recognizable pattern marked by fibrillary astrocytes and stellate cells. Rosenthal fibers and microcystic changes are

TABLE 46-2 -- HISTOLOGICAL CRITERIA FOR CEREBRAL GLIOMAS

<i>Astrocytomas</i>
1. Uniform cells closely resembling mature resting or reactive, nonanaplastic astrocytes
2. Moderate cell density
3. Mitoses absent or very rare
<i>Anaplastic astrocytoma</i>
1. Increased cellular and/or nuclear pleomorphism
2. Increased cell density
3. Increased mitoses
4. Vascular endothelial proliferation
<i>Glioblastoma multiforme</i>
1. All of above
2. Foci of coagulative necrosis

Figure 46-1 Histopathological picture of four types of astrocytoma. A, Pilocytic astrocytoma, elongated bipolar tumor cells forming a dense fibrillary matrix with numerous Rosenthal fibers. B, astrocytoma, elongated hyperchromatic nuclei with diffused infiltration of the white matter (note lack of nuclear pleomorphism). C, anaplastic astrocytoma, demonstrating nuclear pleomorphism, frequent mitosis, and vascular proliferation. D, glioblastoma, small, anaplastic tumor cells, vascular proliferation, and areas of necrosis with pseudopalisading of tumor cells.

often evident. Pleomorphic xanthoastrocytomas are cerebral tumors with lipid-filled cytoplasm found in teens and young adults. Subependymal giant cell astrocytomas are common in the initial decades of life of patients with tuberous sclerosis and arise from the lateral ventricles. Brain stem gliomas are seen in younger individuals and usually are present in the pons or medulla. They rarely undergo biopsy. Magnetic resonance imaging (MRI) usually demonstrates a "fat" pons without gadolinium enhancement. Cervicomedullary gliomas carry a more favorable prognosis than pontine gliomas because brain stem gliomas in the medulla tend to be lower grade tumors.

Epidemiology and Risk Factors. Gliomas are the most common tumors of the brain and spinal cord. Astrocytomas occur most commonly in the 20- to 40-year-old age group and represent about 15 percent of all primary CNS tumors (see [Table 46-1](#)). The incidence of low-grade gliomas appears to be on the rise, perhaps because they are often diagnosed incidentally when patients undergo neuroradiological imaging for other reasons such as trauma. Patients with astrocytomas have a more favorable median survival than those with glioblastomas. But because astrocytomas are usually found in young people, even a survival time of 5 to 10 years appears unfavorable to the patient and the family. As a rule of thumb, gliomas in children are more often found in the posterior fossa, while gliomas in adults are most often located in the cerebral hemispheres. So far, there are no known risk factors associated with the development of astrocytomas.

Clinical Features and Associated Disorders. Patients presenting with low-grade gliomas may have a very gradual onset of symptoms, including headache or subtle neurobehavioral changes. Slowly evolving neurological deficits also raise suspicion of a malignant lesion. These tumors can grow very slowly, and diagnosis may be difficult on initial presentation. For example, increased difficulty with schoolwork or other cognitive tasks is easily blamed on social problems but may indicate a neurological malignancy. Patients with brain stem gliomas present with oculomotor problems or symptoms that may be confused with spinal cord involvement.

Seizures can also occur and may be either focal or generalized; if subtle, they may be mistakenly associated with psychological problems such as anxiety or panic attacks. Among patients with a new onset of seizures about 5 percent are found to harbor a tumor, although approximately 25 percent of patients with gliomas have seizures. If patients who have previously had seizures experience an alteration in seizure characteristics or frequency, or if the seizures become refractory to medication, a re-evaluation with MRI scanning including gadolinium may be warranted. Occasionally, patients with new-onset seizures have normal MRI scans. In these patients, the seizures may be increasingly difficult to control. Repeat neuroradiological

Figure 46-2 MRI picture of a low-grade astrocytoma, demonstrating a hypointense right temporal lesion without contrast enhancement on T1, and hyperintense signal on T2.

imaging after 3 to 6 months may uncover an astrocytoma or other mass lesion.

Differential Diagnosis. The differential diagnosis of astrocytomas includes other malignant gliomas (anaplastic astrocytoma, oligodendroglioma, and glioblastoma multiforme), or primary CNS lymphoma and metastatic lesions. Nonmalignant diagnoses such as abscesses and viral infections including herpes encephalitis, or demyelinating processes should also be considered. In most patients the symptoms evolve slowly over a period of weeks. Occasionally, in older patients a stroke may be diagnosed because a low-attenuation lesion vaguely following a vascular pattern is discovered after a sudden onset of new symptoms. Later, with deterioration of the patient's condition, which is occasionally diagnosed as a progressive stroke in evolution, repeat imaging shows an expanding mass, later diagnosed as a tumor and most likely responsible for the initial symptoms. One must always beware of attempts to diagnose lesions histopathologically based on radiological imaging.

Evaluation. Low-grade gliomas are often seen as diffusely hypodense or isodense lesions with some flattening of the cortical gyral areas on computed tomography (CT) or significant changes on T2-weighted images on MRI (Figs. 46-2 and 46-3). There is correspondingly less edema formation. Often low-grade tumors are not enhanced, or there may be very small areas of enhancement that become more evident on triple-dose gadolinium injection. The presence or absence of enhancement does not predict the pathological diagnosis in an individual patient.

Figure 46-3 MRI picture of a juvenile pilocytic astrocytoma (JPA) of the thalamus, demonstrating contrast enhancement among a hypointense lesion budding into the lateral ventricle.

Surgical evaluation is usually needed to establish the diagnosis. Although a pilocytic astrocytoma of the cerebellum can often be fully resected, hemispheric astrocytomas are diffuse, and occasionally only a biopsy can be performed. Attempts should be made to perform a biopsy of any small enhancing areas to increase the likelihood of obtaining a representative sample for pathological examination. Surgical intervention for brain stem gliomas was previously thought to be impossible except in some cystic tumors that were amenable to decompression. Recent reports suggest that CT-guided biopsy may be feasible. The morbidity rate was found to be around 5 percent, and, surprisingly, 12 percent of the patients who underwent biopsy were found to have a benign pathology, usually infectious in nature. [1] Nonmalignant causes were seen more often in patients with focal enhancing lesions. Therefore, biopsy may be reasonable in selected patients at centers qualified to perform such procedures.

Management. Although surgery can be curative in patients with pilocytic astrocytomas, it is rarely an option in those with low-grade gliomas. Previous studies were directed toward treatment for symptomatic patients, whereas specific treatment regimens for patients whose tumor diagnosis was made incidentally remain highly controversial. The small number of patients diagnosed with these tumors has led to limited enrollment in clinical trials. The evolution of histological criteria, variable patient clinical status, and prolonged patient accrual periods have all led to more heterogeneous criteria for patient inclusion in treatment

studies. Thus, there are no large randomized studies available by which to evaluate the results of postsurgery radiotherapy in these patients. Recently, questions have been raised about whether purported tumors found on radiological imaging even need to undergo biopsy, let alone treatment with radiation. [1] Since histological criteria cannot predict biological behavior, some clinicians advocate the use of serial neuroradiological imaging to establish the growth characteristics of these tumors without intervention that might distort the natural history.

Most studies favor maximum surgical removal and radiotherapy, although certain subgroups of patients may benefit more from this treatment than others. Concern has been raised that because these tumors are so slow growing, standard radiation therapy with 60 to 66 Gy for 6 weeks may not provide treatment when the tumor is more radiation sensitive. Delaying radiotherapy would also delay the neurotoxic effects of radiation that are found many years after treatment, thereby perhaps improving the patient's quality of life. There are incidental reports of successful treatment with chemotherapy following radiotherapy; however, no data are available to support these treatments. Chemotherapy is useful if recurrence is documented and surgical biopsy confirms that the tumor has undergone malignant degeneration.

Pilocytic astrocytomas can be treated with surgical removal alone. Radiotherapy should be reserved for patients in whom resection has been incomplete and evidence of tumor progression is found on clinical evaluation and neuro-radiological imaging. Tumors in patients over the age of 20 can behave more aggressively and should be closely monitored. Cranial irradiation and chemotherapy should be considered following surgery in these older patients.

The primary treatment for brain stem gliomas is radiotherapy to the area of tumor. Recent work has suggested that the brain stem may tolerate higher doses of radiation of up to 72 Gy. Early transient clinical deterioration may result from radiation to the brain stem, but this improves with time. [1] Chemotherapy has not been demonstrated to be beneficial, although in anecdotal cases treatment with nitrosoureas alone has been reported to prolong survival. Prolonged survival in some patients may also be caused by misdiagnosis.

Previous studies have not systematically evaluated the neurobehavioral impact of radiotherapy on long-term survivors. A decline in neurocognitive status 3 to 4 years following radiotherapy has been found in children. [1] Patients must be made aware of the risk of late-onset cognitive decline. Astrocytomas in older patients, especially those over age 45, are most likely to represent a poor sampling of heterogeneous tumors. Survival data indicate that these tumors behave like the more malignant gliomas and should be treated aggressively with radiation and chemotherapy as for anaplastic astrocytoma or glioblastoma multiforme.

Patients should be followed closely during the first years after diagnosis to establish the biological behavior of the tumor. To facilitate comparison, radiological scanning should be performed in a standardized manner using exclusively MRI or CT. Neuroradiological imaging may demonstrate a change in the original resection area consistent with either tumor regrowth and malignant degeneration or radiation necrosis. Pathological confirmation is required to resolve this diagnostic ambiguity and to exclude other possible explanations. No reliable predictor is available except histological examination. Radiation necrosis is becoming more common as newer radiotherapy techniques and more refined radiation therapy protocols are developed. Radiation damage is related to total dose, and there has been a shift toward directing the radiation beam more closely to the tumor areas and less to the surrounding normal brain. Higher local doses in excess of 66 Gy to the tumor bed may lead to increased risk of necrosis. Studies have shown that tumor can lie outside radiographically abnormal areas, leading to concern that as radiotherapy protocols attempt to spare the normal areas, the patient may have an increased risk of far-site recurrence. Presently, far-site recurrences are usually present with local-site regrowth of tumor.

People who undergo cranial radiation while taking phenytoin have an increased risk of developing Stevens-Johnson syndrome. [1] Patients have a higher risk of recurrent seizures with gliomas and a higher incidence of side effects with the use of anticonvulsants, especially if seizures were present at the time of discovery of the tumor. [1] Complications of the tumor and its treatment include neurobehavioral decline, an increased risk of cerebrovascular events, and seizures. Seizures should be treated with the appropriate medical therapy. Any sudden change in the frequency of seizures or the occurrence of new neurological findings should prompt re-evaluation with MRI. Occasionally, seizures can become refractory to medication, although the tumor does not progress. In this instance, surgical intervention may be required. Serial examinations should be conducted to determine whether neurobehavioral sequelae of the tumor and its treatment are present. Careful testing may uncover problems early that can be addressed with counseling, training, and an alteration in lifestyle or work environments that may enhance the patient's quality of life. Complications resulting from the tumor and the treatment may indicate a need for prolonged rehabilitation or assisted care.

Prognosis and Future Perspectives. Patients with low-grade astrocytomas may have prolonged survival with surgery and radiotherapy. Five-year survival occurs in about 25 percent of patients with surgery alone and in 50 percent when radiation is added. [15] Patients with pilocytic astrocytomas can be cured with complete surgical resection; 5-year survival in these patients approaches 90 percent. A similar length of survival can be expected in patients with xanthoastrocytomas, whereas those with brain stem gliomas have a poor prognosis with a survival of only months.

Further examination of these tumors with molecular or genetic markers may provide clinicians with information that will allow them to predict which of these tumors will become more aggressive forms, and which treatment strategies can best prevent this progression. Large randomized trials are needed to study the effects of observation versus radiotherapy or even surgery for low-grade gliomas.

Anaplastic Astrocytoma and Glioblastoma Multiforme

Pathophysiology and Pathogenesis. Malignant tumors are thought to evolve from lower grade tumors, although

they can evolve spontaneously, perhaps as the result of abnormalities of gene function. Alteration of one gene may lead to transformation to a low-grade glioma, and subsequent cell division leads to the accumulation of multiple genetic alterations that ultimately result in a tumor with the histological characteristics of a glioblastoma multiforme. Alternatively, a putative glioblastoma multiforme gene may be affected immediately, resulting in a high-grade malignancy. A low-grade astrocytoma that is first diagnosed in a young patient may, many years later, recur as an anaplastic astrocytoma, and then subsequently as a glioblastoma multiforme. In another situation, a glioblastoma may occur in a patient with only a short history of neurological symptoms and a radiographically small tumor.

In recent years, multiple genetic alterations have been associated with malignant gliomas in different stages of malignant progression. These changes involve chromosomal changes in terms of deletion, addition, or duplication, or mutation or amplification of specific genes, as illustrated in [Table 46-3](#). The most frequently observed alterations include deletions in chromosomes 17p, 9p, and 10q as well as multiple copies of chromosome 7. Some changes are specific to certain types of tumor; for example, losses of genetic materials from chromosomes 1p, 9p, 10p, 10q, 11p, 13q, and 17p are often found in astrocytic tumors, whereas deletions in 19q are seen more often in oligodendrogliomas, and those of 22q occur in meningiomas. Mutations of the p53 gene are found in low-grade as well as high-grade gliomas, indicating that they may represent early events in the malignant transformation of normal astrocytes to astrocytic tumors. Alterations of the p16 and Rb (retinoblastoma) genes as well as the loss of chromosome 10 and amplification of the epidermal growth factor receptor (EGFR, *ERBB*) gene are found mostly in glioblastomas, suggesting that these changes are associated with late-stage tumor progression. Other, less frequently observed genetic abnormalities in malignant gliomas include overexpression of the platelet-derived growth factor (PDGF), transforming growth factor (TGF)-alpha and -beta, basic fibroblast growth factor (bFGF), vascular endothelial growth factor (VEGF), insulin-like growth factors I and II, and the *MYC*, *GLI*, *RES*, *FOS*, and *ROS* oncogenes.^{1,2}

The p53 gene encodes a 53-kD protein that functions as a transcriptional factor and is mapped to the short arm of chromosome 17. The wide-type (WT) p53 protein has been shown to have tumor suppression activity, and mutation of the WT gene has resulted in loss of this tumor suppressive

TABLE 46-3 -- MOLECULAR PHENOTYPES IN GLIOMAS

<i>mdm-2</i>	p53	EGF/EGFR
<i>ras</i>	Retinoblastoma (Rb)	PDGF/PDGFR
<i>c-fos</i>	Chromosome 10q and 10p	TGF-alpha
<i>ros</i>	Chromosome 1p, 11p, 19q, 22q	TGF-beta
<i>gli</i>		IGF-I, IGF-II, VEGF

FGF, Fibroblast growth factor; FGFR, fibroblast growth factor receptor; EGF, epidermal growth factor; EGFR, epidermal growth factor receptor; PDGF, platelet-derived growth factor; PDGFR, platelet-derived growth factor receptor; TGF, transforming growth factor; IGF, insulin-like growth factors; VEGF, vascular endothelial growth factor

function, thus increasing the transformation risk of the normal cells. Deletion of the short arm of chromosome 17 (17p13) on which the p53 gene resides has been observed in over 60 percent of malignant astrocytomas. Mutations of p53 are rare in low-grade astrocytomas but are equally common in anaplastic astrocytoma and glioblastomas, suggesting that this p53 mutation may represent an early event in the genesis of glioma. However, other studies have demonstrated a higher frequency of p53 mutations in glioblastomas than in anaplastic astrocytomas. The fact that p53 mutations are detectable in small numbers of cells in a group of low-grade astrocytomas and are more frequently seen in the recurrent high-grade astrocytomas may indicate that the histological progression of low-grade astrocytoma to high-grade anaplastic astrocytoma is associated with clonal expansion of the transformed astrocytes carrying the same p53 mutations. The p53 protein is also a nuclear protein involved in the regulation of cell cycle proliferation. It mediates its growth effect through two major mechanisms: (1) induction of apoptosis, and (2) transient cell cycle arrest at G1 by induction of the p21 WAF1 (Cip1) protein. Furthermore, p53 gene function is inhibited by the oncogene *mdm-2*. Thus amplification of the *mdm-2* protein may result in an alternative pathway for apoptosis independent of p53.

Loss of or deletions associated with chromosome 10 have been observed in high-grade malignant astrocytomas examined by cytogenetic and molecular techniques. Loss of an entire copy of chromosome 10 occurs in 80 to 90 percent of glioblastomas, and approximately 40 percent of these tumors also show amplification of the EGFR gene. Such a high frequency of loss of genetic material involving an entire copy or a large segment of chromosome 10 strongly suggests the presence of one or more than one tumor suppressor gene (TSG) on chromosome 10. This conclusion is partially substantiated by experiments in which a copy of normal chromosome 10 was reinserted into a glioblastoma cell; the resulting hybrid cells showed reversal of the malignant phenotype in vitro and in vivo. The hybrid cells were not able to form colonies in soft agar nor tumors in nude mice.

Epidermal growth factor receptor (EGFR, *ERBB*), a 170-kd glycoprotein, is amplified and overexpressed in 40 to 60 percent of gliomas. About 40 percent of gliomas show increased autophosphorylation activity of EGFR. However, no apparent relationship between amplification of EGFR and tumor grading can be established except that amplification of EGFR occurs almost exclusively in

glioblastomas. Several structurally and functionally altered EGFRs have also been found in approximately 40 percent of gliomas that show amplification of the EGFR gene. One class of mutant EGFR resembles the ERBB oncoprotein and is unable to bind EGF, but its intrinsic tyrosine kinase activity is not fully activated. A second mutant has an 83-amino acid deletion in domain 4, high-affinity EGF binding, enhanced tyrosine kinase activity, and the ability to transduce EGF-mediated glioma cell proliferation. The third mutant, which is seen in about 30 percent of glioblastoma with amplified EGFR, has an in-frame deletion of 267 amino acids in domains 1 and 2 and exhibits low-affinity binding for EGF, which then activates the intrinsic kinase activity. This mutant has been shown to have transformation activity. The fourth mutant is a larger (190-kd) protein that has autoactivated tyrosine kinase activity.

The TGF-alpha gene, which encodes for the 6-kd TGF-alpha peptide, has increased expression in many glioblastomas and anaplastic astrocytomas. TGF-alpha protein can be detected in all tumor specimens tested, and the higher grade tumors show stronger staining with anti-TGF-alpha monoclonal antibodies. In several glioma cell lines, TGF-alpha is cell associated and is not secreted into the medium. Together with EGFR, TGF-alpha forms an autocrine growth mechanism. Moreover, TGF-alpha also has been shown to have angiogenesis activity that is capable of stimulating endothelial cell growth, thus forming small capillaries feeding the tumor.

Vascular endothelial growth factor (VEGF), a 34- to 43- kd dimeric glycoprotein, induces endothelial cell proliferation, angiogenesis, and capillary permeability. Three mRNA forms are produced by alternative splicing and code for three protein products, VEGF₁₈₉, VEGF₁₆₅, and VEGF₁₂₁. VEGF, as opposed to EGF, is mitogenic specifically for tumor endothelial cells that display increased expression of VEGF receptors, suggesting that VEGF acts as the mediator for tumor angiogenesis. VEGF has also been shown to increase capillary permeability, suggesting that it may play an important role in tumor-induced edema. Because increased tumor vascularity and peritumoral edema are key features of high-grade astrocytomas, and because VEGF plays a unique role in angiogenesis and edema, it is especially important to understand VEGF's role in glioma transformation and progression.

Fibroblast growth factors (FGFs) are a family of heparin-binding proteins that express both mitogenic and angiogenic properties. Elevated levels of aFGF and bFGF are expressed in human glioma cells. More recently, elevated levels of bFGF and bFGF-receptor have been described in a human glioma cell line in which the influence of endogenously excreted bFGF on cellular proliferation is downregulated by antisense oligonucleotide primers. Immunostaining experiments have also demonstrated elevated levels of bFGF in glioma cells as well as endothelial cells in all glioma specimens tested.

The p16 gene, also known as the MTS1 gene, is localized to the 9p21 region. It is a potent inhibitor of the cyclin-dependent kinases 4 and 6 (cdk4 and cdk6) and is often mutated and deleted in a variety of human cancers including gliomas. The p16 protein functions by forming a complex with D1 cyclin and prevents D1 cyclin and cdk4 from forming a phosphoprotein complex, thus paralyzing the activation of the retinoblastoma (Rb) gene and resulting in a G1 blockade. A mutation or deletion of the p16 gene allows formation of an active Rb protein, thus allowing cells to proceed through the normal cell cycle and maintain continued proliferation.

Mutations of the Rb gene, a well-characterized tumor suppressor gene, have been reported in 20 to 30 percent of malignant gliomas. They usually are associated with glioblastomas, suggesting that alteration of the Rb gene represents a late event. Hypophosphorylated Rb protein is essential to allow cells to remain in G1 without entering mitosis and proceeding to the G2 to M phases. Mutation and deletion of the Rb gene renders this critical step inactive and allows cells to continue to go

through proliferation.

Epidemiology and Risk Factors. Malignant astrocytomas, including anaplastic astrocytoma and glioblastoma multiforme, are seen more often in adults and are characterized by a shorter survival time than low-grade astrocytomas. They constitute over 50 percent of all malignant tumors diagnosed and are the third most frequent type of cancer in the 15- to 34-year-old age group and the fourth most frequent in the 35- to 54-year-old age group. Incidence increases with age, especially after 50 years, and a higher frequency of glioblastoma multiforme than anaplastic astrocytoma is seen in successive decades. Malignant astrocytomas arise primarily in the frontal lobes and cerebral hemispheres. Anaplastic astrocytomas are differentiated from astrocytomas by histological evidence of increasing cellular atypia and nuclear pleomorphism. The addition of necrosis labels the tumor as glioblastoma multiforme.

Clinical Features and Associated Disorders. Symptoms of these high-grade tumors can arise gradually, reflecting the manner of evolution of astrocytomas. More often, immediate symptoms are found, such as seizures (either focal or generalized), speech disturbances, a change in or increasingly severe headache, vomiting, nausea, visual disturbances, and weakness or sensory disturbances. Careful interviews with the patient or family members may lead to the unappreciated discovery of neurobehavioral symptoms. Elderly patients may have memory loss, suggesting dementia. Occasionally, older patients present with a sudden onset of focal neurological findings that are believed to be a vascular event. Neuroradiographic imaging abnormalities (often CT performed without contrast dye) are consistent with a vascular distribution, leading to a mistaken diagnosis of stroke. However, instead of improving, these patients often continue to deteriorate. Such patients should be re-evaluated with MRI performed with gadolinium. Malignant gliomas are considered to have no definite hereditary association. There are case reports of family members who have had similar tumors in an autosomal dominant fashion, and studies have found a familial association in 7 percent of cases.^[17] Turcot's syndrome is a genetic disease in which gastrointestinal adenomatous polyps and primary brain tumors, including gliomas and medulloblastoma, are combined. It is dominantly inherited and has been associated with the gene for familial adenomatous polyposis and should be considered a variant. Gliomas are also associated with neurofibromatosis (see subsequent discussion) and tuberous sclerosis.

Differential Diagnosis. Patients with malignant astrocytomas have a differential diagnosis similar to that listed

for astrocytomas. Practitioners must be aware that a definitive diagnosis cannot be made on the basis of the neuroradiological evaluation alone. It is essential to obtain tissue diagnosis by surgical resection or biopsy when feasible. The main differential is between an abscess and a malignant tumor (either a primary brain tumor, lymphoma, or metastasis). Because of the increasing number of multifocal gliomas, the presence of multiple lesions does not always indicate metastatic disease from a systemic cancer.

Evaluation. Patients often present with a single lesion. Physicians may be tempted to undertake an extensive search for a primary cancer elsewhere that is often unfruitful, ultimately requiring resection of the lesion. Patients with large lesions that are amenable to resection should undergo a complete neurological and physical examination with rectal examination and stool guaiac analysis (including a pelvic examination in women and a testicular examination in men), complete blood count, serum chemistries, coagulation profile, chest x-ray, and MRI of the brain with high-dose gadolinium (Fig. 46-4). If no other lesions are seen, biopsy and surgical resection are indicated to determine the pathological diagnosis. Even if the tumor is found to be metastatic, resection of a single metastasis has been shown to prolong survival.^[18]

Comprehensive neurobehavioral studies can be performed prior to surgery to determine pretreatment deficits. After surgery, re-evaluation may be indicated to define areas of improvement and provide a baseline before further therapy is undertaken. These studies can help patients and their families define those areas that may be a problem for the patient. Such studies can help as the patient begins to adjust to daily living at home, and they can also increase the ease of patient care. Recent data documenting the risk

Figure 46-4 MRI picture of a glioblastoma multiforme demonstrating a large contrast-enhancing left temporal lesion with irregular border, as well as a central lucency suggesting an area of necrosis.

of cognitive impairment after surgery have not shown that significant worsening occurs. Indeed, in some patients, surgical debulking may improve cognitive status as well as other neurological symptoms and signs of disease.

Management. Patients are often treated with steroids, usually dexamethasone, immediately on discovery of a lesion in the brain. Unless the patient is in danger of herniation or has another serious problem that specifically requires steroids, such treatment is not indicated. Cases of primary CNS lymphoma in patients without acquired immune deficiency syndrome (AIDS) have increased in frequency (see later discussion). Dexamethasone can be oncolytic to some tumors, especially leukemias and lymphomas, leading to resolution of lesions and causing diagnostic confusion. Therefore, we favor delaying the use of steroids until after the tumor has been evaluated but before surgery. Dexamethasone is the steroid of choice because it is a glucocorticoid with no mineralocorticoid activity and has better CNS penetration than other steroid preparations. Occasionally, patients with large lesions may require dexamethasone for several days before surgery. After surgical debulking has been performed, steroids can be rapidly tapered. Radiation oncologists often maintain patients on low doses of dexamethasone throughout radiotherapy, usually 2 to 4 mg a day. H₂ blockade is routinely given with steroids to prevent ulcers, although some believe the risk of ulceration is not sufficiently high to warrant its use. After radiotherapy is complete, steroids can usually be stopped by gradually tapering the dose.

All patients in whom the tumor has been diagnosed pathologically require surgical intervention. Recently, there has been an increase in the use of limited surgery with stereotactic biopsy. In patients in whom mass lesions can be safely removed, maximum surgery is indicated. Small biopsies may not provide sufficient tissue to allow accurate neuropathological interpretation, leading to incorrect therapeutic intervention. All patients should be offered treatment in clinical trials whenever possible. The advent of computer listings of available studies on the Internet may facilitate enrollment in these studies.

The use of anticonvulsant medications prophylactically in patients with newly discovered mass lesions remains controversial. There are no studies that allow a direct answer to the question of whether patients are at increased risk of seizures. This question is complicated by the fact that virtually all patients undergo surgical decompression or biopsy and are given anticonvulsants at that time. We do not routinely administer anticonvulsants until a patient has sustained a seizure. Certainly, any patient presenting with seizures should be so treated.

Cranial radiation following surgery remains the mainstay of treatment. Maximum radiation dose of 6000 to 6500 cGy is recommended. Recent radiotherapy techniques involve the application of approximately 4600 cGy to a larger field with a 2- to 3-cm margin encompassing the contrast-enhancing tumor, and an additional 2000 cGy delivered to a reduced field encompassing only the contrast-enhancing abnormality. Irradiation to the brain during pregnancy has been shown to be feasible with minimal risk to the fetus.^[19] Brachytherapy, in which radioactive seeds are applied into the tumor area, has been shown to be beneficial in some patients with glioblastoma multiforme. Unfortunately, this

technique yields substantial morbidity; the high risk of radiation necrosis necessitates reoperation in approximately 50 percent of patients undergoing interstitial brachytherapy. It is useful only in a limited number of patients with polar tumors. Stereotactic radiation may increase survival in those patients with radiosensitive tumors^[20]; however, neither the neurobehavioral effects of this treatment or randomized studies have been reported. Effects of radiation include hypersomnolence during treatment and cognitive dysfunction. These effects are more commonly seen in patients with prolonged survival after radiotherapy.

Chemotherapy regimens continue to evolve and have produced improvement in the overall time of tumor progression and patient survival. The standard treatment includes the use of nitrosourea-based regimens such as carmustine (BCNU) alone or the triple drug regimen of lomustine (CCNU), procarbazine, and vincristine (PCV).^[21] Salvage chemotherapy regimens with agents such as carboplatin, VP16, procarbazine, interferons, and diaziquone (AZQ) produce mixed results, but some responses occur. The efficacy of chemotherapy declines with patient age.^[22] Blood-brain barrier disruption agents, carotid artery infusion, and combination therapy with multiple agents have not demonstrated overall benefit. An analysis of the changes in normal biological function or chromosomal aberrations occurring in tumor cells and their response to chemotherapy is under way.^{[23], [24]}

Prognosis and Future Perspectives. Overall, prognosis is related to histological diagnosis, age, performance status, and treatment. Patients who receive more complete surgical resection tend to survive longer. Follow-up resection after tumor regrowth also prolongs survival and increases overall well-being in many patients.

Median survival for patients with a glioblastoma multiforme, without accounting for age, is approximately 1 year. Patients with anaplastic astrocytoma have a life expectancy of 3 to 5 years. Prolonged survival with diagnosis of a malignant glioma can occur but may suggest incorrect pathological diagnosis of tissue type. In a review of patients entered in Radiation Therapy Oncology Group (RTOG) studies, histology was the most important determinant of survival for patients younger than 50 years of age, whereas performance status was the most important variable for patients over age 50.^[25]

Clinical trials have to be conducted to better define the effects of treatment, including surgery, radiotherapy, and chemotherapy. Accrual of all brain tumor patients into clinical studies stands at 10 percent. Careful analysis and evaluation of all patients with these tumors is needed. Recent concerns have been raised about possible enrollment bias.^[26] Newer imaging techniques must be developed to better evaluate both the disease and the treatment response. Positron emission tomography has not been demonstrated to separate reliably the tumor from the treatment effects. Recent phase I studies of gene therapy for these tumors have been initiated, and results have demonstrated infrequent short-term responses. The combination of gene therapy with other modalities, including concomitant chemotherapy, remains to be studied.

Oligodendroglioma and Oligoastrocytoma

Pathogenesis and Pathophysiology. Because these tumors arise from oligodendrocytes, they usually occur in the white matter of the cerebrum, and because there are relatively more oligodendrocytes in the frontotemporal area, oligodendrogliomas have a predilection for these areas. Usually surgical specimens contain areas that are identifiable as astrocytoma. Increasing difficulty in the diagnosis of these tumors centers on the percentage of oligodendro-glioma cells needed to categorize these tumors as pure oligodendrogliomas rather than mixed oligodendroglioma-astrocytoma (oligoastrocytoma). The grading system of Smith^[27] has been used by most neuropathologists for the histological categorization of oligodendroglioma. Only necrosis has been found to be a predictor of biological behavior; mitotic activity apparently becomes more important with advancing age.^[28] On microscopic examination most tumors show tumor cell infiltration into the cortex, and many tumor cells show an artifactual halo around the nucleus (the so-called fried-egg appearance). A delicate vascular pattern is also a prominent feature ([Fig. 46-5](#)).

Epidemiology and Risk Factors. Oligodendrogliomas occur most commonly in young adults. Peak incidence occurs in the third to fifth decade, and the tumor occurs predominantly among men. There are no known established risk factors. Recent epidemiological work has suggested that gliomas may be associated with repeated exposure to high-voltage electrical lines. These tumors have a poorer prognosis with age. Although typically considered to represent about 2 percent of intracranial primary tumors, recently the incidence has been increasing owing to changes in neuropathological diagnostic criteria. For example, at the University of Iowa, 25 patients were diagnosed with oligodendroglioma from 1961 to 1991, whereas from 1992 to 1995, 48 such diagnoses were made.

Clinical Features and Associated Disorders. Because of their infiltrative nature, oligodendrogliomas commonly cause seizures. Occasionally, patients with medically refractory seizures who undergo surgical abolition are found to have an oligodendroglioma. These tumors can infiltrate and surround the neuronal networks without causing loss of function until they achieve a rather large volume. Retrospectively, subtle neurobehavioral changes can be detected long before the tumor is discovered. As with other gliomas, patients may also present with symptoms of hydrocephalus,

Figure 46-5 Histopathological picture of an oligodendroglioma; nuclei are surrounded by swollen, clear cytoplasm, demonstrating a "fried-egg" appearance, and fine vascular channels.

headache, and sudden focal neurological findings consistent with acute hemorrhage into the tumor. There is also a higher risk of dissemination through the cerebrospinal pathways resulting in spinal cord or patchy symptoms within the neuroaxis, which are sometimes confused with metastatic disease.^[29] Rarely, oligodendrogliomas can metastasize outside the central nervous system.

Differential Diagnosis and Evaluation. Evaluation of oligodendrogliomas is the same as that discussed earlier for astrocytomas and glioblastoma multiforme. The differential diagnosis for oligodendroglioma and oligoastrocytoma is similar to that for astrocytomas. Since oligodendrogliomas are more often non-contrast-enhancing on MRI scans, they may be confused with low-grade gliomas. With CT imaging, hypodense areas may also cause confusion with stroke or gliosis. Oligodendrogliomas are commonly found to have calcium deposits, and in many cases, contrast-enhancing areas are also found in the lesions on CT imaging. However, patients should undergo MRI to better define the areas of tumor involvement. Surgical diagnosis and attempts to achieve maximum cytoreduction are mandatory. Small stereotactic or open biopsies may lead to a misdiagnosis of astrocytomas, thereby affecting subsequent radiotherapy and chemotherapy treatment of these tumors.

Management. Neurological problems such as seizures should be treated with appropriate medications as discussed earlier for astrocytomas. Patients should be monitored closely for tumor regrowth or dissemination within the neuroaxis. The treatment of these tumors has become increasingly controversial. Some believe that these tumors are biologically less aggressive and can be observed with serial imaging until tumor growth is apparent either clinically or radiographically. Others believe that all oligodendrogliomas should be treated with radiation after histological confirmation. A large study at Duke University has suggested that radiotherapy may not benefit patients with oligodendrogliomas.^[30] Recent studies have also suggested that anaplastic oligodendrogliomas are more responsive to chemotherapy and should be treated with PCV in addition to radiation, especially for Smith grade B, C, and D lesions.^{[31][32][33]} Others have suggested that although chemotherapy for these oligodendrogliomas before radiotherapy may be harmful, this combination of chemotherapeutic agents is beneficial for patients with oligoastrocytomas.^[34] Finally, some reports have appeared of treatment with chemotherapy alone for patients who have a more benign appearing histological diagnosis.^[35] An ongoing RTOG study of anaplastic oligodendrogliomas randomized between radiotherapy alone and chemotherapy with PCV followed by radiotherapy may shed further light on this discussion. Until better information is available, every effort should be made to enroll all patients in clinical studies.

Prognosis and Future Perspectives. Patients with oligodendrogliomas presenting with seizures seem to survive longer, possibly due to earlier discovery of the tumor. Reported overall median survival ranges from 5 to 10 years depending on the study, the reporting period, and the treatment regimen. Survival statistics will probably change as the diagnostic criteria continue to evolve. Survival for patients with oligoastrocytomas is similar to that for patients with anaplastic astrocytomas. Better neuropathological criteria for diagnosis of these tumors and higher enrollment of patients into clinical trials will provide better and more timely data on the optimal treatment for these tumors. As molecular definitions of these tumors are further refined, we may begin to base treatment of these tumors less on histological criteria and more on the presence of genetic abnormalities.

Ependymoma

Pathogenesis and Pathophysiology. There are no known risk factors for these tumors. Ependymomas arise from ependymal cells lining the ventricles and the spinal cord central canal. Histologically, ependymomas are well demarcated from the surrounding structures and are marked by pseudorosettes, often located in the perivascular region. Blepharoplasts, intracellular structures associated with cilia formation, are also present. Anaplastic ependymomas have increasing features of nuclear atypia, necrosis, and mitotic figures. Myxopapillary ependymomas are usually confined to the filum terminale and have a distinctive fibrillary pattern with mucin secretion.^[36]

Epidemiology and Risk Factors. Ependymomas represent less than 5 percent of all intracranial tumors. They occur in younger patients, usually in children, with a slight predominance among young men, although they can present in adults up to 30 years of age. An infratentorial location is more common in children, whereas supratentorial ependymomas are more common in adults. Cerebrospinal fluid dissemination and systemic metastasis can occur.

Clinical Features and Associated Disorders. Patients with ependymomas have symptoms corresponding to the part of the neuroaxis affected by the tumor. For example, tumors arising in the spinal cord can lead to localized back pain, sensory disturbances with a demonstrated dermatomal line, weakness of both legs, or disturbances of bowel or bladder control. Ependymomas arising in the fourth ventricle, brain stem, or lateral ventricles can present with evidence of headaches or other symptoms of hydrocephalus (especially nausea and vomiting), ataxia, and increasing head circumference. Neck pain and behavioral changes also are common presenting complaints in children. Because ependymomas may be present for as long as 3 to 6 months before they come to clinical attention, symptoms may sometimes be labeled chronic.

Differential Diagnosis and Evaluation. The differential diagnosis of these tumors includes other CNS tumors such as medulloblastoma and low-grade glioma. Other more benign lesions such as meningioma do not have similar characteristics on MRI. Patients require surgical intervention when this tumor is diagnosed

pathologically. Prior to surgery, the entire neuroaxis should be imaged with gadolinium-MRI to determine involvement of other sites such as "dropped" metastasis. The resection attempt should be as extensive as possible, but occasionally this is not feasible. At least 2 weeks following surgery and before radiotherapy, the cerebrospinal fluid should be evaluated for seeding of the cerebrospinal pathways with tumor cells.

Management. After surgery radiotherapy is the mainstay of treatment for patients with residual tumor.^[37] Craniospinal irradiation is often given to treat clinically undetected

seeding of cerebrospinal spaces. In patients with negative cerebrospinal fluid examination after surgery, this is not indicated because it may hamper future treatment of localized recurrence. Myxopapillary ependymomas can often be cured with complete surgical resection. Chemotherapy has been shown to be of minimal benefit in patients with anaplastic ependymoma, although chemotherapy regimens including carboplatin and etoposide have been shown to prolong survival in several small series.^[38] The use of craniospinal irradiation results in extensive treatment of the vertebral bone marrow, leaving little reserve for the cytotoxic chemotherapy. With newer cytokines such as the colony-stimulating factors that stimulate bone marrow function, patients may be able to tolerate more chemotherapy, allowing better appraisal of its use in these patients. Recurrence is usually local, although patients can develop distant metastasis. An increased risk of recurrence is associated with incomplete resection. Surgical resection, if feasible, should be strongly considered when the tumor recurs, followed by conventional radiotherapy to previously nonirradiated areas. Salvage chemotherapy also remains an option at recurrence.

Prognosis and Future Perspectives. Survival may be increased in patients who undergo resection of tumor and radiotherapy. Overall survival is similar to that for low-grade gliomas or oligodendrogliomas. Patient age of less than 5 years and a posterior fossa location of the tumor suggest a worse outcome. No histological predictors of survival are available at this time. Future improvements in therapy can be expected with better understanding of the histological variants, application of radiotherapy and chemotherapy to more malignant subtypes of these tumors, and a better understanding of the molecular basis of tumor pathogenicity.

Medulloblastoma

Pathogenesis and Pathophysiology. Almost two thirds of these tumors are located in the midline cerebellum, and over 90 percent are located in the vermis with encroachment on the cisterna magna. Laterally placed tumors are more common in adults. The macroscopic appearance is that of a soft friable tumor with central necrosis. In children, these tumors are moderately demarcated, but in adults they are highly demarcated. Microscopically, neuropathological analysis has attempted to define these tumors as a subset in a larger category termed primitive neuroectodermal tumors (PNET).^[39] This classification stems from the belief that these tumors result from the germinal neuroepithelium during embryogenesis and thus can differentiate into tumor cells with neuronal, glial, or ependymal characteristics. Medulloblastomas are often classified as small blue cell tumors with little cytoplasm and pseudorosettes, which may signify neuronal differentiation (Fig. 46-6). A desmoplastic variant has been proposed for tumors in adults and may signify a different cell of origin.

Epidemiology and Risk Factors. Medulloblastomas are usually located infratentorially, accounting for approximately 2 percent of all CNS tumors in adults and 25 percent of intracranial tumors in children, second only to

Figure 46-6 Histopathological picture of a medulloblastoma, showing primitive, undifferentiated tumor cells with numerous neuroblastic (Homer-Wright) rosettes.

cerebellar astrocytomas. Although 50 percent of medulloblastomas are seen in children in the first decade of life, approximately 25 percent occur in patients over the age of 18. Tumors diagnosed in the seventh decade of life have been reported. There is a small second peak in incidence in patients 20 to 25 years of age. Interestingly, there seems to be a seasonal variation, with higher incidences in children born during the winter months and in those with congenital cerebral defects, possibly suggesting that these tumors are a remnant of embryonic dysfunction. Familial cases are known, including four cases in monozygotic twins, although there is no proven familial association. An association with leukemias and other CNS tumors, such as glioblastoma multiforme in first-degree relatives, has been noted.

Clinical Features and Associated Disorders. Patients often present with subtle problems that evolve over extended periods of time. In some patients, symptoms can exist for over 3 months before the tumor is diagnosed. The most common complaints include symptoms of increased intracranial pressure such as headache (especially in the morning) and vomiting. In younger children, behavioral changes such as decreases in activity or appetite may exist. Examination may demonstrate papilledema, truncal or limb ataxia, or nystagmus. A few patients have an increased head circumference or symptoms of leptomeningeal seeding similar to that seen in metastatic meningitis. There is a higher incidence of medulloblastoma in patients with nevoid basal cell syndrome, Turcot's syndrome, ataxia telangiectasia, and xeroderma pigmentosa.

Differential Diagnosis and Evaluation. The differential diagnosis for these tumors includes other primary CNS tumors such as ependymomas or gliomas, as discussed earlier, or metastatic tumors. Although CT scans are more readily available and may reveal evidence of hydrocephalus, all patients should undergo MRI with gadolinium. Occasionally, subarachnoid seeding is evident on initial imaging. CT or MRI scans usually demonstrate a hypodense mass with variable heterogeneous enhancement. Patients often present with evidence of obstructive hydrocephalus that requires immediate neurosurgical intervention such as shunting. Often conservative management with corticosteroids

allows surgical planning, and some reports suggest that shunting should not be performed if at all possible. Some believe that midline lesions are more commonly medulloblastomas whereas hemispheric lesions are more often astrocytomas, but histological confirmation is mandatory. Gross total resection of tumor should always be the goal.

Management. Once the diagnosis has been established, patients should receive craniospinal MRI with gadolinium enhancement to study the entire neuroaxis for tumor dissemination. This also allows examination of the resection bed without worry about postoperative enhancement caused by the surgery. If MRI of the spine is contraindicated, myelography can be performed. Patients should undergo cytological evaluation of cerebrospinal fluid at least 2 weeks after surgery. Although medulloblastomas have been known to spread outside the nervous system, especially to the bone and lungs, staging with bone marrow biopsy and imaging of the chest or radioactive bone scan should be performed only when such spread is clinically suggested. Reoperation should be considered at the time of tumor regrowth.

Patients have an increased risk of recurrence if gross total resection was not possible, if they are less than 4 years old, or if the tumor has a lateral location, evidence of cerebrospinal fluid dissemination, or a differentiated cellular histological appearance. Those patients younger than 18 months should undergo chemotherapy alone, whereas older patients should receive both radiotherapy and chemotherapy. Patients without the features just mentioned are considered to have a decreased risk of recurrence and can receive craniospinal irradiation and observation, with chemotherapy given only with evidence of recurrence.

Radiotherapy remains the mainstay of postsurgical treatment. Typically, craniospinal irradiation with increased doses to the tumor bed is performed because undetected tumor may be disseminated in the spinal cord. Recent advances in chemotherapy include the use of CCNU, carboplatin, and vincristine.^[40] Treatment failure is usually evident at the original site alone; cerebrospinal dissemination may occur, or systemic involvement may be seen in a later stage. Almost half the patients show evidence of cerebral hemispheric involvement at recurrence. Refinements in radiotherapy may increase the incidence of systemic dissemination at relapse.^[41]

Neurobehavioral abnormalities such as mutism, pseudobulbar affect, or derangements of eyelid opening have been documented in children undergoing posterior fossa tumor resection.^[42] These usually resolve within months of surgery. Patients may have problems with cerebrospinal fluid drainage, requiring shunting. Children are at risk of decline in intellectual performance related to radiotherapy and possibly chemotherapy, especially if they are younger than 7 years old. Endocrinological problems resulting from pituitary failure, including delay of puberty, may be seen. Children who survive for a long time display decreases in perceptual motor tasks, manual dexterity, learning, and physical growth and development.^[43]

Prognosis and Future Perspectives. Medulloblastoma seems to follow Collin's law that the risk of recurrence of tumor is highest during the period equal to the patient's age at diagnosis plus 9 months.^[44] Survival is correlated with the extent of surgical resection for those over the age of 3 in whom dissemination is absent.^[45] Five-year survival can occur in nearly 75 percent of patients who undergo high-dose craniospinal irradiation after gross total resection. Survival is poorer in patients

younger than 5 years of age. Adults seem to have the same survival duration as children. [46]

Primary CNS Lymphoma

Pathogenesis and Pathophysiology. The reason for the increase in primary CNS lymphoma (PCNSL) in the immunocompetent and immunocompromised population is unknown. Because there are no lymphatics in the CNS, the mechanism for neoplastic transformation remains unknown. Viral causes have been suggested. In studies of AIDS-related PCNSL, the Epstein-Barr virus was found in a majority of cases, [47] but this was not found in samples analyzed from immunocompetent patients. Herpes virus type 6 has also been proposed as a causative agent. PCNSL is considered a non-Hodgkin's lymphoma, usually of B-cell origin, with a high-grade diffuse large cell, immunoblastic, or lymphoblastic type. T-cell PCNSL has been reported but is rare. Microscopically, the tumors aggregate near blood vessels and may provoke a normal reactive immune response. The tumor cells stain positive for appropriate immunohistological B-cell or T-cell markers. In the older literature, PCNSL was described as a reticulum cell sarcoma because the tumor stroma stained positive for reticulum.

Epidemiology and Risk Factors. The incidence of PCNSL has shown a three- to fivefold rise during the last 20 years. [48] Because the treatment for PCNSL is vastly different from that for malignant gliomas, clinicians should always keep the diagnosis of PCNSL in mind during the evaluation of a patient with a new cerebral lesion. The peak incidence occurs in the fifth and sixth decades, there is a slight predominance in men, and the tumor is commonly associated with immunodeficiency states such as that of AIDS, that caused by immunosuppressive therapy for organ transplants, and other genetic immune deficiency states.

Clinical Features and Associated Disorders. Patients with PCNSL commonly present with focal findings or evidence of elevated intracranial pressure. Those patients with frontal lesions or the elderly may have additional neurocognitive changes that are sometimes confused with a dementing process. Because PCNSL is located more often in the white matter, seizures are common, especially in immunocompromised patients. Although ocular involvement is common, only occasionally do patients have ocular complaints such as blurred vision combined with identification of cells in the vitreous.

The highest incidence of PCNSL is found in the immunocompromised population, especially those infected with human immunodeficiency virus (HIV), the virus that causes AIDS. In this population it is the most common intracranial lesion of noninfectious origin. PCNSL is also found in other immunologically compromised patients including those with genetic immunocompromise such as the

Wiskott-Aldrich syndrome and those with treatment-related conditions such as immunosuppressive agents taken for renal transplants.

Differential Diagnosis. The differential diagnosis for PCNSL includes primary gliomas, demyelinating processes such as multiple sclerosis, or acute encephalomyelitis. In the immunocompromised population toxoplasmosis, progressive multifocal leukoencephalopathy, or other infectious causes should also be considered.

Evaluation. Neuroradiologically, PCNSL may be missed on CT; hence MRI is the imaging modality of choice. Because PCNSL is often densely cellular and highly vascular, lesions usually enhance brightly on MRI with gadolinium, although exceptions have been reported in the literature. In the non-AIDS population, lesions are usually multifocal and periventricular in location. Immunocompromised patients are more likely to have single lesions, which are often confused with those of toxoplasmosis, and radiographically they have a higher incidence of necrosis with the appearance of ring enhancement. Edema is usually minimal. Leptomeningeal spread of PCNSL is present in more than a quarter of patients. Cytological examination of spinal fluid in patients in whom lumbar puncture can be performed is mandatory. Spinal fluid should be evaluated for the concentration of beta-2 microglobulin and compared to serum levels as a marker of disease. Slit-lamp evaluation can sometimes provide diagnosis of vitreous or choroid involvement.

Because steroids can be oncolytic and can change the appearance of PCNSL on CT or MRI scans, patients should not be given steroids before diagnostic studies have been completed whenever possible. A marked reduction in tumor size and contrast-enhancing pattern occurs shortly after steroid therapy is initiated. All immunocompetent patients should undergo biopsy for pathological confirmation of disease. Although neurosurgical intervention with maximum cytoreduction is favored in patients with malignant gliomas, in those with PCNSL, which is very sensitive to radiotherapy and chemotherapy, stereotactic biopsy for tissue confirmation is a reasonable option. However, because of concern about the disease and the lack of identifying markers to separate PCNSL from malignant gliomas, open biopsy and tumor resection is usually performed. Once the diagnosis of PCNSL has been established, further resection is not warranted.

Figure 46-7 MRI picture of a patient with primary CNS lymphoma (HIV negativ). Left, Before therapy; right, after 6 months of therapy with preradiotherapy methotrexate, procarbazine, vincristine, and dexamethasone, followed by radiotherapy and postradiation Ara-C.

In the AIDS population, stereotactic biopsy is the rule. In AIDS patients in whom a single lesion is seen on MRI, treatment is often first performed with antitoxoplasmosis agents. Patients who are unresponsive to treatment, as evidenced by clinical or radiographic deterioration, then receive biopsy. Patients with multifocal disease and negative toxoplasmosis antibody titers should undergo biopsy. Occasionally, some patients may harbor both toxoplasmosis and lymphoma.

Management. After the diagnosis has been confirmed, patients should have a complete neuroradiological evaluation of the spinal cord with gadolinium-enhanced MRI. If not performed previously, a full ophthalmological evaluation and cytological examination of cerebrospinal fluid are also required. Because systemic lymphomas spread into the CNS in approximately 10 percent of patients, the initial evaluation should include a complete physical examination, chest x-ray, abdominal CT, routine serum chemistries, and complete blood count to rule out systemic lymphoma. Further evaluation such as bone marrow biopsy or lymphangiograms is usually not necessary because the diagnostic yield is low.

Treatment of PCNSL includes the use of steroids, which may produce a significant decrease in tumor burden. [49] Radiotherapy alone has produced little overall increase in survival beyond 12 months [50] and is no longer appropriate except in patients with AIDS or other immunocompromised states. Routine treatment now includes chemotherapy, both intrathecally and systemically, followed by radiotherapy. Chemotherapy has been shown to markedly improve survival, especially when methotrexate is included (Fig. 46-7). In 1992, DeAngelis and colleagues reported that a regimen that included intrathecal and systemic methotrexate, procarbazine, vincristine, and Decadron followed by radiation therapy and subsequent treatment with systemic ara-C yielded an increase in median survival of 41 months compared with 10 months for patients receiving radiotherapy alone. [51] Other reports of preradiation treatment with high-dose methotrexate have provided similar results. [52] There have been reports that radiotherapy followed by the PCV chemotherapy typically used for malignant gliomas may also induce remission. [53] Methotrexate following radiotherapy should be avoided because it is associated with an increased risk of treatment-related encephalopathy. Occasionally, ocular deterioration requires

directed radiotherapy to the orbit. Immunocompromised patients with AIDS should receive whole brain radiotherapy. Craniospinal radiotherapy should be avoided in patients with localized disease.

Prognosis and Future Perspectives. Survival of patients with PCNSL who receive no treatment except surgery is poor, usually only several months. Radiotherapy alone can extend survival to about 1 year. Chemotherapy combined with radiation therapy can extend survival to about 3 to 4 years. Future work should examine the response of this tumor to various combinations of chemotherapy. An interesting issue is the study of whether radiotherapy should be performed only at relapse or at the failure of chemotherapy. Further examination of the origins of this tumor and a study of the pathological parameters related to treatment response may offer more information that can be used to direct management.

NERVE SHEATH TUMORS

Acoustic Schwannoma and Trigeminal Neurilemmoma

Pathogenesis and Pathophysiology. Acoustic neuromas, found incidentally on imaging performed for other reasons or due to new symptoms as described below, have a variable course. Less than 10 percent have a familial association. There appears to be no association with unilateral acoustic neuromas or with either form of neurofibromatosis. Some investigators have tried to examine the growth rates of these tumors by performing serial neuro-imaging of the tumors to gauge their growth. Some suggest that the female predominance of these tumors indicates a sex hormonal influence.

Epidemiology and Risk Factors. Neuromas (schwannoma and neurilemmoma) are benign tumors that usually involve the sensory and motor cranial nerves, most commonly the eighth, fifth, and seventh cranial nerves. Neuromas represent about 10 percent of all intracranial tumors, the majority being acoustic neuromas. They present most frequently in the fourth and fifth decades of life, predominantly among women. Except for bilateral acoustic neuromas, which are pathognomonic for neurofibromatosis II (see subsequent discussion), they are usually unilateral.

Clinical Features and Associated Disorders. Acoustic neuromas are considered slow growing, but they grow in a physiologically eloquent area, the cerebellopontine angle, thus leading to subtle complaints that may evolve slowly over many years. Symptoms may progress slowly, although sudden presentations can be seen. Patients usually present with hearing loss (especially sound discrimination), tinnitus, loss of balance, nystagmus, loss of facial sensation, or loss of function of the facial muscles or the muscles of mastication. Pain is uncommon but may sometimes mimic trigeminal neuralgia. Cerebellar findings such as ataxia and gait abnormalities may be noted when extremely large tumors have extended into the cerebellum. In patients with trigeminal pain multiple sclerosis may be diagnosed initially; only with further hearing loss and a lack of involvement of other areas of the nervous system will re-evaluation be conducted. Meningiomas are occasionally confused with neuromas. Rarely, cholesteatomas or choroid plexus papillomas are identified at surgery.

Evaluation. Sometimes early neuroradiological examination may fail to detect these tumors. Patients with increasing symptoms that are not amenable to medical treatment may require repeat studies. MRI with gadolinium enhancement remains the imaging modality of choice because it permits better definition of soft tissue involvement and identification of alternative diagnoses. Neuromas most often demonstrate bright enhancement with contrast agents. CT is performed to evaluate bony erosion of the skull. All patients should undergo audiometry and brain stem auditory evoked potentials at presentation to define pretreatment abnormalities.

Management. Surgical removal remains the mainstay of treatment. Recent reports have focused on the use of stereotactic irradiation or gamma knife surgery. No large series are available to compare their efficacy with that of surgery alone. After surgery patients are at risk of hearing loss and facial nerve paralysis. In patients with smaller tumors, hearing can sometimes be preserved. Radiotherapy has been shown to delay tumor regrowth after subtotal resection but carries a risk of radiation damage to other cranial nerves and brain stem vascular events. Chemotherapy has so far not been sufficiently explored.

Neurofibroma

Pathogenesis and Pathophysiology. Both types of neurofibroma are associated with a gene localized to chromosome 17q11.2 for NFI^[54] and to chromosome 22 for NFII. The NFI gene encodes a protein termed neurofibromin that is involved in regulation of the RAS protein.

Epidemiology and Risk Factors. Neurofibromatosis (NFI), also known as von Recklinghausen's disease, comprises a constellation of tumors of the CNS. NFII is defined by bilateral acoustic neuromas. Patients with NFI have an increased risk of astrocytic tumors including optic pathway glioma and brain stem gliomas. Patients with NFII are at risk of ocular abnormalities, other cranial nerve schwannomas, and meningiomas. Spinal cord gliomas are seen more commonly in those with NFII. NFI has a frequency of about 1 in 4000, and the frequency of NFII is 1 in 40,000. Both are inherited as autosomal dominant traits, with NFI having incomplete penetrance (see [Chapter 32](#)).

Clinical Features and Associated Disorders. In NFII the bilateral acoustic neuromas usually become evident at the same time. Presenting complaints include tinnitus or hearing loss. Most patients have a first-degree relative who is similarly afflicted. Patients with NFII are also at risk of meningioma, gliomas, ependymoma, and schwannoma. Symptoms are the same as those discussed under the respective tumors.

Differential Diagnosis and Evaluation. Patients with NFI must be closely examined for any history consistent with visual disturbances or other visual abnormalities or signs of nerve root impingement, including bowel and bladder dysfunction or constipation. Patients may show

evidence of peripheral nerve dysfunction caused by impingement by a neurofibroma. Only when the clinical findings suggest changes requiring intervention should tests be performed. Yearly MRI scans of the brain and spinal cord looking for tumor are not indicated. Some clinicians advocate yearly screening of children with visual-evoked potentials for early detection of optic gliomas.^[55] Patients and their spouses need genetic counseling for family planning purposes^[56] and extensive social work intervention to help with issues related to the disease and the possibility of tumor generation.

Patients with NFII should be closely observed for any changes in auditory function, including hearing loss and tinnitus. During the neurological examination, particular attention should be focused on other cranial nerve abnormalities. Physicians should monitor the patient for any evidence of vertigo or difficulty with balance, possibly with yearly brain stem auditory evoked potentials. Formal audiometry on a yearly basis is a reasonable alternative as well; yearly MRI scanning is not generally indicated but may be repeated serially to allow a gauge of tumor enlargement.

Management. Patients with NFI should be monitored closely for development of treatable abnormalities as previously described. Optic gliomas can be treated with surgical removal when feasible or with radiotherapy.^[57] Malignant degeneration of a schwannoma or a neurofibroma (neurofibrosarcoma) occurs in 5 percent of patients. Patients with NFII require intervention to remove the acoustic neuromas as described previously. In these patients, referral to a center that has facilities to perform a cochlear implant should be considered because these patients are at great risk of bilateral hearing loss. Patients receiving radiotherapy, especially children, are at risk for further neurobehavioral deterioration and endocrine abnormalities.

Prognosis and Future Perspectives. Further investigation into the genotype and how it relates to the variable phenotypic expression and manifestation of tumors remains to be conducted. A better understanding of the mechanism of action of the genes responsible for these diseases and the way in which malignant degeneration occurs may advance treatment of patients not only with NF but with gliomas as well. In utero diagnosis remains a possibility. Genetic analysis of families and in family planning should be thoroughly explored.

Other Peripheral Nerve Tumors

Benign tumors of the peripheral nerves are often localized to single sites and are related to pressure or trauma. For example, Morton's neuroma is commonly associated with increased pressure or tight-fitting shoes and represents fibrotic swelling of the nerve in response to repeated insult. Located on the plantar surface of the foot, it is treated with excision or observation. Symptoms include localized pain, tenderness, and weakness of the distally affected muscles innervated by the nerve. Ganglion cysts may result from repeated trauma, leading to undue inflammation and cystic degeneration. In other cases, transected stump nerves undergo unorganized sprouting, leading to a large clump of disorganized cells and their processes.

SPINAL CORD TUMORS

Although rare, spinal cord tumors continue to carry a grave prognosis for patients. They are difficult to resect and treat. Both the tumor itself and the treatment often lead to profound physical and neurological disability due to spinal cord damage. Spinal cord tumors represent about 7 percent of all primary tumors of the CNS and are seen more commonly in children, in whom they represent up to a fourth of all intra-axial tumors by location. The most common histological type is that of the glioma histology, especially astrocytomas and ependymomas. Their frequency is undoubtedly related to the percentage of total tissue of the spinal cord involved.

Often patients are brought to medical attention because of weakness of the legs, loss of bowel or bladder control, back pain, or, rarely, loss of sensation. In children, these symptoms may be confused with "regression" of the child's development, "growth pains," or muscle disease. Often a child's lesion is discovered incidentally during evaluation for a minor injury such as a sledding accident, when studies are performed to calm the fears of worried parents. Cervical or foramen magnum lesions may present with torticollis or nuchal rigidity.

Most patients are evaluated by MRI imaging, which demonstrates an enlarged or thickened cord. Frequently, the spinal canal may be enlarged around the area of the slowly expanding tumor. Once the tumor has been identified, the entire neuroaxis should be studied for any other areas of involvement. Although a tissue diagnosis may be suggested by the tumor's location and radiographic pattern, pathological confirmation is essential prior to treatment. All patients should be evaluated by a neurosurgeon for consideration of biopsy or evacuation of the lesion. Preoperative and postoperative testing with evoked potentials can be performed to monitor disease evolution. Because of the location, patients are at a significant risk of morbidity from the tumor and any treatment for it.

Treatment of these tumors includes surgical evacuation when possible, followed by radiotherapy to a malignant lesion and the surrounding cord. Low-grade tumors may be monitored closely for evidence of recurrence or malignant degeneration. In children, consideration of a delay in radiotherapy is essential to prevent unwanted side effects due to the treatment. Although chemotherapy has not been systematically studied in these patients, one would intuitively expect that agents with known effects on supratentorial tumors would also be effective on spinal tumors with a similar histology. Patients with spinal column defects, such as scoliosis, that are related to the tumor or treatment can be treated appropriately with surgery (if necessary) and physical therapy.

PITUITARY TUMORS

Adenomas

Pathogenesis and Pathophysiology. Pituitary adenomas are neuroepithelial tumors of the adenohypophysis. They are generated in a stepwise fashion from initiation to

growth evolution, probably in a fashion similar to that characteristic of other CNS tumors. This growth may be caused by derangements in the metabolic processing of cells of the adenohypophysis due to mutations of as yet undetermined gene alterations. Several putative gene alterations have been proposed, including the retinoblastoma gene and, because of its association with pituitary adenomas, the multiple endocrine neoplasia type I (MEN-I) tumor suppressor gene. Approximately 3 to 4 percent of adenomas of the pituitary are associated with MEN-I. Certainly other gene elements will also be found to play a role as laboratory investigations continue. An alternative hypothesis suggests that overstimulation or deranged signaling from the hypothalamus leads to pituitary cell dysfunction and inappropriate growth.

Pituitary adenomas can be classified by size, hormonal secretion, or histological appearance. Tumors less than 1 cm in diameter are considered microadenomas, and those larger than 1 cm are considered macroadenomas. Alternatively, pituitary adenomas can be classified as hormone secretors or nonsecretors. Approximately 15 to 20 percent of these tumors do not secrete hormone under current detection techniques. Of those that do, the majority secrete prolactin, followed by growth hormone, adrenocorticotrophic hormone (ACTH), gonadotropins, and thyrotropic hormone. Some tumors secrete multiple hormones and are termed null tumors. Null tumors that contain a buildup of mitochondria are termed oncocytomas, but this fact has no clinical relevance. Histologically, cells can appear acidophilic, basophilic, or chromophobic on routine staining techniques. On histological diagnosis the tumor can be difficult to differentiate from normal tissue or metastatic disease. Immunohistochemical staining and evaluation by a neuropathologist is essential.

Epidemiology and Risk Factors. Aside from craniopharyngiomas in childhood, pituitary adenomas are the most common tumor in the region of the sella, comprising about 6 percent of all CNS tumors. Although pituitary adenomas are clinically evident more often in young women, autopsy series suggest that they appear equally in men and women. Recently, in a survey of clinically normal asymptomatic men and women, a 10 percent incidence of focally abnormal areas within the pituitary was found on MRI scans with contrast agent.

Clinical Features and Associated Disorders. The reason most pituitary adenomas can be detected while

TABLE 46-4 -- CLINICAL FEATURES OF DERANGEMENT OF PITUITARY HORMONE FUNCTION

Hormone		Clinical Features
Prolactin	Excess	Hypogonadism, galactorrhea, amenorrhea, infertility, sexual activity dysfunction, impotence
	Deficiency	Infertility, ? impotence
Growth hormone	Excess	Acromegaly--hypertension, diabetes mellitus, coarse facial features, increased height, gigantism, nerve entrapment, visceromegaly, headaches, visual impairment, myopathy
	Deficiency	Growth failure, dwarfism
Thyroid-stimulating hormone	Excess	Weight loss, personality changes, psychosis, cardiac dysfunction, myopathy
	Deficiency	Cold intolerance, headache, constipation, paresthesias, infertility
Follicle-stimulating hormone, luteinizing hormone	Excess	Precocious puberty, amenorrhea, infertility
	Deficiency	Delayed puberty, impotence amenorrhea
Adrenocorticotrophic hormone	Excess	Cushing's syndrome--easy bruising, amenorrhea, hirsutism, hypertension, diabetes mellitus, acne, moon facies, truncal obesity, purple striae, psychiatric disturbance
	Deficiency	Nausea, malaise, weakness, hypotension

they are relatively small is because they are located in an exquisitely sensitive area that controls hormonal function, just below the hypothalamus, and in close proximity to the optic chiasm ([Table 46-4](#)). If hormonal derangements do not bring the patient to medical attention, the tumor may be discovered during ophthalmological examination for a visual disturbance. Early pressure on the optic chiasm may result in a superior bitemporal quadrantanopia and can lead to a full bitemporal hemianopia. Alternatively, pressure symptoms such as headache may lead the patient to seek medical advice. The headaches can be diffuse and nonpulsatile and may be mistaken for daily headaches. As the adenoma enlarges, the patient may note hypothalamic dysfunction, basal forebrain abnormalities, anosmia, and seizures.

Symptoms of pituitary dysregulation are common. Prolactin-secreting tumors may lead to clinical presentation in women because of menstrual irregularities (usually amenorrhea), galactorrhea, and an inability to conceive. Men have a decrease in potency and libido. Abnormal prolactin function may also result from other pituitary tumors due to obstruction of the dopaminergic pathways between the hypothalamus and the pituitary. Growth hormone-secreting pituitary adenomas usually present at a younger age with evidence of acromegaly. Gonadotropin-secreting tumors cause precocious puberty, infertility, or impotence. Adrenocorticotrophic hormone alterations cause the typical features of Cushing's syndrome including hypertension, diabetes mellitus, fat deposition around the neck and shoulders (buffalo hump), acne, myopathy, or purple striae. Occasionally, patients present with psychiatric disturbances such as psychosis, mood alterations, or sleep disturbances, especially when the regulation of cortisol or prolactin is altered.

Differential Diagnosis. The differential diagnosis of a pituitary adenoma includes other space-occupying lesions in this area such as meningioma, metastatic tumors, craniopharyngioma, glioma, or, rarely, pituitary carcinoma. These alternatives can in most cases be resolved by surgical intervention performed with histological diagnosis. Confusion about compression of the sella area due to hemorrhage, a carotid aneurysm, or an empty sella caused by herniation of the meninges into the sella can often be resolved by appropriate neuroradiological imaging. An appropriate history will resolve questions about possible trauma to the area from a skull base fracture, previous surgery in an area near the sella, or a history of irradiation. Autoimmune or

TABLE 46-5 -- TESTS FOR ANTERIOR PITUITARY FUNCTION^a

Pituitary Function	Hormone	Laboratory Test
Thyrotropin (TSH)	Thyroxine	TSH, free thyroxine (free T ₄)

Somatotropin	Somatomedin	Morning growth hormone
		Somatomedin-C
Lactotropin	Prolactin	Prolactin

^a Test results may be altered by pharmacological agents. ^b Tests should be performed and related to normal values for timing of menstrual cycle.

infectious causes of problems, including sarcoidosis, histiocytosis X, bacterial meningitis, tuberculosis, or abscess, are typically resolved by the presence of other findings of these diseases. Lymphocytic hypophysitis and Sheehan's syndrome often occur in the peripartum. Finally, one must always be vigilant to detect prescription or recreational drugs that interfere with normal pituitary function.

Evaluation. X-ray examination of the skull is of limited use in the evaluation of the patient with a suspected pituitary adenoma. CT scanning with bone windows is usually selected first, but this may miss a very small adenoma. MRI with contrast enhancement defines the soft tissue characteristics and is more sensitive to tumor identification in patients with large tumors. Angiography may be necessary to define the arterial supply for surgical planning and to exclude the presence of aneurysm. Neuro-ophthalmological evaluation for accurate mapping of visual disturbances is important prior to surgery. Evaluation of pituitary function is needed in all patients ([Table 46-5](#)). All patients require evaluation for cortisol insufficiency, especially to guard against cortisol insufficiency postoperatively.

Management. Prolactin-secreting tumors can be managed with the use of dopamine agonists such as bromocriptine (0.5 to 2.5 mg/day). These drugs interfere with the dopaminergic pathways between the hypothalamus and the pituitary. Ketoconazole has been proposed to stop the effects of ACTH hypersecretion. Use of somatostatin for GH-secreting tumors is still under investigation. Surgery remains the best way to produce a definitive diagnosis. The typical surgical pathway is a transsphenoidal approach and is usually curative. Use of radiotherapy (including stereotactic radiation) remains effective for patients with evidence of recurrence and for those who are not surgical candidates or who have not benefited from postsurgical medical intervention. After surgery, patients remain at risk for visual field defects or pituitary insufficiency, including panhypopituitarism requiring hormonal supplementation.

Prognosis and Future Perspectives. Because of the success of surgical intervention, these tumors have a very favorable prognosis. Recurrence is usually confined to patients in whom resection is incomplete. Further refinements in the medical treatment for microadenomas may allow nonsurgical treatment throughout life in some patients.

Craniopharyngioma

Pathogenesis and Pathophysiology. Craniopharyngiomas are thought to be congenitally derived and to arise from remnants of Rathke's pouch. Embryonic collections of epithelial cells remain after absorption of the hypophyseal pharyngeal duct, from which the infundibulum/tuber cinereum is derived ([Fig. 46-8](#)). The squamous cells are found to be metaplastic and may be present for a significant period before transformation occurs. Alternative proposals suggest that these tumors are derived from a malformation of the embryonic cells that can linger in the area and are not absorbed during fetal life for a significant period of time, leading to abnormal growth. There are two main histological types, one seen in children and the other in adults, suggesting the possibility of two different explanations for their origin.

These tumors range in size from very small round nodules to large loculated cysts. Two main histological types are found. In the majority of children, an adamantinomatous form that appears to resemble tooth-forming material is composed of interspersed fibrous and necrotic tissue as well as many multiloculated cysts. Cholesterol and an oily, thick cystic fluid may also be present, and this fluid can spill from the sack into the subarachnoid space, causing a chemical meningitis. These types of craniopharyngiomas are more often found to have calcium deposits that can be

Figure 46-8 MRI picture of a craniopharyngioma, demonstrating a cystic contrast-enhancing mass in the suprasellar area extending upward, compressing the hypothalamus.

visualized on plain skull radiographs. In adults, a squamous papillary form occurs; although it has no adamantinomatous features, a less cystic stratified squamous epithelium is found histologically. Keratin deposition may also occur. In many cases it may be difficult to differentiate these two main forms, leading some to propose the presence of a third mixed form.

Epidemiology and Risk Factors. Craniopharyngioma is an epithelial tumor arising from the region of the sella and represents 3 percent of all primary intracranial neoplasms. It is the most common childhood tumor involving the sella area. Although it is the third most common tumor in childhood, about 50 percent of all cases occur in adults. There are no known risk factors.

Clinical Features and Associated Findings. Because this tumor is located near the pituitary, the resulting syndromes resemble those characteristic of pituitary adenomas. Symptoms can arise slowly over many months. The most common presenting complaints are compression of the chiasm, causing visual disturbances in the form of bitemporal visual field loss or obstruction of the cerebrospinal fluid pathways yielding papilledema, headache, nausea, or vomiting. Involvement of the hypothalamus or pituitary may lead to endocrinological disorders. With enlargement, pressure on the third ventricle in children can lead to a failure to attain developmental milestones or, in adults, a dementing process. In 90 percent of cases, endocrinological abnormalities are present, usually involving the anterior pituitary, yet most patients do not seek initial evaluation for problems related to endocrinological dysfunction. Notwithstanding, almost half of affected children are of short stature, and a quarter are obese at presentation. The primary endocrinological disturbance found is related to GH production; next in frequency are disturbances in LH/FSH, ACTH, and TSH. In contrast to pituitary adenomas, abnormalities of prolactin are seen in only about a fifth of cases.

Differential Diagnosis. Craniopharyngiomas usually have a characteristic radiographic appearance that generally excludes other pathological processes. The differential diagnosis of these tumors includes pituitary adenomas, which have no calcifications, and separation of these two possibilities without surgery may be difficult in adults. Rathke's pouch cysts are usually single cysts and lack a solid component. Meningiomas often possess a "dural tag," and a cleavage plane can be visualized on imaging studies. In adults, metastatic tumors such as melanoma should also be considered.

Evaluation. Neuroradiographic studies should be designed to aid in surgical planning. Plain skull radiographs may show enlargement of the sella or calcium deposits, thereby giving a hint of potential diagnoses, especially in children. CT scans with and without contrast agent and paying attention to the sella in the coronal section may show bony alterations, whereas MRI with and without gadolinium can define the soft tissue extension of the tumor and the presence of cysts. Craniopharyngiomas tend to extend downward into the sella, whereas pituitary adenomas, in contrast, extend upward from the sella. Occasionally, angiography is required to define lateral displacement that can interfere with arterial blood supply, especially the internal carotid artery. Full endocrinological evaluation is mandatory before and after surgery (see [Table 46-5](#)).

Management. Surgical resection remains the mainstay of treatment to establish diagnosis and to relieve pressure from the surrounding structures. ^[59] Patients need cortisol at the time of surgery regardless of their preoperative status. All patients require assessment of fluid and electrolyte balance, which should be monitored closely in the operative period. Derangements in water and electrolyte balance caused by diabetes insipidus, the syndrome of inappropriate antidiuretic hormone secretion, or cerebral salt wasting ^[60] are common in the postoperative period. Following total removal of the tumor, further treatment is usually not required. With subtotal removal, patients can be evaluated with serial neuroradiological imaging, and reoperation at regrowth of the tumor can be considered. Alternatively, depending on the amount of residual tumor, radiotherapy is also an option. There is increasing controversy about the role of stereotactic radiation or gamma knife as the sole treatment modality. Follow-up periods for patients treated with radiosurgery have been relatively short, and further research in this area is required. Instillation of radioactive phosphorus may be considered in some patients with cystic lesions. ^[61] Endocrinological evaluation and postoperative treatment are similar to the regimen followed for patients with pituitary adenomas. Children require close observation with careful monitoring of neurocognitive and hormonal status.

Prognosis and Future Perspectives. Even when these tumors are detected before any neurological deficits become apparent, the prognosis remains guarded. Recurrence approaches 30 percent within 5 years and is higher in children and in those who have undergone incomplete resection. A significant number of patients continue to require hormonal supplementation. Further work is needed to determine ways to identify more aggressive tumors for which the use of radiotherapy and

chemotherapy at initial tumor diagnosis may prevent recurrence.

[PreviousNext](#)

MENINGIOMAS

Pathophysiology and Pathogenesis. Many classification schemes are used for meningiomas, usually based on the histological appearance (see [Table 46-6](#)). Meningiomas have a firm off-white appearance, and because they are extra-axial, they are usually well demarcated from the surrounding brain. Microscopically, they display a characteristic

TABLE 46-6 -- CLASSIFICATIONS OF MENINGIOMAS

Histological Label	Features
Fibroblastic	Narrow, long cells in sheets; less commonly, whorls, psammoma bodies
Synehtial	Meningothelial cells, whorls, psammoma bodies
Transitional	Features of both synehtial and fibroblastic
Angioblastic	Intertwined, complex, thickened blood vessels, reticulin background, seldom contain whorls, psammoma bodies

whorled pattern with calcifications (psammoma bodies). Discussion abounds about the classifications and subtypes and the histological characteristics of these tumors and their clinical course. For example, proposed papillary and clear cell forms appear to be found more commonly in younger people and children and seem to behave more aggressively. Various cell labeling tests and analysis of estrogen and progesterone receptor concentrations have been proposed to predict biological growth. However, the pathological features of brain invasion and mitotic activity are the most important pathological determinants of aggressive behavior. Hemangiopericytomas are highly vascular tumors that are seen equally often in usually younger men and women. Histologically similar tumors can be found in non-CNS regions. They are more prone to malignant behavior.

Epidemiology and Risk Factors. Meningiomas are extra-axial tumors that arise from dural elements within the cranial and spinal spaces. Although considered benign, they can enlarge and cause compression of neural elements and can behave aggressively, invading the bone or brain and threatening life. They comprise about 15 percent of all intracranial tumors and increase in incidence with age. Meningiomas have estrogen and progesterone receptors, possibly explaining why they occur in women almost a third more often than in men. Because of these receptors, meningiomas show increased growth during pregnancy. Further, meningiomas in the spine are almost always found in women. However, in blacks, men are more often affected. Several risk factors have been proposed for their occurrence, including trauma, infections, electrical exposure, and exposure to radiotherapy. Meningiomas are common in patients with neurofibromatosis II, in whom multiple tumors are commonly found.

Clinical Features and Associated Findings. Meningiomas can arise in virtually any location in the central nervous system, although certain locations predominate ([Table 46-7](#)). Patients can present with epilepsy or subtle symptoms such as progressive headache, memory loss, or cognitive changes, which occur over an extended period of time. Slow progressive dementia or chronic depression in an older patient are also common presentations. Location of the tumor along the motor strip may present, possibly suddenly, with hemiparesis. Sagittal tumors along the falx may cause the development of bilateral leg weakness. Sphenoid area tumors may cause ophthalmological or cavernous sinus symptoms, and olfactory groove meningiomas

TABLE 46-7 -- LOCATIONS AND PRESENTATIONS OF MENINGIOMAS

Location	Presenting Manifestation
Parasagittal	Urinary incontinence, dementia, gradual paraparesis, seizures
Lateral convexity	Variable depending on structures compressed, including slow hemiparesis, speech abnormalities
Olfactory groove	Anosmia, visual disturbance, dementia, Foster-Kennedy syndrome
Suprasellar	Hormonal failure, bitemporal hemianopia, optic atrophy
Sphenoid ridge	Extraocular nerve paresis, exostoses, proptosis, seizures

Figure 46-9 MRI picture of a posterior fossa meningioma, demonstrating an extra-axial, homogeneously contrast-enhancing mass arising from the tentorium and compressing the cerebellar hemisphere.

may lead to anosmia. Because these tumors grow slowly, they may be identified incidentally in asymptomatic patients. Although hydrocephalus is extremely rare, children are more likely to present with symptoms of this entity.

Differential Diagnosis. Meningiomas are often "diagnosed" from neuroradiological scans. The typical features and location do offer a reasonable amount of certainty in this diagnosis, yet clinicians must always be vigilant for unexpected possibilities. The ability to characterize these tumors radiographically still does not allow differentiation of a benign from a malignant meningioma. Malignant forms are more commonly seen in men, and unexpected metastatic deposits may be discovered. Suprasellar lesions may be confused with pituitary adenoma or craniopharyngioma. Extremely vascular lesions may be hemangiopericytomas.

Evaluation. MRI with gadolinium remains the diagnostic method of choice. Contrast agents demonstrate significant homogeneous enhancement ([Fig. 46-9](#)) and may highlight a dural "tail." CT may complement MRI findings and should include bone windows to show evidence of hyperostosis, calcifications within the tumor, and bone invasion. MRI angiography or routine angiography may reveal a tumor blush and can help with presurgical planning. In elderly patients preoperative and postoperative neuropsychological testing can be performed to evaluate patient response to and recovery from surgical resection.

Management. Meningiomas can be cured surgically. The location and size of the tumor and its involvement with close vital structures partially determine the extent of resection that is feasible. For example, sphenoid ridge meningiomas are rarely fully removed. The main decision is whether surgery is required. In patients in whom the

tumor is an incidental finding or who are poor surgical risks, observation with serial scanning may be appropriate. [\[62\]](#) In those with large meningiomas, angiography

and embolization are frequently used to aid in surgical removal. Extremely vascular lesions may be hemangiopericytomas. Following surgery, whether complete or near-complete, patients should be observed with serial MRI or CT scans for evidence of regrowth. Recurrence is related to extent of resection and location because the site of resection may preclude complete removal. Radiotherapy can be given for relapse following a second surgery or for anaplastic meningiomas. ^[63] Stereotactic radiotherapy and brachytherapy are under evaluation, but the early results appear promising, although observation times have been short. Patients must be watched closely for evidence of cognitive decline from these intensive radiation doses. Chemotherapy with cytotoxic agents has met with limited success. Because meningiomas do possess estrogen and progesterone receptors, endocrine manipulation of the tumor residua with hormonal or biological agents such as tamoxifen, beta-interferon, or RU-486 is under study and at this point remains investigational.

Prognosis and Future Perspectives. As the population continues to age, the frequency of meningiomas can only increase. Histological variations and groups must be standardized to allow more timely and thorough evaluation of therapeutic treatments designed for a homogeneous population of tumors. Because meningiomas are amenable to resection but can remain to invade and disrupt vital neurological structures, future work must include detailed studies of their nonsurgical management, in relation to both timing and type of therapy. Attempts to predict biological behavior through histological and cell kinetic studies can help in management by identifying which patients are at increased risk of tumor regrowth and which have the potential to respond to medical management.

CONGENITAL TUMORS

Dermoid, Epidermoid, and Teratoma

These rare embryonic remnant tumors may present anywhere in the CNS but most commonly occur in the posterior fossa and the cauda equina. They are congenital tumors and may be seen at any age; however, they are more likely to occur in children or young adults of either sex. They are slow growing and present with symptomatology specific for compressive syndromes at their location within the central nervous system. These symptoms can be insidious, and blockage of cerebrospinal flow occurs rarely. Seizures or headaches are not common. Skin lesions are commonly associated with these tumors, and any infant with a dermal sinus tract should undergo neuroradiological evaluation to exclude these growths. Communication with a dermal tract may lead to recurrent meningitis, and any patient with repeated meningitis, whether associated with a bacterial cause or not, should undergo evaluation for an unnoticed dermal sinus. Prenatal diagnosis with ultrasound and resection shortly after birth are now possible. ^[64]

Epidermoid tumors, or cholesteatomas, are composed of ectodermal remnants and present as cystic structures in lateral positions within the central nervous system, especially around the brain stem or thoracic cord. Neuroradiological imaging usually demonstrates a hyperdense structure with poor enhancement characteristics. MRI scans demonstrate low but variable signals on T1-weighted images and high but variable signals on T2 images. CT scans may demonstrate bone destruction and calcium within the lesion. These tumors have a thick ring that may be calcified and can appear "pearl-like." Epidermoids can interdigitate around vital neuronal structures, complicating surgical removal. Care should be taken during removal to prevent spilling the contents to avoid a chemical meningitis. Complete surgical removal is curative.

Dermoid tumors, composed of ectoderm and mesoderm, are more likely to be found in the midline, especially in the lumbar area and in the brain stem. Neuroradiological imaging usually shows an appearance similar to that of epidermoids with poor enhancement characteristics. These tumors are round multilobulated lesions containing fluid that also leads to a risk of chemical meningitis if the cysts are ruptured. Dermoids should be considered whenever lumbar puncture yields fat in the CSF. ^[65] Surgical removal is usually curative.

Teratomas are composed of ectoderm, mesoderm, and endoderm and are most often seen in infants and children, especially in the pineal region or the spinal canal. Because these tumors are composed of cells of all embryonic layers, they can generate hair, teeth, or other elements. Surgical removal, often not complete, is curative. Observation and an attempt at more complete re-resection may be feasible.

Pineal and Germ Cell Tumors

Pineal region tumors account for about 1 percent of all brain tumors. They can be extremely difficult to diagnose and treat because of their location. Tissue confirmation is important because of the varied histologies found in this region as well as the implications of these differences in influencing treatment options. Occasionally, small samples of benign lesions may be confused with more malignant processes.

Patients with pineal region tumors often present with symptoms of hydrocephalus caused by compression of the cerebral aqueduct that result in elevated intracranial pressure ([Table 46-8](#)). Patients may present acutely with nausea, vomiting, lethargy, headaches, or changes in sensorium and mentation. Enlargement and infiltration of the nearby structures, including the midbrain, may lead to a kinetic mutism. Further expansion to involve the superior colliculus can lead to Parinaud's syndrome, characterized by paralysis of upgaze, near-light dissociation, and convergence-retraction nystagmus. Further compression may result in paralysis of downgaze. In patients with germ cell tumors, precocious puberty, especially in boys, may be observed.

The primary differentiation of lesions in this location can be separated into tumors and cysts or, in infants, a vein of Galen aneurysm. Tumors can be divided into germ cell tumors (germinomas, teratomas, or choriocarcinomas), intrinsic pineal tumors (pinealcytomas or pinealblastomas),

TABLE 46-8 -- PRESENTATION AND EVALUATION OF PINEAL REGION LESIONS

Type	Clinical Presentation	Evaluation	Treatment
Germ cell tumor	Headache, Parinaud's syndrome, endocrine dysfunction, nausea, vomiting, diabetes insipidus	MRI with gadolinium, hormone evaluation; when feasible, CSF evaluation including beta-hCG	Biopsy radiotherapy
Pineoblastoma	Headache, Parinaud's syndrome, endocrine dysfunction, nausea, vomiting	MRI with gadolinium	Resection radiotherapy
Glial neoplasms (astrocytomas, ependymomas, etc)	Slowly progressive, headache, nausea, vomiting	MRI with gadolinium	Resection, chemotherapy, radiotherapy
Meningioma	Slowly progressive, headache, late nausea, vomiting	MRI with gadolinium	Resection, radiotherapy with incomplete resection
Lymphoma	Headache, Parinaud's syndrome, endocrine dysfunction, nausea, vomiting, diabetes insipidus	MRI of craniospinal contents; when feasible, CSF evaluation including beta-2 microglobulin	Biopsy, chemotherapy, (?) radiotherapy
Metastatic tumors	Often history of cancer	MRI with gadolinium, evaluation for other metastatic deposits	Resection, radiotherapy, (?) chemotherapy
Pineal cysts	Slowly progressive, headache, late nausea, vomiting, or incidental finding	MRI with gadolinium	Observation, reduction
Vein of Galen	Most commonly male, high cardiac output, cranial bruit, enlarging head	CT with contrast	Surgery, (?) embolization

CSF, Cerebrospinal fluid; CT, computed tomography; hCG, human chorionic gonadotropin; MRI, magnetic resonance imaging.

metastatic lesions, or other tumors including ependymomas, astrocytomas, or meningiomas. Patients should undergo MRI with gadolinium or, if this is unavailable, CT with a suitable contrast agent. This will help to localize the tumor and define the involvement of local structures. Occasionally, angiography is required for surgical planning or to exclude an aneurysm of the vein of Galen.

MRI can help in differentiating possible pathological causes. For example, teratomas usually contain fat and calcium, whereas meningiomas may reveal a dural tag. All patients should undergo cerebrospinal fluid analysis including cytological examination when feasible. Measurement of alpha-fetoprotein and beta-human chorionic gonadotropin (hCG) in the CSF should be compared with serum levels. Any clinical evidence of pituitary dysfunction should prompt thorough endocrinological studies.

Pineal region tumors require histological confirmation. Total resection is curative for benign lesions, whereas maximum resection may improve the overall survival of patients with malignant lesions. Hydrocephalus requiring shunting is common. Pineal or germ cell tumors require postoperative MRI for evaluation of seeding of the cerebrospinal pathway. Patients with germ cell tumors should undergo CSF evaluation when feasible. Testing should include a comparison of serum with CSF beta-hCG and alpha-fetoprotein, which can be used as markers for disease. Radiotherapy can be curative for localized lesions. Patients with evidence of cerebrospinal dissemination require craniospinal radiation. Because these tumors are so radiation sensitive, the use of chemotherapy with cisplatin and etoposide has often been reserved for patients with recurrent disease or those with more malignant tumors such as yoke-sac tumors or malignant choriocarcinoma. Although systemic germ cell tumors are very sensitive to chemotherapy, CNS germ cell tumors appear to be less responsive. Use of chemotherapy before or after primary treatment with radiotherapy remains to be studied. Relapse most commonly occurs locally or with CSF dissemination. Overall, survival approaches 75 percent at 5 years, and survival of patients with germinomatous germ cell tumors is over 90 percent.

OTHER TUMORS

Hemangioblastoma

Hemangioblastoma, a benign vascular tumor, is seen primarily in middle-aged adults but often presents at a younger age in patients with von Hippel-Lindau disease. These tumors are primarily located in the posterior fossa, although they can occur anywhere within the neuroaxis. They are usually cystic and are sometimes classified as a variant of meningiomas (angioblastic variant). Histologically, they are characterized by distinctive vascular channels with fat-laden cells. Occasionally they can be mistaken for xanthochromic astrocytomas.^[66]

The clinical presentation is similar to that of other posterior fossa lesions. The neuroradiological appearance is that of a well-demarcated, cystic lesion with a distinctly enhanced tumor nodule on administration of contrast material. Identification should prompt a search for other lesions including lesions of the cervical spine, especially in those with von Hippel-Lindau disease; retinal examination and evaluation for intra-abdominal neoplasms such as renal cell carcinoma or pheochromocytoma should also be done. Angiography is performed to help in this search for radiographically silent lesions and to aid in preoperative planning. Surgery is usually curative, although the use of stereotactic radiation is being explored. Because these tumors are known to express an erythropoietin-like factor, the accompanying erythrocytosis may be a marker for the extent of resection or for occult lesions in patients with known hemangioblastoma or von Hippel-Lindau disease.

Chordoma

Chordomas are often considered "benign" tumors that are amenable to surgical resection alone. However, they can be invasive and can metastasize, and, without complete resection, they can produce local regrowth. They are considered embryonal tumors and are remnants of the notochord. The primary histological feature is the presence of large mucin-containing physaliferous cells. Areas of hemorrhage and calcification may also be seen. Chordomas may degenerate to a more malignant histological appearance, the chondrosarcoma. Chordomas originate in essentially two locations, the clivus or sphenoid region and the sacrococcygeal region, although they can arise in other areas as well, including infiltration into the facial structures. They are relatively rare and account for less than 1 percent of primary CNS tumors. They usually occur at mid-life and predominate in men. Men who have smaller non-necrotic tumors seem to have a better overall outcome.^[67]

Clinical presentations of patients with clivus or cervical region tumors include headache, oculomotor nerve abnormalities, or other cranial nerve dysfunction, especially in the lower motor nerves. Tumors in the sacrococcygeal region present with symptoms similar to those typical of cauda equina or conus medullaris disruption. Radiological evaluation should include both CT for examination of bone abnormalities and MRI to evaluate soft tissue destruction. These tumors are extra-axial, and displacement of brain stem or other structures may be seen. Nerves exiting from the nervous system may become entrapped in the tumor. Chordomas can be confused with craniopharyngiomas, meningiomas, metastatic carcinoma, or possibly adenoma. They show variable enhancement with contrast dye. Angiography may be necessary to define the arterial structures prior to surgery. The differential diagnosis for these tumors includes the malignant variant, chondrosarcoma, and other lesions known to occur in this region such as meningiomas or schwannomas, metastatic tumors such as carcinomas, or, remotely, craniopharyngiomas.

Definitive surgery for diagnosis and maximum tumor removal is imperative. Patients should be referred to large centers staffed by neurosurgeons who are adept at skull-base surgery. Tumors usually exhibit regrowth at the site of the previous resection. Radiotherapy, including directed stereotactic radiotherapy, is improving overall survival; however, radiotherapy should be reserved for patients who show evidence of tumor after surgery.

In a recent report of 60 patients with chordoma or chondrosarcoma, overall regrowth-free survival at 5 years was found in 84 percent of patients with near-total resection and in 64 percent of patients with partial resection.^[68] Extent of surgical resection was the greatest predictor of overall survival. Importantly, extent of surgical resection did lead to some decrease in patient performance postoperatively, but with rehabilitation, most patients regained their level of preoperative performance in about 6 months.

Glomus Jugulare (Carotid Body) Tumors

Glomus jugulare tumors arise from the paraganglionic tissue surrounding the jugular vein in the area of the middle ear. These tumors most often present late in life, in the sixth or seventh decade, and may have a genetic predisposition. They are locally invasive and highly vascular. Although presenting symptoms include complaints similar to those typical of acoustic neuromas, with tinnitus or hearing loss, the key differentiating features of these tumors are pain and the presence of loud pulsations in the ear. Occasionally, blood may drain from the ear. On examination, the patient may have tumor visible in the ear canal and, with larger lesions, evidence of cranial nerve or cerebellar dysfunction. The differential diagnosis includes neuromas, cholesteatomas, meningiomas, vascular malformations, or metastatic disease.

MRI with gadolinium enhancement demonstrates a brightly enhancing lesion and defines the spread and involvement of the local structures. Angiography is important to define the presence of vascular involvement before any attempts are made to remove the tumor surgically. Often, preoperative embolization of the involved vascular territories and intraoperative electrophysiological monitoring will help in surgical removal, which can be curative. Radiotherapy, including the use of stereotactic radiation or gamma knife, is an option for patients who are poor risks for surgery or who have residual disease that appears to be growing on serial MRI examinations. Prognosis is excellent.

Colloid Cysts

Colloid cysts are benign tumors that are amenable to curative neurosurgical resection. They must be diagnosed promptly before symptoms develop that can lead to acute conditions and sudden death. They are rare tumors but, with the advent of neuroradiological imaging, can be identified incidentally when imaging is performed for other reasons. They typically present in midlife, although pediatric diagnoses are known. They are located most frequently in the third ventricle and can cause variable symptoms due to intermittent obstruction of CSF pathways.

Patients may have weakness in the legs not associated with loss of consciousness, headache that is progressive, or paradoxical lightning headache that is relieved by positional changes of the head. Papilledema may be present on examination. Occasionally, patients with colloid cysts present with symptoms consistent with normal pressure hydrocephalus. Imaging with noncontrast CT demonstrates ventricular obstruction and dilatation with a hyperdense mass in the third ventricle. Coronal MRI usually demonstrates the mass in the anterior third ventricle. These tumors can be confused with basilar aneurysms or choroid plexus papilloma, although these lesions are not as hyperdense on noncontrast neuroradiological studies. Management includes immediate attention to hydrocephalus, often with ventricular drainage. Early surgical intervention is recommended to prevent neurological deterioration.^[69]

Choroid Plexus Papilloma

Choroid plexus papillomas are extremely rare vascular tumors that are often located in the ventricular areas of

infants and children of both sexes. Although the lateral ventricles are the most common location, these tumors can present in the third or fourth ventricles, especially in adults. Although some believe the childhood predilection suggests that these tumors are congenitally derived, no risk factors are known.

Patients commonly present with symptoms of increased intracranial pressure. In infants and small children these manifestations can include changes in behavior and decreased feeding. Seizures are not uncommon, and hemorrhages are known to occur. The main differential factor is that of malignant degeneration to a choroid carcinoma or an ependymoma. Choroid plexus carcinomas are more common in children, whereas in adults the differentiation of a choroid plexus carcinoma from a metastatic carcinoma may be difficult.^[70] Occasionally, these tumors can be confused with colloid cysts, although the latter lesions have much different imaging characteristics as discussed previously.

Evaluation usually begins with CT or MRI imaging. CT imaging reveals hydrocephalus with a brightly enhancing rounded mass located within or near the ventricular

system. MRI imaging usually establishes the intraventricular location and may identify leptomeningeal seeding of malignant forms. Calcifications may be present. These tumors can be extremely vascular, necessitating angiography prior to surgery.

Shunting may be required prior to surgery to allow time for thorough surgical preparation. Since papillomas are usually well-demarcated lobules that shell out easily, these tumors can be cured with surgical resection. Those that are more adherent suggest a more malignant type. Choroid plexus papillomas require no further treatment beyond serial neuroradiographic studies to survey for early asymptomatic regrowth. In patients with choroid plexus carcinomas, further treatment is important. Patients require evaluation of the neuroaxis of any evidence of seeding by craniospinal MRI imaging and CSF evaluation. Since radiotherapy is not favored in young children, chemotherapy is the mainstay of treatment for choroid plexus carcinomas that are not completely resected, those that show evidence of regrowth, and those that have malignant potential. No large series exist in regard to the choice of optimal chemotherapeutic agents, although carboplatin and etoposide are commonly used. Some advocate presurgical chemotherapy in patients who require reoperation.

Cancer is the leading cause of death for patients 35 to 64 years of age and the overall second leading cause of death in the United States. ¹ More than 15 percent of patients with systemic cancer suffer neurological complications. An estimated 120,000 individuals are believed to experience consequent morbidity from either the direct or the remote effects of a systemic neoplasm on the neuraxis. One fifth of the yearly cost of cancer in the United States is relegated to therapy for patients with primary or secondary cancer of the nervous system. Reflective of the repetitive hospitalizations, neurological morbidity, specialized therapy, and extended rehabilitation required, this care commonly exceeds \$100,000 per patient. ²

Several autopsy and clinical reports suggest a trend of increasing incidences of intracranial and leptomeningeal metastases. Although this trend may in part be related to improved imaging techniques, patients with cancer who benefit from improved supportive care live longer and may experience the morbidity of wider dissemination of metastases. As the treatment of cancer becomes more vigorous, the nonmetastatic effects of cancer, including the complications of radiation therapy and chemotherapy, may be more apparent and more disabling. Recognition of these complications, requiring familiarity in both neurological disease as well as the common causes of neurological dysfunction in patients with cancer, places an increased burden for early recognition and intervention on the neurologist and internist. The neurological complications of cancer are outlined in [Table 47-1](#). This discussion focuses on direct metastatic effects and paraneoplastic syndromes.

DIRECT METASTATIC DISEASE

Intraparenchymal Metastases

Pathogenesis and Pathophysiology. To establish a metastatic colony, tumor cells must grow within the primary site of malignancy, escape from the primary tumor, penetrate the circulatory system either as single cells or small tumor emboli, survive while circulating, arrest in the microvasculature of other organs, extravasate into the organ parenchyma, and efficiently grow and compress or invade tissue at the secondary site.

Solid tumors or metastases larger than 1 or 2 mm in diameter must be able to induce blood vessel sprouting from vessels in surrounding normal brain tissue. For metastases to occur, tumor cells must be able to penetrate the basement membrane, enter the stroma, and cross the subendothelial membrane into capillaries. To perform this migration, tumor cells utilize proteolytic enzymes, particularly metalloproteinases and cathepsins, and tend not to retain fibronectin, collagen, or laminin, possibly the result of a change in their specific integrin receptors. Metastases tend to colonize specific organs. The preferential adhesion of tumor cells to endothelial cells in specific target organs reflects their metastatic distribution. These adhesive interactions are mediated by the expression on endothelial cells of a category of molecules named vascular addressins. Malignant cells also survive the local killing effects of macrophages, natural killer cells, and cells of the reticuloendothelial system. Very often tumor cells produce growth factors that stimulate their own growth. The presence in target organs of paracrine growth factors also influences the outcome of metastatic colonies.

Epidemiology and Risk Factors. Virtually all systemic cancers have the capacity for brain metastasis. The most common sources of metastases to the brain are tumors of the lung, breast, kidney, and gastrointestinal tract (colon and cecum) and malignant melanoma, reflecting the frequent occurrence of these primary malignancies ([Table 47-2](#)). The predilection of melanoma to spread to the brain is emphasized because its histological pattern is different from other metastases. Other sources that are relatively

autopsy, demonstrates that these lesions often go undiagnosed.^[4]

Wide variability in the interval between the appearance of the primary cancer and that of the cerebral metastasis is observed. In many instances, the cerebral metastasis represents the first manifestation of a malignant neoplasm, usually of lung or melanoma origin. Slow-growing neoplasms of breast, ovarian, or uterine origin can result in cerebral metastasis up to 15 years after the diagnosis of the primary tumor. The average interval between the diagnosis of the primary carcinoma and the development of brain metastasis is 4 months for lung carcinoma and 3 years for breast cancer. The pulmonary circulation represents the major passage for lesions eventually entering the cranial vault.

Two thirds of brain metastases are intraparenchymal, with the remaining one third situated in the subdural or extradural space sometimes causing compression, though not necessarily invasion, of the brain. Metastatic cancers invade regions of brain in proportion to both tissue volume and blood flow. Thus, highly vascularized areas, including the leptomeninges, ventricles, and pituitary gland, receive a disproportionately large number of cancers. Hemispheric metastases prefer the anatomical "watershed areas"--the zones of marginal arteriolar supply from major intracranial arteries. This area representing 29 percent of the brain surface contains 37 percent of the metastases.^[5]

Twenty to 30 percent of patients with brain metastases have cerebellar involvement. Forty-four percent of cerebellar metastases are solitary, and the rest are associated with multiple metastases. In general, tumors of the pelvis or retroperitoneal space have a proclivity for the posterior fossa of the brain whereas those passing through the pulmonary circulation metastasize to supratentorial locations.^[6] Metastases to the dura frequently result from contiguous masses in the cranial sinuses (carcinomas of the sinus epithelium or parotid, submandibular, or maxillary glands) or cranial lymphoid epithelium (lymphoma or plasma cell tumors) spreading directly through the bone and periosteum to the dura. Dural masses either produce masses in the subdural or epidural space or invade the cranial nerve exit zones within their foramina.^[7], ^[8]

Brain stem metastases are uncommon. Other uncommon metastatic sites include the pineal body, optic nerve, choroid plexus, hypothalamus,^[9] and pituitary gland,^[10] although the latter site is favored by breast cancer. Cases of metastasis developing in another tumor, such as breast cancer metastasizing to intracranial meningiomas or to a vascular malformation, have been reported.^[10]

The occurrence of two different primary tumors may have a number of explanations, including shared risk factors and treatment effects. Researchers have sought to identify potential risk factors for *primary* brain tumors that occur in the setting of systemic malignancy. Those brain tumors occurring after bladder cancer likely reflect the carcinogenic effects on the bladder and brain of occupational chemical exposure. Given the elevation of brain tumor risk after breast, endometrial, and colorectal cancer, an association between brain tumors and reproductive hormonal exposure is also possible. The occurrence of sporadic cases of brain tumor after acute leukemia is probably due to the treatment effects of cranial irradiation. Additionally,

shared genetic predispositions can explain associations between brain tumors and sarcoma observed in Li-Fraumeni syndrome and the association of brain tumors and colorectal cancer^[11] in Turcot's syndrome.

Clinical Features and Associated Findings. The most common presenting symptoms of intracranial metastases are headache, weakness, and behavioral changes. These findings reflect brain edema, hydrocephalus, or compression of the dura ([Table 47-3](#)). Headache, the presenting complaint in one half of patients, is mild and not particularly disabling. Patients with systemic cancer often exhibit impairment without being conscious of their symptoms. Seizures, the presenting complaint in up to one third of patients with intracranial metastasis, can also appear late in the disease. Careful examination discloses weakness in two thirds of patients, of whom only one half complain of focal weakness. Similarly, although only one third of patients note behavioral or mental status changes, when careful mental status testing is done, impaired cognitive function is apparent in three fourths.^[12] Metastases in the frontal, temporal, and occipital lobes may be "silent" when not associated with focal weakness. Thus the apathy, inattention, and abulia that accompany frontal lobe lesions are commonly attributed to exogenous depression. Psychotic thought disorders, food intolerance, or olfactory or sensory hallucinations may accompany lesions of the temporal lobe.^[13], ^[14] Right parietal lobe lesions alter the ability to attend to one side of space, produce apraxia or difficulty with dressing, and may contribute to motor vehicle accidents. Miliary metastases can produce a progressive confusional state. Cerebellar metastases, likely the most symptom-inducing lesions of all intracranial tumors, are heralded by headache or gaze-evoked nystagmus, associated rarely with dizziness. Often gait is afflicted, appearing wide based and staggering. Dysarthria and tremor are uncommon.^[15]

Intraparenchymal hemorrhage into a metastatic brain tumor, occurring in one tenth of patients, produces acute symptoms. Metastases of choriocarcinoma, melanoma, bronchogenic carcinoma, thyroid carcinoma, and renal cell carcinoma are most prone to bleeding.^[16], ^[17] These hemorrhages occur within the metastatic deposit, whereas the rarer subdural hematomas reflect the effects of head trauma or anticoagulation use.

Differential Diagnosis. Mass lesions in the brain are not necessarily metastatic. Abscess, granuloma, acute demyelinating disease, resolving cerebral hematoma, cerebral infarction, radiation necrosis, and postoperative changes represent other causes of mass lesions in patients with systemic cancer. Although the incidence of brain abscesses

TABLE 47-3 -- PRESENTING SYMPTOMS AND SIGNS OF BRAIN METASTASIS

Symptom	Common Signs
Headache	Focal weakness or unexplained falls
Mental status change	Focal sensory deficits
Altered level of consciousness	Speech difficulty
Seizures occurring when older than 35 years of age	Aphasia, focal weakness
Papilledema or visual obscurations	Ataxia
Visual complaints or unexplained motor vehicle accidents	Visual field defect

is only one fiftieth as frequent as that of intracranial tumors, it is rising owing to the acquired immunodeficiency syndrome.^[18], ^[19] Granulomas in the brain are rare and result from infection with *Mycobacterium*, *Candida*, *Aspergillus*, *Cryptococcus*, and *Histoplasma* species. Sarcoidosis and central nervous system Whipple's disease can cause granulomas in the cerebral hemispheres.^[20] Demyelinating lesions, commonly acute postinfectious or postimmunization, occasionally present as large ring-enhancing masses with the clinical presentation of acute-onset focal neurological dysfunction or seizures.^[21]

Nonbacterial thrombotic endocarditis (NBTE) can cause cerebral infarction by embolization of cardiac vegetations to the brain or by intravascular thrombosis from an associated coagulation disorder. Tumors of the lung, gastrointestinal tract, breast, and genitourinary tract and tumors of hematopoietic origin most commonly result in NBTE. Although most patients with NBTE have disseminated cancer, rarely do vascular occlusions or vasospasms affect those with tumors in remission or before the diagnosis of malignancy. Stroke, metabolic encephalopathy, or complicated migraine is observed. Coagulopathy in the presence of anticardiolipin antibodies or of abnormalities of Russell viper venom coagulation studies may involve patients with breast cancer and leukemia. Intravascular coagulation produces a diffuse encephalopathy frequently characterized by focal signs.^[22]

Evaluation. The evaluation of the number and extent of metastases depends solely on neuroimaging ([Fig. 47-1](#)). In the computed tomography (CT) era, 20 percent of seeming "solitary" lesions were found to be multiple after administration of nonionic contrast media. Multiple small metastases are often identified using magnetic resonance imaging (MRI) at gapless 3-mm intervals with single-dose and then triple-dose administrations of gadolinium, often with delayed imaging times ([Fig. 47-2](#)).

[23]

The surgical evaluation of brain metastases provides definitive diagnostic information when systemic cancer has not previously been identified and is not apparent on clinical examination, chest radiograph, or mammogram. The histological evaluation of these surgical specimens makes use of antibodies that are tumor specific and/or organ specific ([Table 47-4](#)).

Management. Untreated, brain metastases are fatal within 1 month of diagnosis. Brain malfunction is the usual cause of death. Patients treated with whole-brain radiotherapy, the current mainstay of palliation, have a median survival of 3 to 6 months. [24], [25] Radiotherapy typically consists of 30 Gy in 10 fractions over 2 weeks. Radiosurgery, utilizing single fractions provided by "gamma knife" or similar photon devices, protons, or interstitial x-ray generation, is a treatment option for lesions less than 3 cm in size in areas likely to tolerate the resulting foci of necrotic and edematous tumor.

Conventionally fractionated radiotherapy is successfully given to "radiation-sensitive" tumors of lung, breast, colon, or germ cell origin whereas "resistant" lesions are best treated with necrotizing single fractions and include those of melanoma, renal cell carcinoma, or sarcoma origin. [26], [27] Future trends are likely to focus on the management of brain metastases and the role of improved chemotherapy, radiosensitizers, and radiotherapy techniques.

Figure 47-1 Evaluation of patients with suspected metastatic cancer to the central nervous system. AFP, alpha-fetoprotein; CEA, carcinoembryonic antigen; CT, computed tomography; EEG, electroencephalogram; EMG/NCV, electromyography/nerve conduction velocities; hCG, human chorionic gonadotropin; LEMS, Lambert-Eaton myasthenic syndrome; MRI, magnetic resonance imaging; PSA, prostate specific antigen; TAH/BSO, total abdominal hysterectomy/bilateral salpingo-oophorectomy.

Although brain metastases of lung origin may be identified before systemic deposits, 10 times as many brain metastases are discovered after the passage of 2 years from the diagnosis of the primary malignancy. Prophylactic cranial irradiation provided in the setting of small cell lung cancer reduces the likelihood of central nervous system relapse by 20 percent, although it does not provide long-term survival benefit.

Figure 47-2 Multiple metastases on MRI scan are associated with lung carcinom(Courtesy of Todd Brack, D.O.)

Prognosis and Future Perspectives. Therapy is often based on the prognosis of the systemic cancer. With surgical resection and whole-brain radiation therapy, patients with solitary brain metastases survive longer and remain functionally independent in comparison to recipients of radiation alone. [28], [29] Multiple brain metastases of breast origin or absent systemic primary lesions may benefit from surgical removal of all lesions. [30] Similarly, reoperation for recurrent hemorrhagic, edematous, or posterior fossa brain metastases can prolong survival and improve quality of life. Poor prognoses are associated with extensive systemic disease, Karnofsky performance score below 70, recurrence within 4 months, age older than 40 years, and tumor of breast or melanoma origin. [30], [31]

TABLE 47-4 -- HISTOLOGIC STAINS WITH TUMOR SPECIFICITY

Histologic Stain	Tumor Specificity
Keratin	Carcinomas

Data from Olsen ME, Chernik NL, Posner JB. Leptomeningeal metastases from systemic cancer: A report of 47 cases. *Trans Am Neurol Assoc* 1971;96:291-293; and Wasserstrom WR, Glass JP, Posner JB: Diagnosis and treatment of leptomeningeal metastases from solid tumors: Experience with 90 patients. *Cancer* 1982;49:759-772.

Meningeal and Ventricular Metastases

Pathogenesis and Pathophysiology. Leptomeningeal metastases can develop when malignant cells reach the cerebrospinal fluid (CSF). Tumor cells may enter through leptomeningeal veins, the choroid plexus, [32] or veins draining the bone marrow of the skull. Malignant cells may grow along cranial or peripheral nerve routes. Rarely, metastases to the parenchyma of brain or spinal cord seed into the CSF. [32]

Epidemiology and Risk Factors. Unlike intracerebral metastases reflective of a variety of histological origins, metastases to the subarachnoid space, ventricular system, and choroid plexus are most commonly of adenocarcinoma (usually of breast, lung, or gastrointestinal), melanoma, or lymphoma origin ([Table 47-5](#)). Although days to years may pass before the meninges are invaded, the diagnosis of leptomeningeal involvement is most commonly made 6 months to 3 years after the primary tumor is discovered.

Clinical Features and Associated Findings. Symptoms resulting from leptomeningeal metastases are seldom separable from those of parenchymal brain

involvement. Infiltrates of the pia and Virchow-Robin spaces affect the cerebrum, cranial nerves, and spinal roots. Communicating hydrocephalus, with associated diminished attention, gait apraxia, and urinary incontinence, results from obstruction of the arachnoid granulations within the subarachnoid space. As the intracranial pressure rises and the dura is stretched, bifrontal, diffuse, or radiating skull-based headache may develop. Nausea, vomiting, or lightheadedness ensues, often with confusion and memory loss. Episodes of altered consciousness, seizures, nausea and vomiting, dizziness or lightheadedness, and gait ataxia reflect changes in cranial pressure or localized nonatheromatous changes in arterial or venous perfusion ([Table 47-6](#)). The cranial

TABLE 47-6 -- CEREBRAL SYMPTOMS AND SIGNS IN PATIENTS WITH LEPTOMENINGEAL METASTASES FROM SOLID TUMORS

Symptoms	Common Signs
Headache	Papilledema
Mental status changes	Dysarthria/dysphasia
Nausea/vomiting	Extensor plantar
Vertigo/lightheadedness	Hemiparesis
Seizures	Diabetes insipidus

nerves are either compressed by tumor cells or rendered ischemic when tumor invades the feeding vessels. Frequently overlooked is symptomatic diplopia, hearing loss, facial numbness, and impairment of visual acuity. The compromised spinal nerve roots induce diffuse back pain, radicular pain, and paresthesias. Involvement of the cauda equina produces obstipation, constipation, and urinary hesitancy. ^[32]

Differential Diagnosis. Multifocal neurological symptoms are common to many metastatic sites. Cranial and spinal nerve dysfunction may be mimicked by epidural or intra-axial lesions, infection, or coagulation abnormalities.

Evaluation. The diagnosis of meningeal cancer is generally difficult. A single CSF examination reveals tumor in 50 percent of patients, rising to 85 to 90 percent after three procedures. Certain tumors, such as sarcomas or malignant gliomas, strongly adhere to the leptomeninges or occur as focal nodules rather than widespread leptomeningeal disease. ^[34] CT and MRI are valuable tools in the investigation of leptomeningeal metastasis. Often these studies are definitive in the absence of CSF cytological abnormalities ([Fig. 47-3](#)). Typically, these studies delineate leptomeningeal or subependymal enhancement, dural enhancement, superficial cerebral lesions, enhancement of cranial nerves, or communicating hydrocephalus, the latter occurring most often in patients with solid, rather than hematological, tumors. ^[35]

Management. Therapy is based on irradiation and chemotherapy. Chemotherapy can be administered either systemically or intrathecally. Intrathecal chemotherapy via an Ommaya device is the preferable route of administration. Commonly used chemotherapeutic agents include methotrexate, 12 mg twice a week with an oral leucovorin rescue, cytarabine, 50 mg twice a week, and thiotepa, 10 mg twice a week. Radiation therapy is provided to symptomatic lesions or tumor nodules larger than 5 mm. Commonly, these lesions receive local boosts as part of the treatment of the entire neuraxis at doses of 30 Gy in 10 fractions. Radiolabeled monoclonal antibodies, lymphokine-activated killer cells, and oral etoposide are other therapeutic alternatives.

Prognosis and Future Perspectives. Although a percentage of patients with leukemia, lymphoma, and breast cancer respond to some treatment, the prognosis for patients with non-small cell lung cancer, melanoma, and other adenocarcinomas is extremely poor. Future trends are likely to concentrate on treatment utilizing slow-release chemotherapy agents.

Spinal Metastases

Pathogenesis and Pathophysiology. The vertebral column is the most common site of skeletal metastases, which may be due to the rich concentration of growth factors in its bone marrow stroma that may stimulate proliferation of malignant cells in vitro. ^[36] Spread from the primary site to the bone marrow occurs through the arterial system, retrograde spread of malignant cells through Batson's plexus particularly during Valsalva maneuvers, and direct invasion of the tumor through the intervertebral foramina.

Figure 47-3 Meningeal carcinomatosis. Sagittal MRI scans showing deposition of tumor (Courtesy of M. Huckman, M.D.)

An epidural mass lesion can produce damage to the spinal cord either by mass effect resulting in mechanical distortion with demyelination or axonal destruction or from vascular compromise producing venous congestion and vasogenic edema of the spinal cord with resultant venous hemorrhage and loss of myelin and ischemia.

Epidemiology and Risk Factors. Seventy-five percent of patients with breast cancer and one third of patients with solid tumors have spinal metastases at autopsy, though only 5 to 10 percent of patients with solid tumors ever have epidural spinal cord compression. The most commonly identified cancers causing epidural spinal cord compression are breast, lung, prostate, and renal cancers, lymphoma, sarcoma, and melanoma ([Table 47-7](#)). Eighty-five percent of cases of epidural spinal cord compression arise from metastases to the vertebral column. The vertebral body is the portion most frequently involved. The pedicle or posterior arch is less frequently involved. In 10 to 15 percent of cases, epidural spinal cord compression arises from tumor spreading through the intervertebral foramina and is typically associated with lymphoma or renal cell cancers. ^[37]

Several studies have shown that metastatic epidural spinal cord compression occurs at multiple noncontiguous sites in 10 to 38 percent of cases. Multifocal involvement is particularly high in patients with breast and prostate cancer. Usually the tumor occupies the anterior or anterolateral spinal cord. The sites of spinal involvement are 70 percent thoracic, 20 percent lumbosacral, and 10 percent cervical. ^[37]

Clinical Features and Associated Findings. Back pain, usually local, radical, or segmental, is the most common

TABLE 47-7 -- COMMON PRIMARY MALIGNANCIES IN PATIENTS WITH SYMPTOMATIC SPINAL CORD COMPRESSION

Breast
Lung
Prostate
Lymphoreticular system
Sarcomas
Kidney
Unknown primary

initial symptom ([Table 47-8](#)). Local pain, usually secondary to stretching of the pain-sensitive bony periosteum, is constant, relentlessly progressive, and exacerbated by coughing, sneezing, or straining. With epidural spinal cord compression, pain increases with recumbency, forcing some patients to sleep in a sitting position to obtain relief of their pain. Even when pain is absent in a lying position, a movement such as turning over in bed or rising from a lying position may be painful. Tenderness to percussion over the vertebral body at the site of compression is present.

The site of the compression in the transverse plane may determine the clinical symptoms, particularly when the compression develops slowly. For example, a laterally located lesion compressing one side of the cord may cause a Brown-Sequard syndrome consisting of ipsilateral hemiparesis with vibration and position sense loss and contralateral pain and temperature loss. Compression of the posterior portion of the cord may cause bilateral position and vibratory loss with preservation of pain and temperature sensation and strength. Because most lesions twist the cord as they compress and also interfere with the vascular supply to sites beyond the compression, neurological signs may not demarcate the exact transverse site. Certain spinal tracts are more vulnerable to compression than others. Corticospinal

tracts and the posterior column are particularly vulnerable. Spinothalamic and descending autonomic fibers are less vulnerable. Weakness, spasticity, and hyperreflexia are the earliest signs of epidural spinal cord compression. Loss of pain and temperature sensation and bowel and bladder dysfunction occur late in the disease. Gait ataxia due to spinocerebellar tract compression may minimize cerebellar disease and may be the only sign of epidural cord compromise.

The longitudinal location of the lesion is clinically important.

TABLE 47-8 -- SIGNS AND SYMPTOMS OF SPINAL CORD COMPRESSION

Pain
Weakness
Autonomic dysfunction
Sensory loss
Ataxia

Cervical lesions cause quadriplegia, and thoracic lesions cause paraplegia. The conus medullaris syndrome is due to upper lumbar lesions and results in normal motor function, bowel bladder dysfunction, and extensor plantar responses. Lesions below the first lumbar vertebral body compromise the cauda equina, causing early lower motor neuron weakness, hyporeflexia, normal plantarflexion, and later bowel and bladder dysfunction.

Differential Diagnosis. Other spinal diseases occur in cancer patients. Additional diagnostic considerations are disc herniation, spinal cord ischemia, hemorrhage or infarction, infections of the nerve roots, necrotizing complications of chemotherapy or radiation therapy, leptomeningeal cancer, demyelinating disease, paraneoplastic myelitis, necrotizing myelopathy, or fat deposition associated with chronic corticosteroid use.

Evaluation. Visualization of the epidural space can be accomplished with MRI, myelography, and CT-myelography. Definitive imaging is recommended before treatment to aid in outlining radiation portals and creating a treatment plan that reflects the emergency of the clinical condition. Before performance, corticosteroid therapy invariably improves neurological function. Epidural disease cannot be confirmed or excluded by routine radiography or bone scintigraphy; epidural disease is found in 87 percent of patients with more than 50 percent collapse of the vertebra on radiographs, 31 percent of those with pedicle erosion without major vertebral collapse, and 7 percent of those with tumor limited to the vertebral body without collapse. Vertebral body collapse is, therefore, a highly specific indicator of epidural disease.^[38] Normal spine radiographs do not exclude epidural disease. For example, in patients with lymphoma, more than 60 percent of those with epidural disease showed no demonstrable spinal abnormality.^[39] Bone scintigraphy is generally more sensitive, but less specific, than plain radiography. A positive bone scintigram with a normal radiograph is associated with epidural disease in 17 percent of patients with back pain and no neurological findings.^[40] If bone scintigraphy and plain radiographs are normal and patients continue to have severe or progressive pain, definitive imaging with MRI or CT-myelography is warranted.

Management. The management of metastatic epidural compression is evolving. For most patients, corticosteroids and radiation therapy are the mainstays of treatment. Clinical and laboratory studies demonstrate that corticosteroids improve neurological function and alleviate pain in the short term, but their contribution to ultimate recovery is unknown. Corticosteroids should be administered promptly to patients in whom the clinical manifestations of metastatic epidural compression have been confirmed by diagnostic imaging or in whom compression is strongly suspected on clinical grounds, pending confirmation by diagnostic imaging. The dosage of dexamethasone, the corticosteroid most commonly used, remains controversial. Although some authors recommend 4 mg four times a day, laboratory studies have shown a dose-related benefit with dexamethasone, leading to the clinical use of a loading dose of 100 mg followed by 24 mg four times a day. Recommendations are for an immediate intravenous dose of 10 to 100 mg followed by 4 to 24 mg either intravenously or orally four times a day. Larger doses are used in patients with profound or rapidly progressive neurological injury, with lower doses in those with mild or equivocal signs. The administration of corticosteroids is usually continued in a tapering dose throughout radiation therapy, the latter consisting of 30 Gy in 10 fractions.^[41]

Excellent results with anterior decompression in selected patients have renewed interest in surgery. There is no consensus concerning the treatment of neoplastic spinal cord compression. Traditionally, criteria for surgery include histological diagnosis and the salvage of patients whose condition either deteriorates during radiation therapy or in whom relapse occurs after a course of radiation to the spine and those with symptomatic spinal instability or bone compression of neural structures.^[42] In such patients, considerable surgical morbidity is encountered, chiefly from wound breakdown and sepsis. In the past, surgical failure may have been due to indiscriminate use of laminectomy in all patients regardless of the anatomical site of compression within the spinal canal.^[43] Proper tailoring of the operative approach to maximize tumor resection and to provide stability to the spine is now an accepted prerequisite for successful treatment.

Prognosis and Future Perspectives. The importance of early diagnosis is emphasized because pretreatment neurological status is one of the most important prognostic factors affecting outcome. Patients who are ambulatory at the onset of radiation are likely to maintain ambulation. The rate at which a patient's neurological symptoms progress is an important determinant of eventual outcome; slow progression predicts a better recovery. Several reports have demonstrated the value of the anterior approach in patients who fail radiation therapy, with short-term improvement rates ranging from 60 to 80 percent. Recompression at the operative site occurred in more than one third of previously irradiated patients, whereas a high proportion of patients undergoing de novo surgery, the majority an anterior vertebral body resection, maintained their ambulatory status until death.^{[44], [45]}

Metastases to the skull base usually fall within the province of the otolaryngological surgeon or oncologist. Cancers of the breast, lung, and prostate have a propensity to produce skull-base metastases ([Table 47-9](#)). Skull-base metastases

TABLE 47-9 -- SYNDROMES OF BASE OF SKULL METASTASES AND THEIR ASSOCIATED SYMPTOMS

Syndrome	Signs and Symptoms
Orbital and parasellar	Progressive, dull, continuous pain in the supraorbital area over the affected eye, diplopia, proptosis of the involved eye, external ophthalmoplegia, first-division trigeminal sensory loss
Parasellar	Ipsilateral frontal headache, oculomotor or abducens palsies without associated proptosis or visual loss
Middle fossa	Facial pain or numbness referable to the second or third divisions of trigeminal nerve
Jugular foramen	Paralysis of cranial nerves IX through XI
Occipital condyle	Unilateral occipital pain and unilateral tongue paralysis

Data from Greenberg HS, Deck MDF, Vikram B, et al: Metastasis to the base of the skull: Clinical findings in 43 patients. *Neurology* 1981;31:53s537.

most commonly involve the middle cranial fossa. Other sites include the jugular foramen, occipital condyle, parasellar region, and orbit. Metastases to the skull base entrap the cranial nerves and vessels at their exit foramina. Often the cancer appears en plaque as a thin skein of tumor cells. Greenberg has identified five clinical syndromes: orbital, parasellar, middle fossa, jugular foramen, and occipital condyle.^[36]

Owing to their insidious subacute onset, skull-based metastases are difficult to identify on MRI or CT where masses may coalesce with changes of prior irradiation or surgical extirpation. Often the T2-weighted changes in contiguous bone after radiotherapy may be confused with tumor. Treatment depends on the nature of the underlying tumor and is typically confined to irradiation as previously described.

Peripheral Nerve Metastases

Cancer can affect peripheral nerves either by compression or direct invasion. Direct invasion occurs either from hematogenous spread of tumor to peripheral nerves or dorsal root ganglia or by direct extension to nerve from surrounding structures. Typically, head and neck malignancies, melanoma, lung and breast cancer, and

abdominal and pelvic tumors cause either cranial or peripheral nerve dysfunction. Occurring either early or late in the disease process, the clinical signs and symptoms are reflective of the anatomical sites and nerves involved. Frequently pain, sensory symptoms, or weakness are manifested by involvement of either single or multiple cranial nerves, spinal roots, nerve plexi, or peripheral nerves. Complications of therapy including radiation fibrosis and chemotherapy-induced neuropathy can mimic peripheral nerve metastases. Acute ischemic or inflammatory neuropathies and complications of paraneoplastic neurological syndromes should also be considered. Diagnosis may be challenging, requiring frequent neuroimaging studies of the appropriate area. Either CT or MRI of the appropriate area is performed in an attempt to either delineate discrete tumors or areas of enhancement. If imaging studies fail to reveal the presence of tumor, exploration of the affected area may be recommended depending on extent of the underlying malignancy, degree of patient's disability, and surgical accessibility and morbidity. Control of pain, which is frequently severe and unrelenting, is a priority. This control may be achieved with systemic chemotherapy or focal radiation. Additionally, pain control with analgesics or anesthetic blocks may be successful. The extent and response of the underlying tumor to therapy and severity of pain portends the prognosis.

[PreviousNext](#)

PARANEOPLASTIC SYNDROMES

The neurological paraneoplastic syndromes represent nonmetastatic complications of cancer and constitute disorders affecting multiple levels of the nervous system ([Fig. 47-4](#)). In approximately two thirds of patients, the neurological syndrome precedes the diagnosis of cancer; months to years may pass between symptom onset and identification of the causative malignancy. When identified, the tumor is likely to be indolent. On occasion, a paraneoplastic syndrome develops in the setting of prior cancer that can no longer be identified. The syndromes, not a direct target

Figure 47-4 Evaluation of paraneoplastic syndromes. TAH/BSQ, total abdominal hysterectomy/bilateral salpingo-oophorectomy.

of malignant spread, do not reflect the effects of metastatic disease, metabolic, or nutritional disorders, infection, stroke, or the complications of therapy. The syndromes are thought to be immunologically mediated.

Patients with these syndromes often harbor antibodies in their serum and CSF that recognize antigens shared by neurons and tumor cells. Paraneoplastic syndromes result when an appropriate immune response against a tumor antigen cross-reacts with similar antigens expressed by the nervous system. For example, in patients with Lambert-Eaton myasthenic syndrome, paraneoplastic cerebellar degeneration, paraneoplastic encephalomyelitis, paraneoplastic opsoclonus-myoclonus, and ataxia, both CSF and serum harbor high titers of antibodies that recognize an antigen shared by the nervous system and the tumor. Finding one of these tumor-specific autoantibodies (anti-Yo, Hu, Ri) in a patient with a neurological syndrome predicts the identification of an underlying carcinoma of a specific histological type.

Few patients develop these syndromes. Of the 1465 cancer patients in the London Hospital "carcinomatous neuromyopathy" was found in 7.2 percent. Of this number, 4.2 percent were afflicted with neuromyopathy or "proximal weakness and wasting of muscles associated with diminution or loss of two or more tendon reflexes." Three percent of patients had more specific syndromes; 2.3 percent had either neuropathy, myopathy, or a myasthenic syndrome; and 0.6 percent had a central paraneoplastic syndrome.^[46]

Traditionally, paraneoplastic syndromes are classified according to the affected anatomical level, as outlined in [Table 47-10](#) . The clinical features of only a few of the major syndromes are highlighted. Management and prognosis are discussed for the entire group of disorders at the end of the chapter.

Encephalomyelopathies

Pathogenesis and Pathophysiology. Strong evidence exists that these neurological syndromes result from attacks by humoral and cellular arms of the immune system. Some patients with paraneoplastic encephalomyelitis with small cell lung cancer harbor high titers of IgG antibodies against a set of 35- to 40-kd proteins that are selectively expressed in the nuclei of neurons throughout the human nervous system and in all small cell lung cancers, some neuroblastomas, and medulloblastomas.^[47] ^[48] ^[49] These antibodies, designated as anti-Hu, are present in higher concentrations in the CSF than in the serum, suggesting that their synthesis likely occurs within the central nervous system.^[50] The antibodies can be detected within the neuronal nuclei of patients with paraneoplastic encephalomyelitis. A correlation between sites of accumulation and those areas most affected by the paraneoplastic syndrome is observed.^[51] Although there is a high correlation between the presence of high titers of anti-Hu antibody and the development of paraneoplastic encephalomyelitis and sensory neuronopathy the exact role of these antibodies in the pathogenesis of this disease is unclear. These proteins are likely to promote neuronal differentiation and maintenance of the

neuronal phenotype. The mechanism for the inflammatory infiltrates, which consist of B cells, CD4+ and CD8+ lymphocytes, and macrophages, remains to be elucidated.

Epidemiology and Risk Factors. All small cell lung cancers with or without paraneoplastic symptoms express the Hu antigen, and 16 percent of patients with small cell lung cancer but lacking neurological dysfunction develop low titers of anti-Hu antibody. There is no overlap between the titers of anti-Hu antibodies in small cell lung cancer with paraneoplastic encephalomyelitis and sensory neuronopathy (average titer, 4592 U/ml) and those without neurological symptoms (average titer, 76 U/ml). All patients with low titers of anti-Hu antibody had the tumor confined to the thorax at diagnosis. In contrast, more than 50 percent of patients with small cell lung cancer without the anti-Hu antibody had systemic metastases at diagnosis. These findings, and the tendency of small cell lung cancer from patients with paraneoplastic encephalomyelitis and sensory neuronopathy to remain localized and undetectable until autopsy, suggest that the antitumor immune response contributes to the more indolent course of this neoplasm.^[52]

Clinical Features and Associated Findings. Paraneoplastic encephalomyelitis with inflammatory infiltrates occurring throughout the neuraxis is described in a number of different syndromes all associated with small cell lung cancer.

Limbic encephalitis typically due to lymphocytic infiltration

and neuronal loss within the temporal lobes initially manifests as anxiety and depression, then progresses to loss of recent memory, agitation, confusion, hallucinations, behavioral abnormalities, hypersomnia, generalized or partial complex seizures, and progressive dementia.^[53] Similarly, any level of the brain stem may be impaired with signs and symptoms reflective of that level of involvement. Involvement of the medulla oblongata produces nausea, vomiting, vertigo, nystagmus, ataxia, and bulbar palsy. Less commonly, disorders of eye movements occur when the midbrain or pons is involved. Extrapyramidal syndromes including parkinsonism, dystonia, respiratory abnormalities, deafness, and myoclonus of the bronchial musculature have been observed.^[54]

When paraneoplastic cerebellar degeneration develops in patients with small cell lung cancer it is usually a minor component of a more widespread paraneoplastic encephalomyelitis and sensory neuronopathy. Paraneoplastic cerebellar degeneration as an isolated or predominant syndrome may occur in patients with small cell lung cancer with or without Hu antibody. Paraneoplastic cerebellar degeneration with Hu antibody is distinguished from that without Hu antibody by a female predominance, frequent association with paraneoplastic sensory neuronopathy, and neurological death. Progressive neurological deficits eventually plateau at the stage of severe affliction.

Evaluation and Differential Diagnosis. Before the era of neuroimaging the diagnosis of many paraneoplastic neurological syndromes was delayed or made at autopsy. Typically, in paraneoplastic encephalomyelitis pathological examination reveals predominant perivascular lymphocytic inflammation within the gray matter and overlying meninges in addition to neuronal loss, gliosis, and wallerian degeneration. The pathology of paraneoplastic encephalomyelitis and sensory neuronopathy is characterized by perivascular and parenchymal inflammatory infiltrates consisting of Hu-specific B and T lymphocytes, macrophages, and microglia. The trigger for these inflammatory infiltrates is unknown but is postulated to be circulating activated Hu-specific T lymphocytes; the resulting breakdown of the blood-brain barrier and intrathecal synthesis of anti-Hu antibody may then add to the pathology.^[55] White matter changes are uncommon. Limbic encephalitis shows prominent involvement of the amygdala and neuronal loss within the pyramidal layer of the hippocampus with associated gliosis. MRI is either normal or can reveal T2-weighted signal abnormalities with mass effect within the mesial temporal structures in patients with limbic encephalitis. In patients with encephalitis involving the brain stem, atrophy of affected structures occurs over time.

Paraneoplastic Cerebellar Degeneration

Pathogenesis and Pathophysiology. Anti-Yo, an antibody of 34 and 62 kd that binds to a cytoplasmic antigen, is associated with ovarian cancer, breast cancer, and other gynecological malignancies and rarely to adenocarcinoma of the lung or unknown primary lesions. In contrast to the anti-Yo associated paraneoplastic cerebellar degeneration, in which patients are usually older women, a subset of paraneoplastic cerebellar degeneration is associated with Hodgkin's disease, in which patients are predominantly younger men.^[56] A further subgroup of cerebellar degeneration is associated with small cell lung carcinoma and Lambert-Eaton myasthenic syndrome and an antibody against the presynaptic voltage-gated calcium channel.^[57]

Epidemiology and Risk Factors. This entity, the most common paraneoplastic syndrome affecting the brain, may complicate any malignant tumor but is most commonly associated with lung cancer, particularly small cell lung cancer, and gynecological cancers, including endometrial, fallopian, ovarian, and breast cancer and lymphoma.

Clinical Features and Associated Findings. Neurological manifestations can precede detection of the associated cancer in more than one half of patients by months and, occasionally, up to 4 years, or manifestations may develop 2 years after the diagnosis of cancer. Although a more rapid onset within a few hours or days can occur, neurological signs usually develop over weeks to months. These signs include gait ataxia, which, over a few weeks to months, may progress to severe symmetrical or asymmetrical truncal and appendicular ataxia, dysarthria, and nystagmus.

Evaluation and Differential Diagnosis. Although no abnormalities exist on MRI in the acute setting, cerebellar atrophy can be seen later in the course of the illness. At autopsy the cerebellum is atrophic with near-complete loss of Purkinje cells throughout the cerebellar cortex. The differential diagnosis includes direct metastatic lesion of the cerebellum or outflow pathways, medication effects, or cerebrovascular accidents.

Paraneoplastic Opsoclonus-Myoclonus

The brain in patients with paraneoplastic opsoclonus-myoclonus rarely reveals Purkinje cell loss, changes in the dentate nucleus, or demyelination of cerebellar white matter. Less certain are examples without neuronal loss and scattered perivascular lymphocytes.^[58]^[59]^[60]

A subset of those with paraneoplastic opsoclonus-myoclonus produces high titers of an antibody, anti-Ri, that cross-reacts with an antigen in the nuclei of all central nervous system neurons and in tumor cells of affected patients. Anti-Ri antibody recognizes a protein of 55 kd as well as another of 80 kd. The distribution of these proteins is widespread. Although the exact pathogenetic anatomical location is unknown, anti-Ri-associated immunological responses appear to target the basis pontis and dorsal mesencephalon.^[61]

This syndrome occurs in association with childhood neuroblastoma and in adults in association with malignancy.^[62] Commonly, these cancers are of breast, gynecologic, or small cell lung origin. The disorder produces saccadic eye movements in combination with myoclonus involving facial muscles, limbs, or trunk and truncal ataxia. Sporadically, opsoclonus-myoclonus occurs after viral infections or medication use.

Paraneoplastic Retinal Degeneration or Cancer-Associated Retinopathy

Sera from patients with paraneoplastic retinal degeneration or cancer-associated retinopathy contain antibodies

binding antigens that are both a photoreceptor cell-specific protein and a protein expressed by small cell lung cancer.^[63] Pathologically, widespread degeneration of

the outer retinal layers with relative preservation of the other retinal layers occurs. This syndrome is usually associated with small cell lung cancer but is also observed with other tumors, including melanoma and cervical cancer. The distinctive clinical triad consists of photosensitivity, ring scotomatous visual field loss, and attenuated caliber of retinal arterioles. ^[64]

Motor Neuron Diseases

An illness similar to motor neuron disease manifested as spinal cord or anterior horn cell disease has been linked with cancer. Motor neuronopathy with loss of anterior horn cells can occur as part of a paraneoplastic syndrome. In addition, a motor neuronopathy with multifocal conduction blocks can be seen. Patients with predominant motor neuron involvement may have the anti-Hu antibody, and patients with motor neuron disease and cancer may have resolution of their neurological symptoms congruent with successful treatment of their cancer. Patients in whom motor neuron disease is a fragment of a widespread encephalomyelitis syndrome should be examined for anti-Hu antibodies and, if positive, suspected of harboring small cell lung cancer. An association between motor neuron disease and non-Hodgkin's lymphoma, infrequently with a paraproteinemia, has also been observed. ^[65] Subacute motor neuronopathy can develop with Hodgkin's disease and is characterized by subacute progressive painless and often asymmetrical lower motor neuron weakness; some patients have sensory symptoms, but there are few or no signs of sensory involvement. Reflexes are decreased or absent, and the bulbar muscles are usually spared. Fasciculations are rare, and the course is usually benign. A pure lower motor neuron syndrome, such as subacute motor neuronopathy, requires a careful evaluation to detect an underlying lymphoma. ^[66] Women who have an upper motor neuron syndrome resembling primary lateral sclerosis should undergo mammography to rule out breast cancer. Rarely, a necrotizing myelopathy that mimics an acute transverse myelitis or spinal cord compression has been described. Usually acute and rapidly evolving, the process extends to involve the spinal cord at the thoracic level. The CSF protein level is usually elevated, and MRI can show patchy gadolinium enhancement and T2-weighted signal abnormality occurring within 2 to 4 weeks. ^[67] Pathologically, widespread spinal cord necrosis with little inflammatory response or vascular occlusion is seen. ^[68]

Neuromuscular Junction and Muscle Disorders

In Lambert-Eaton myasthenic syndrome (LEMS), autoantibodies disrupt the function of neuronal voltage-gated calcium channels, leading to a reduction in the release of acetylcholine at the neuromuscular junction and at synapses of autonomic nerves. Changes in membrane voltage and depolarization of the neuronal membrane by influx of potassium ions leads to the opening of calcium channels. Calcium ions flow into the nerve terminal, and neurotransmitter vesicles fuse with the neuronal membrane, releasing acetylcholine in the neuromuscular junction. When muscle biopsy specimens from LEMS patients receive a single supramaximal stimulus, there emerge miniature end-plate potentials that are normal in amplitude but reduced in number, suggesting a reduction in the number of quanta of acetylcholine being released into the neuromuscular junction. ^[69]

LEMS is either associated with malignancy, most commonly small cell lung cancer, or with other autoimmune disorders, including thyroid disease, pernicious anemia, vitiligo, and type I diabetes mellitus. General fatigue commonly precedes weakness. Gait dysfunction usually follows weakness on standing. Autonomic dysfunction, commonly cholinergic and involving nicotinic and muscarinic synapses, produces xerostomia and erectile failure. Orthostatic hypotension is not usually a feature. Although sluggish pupillary responses may occur, ocular symptoms are rare. Repetitive or sustained contraction can improve the lower extremity proximal muscle weakness. The combination of proximal muscle weakness and hyporeflexia are hallmarks of this disease. Neurophysiological studies help confirm the diagnosis. The weakened muscles exhibit reduced amplitude compound motor action potential (CMAP) with facilitation characterized by a twofold increase in CMAP after rapid stimulation at 20 to 50 Hz. Repetitive stimulation at rates of 2 Hz is associated with a decremental response.

Peripheral Neuropathies

Approximately 5 percent of cancer patients have clinical neuropathy, 12 percent have abnormalities on quantitative sensory testing, and 40 percent have electrophysiological abnormalities. ^[70] Typically, women with small cell lung or breast carcinoma present with asymmetrical upper limb pain, paresthesia, and sensory loss preceding the diagnosis of cancer. When proprioception is lost, pseudoathetosis occurs. Subacute sensory neuronopathy results from inflammation and degeneration of the dorsal root ganglion cells. A lymphocytic response gives way to fibrosis. The loss of the dorsal root cells is accompanied by marked secondary demyelinating changes in the dorsal columns and peripheral sensory nerves. ^[71] Damage to the dorsal root ganglion cell results in a sensory neuronopathy characterized by pain and sensory loss. The sensorimotor neuropathies may be acute, subacute, or relapsing. Acute neuropathy similar to acute inflammatory demyelinating polyneuropathy has been described with a number of malignancies, including Hodgkin's disease. ^[72] The origin of peripheral neuropathies in patients with cancer is often obscured by the peripheral neurotoxic effects of chemotherapeutic agents, metabolic disorders, and inactivity.

Stiff-person syndrome, characterized by muscle rigidity and painful spasms, has been described in association with breast cancer and autoantibodies against a 128-kd neuronal antigen concentrated at synapses and identified as amphiphysin. ^[73], ^[74]

Management and Prognosis of Paraneoplastic Syndromes as a Group

Paraneoplastic syndromes may be separated into those that are responsive and those that are unresponsive to therapy. Frequently, the syndromes responsive to therapy are characterized by antibodies directed against neurotransmitters or physiological processes: stiff-person syndrome with antibodies to glutamic acid dehydrogenase and Lambert-Eaton myasthenic syndrome with antibodies to gated sodium channels. More than one half of these patients with "neurophysiological or neurochemical" disorders of the brain stem, including opsoclonus with or without myoclonus or calcium channels such as stiff-person syndrome, are likely to respond to therapy. Less responsive are processes with a profound inflammatory component, including limbic encephalitis and peripheral microvasculitis of nerve and muscle. Refractory to therapy are cell degenerative processes: cerebellar degeneration with Purkinje cell loss, retinopathy, and motor neuronopathy.

Fully three fourths of patients with paraneoplastic syndromes, particularly those neurological syndromes reflecting neuronal loss within the cerebellum, brain stem, or spinal cord or pathological entities such as neuropathies with myelin loss, fail to respond to therapy and progress with their deficits. Broad therapeutic guidelines are difficult to outline. Faced with a possible paraneoplastic syndrome, expedient diagnostic procedures are warranted (see [Fig. 47-4](#)). If an underlying malignancy is found, appropriate treatment with surgery, chemotherapy, or radiation therapy is recommended. Concomitant treatment of the paraneoplastic syndrome is required to minimize injury to the neuraxis. In most cases of paraneoplastic syndromes, immunosuppressive therapy is necessary but may be difficult to coordinate with concurrent chemotherapy. Of the paraneoplastic syndromes that we term *neurophysiological* or *neurochemical*, the Lambert-Eaton myasthenic syndrome should be treated with 3,4-diaminopyridine. Because of the renal toxicities of guanidine, use of this drug should probably be avoided in a patient who may be undergoing chemotherapy with agents that require renal clearance. The remaining neurophysiological or neurochemical and inflammatory and degenerative paraneoplastic syndromes should be managed with immunosuppressive therapy.

Metastases to the nervous system and paraneoplastic neurological syndromes are an increasingly significant complication of systemic cancer. Early recognition allows for early therapeutic intervention in an attempt to improve quality of life and prolong survival.

HISTORY

Multiple sclerosis (MS) is now known to be a common malady even though it was first recognized as a distinct clinicopathological entity less than 150 years ago. ¹ The lack of reports before the early 1800s is sometimes interpreted as evidence that MS is a relatively new disease. However, it is more likely that the evolution of medicine as a science, which began at approximately the same time, led to more precise observation and description of human diseases. This view is strengthened by the observation of what may be the earliest clinical description of MS: the case of St. Lidwina of Schiedam (1380-1433), who developed a relapsing neurological disorder at the age of 18. ² Ollivier was the first to report a clinical case in the medical literature in 1824. ³ Shortly thereafter, Carswell illustrated a case of what is now clearly recognizable as MS in his atlas of anatomical pathology. Cruveilhier published gross pathological descriptions of MS together with clinical case descriptions. Although others certainly contributed (including Frerichs, Valentiner, Turck, Rokitansky, and Rindfleisch), Vulpian first suggested the rubric of "sclerose en plaque" in 1866. Charcot was primarily responsible for establishing MS as a unique and recognizable syndrome. ⁴ He also described the clinical spectrum and the histological appearance. Pierre Marie was the first to suggest an infectious cause of MS in 1884, a hypothesis that is still debated. Toxins were also considered to be responsible in the early 1900s. A major advance toward the understanding of demyelinating diseases was the discovery of experimental allergic encephalomyelitis (EAE) by Rivers in 1935. ⁵ A variety of different demyelinating diseases have subsequently been described ([Table 48-1](#)).

ROLE OF MYELIN

Myelin provides insulation for axons and is necessary for saltatory conduction. It is composed of tightly wrapped lipid bilayers with specialized protein constituents. Peripheral nervous system (PNS) myelin is formed by the extension of Schwann cells, and central nervous system (CNS) myelin is produced by oligodendrocytes. As the cell processes wrap around the axon, cytoplasm is extruded, leaving the inner (cytoplasmic) and outer (extracellular) plasma membrane leaflets in close apposition. Electron microscopy reveals several dozen spirals containing dense lines. The darker, major dense line is formed by the apposition of the inner leaflets, and the lighter, intraperiod line is formed by the close approximation of outer leaflets (Fig. 48-1 (Figure Not Available)). ¹ The myelin coating is interrupted at regular intervals (nodes of Ranvier) where the axon membrane with its concentration of voltage-gated sodium channels is exposed to the extracellular environment.

CNS and PNS myelin differ in a number of important ways. Schwann cells myelinate only one internodal segment from a single PNS axon, whereas oligodendrocytes myelinate multiple CNS axons. The proteins also differ. Proteolipid protein (PLP) accounts for approximately 50 percent of the CNS myelin proteins. PLP is an integral membrane protein responsible for holding the outer

leaflets together at the intraperiod line. Mutations in this highly conserved protein cause Pelizaeus-Merzbacher disease. Protein zero (P0) is the major PNS myelin protein and performs a function similar to PLP in compacting the intraperiod line. Myelin basic protein (MBP) makes up 30 percent of CNS and 10 percent of PNS myelin proteins. MBP is not an integral protein but binds to the cytoplasmic surface and is responsible for compaction at the major dense line. Myelin associate glycoprotein (MAG) accounts for about 1 percent of both peripheral and central myelin. Myelin oligodendrocyte glycoprotein (MOG) and cyclic nucleotide phosphodiesterase (CNP) are minor constituents of CNS myelin and are not found in the PNS. Peripheral myelin protein 22 (PMP22) is a minor component of PNS myelin.

MULTIPLE SCLEROSIS

Multiple sclerosis is an inflammatory relapsing or progressive disorder of CNS white matter and a major cause of disability in young adults. Pathologically, it is characterized by multifocal areas of demyelination with relative preservation of axons, loss of oligodendrocytes, and astrogliosis. Although certain clinical features are characteristic of MS, investigative studies are often needed to confirm the clinical suspicion and exclude other possibilities. These tests may be useful in monitoring disease activity in patients with MS. Recently, there have been advances in our understanding of the etiology, mechanisms of myelin injury, and potential for repair. Although ideal treatment does not exist, several new therapies are being investigated and others are or soon will be available for use.

Pathogenesis and Pathophysiology (Fig. 48-2). The pathogenesis and pathophysiology of MS is at best incompletely understood. There are several proposed mechanisms that may be important in the production of MS plaques: autoimmunity, infection, bystander demyelination, and heredity. Although convincing proof is lacking, dietary factors and toxin exposure have been hypothesized to contribute as well. These mechanisms are not mutually exclusive, and the true pathophysiology is likely to depend on more than one of them.

Autoimmunity. During ontogenesis, autoreactive lymphocytes normally undergo clonal depletion, but some escape and are merely suppressed, becoming tolerant of their antigens. Low levels of autoreactive T and B cells persist even in normal individuals. Autoimmune disorders occur when the tolerance of these cells toward their antigen is broken. The decreased suppressor activity of circulating lymphocytes from patients with MS and other presumed autoimmune diseases may reflect loss of tolerance.^[1] One potential mechanism that may break tolerance is molecular mimicry between self and foreign antigens. Autoreactive T4 lymphocytes may become activated on exposure to structurally similar foreign antigens. Some evidence suggests that molecular mimicry is relevant in MS. Not only do several viral and bacterial peptides share structural similarities with MBP, but it has also been demonstrated that a few of them are able to activate MBP-specific T-cell clones derived from MS patients.^[2] Blood-brain barrier leakage alone may break tolerance because it gives CNS-reactive lymphocytes easy access to otherwise inaccessible antigens. Alternatively, a primary event such as an infection or injury may release CNS antigens into the periphery, where they may activate corresponding autoreactive cells. The major support for autoimmunity in the pathogenesis and pathophysiology of MS is by analogy to EAE, the major animal model for MS (see later). EAE is, however, an artificial situation and there is no spontaneous autoimmune animal model of MS.

MBP has been the leading candidate for the autoimmune target in MS because of its ability to induce EAE. Humoral and T-cell immune responses to MBP are found in the blood of both MS patients and healthy controls, although the level may be higher in actively relapsing MS patients. MBP-reactive T-cells activated *in vivo* have also been identified in peripheral blood of MS patients.^[3] In the cerebrospinal fluid (CSF), MBP-reactive B and T lymphocytes and anti-MBP IgG are often present in patients with MS and other neurological diseases.^[4] The level of these findings seems to correlate with the extent of tissue injury but not necessarily with the etiology. Immune responses toward other CNS antigens have not been investigated as thoroughly but could be important. The findings of MBP-specific T and B cells in CSF and MBP-specific B cells and possibly T cells within CNS lesions leave little doubt as to the existence of an autoimmune response in MS. Because this response may be secondary to the release of sequestered CNS antigens by a primary event, it is uncertain if and to what extent autoimmunity is responsible for the pathology.

Infection. The role of viral infections in the initiation and maintenance of MS has been debated for some time. Several viral infections are known to cause demyelination in animals, including visna virus of goats and sheep, canine distemper virus, and Theiler's murine encephalomyelitis virus (TMEV). Viral infections in humans can also cause demyelination (progressive multifocal leukoencephalopathy [JC papilloma virus], subacute sclerosing panencephalitis [measles virus], and human T-cell lymphotropic or leukemia

virus type I [HTLV-I]-associated myelopathy). The epidemiology of MS suggests that environmental factors may promote the disease state, possibly due to one or more viruses. There are many ways in which a virus may be involved in the pathogenesis of MS:

1. Transient or persistent infection outside the CNS may activate autoreactive T cells by means of molecular mimicry or by other nonspecific means (as superantigens do).
2. Transient CNS infection may initiate a cascade of events that foster autoimmunity (breach the blood-brain barrier, release CNS antigens).
3. Recurrent CNS infections may precipitate repeated inflammation and demyelination.
4. Persistent CNS viral infection could either incite inflammatory reactions detrimental to oligodendrocytes or directly injure them.

Beyond speculation and epidemiology, there is slim evidence for a viral infection in MS. Early serological studies are difficult to interpret because of the nonspecific immune activation and resulting elevation of titers to many different viruses. Many MS patients have elevated CSF titers to such viruses as measles and herpes simplex (HSV), but this also appears nonspecific. Virus has rarely been cultured from CSF of MS patients, but a new strain of HSV (the MS strain) and a new virus (Inoue-Melnick virus) were first isolated from the CSF of MS patients.^{[10], [11]} Newer molecular techniques to search for a viral genome in CSF and brain have rejected the claim that HTLV-I is associated with MS. In addition, reverse transcriptase activity has not been detected in CSF using a very sensitive assay, thus disputing the involvement of any retrovirus. The finding that human herpesvirus 6, although present in 70 percent of brains from both controls and MS patients, is localized to the oligodendrocyte nuclei near plaques of MS patients and to oligodendrocyte cytoplasm in controls indicates that persistent CNS viral infection is common.^[12] This raises the possibility that MS may depend on an aberrant host response to this normal condition or that a defective virus that lacks the ability to evade immune detection may be to blame.

"Bystander" Demyelination. Immune actions may mediate myelin injury in a nonspecific manner. Many soluble products of the immune response other than immunoglobulins are known or suspected to be toxic to myelin and oligodendrocytes. Activated complement is capable of lysing oligodendrocytes in an antibody-independent fashion.^[13] The proinflammatory cytokine tumor necrosis factor- α causes myelin disruption and oligodendrocyte apoptosis *in vitro*.^[14] Arachidonic acid metabolites may also participate in myelinolysis, and reactive oxygen species released by macrophages cause lipid peroxidation that can damage myelin. Other soluble substances that are potentially

88

toxic to myelin include nitrous oxide and vasoactive amines.

Heredity. Epidemiological findings support a polygenic hereditary predisposition to MS. A number of candidate genes have been investigated, often with contrary results. The only definitively proven genetic association in MS is with serologically defined human leukocyte antigen (HLA) DR15, DQ6 (one of the DR2 haplotypes and also known as Dw2 in cellular terminology and DRB1*1501, DQA1*0102, DQB1*0602 in molecular nomenclature). However, the risk conferred by this haplotype is small (relative risk of 3 to 4), and it is neither necessary nor sufficient for the development of MS. Linkage to this locus has not been proven, indicating that it plays only a minor role in familial susceptibility. Other susceptibility genes undoubtedly contribute and may include the T-cell receptor (TCR) variable beta region and the IgG heavy-chain variable region, but these have not been confirmed. Twenty percent of MS patients have at least one affected relative. Only about 4 percent of first-degree relatives of patients develop MS, but this represents a 20- to 40-fold increase in risk compared with the general population. Unaffected family members sometimes have abnormal results of head magnetic resonance imaging (MRI), implying that this risk is even higher. One study of MS rates in adopted relatives of MS

patients verified that the familial distribution is due to genetic factors rather than shared environment. ^[15] Twin studies lend support to both genetic and environmental influences on MS development. Genetically identical monozygotic twins are more often concordant for MS than dizygotic twins (26 percent and 2.4 percent, respectively), indicating a genetic component ^[16]; however, even after following monozygotic twins past age 50 or using MRI data, less than 50 percent are concordant, suggesting a role for environmental factors.

Epidemiology and Risk Factors. MS is not a rare disease. It affects millions worldwide and approximately 400,000 in the United States alone. Symptoms usually begin during young adulthood, with the peak onset at age 24. Generally it occurs in persons between the ages of 15 and 50, although the first manifestations occasionally start during childhood or after age 50. Women are affected nearly twice as often as men. MS has a predilection for whites, especially those of northern European heritage. Other races and ethnic populations are resistant to a variable extent. It is virtually unknown among black Africans but occurs in African-Americans at half the rate of whites, possibly due to racial admixture or environmental factors. MS is rare in tropical areas, and the prevalence increases proportional to the distance from the equator, excluding polar regions. Although usually interpreted as the effect of environmental factors, the prevalence gradient is at least partially due to racial susceptibility. ^[17]

Perhaps the most incriminating evidence for the role of environmental factors in the development of MS are the changing risk with migration and the occurrence of MS clusters and epidemics. Immigrant populations tend to acquire the MS risk inherent to their new place of residence. Furthermore, the age at immigration is important in the subsequent risk of MS. Migration from high to low prevalence before the age of 15 lowers the MS risk, whereas migration after this age does not affect risk. ^[18] Migration from low to high prevalence areas increases the risk of MS, but the effect of age is less clear. Many clusters of MS have been reported. One of the more notable ones occurred in Key West in the mid 1980s. ^[19] Several others have been disputed; and despite wide speculation, no environmental cause for clustering has been identified. In fact, the majority of community-identified clusters are likely due to statistical chance alone. ^[20] The occurrences of MS epidemics in Iceland and the Faroe Islands have been proposed to be the result of exposure to a pathogen brought by British troops during their occupation in World War II.

Epidemiological data support the view that MS is caused or triggered by an environmental factor in persons who are genetically susceptible. The familial frequency and distribution implies that several genes contribute to susceptibility, and this is consistent with the low relative risk conferred by the genetic loci studied so far. Data from clusters, migration studies, and family studies reveal that there is a latent period of some 20 years between exposure to the environmental factor and the development of clinical symptoms and that the age at exposure is around 15, the putative age at acquisition.

The precise environmental events that lead to CNS demyelination are uncertain. Viral infection is the most plausible, but because of the nonspecific elevation of viral titers and long latent period there is little direct evidence. Minor respiratory infections precede 27 percent of relapses in patients with established MS. Measles infection was found to have occurred at a later age in MS patients than controls, although the incidence of MS has not been reduced by immunization against measles. Head injury and trauma have received attention as putative triggering events, but cohort studies have not verified any link. Pregnancy does not alter the risk of developing MS, but it does seem to influence disease activity. The relapse rate drops by about one third during the last two trimesters, but this is offset by an increase in relapse rate in the postpartum period. Most studies have found no long-term effects of pregnancy on the prognosis for progression or disability, although one did report a favorable effect. ^[21] A multitude of other environmental factors have been suspected to alter the risk for MS (cold climate, precipitation, amount of peat in the soil, exposure to dogs, and consumption of meat, processed meat, and dairy products), but none has been verified to be an independent risk factor.

Clinical Features and Associated Findings. MS can cause a wide variety of clinical features. Many signs and symptoms are characteristic, and a few are virtually pathognomonic for the disorder. Conversely, some symptoms are atypical and some are so rare as to suggest a different diagnosis ([Table 48-2](#)). The course of the illness is also variable, but it remains a critical consideration in the diagnosis of MS.

Sensory symptoms are the most common presenting manifestation in MS and ultimately develop in nearly all patients. ^[22] Loss of sensation (numbness), paresthesias (tingling), dysesthesias (burning), and hyperesthesias are common. These may occur in practically any distribution: one or more limbs, part of a limb, trunk, face, or combinations.

The more distinctive sensory relapses of MS consist of the sensory cord syndrome and the useless hand syndrome.

TABLE 48-2 -- DIAGNOSIS OF MULTIPLE SCLEROSIS

Clinical Features Suggestive of MS	Clinical Features Not Suggestive of MS
Onset between the ages of 15 and 50	Onset before the age of 10 or after 55
Relapsing/remitting course	Continued progression from onset without relapses
Optic neuritis	
Lhermitte's sign	Early dementia
Partial transverse myelitis	Seizures
Internuclear ophthalmoplegia	Aphasia
Sensory useless hand	Agnosia
Acute urinary retention (especially in young men)	Apraxia
Paroxysmal symptoms	Homonymous or bitemporal hemianopia
Diurnal fatigue pattern	Encephalopathy
Worsening symptoms with heat or exercise	Extrapyramidal symptoms
	Uveitis
	Peripheral neuropathy

Whereas features listed in the right column may be seen in MS, they are atypical and should prompt consideration of alternate explanations.

A common scenario is that of numbness or tingling beginning in one foot, ascending first ipsilaterally and then contralaterally. The sensory symptoms may ascend to the trunk, producing a sensory level, or may involve the upper extremities. Associated symptoms commonly include poor balance, weakness, urinary urgency, constipation, and Lhermitte's sign (see later). Brown-Sequard syndrome may occur with sensory disassociation and hemiparesis. The sensory cord syndrome reflects an evolving demyelinating lesion that begins in the medial posterior column ipsilateral to the first symptoms. A suspended sensory loss on one side of the trunk may also occur, possibly involving the upper extremity. Sensory cord syndromes are common in MS and suggest the diagnosis when they occur in young persons and remit spontaneously or in response to corticosteroids. Patients with the sensory useless hand may note subjective numbness and lose discriminatory and proprioceptive function, resulting in difficulty writing, typing, buttoning clothes, and holding on to objects especially when not looking at their hand. This can occur bilaterally even without lower extremity symptoms. The responsible lesion is in the lemniscal pathways either in the cervical spinal cord or in the brain stem. This syndrome usually remits over several months. The useless hand syndrome is a very specific symptom and is only rarely caused by other disorders.

A large portion of MS patients have persistent sensory loss usually consisting of diminished vibratory and position sensation in distal extremities. Itching may occur in a dermatomal distribution with relapse or in paroxysms. Pain is not a major manifestation of MS, but when it does occur it can be distressing to the patient. The most common complaints of pain are lower extremity dysesthetic pain associated with spinal cord involvement, radicular pain from lesions at the root entry zone, paroxysms (see later), and an uncomfortable sensation of pressure or tightness surrounding a leg or the trunk.

Pyramidal tract dysfunction is common in MS and causes weakness, spasticity, loss of dexterity, and hyperreflexia. Motor deficits can occur acutely or in a chronic progressive fashion and are usually accompanied by other symptoms. Paraparesis, quadriparesis, hemiparesis, weakness of one limb, and facial weakness are common manifestations. Subtle deficits are frequently worsened by exercise or heat. Weakness of trunk muscles resulting from spinal cord lesions may cause abnormal posture and occasionally respiratory muscle weakness occurs from cord or brain stem lesions. Symptoms of spasticity such as leg stiffness that impairs gait and balance or extensor and flexor spasms are other major causes of disability. Muscle atrophy is usually due to disuse, but lesions of the exiting lower motor neuron

fibers or of the anterior horn itself can cause a pseudora-diculopathy with segmental weakness, atrophy, and diminished reflexes.

The initial symptom of MS is optic neuritis in 17 percent of patients, and more than 50 percent experience a clinical episode of optic neuritis during their lifetime. The most common manifestation is visual loss in one eye that evolves over a few days. Periocular pain, especially with eye movement, usually accompanies and may precede the visual symptoms. Bilateral simultaneous optic neuritis is uncommon in adults, but formal visual field testing reveals unexpected defects in the clinically normal eye in a substantial number of patients. Children and Asian patients are more likely to have bilateral simultaneous optic neuritis. Examination shows an afferent pupillary defect, diminished visual acuity, subdued color perception, and often a central scotoma. Funduscopy examination is usually normal but occasionally will reveal papillitis (more common in children) or venous sheathing. Most patients begin to recover within 2 weeks, and significant visual recovery is common. There may be persistent visual blurring, altered color perception, or Uhthoff's sign (see later). Progressive worsening of visual acuity sometimes occurs, and MS patients without a clinical history of optic neuritis often have evidence of optic nerve involvement on funduscopy examination or visual evoked potentials.

Cerebellar pathways are frequently involved during the course of MS, but a predominately cerebellar syndrome is uncommon at onset. The manifestations include dysmetria, dysdiadochokinesia, action tremor with terminal accentuation, dysrhythmia, breakdown of complex motor movements, and loss of balance. Symptoms range from mild dyscoordination or gait unsteadiness to violent movement-induced tremor and complete loss of balance. Patients with long-standing MS may develop a "jiggling" gait and an ataxic dysarthria with imprecise articulation, scanning speech, or varying inflection, giving it an explosive character.

Urinary urgency, frequency, and urge incontinence (due to detrusor hyperreflexia or detrusor-sphincter dyssynergia) result from spinal cord lesions and are frequently encountered in MS patients. Symptoms of bladder dysfunction may be transient and occur with an exacerbation but are commonly persistent. Impaired vesicular sensation causes a high capacity bladder and may lead to bladder atonia with thinning and disruption of the detrusor muscle. This is an irreversible condition in which overflow incontinence results in constant dribbling of urine. Interruption of brain stem micturition center input sometimes leads to co-contraction of the urinary sphincter and detrusor muscles or detrusor-sphincter dyssynergia. The resulting high pressure

may lead to hydronephrosis and chronic renal failure if untreated. Constipation is a common problem, especially in patients with limited activity and spinal cord involvement. Fecal incontinence is a socially devastating symptom that is often associated with perineal sensory loss in MS patients.

Sexual dysfunction is a common problem of MS that is seldom mentioned. Nearly two thirds of patients report diminished libido. One third of men have some degree of erectile dysfunction, and a similar percentage of women have deficient vaginal lubrication. Besides direct neurological impairment, sensory loss, physical limitations, depression, and fatigue additionally contribute to sexual difficulties in MS patients. In addition, the partner's attitude and psychological factors dealing with self-image, self-esteem, and fear of rejection may also lead to impotence or loss of libido.

Intense vertigo associated with nausea and emesis is an occasional manifestation of MS relapse. In the absence of a clear diagnosis of MS, these symptoms are often attributed to vestibular neuronitis. Patients may also develop more persistent mild vertigo that is precipitated by movement, or this may be the residua after an acute relapse. Internuclear ophthalmoplegia, caused by a lesion in the medial longitudinal fasciculus, is the most common cause of diplopia in MS patients. When symptomatic, it produces horizontal diplopia on lateral gaze that usually remits. Examination discloses incomplete or slow adduction of the eye ipsilateral to the lesion and nystagmus of the contralateral eye during abduction (see [Chapter 9](#)). Dissociated nystagmus may be the only finding of an old or subtle internuclear ophthalmoplegia. Bilateral internuclear ophthalmoplegias are strongly suggestive of MS, although they rarely occur with tumor, infarct, mitochondrial cytopathy, Wernicke's encephalitis, and Chiari malformation. Vertical and diagonal diplopia usually result from skew deviation. Nystagmus, slow saccadic movements, broken ocular pursuits, and ocular dysmetria are other eye findings produced by lesions of cerebellar and vestibular pathways (see [Chapter 12](#)). Cranial nerve impairment is an unusual cause of diplopia in MS patients. Abducens paresis occurs on occasion, but oculomotor and trochlear nerve impairment are rare.

Brain stem plaques are seen on MRI more often than the occurrence of acute brain stem relapses. Corticospinal, spinothalamic, lemniscal, vestibular, and cerebellar pathways can all be affected. In addition, cranial nerve impairment may be seen with lesions that affect brain stem nuclei or exiting and entering fibers. Usually this occurs in association with other symptoms. Because of the long spinal tract and nucleus, the trigeminal nerve is frequently involved. Facial nerve paresis does occasionally occur, but MS is an extremely rare cause of Bell's palsy in patients without previous symptoms. Acute unilateral hearing loss is a fairly uncommon manifestation. Dysphagia is often due to impairment of cranial nerves IX, X, and XII and generally appears late in the course of some patients.

Once thought uncommon, cognitive disorders are now known to be present in 40 to 70 percent of MS patients.^[23] Age, duration of MS, and physical disability do not predict the presence of cognitive dysfunction, but the total lesion load seen on MRI does seem to correlate with the degree of cognitive decline. Brain atrophy, enlarged ventricles, and thinning of the corpus callosum also portend symptoms of cognitive dysfunction. Often the problems are subtle and may not be detected on standard mental status evaluation. The pattern of cognitive decline in MS is typified by memory loss, inattention, slow information processing, and difficulty with abstract concepts and complex reasoning. General intelligence is not typically affected. As expected, cortical symptoms such as aphasia, apraxia, and agnosia are distinctly unusual. Homonymous hemianopia, which can be caused by cortical or subcortical lesions, is also uncommon. Despite prominent cerebral white matter involvement, many of the disconnection syndromes such as alexia without agraphia, conduction aphasia, and pure word deafness have not been reported in MS patients.

Affective disorders are more frequent in MS patients than in the general population. These include both anxiety and depression. Neither of these symptoms is related to physical or cognitive disability or the lesion load visualized by MRI. Patients sometimes experience uncontrollable weeping or less commonly laughter noncongruent with their mood. Interruption of inhibitory corticobulbar fibers is responsible for these symptoms (pseudobulbar affect).

Fatigue is a pervasive symptom among MS patients that is not related to disability or depression. Severely affected patients often have a lack of initiative for both physical and mental activity and become easily tired. A diurnal pattern is characteristic and follows the normal circadian pattern of body temperature fluctuations, with the worse symptoms occurring in afternoon hours (peak core body temperature) giving way to improvement in the late evening.

MS symptoms may fluctuate in a predictable fashion. Transient worsening of symptoms frequently follows exercise or elevation of body temperature. One example is Uhthoff's phenomenon, in which visual blurring occurs during strenuous activity or with passive exposure to heat. These episodes resolve when the body temperature cools to normal or after a period of rest. An intercurrent infection with fever can induce worsening of symptoms and may be confused with a relapse. Heat sensitivity is presumably related to conduction block because demyelinated axons are more prone to failed conduction than normal, myelinated fibers.

Paroxysmal symptoms are characteristic of MS. They are believed due to the lateral spread of excitation, or ephaptic transmission, between denuded axons in areas of demyelination. Symptoms are typically brief in duration (seconds to 2 minutes) and occur frequently, occasionally dozens of times per day. They may be precipitated by hyperventilation, certain sensory input, or particular postures. Tonic spasms (paroxysmal dystonia) most often affect the arm and leg on one side, but the face, one limb, or bilateral limbs are sometimes involved. These spasms can result from lesions anywhere along the corticospinal tract. They often begin during the recovery phase after an acute relapse and remit after a few months. Intense pain and ipsilateral or crossed sensory symptoms may accompany them. Paroxysmal weakness occurs, but it is uncommon.

A wide variety of paroxysmal sensory symptoms may occur with MS, including tingling, prickling, burning, or itching; and sharp neuralgic pain is not uncommon. Trigeminal neuralgia may appear in patients with MS. The

occurrence of trigeminal neuralgia in a person younger than 40 is suggestive of MS. Lhermitte's sign (transient sensory symptoms usually precipitated by neck flexion) is usually described as an electrical or tingling sensation that travels down the spine or into the extremities. Although quite common in MS, Lhermitte's sign can also occur with a wide variety of other disorders, such as vitamin B₁₂ deficiency, spondylosis, Chiari malformation, and tumors, and after cisplatin chemotherapy. Several other paroxysmal symptoms are occasionally encountered, including paroxysmal dysarthria and ataxia, paroxysmal dyskinesia/dystonias, paroxysmal diplopia, and combinations of these symptoms. Facial myokymia and hemifacial spasm are additional transient (lasting months) phenomena sometimes due to brain stem demyelination.

Seizures occur in about 10 percent of MS patients. Focal motor seizures, possibly with secondary generalization, are the most frequent. The occurrence of seizures usually follow one of two patterns. On occasion, focal onset seizures begin early in the course of MS and later remit. The start of seizures late in the course of MS

more often poses a chronic problem and are frequently difficult to control.

MS is typified by multifocal CNS involvement and acute relapses, remissions, and/or slow progression of neurological deficits. A single episode of neurological dysfunction can be suggestive of MS if it follows the typical time course of a relapse: progression over less than 2 weeks (usually days), with or without a period of stabilization, and improvement or resolution (often over months). Insidious progression of deficits localized to a single site in the CNS can also be due to MS, but other possible causes must be excluded. The temporal course of MS can be described by one of four categories: relapsing/remitting (RR), secondary progressive (SP), primary progressive (PP), and progressive relapsing (PR).^[24]

Other terms have been used in the past to designate the course of MS, but because of the nonspecific terminology and overlapping course descriptions they are no longer used. Many previous clinical drug trials were performed in patients with a chronic progressive course. It is difficult to interpret these data because patients with both PP and SP MS were included and these patients may respond differently to treatment. Many physicians use the term *relapsing progressive*, which encompassed patients with SP, PR, and even those with RR MS who have stepwise relapse-related worsening disability. This term has recently been abandoned. Other terms that relate to the course of MS but have no consensus regarding their definition are sometimes encountered. *Benign MS* generally refers to patients who have had MS for a long period of time but yet have little or no disability. *Malignant MS* is sometimes used to describe patients with frequent relapses and incomplete recovery but is also used in reference to patients with acute fulminant demyelinating syndromes (see later).

The eye is the only organ outside the nervous system that is sometimes involved in MS. Uveitis and retinal periphlebitis each occur in at least 10 percent of MS patients. The uveitis can involve the posterior, intermediate (pars planitis), or rarely anterior portion and resembles that seen in other inflammatory (e.g., sarcoid, Reiter's syndrome, Behcet's syndrome, inflammatory bowel disease, systemic lupus erythematosus) and infectious (e.g., syphilis, tuberculosis, Lyme disease) conditions. Periphlebitis is seen as venous sheathing on fundoscopic examination and is histologically identical to the perivascular inflammation present in brain white matter. It is interesting that inflammation commonly occurs in the retina, which has a peripheral type of myelin produced by Schwann cells.

There are occasional reports of peripheral nerve or nerve root demyelination in MS patients as well as central demyelination in acute inflammatory demyelinating polyradiculoneuropathy and chronic inflammatory demyelinating polyradiculoneuropathy (see [Chapter 49](#)). Some of these cases may be due to the incidental occurrence of two unrelated disease processes. However, because the PNS and CNS share many antigens, including MBP, it is possible that an autoimmune reaction or a viral infection could involve both the CNS and PNS.

Persons with one autoimmune disorder generally have an increased risk of others. Even though there are several reports of systemic and organ-specific autoimmune diseases in MS patients, population-based studies have not confirmed any increase in prevalence of these disorders among MS patients.^[25] In fact, there appears to be a negative association between MS and rheumatoid arthritis. No increased risk of brain tumors or hematological malignancies have been found despite occasional reported associations.

Differential Diagnosis. There are few diseases that cause neurological deficits, regress spontaneously, and relapse in different areas of the CNS over the course of many years. However, because of the remarkable heterogeneity of MS, many disorders may resemble MS ([Table 48-3](#)), especially in the first years of active disease.

Other primary idiopathic inflammatory demyelinating CNS disorders may be mistaken for MS. Acute disseminated encephalomyelitis (ADEM) usually causes monophasic CNS demyelination. Although it frequently involves multifocal areas of white matter near simultaneously, ADEM cannot always be reliably differentiated from the initial clinical episode of MS. Fulminant brain demyelination in persons without previous symptoms of MS is more likely due to ADEM or other conditions (Schilder's myelinoclastic diffuse sclerosis, Balo's concentric sclerosis, Marburg's variant of MS). Neuromyelitis optica differs from MS primarily in the topography and intensity of the lesions.

Several systemic or organ-specific inflammatory conditions can involve the CNS white matter. Optic neuritis, myelitis, and other syndromes sometimes occur with systemic lupus erythematosus. Whether this autoimmune disease increases the risk of developing MS or causes similar syndromes by a different pathological process is unknown. Sarcoidosis can affect the nervous system in several ways, including multifocal corticosteroid-responsive white matter lesions. Sjogren's syndrome sometimes occurs with MS, but this may only represent a chance association. Behcet's disease has a predilection for the brain stem when it involves the CNS. Occasionally, isolated demyelinating syndromes are associated with inflammatory bowel disease.

A wide variety of vasculitic syndromes (e.g., primary angiitis of the CNS, periarteritis nodosa, Wegener's granulomatous angiitis, vasculitis associated with rheumatoid arthritis, Susac's syndrome, Eales' disease) may mimic MS. However, these syndromes can usually be distinguished by involvement of the cortex, seizures, early dementia,

TABLE 48-3 -- DIFFERENTIAL DIAGNOSIS OF MULTIPLE SCLEROSIS

Other inflammatory demyelinating CNS conditions	Cerebrovascular disorders
	Multiple emboli
	Hypercoagulable states
Acute disseminated encephalomyelitis	Sneddons syndrome
	Neoplasms
Neuromyelitis optica	Metastasis
Systemic or organ-specific inflammatory diseases	Lymphoma
	Paraneoplastic syndromes
Systemic lupus erythematosus	Metabolic disorders
Sjogrens syndrome	Vitamin B ₁₂ deficiency
Behcets disease	Vitamin E deficiency
Inflammatory bowel disease	Central (or extra) pontine myelinolysis
Vasculitis	
Periarteritis nodosa	Leukodystrophies (especially adrenomyeloneuropathy)
Primary CNS angiitis	
Susac's syndrome	Leber's hereditary optic neuropathy
Eales' disease	Structural lesions
Granulomatous diseases	Spinal cord compression
Sarcoidosis	Chiari malformation
Wegener's granulomatosis	Syringomyelia/syringobulbia
Infectious disorders	Foramen magnum lesions
Lyme neuroborreliosis	Spinal arteriovenous malformation/dural fistula
Syphilis	
HTLV-I associated myelopathy	Degenerative diseases
	Hereditary spastic paraparesis

Viral myelitis (HSV, VZV)
Progressive multifocal leukoencephalitis

Subacute sclerosing panencephalitis

Spinocerebellar degeneration
Olivopontocerebellar atrophy
Psychiatric disorders
Conversion reactions
Malingering

HTLV-I, human T-cell lymphotropic virus type I; HSV, herpes simplex virus; VZV, varicella-zoster virus; CNS, central nervous system .

personality changes, psychosis, infarcts involving large vessel territories on MRI, and lack of improvement. Findings characteristic to the particular vasculitis (uveitis and vitreal hemorrhage in Eales' disease; retinal and cochlear involvement in Susac's syndrome; upper and lower respiratory tract involvement in Wegener's granulomatosis) also aid in the correct diagnosis.

A few infections must also be considered in the differential diagnosis of MS. Both Lyme disease and syphilis may cause multifocal white matter lesions. HTLV-I causes a chronic progressive myelopathy (HTLV-I-associated myelopathy/tropical spastic paraparesis). Acute or recurrent myelitis can be caused by varicella-zoster virus or HSV. Progressive multifocal leukoencephalopathy and *Toxoplasma* abscesses should be considered in immunocompromised patients with progressive neurological decline. Bacterial endocarditis with brain abscess formation, subacute sclerosing panencephalitis, or chronic rubella encephalomyelitis may need to be considered in the appropriate circumstances.

Cerebrovascular disease is only rarely mistaken for MS. Occasionally, however, an MS relapse has an abrupt onset that may mimic an infarct, especially in those not previously diagnosed with MS. The usual circumstance is that of a hemisensory or hemimotor deficit imitating a lacunar infarct. Disorders with multiple cerebral infarcts (emboli, hypercoagulable states, Sneddon's syndrome, vasculitis) may produce an MRI appearance and course resembling MS. Vascular malformations may also produce symptoms similar to MS.

Additional neurological illnesses capable of producing multifocal lesions rarely manifest similar to MS. Metastatic tumors and multifocal gliomas have been reported as being suggestive of MS, but this must be considered extraordinarily rare. Lymphoma more commonly masquerades as MS because the lesions may involve the white matter, may be multifocal, and are corticosteroid responsive. In addition, demyelination sometimes presents as one (or a few) mass lesion(s). In this situation, biopsy may be needed for diagnosis. Neoplasms can cause paraneoplastic syndromes that may be confused with MS. A high index of suspicion must be kept for older age at presentation, subacute ataxia, early dementia, and personality changes.

A few metabolic disorders may resemble MS such as vitamin B₁₂ deficiency, vitamin E deficiency (seen in Bassen-Kornzweig syndrome, hypobetalipoproteinemia, and Refsum's disease), and central pontine or extrapontine myelinolysis. Leukodystrophies are usually not difficult to distinguish from MS. Krabbe's disease (galactocerebroside-beta-galactosidase deficiency), metachromatic leukodystrophy (arylsulfatase A deficiency), and the usual adult form of adrenoleukodystrophy (ALD) and adrenomyeloneuropathy (AMN) exhibit both central and peripheral dysmyelination. Blood leukocyte or fibroblast culture enzyme activity levels will confirm the diagnosis of Krabbe's disease and MLD, and elevated levels of very long chain fatty acids occur in ALD/AMN. Mitochondrial disorders should also be given consideration because symptoms and MRI appearance may be similar to MS. A relapsing remitting disorder identical to MS is sometimes seen in patients with the mutations responsible for Leber's hereditary optic neuritis.^[26] This usually occurs in female patients, and there may not be a family history of visual loss. A number of rare biochemically defined illnesses and other genetic disorders may occasionally merit consideration (including cobalamin and folate dysmetabolism, adult polyglucosan body disease, hereditary spastic paraparesis, spinocerebellar degeneration, and hereditary cerebrotretinal vasculopathy).^[27]

Several additional disorders must be excluded before diagnosing primary progressive MS. Spinal cord compression from spondylosis or tumor may produce chronic progressive myelopathy. Chiari malformations, syringomyelia, syringobulbia, other foramen magnum lesions, spinal arteriovenous malformations, and dural fistulas may also need consideration. These structural abnormalities are readily identified by imaging. Degenerative diseases such as olivopontocerebellar atrophy may mimic PP MS. MRI and CSF examination will help distinguish between the two.

When clinical and paraclinical findings are absent among a multitude of complaints or when apparent severe loss of function, without clinical evidence of neurological disease, is faced with a lack of concern, it may be appropriate to consider psychiatric disorders such as somatization, malingering, or conversion reactions.

Evaluation. The diagnosis of MS is based on the demonstration of white matter lesions disseminated in time and space in the absence of another identifiable explanation. MS remains a clinical diagnosis, although MRI, evoked potentials, and CSF examination can help clarify less certain cases. For research purposes, various categories of MS have been defined based on the certainty of the diagnosis.^[28] At least two attacks and evidence of two separate CNS

”

Figure 48-3 Head MRI of patients with MS. A, T1-weighted sagittal image showing multiple hypointense periventricular lesions. B, Axial T2-weighted image showing confluent periventricular high-intensity lesions most prominent at the frontal and occipital horns. A focal lesion is also present in the posterior limb of the left internal capsule. C and D, Periventricular lesions suggestive of MS. E, A single large right cerebellar hemisphere lesion seen on T2-weighted MRI. F, Peripherally gadolinium-enhanced large right occipital white matter lesion. Enhancement can also be seen along the temporal horn of the lateral ventricles.

lesions (clinical or paraclinical) are required for the designation of *clinically definite MS* (CD MS). Two attacks and evidence for one or one attack and evidence of two CNS lesions (clinical or paraclinical) is considered *clinically probable MS*. Cases that fulfill the criteria for clinically probable MS and have supportive CSF findings are labeled as *laboratory-supported definite MS*. Patients with a clear history of at least two attacks and supportive CSF but a normal neurological examination and no paraclinical evidence of CNS lesions are categorized as having *laboratory-supported probable MS*. Suspected cases that do not fit any of these criteria may be regarded as *possible MS*. Paraclinical evidence generally refers to abnormalities on evoked potential studies or imaging procedures, but urological studies and hot bath tests can also be used. To exclude the simultaneous development of lesions, as in ADEM, when using paraclinical evidence in patients with only one attack it must be known that the studies were normal at the time of that attack or, in the case of MRI, that new lesions have developed. The presence of both enhancing and nonenhancing white matter lesions on a single MR image must not be used as evidence of dissemination in time as well as space, because these can also be seen in ADEM. The presence of oligoclonal bands (OCBs) and an elevated IgG index or synthesis rate provide supportive CSF findings.

Ancillary tests are frequently required to confirm the diagnosis of MS and to exclude other possibilities. Laboratory tests on peripheral blood can help to exclude many of the infectious and other inflammatory disorders. A chest radiograph is generally needed to assess for sarcoid or paraneoplastic disorders if these are under consideration. An ophthalmological examination may be needed to search for alternate causes of visual loss. Imaging studies, CSF examination, and evoked potentials are often helpful because characteristic abnormalities are frequently present.

MRI of the head is the most sensitive study for MS and

”

is far more useful than computed tomography (CT). Eighty-five to 95 percent of CD MS patients have abnormalities on head MRI (Fig. 48-3). Focal areas of increased T2-weighted and decreased T1-weighted signal reflect the increased water content associated with demyelinated plaques. The MRI appearance of MS lesions, however, is not specific and similar abnormalities may be seen in normal aging, small penetrating vessel infarcts, Lyme disease, tropical spastic paraparesis/HTLV-I associated myelopathy (TSP/HAM), sarcoid, systemic lupus erythematosus, Sjogren's syndrome, mitochondrial cytopathies, vasculitis, and ADEM. The specificity for MS can be increased by consideration of lesion number, size, location, and shape.^[29] This is especially important in persons older than 50. MRI characteristics that are strongly suggestive of MS include multiple lesions (more than three), size larger than 6 mm, oval shape (often with the long axis directed perpendicular to lateral ventricles), and locations in the periventricular area, corpus callosum, and posterior fossa.

Longitudinal MRI studies have shown the evolution of MS lesions.^[30] Gadolinium enhancement, indicating blood-brain barrier disruption, sometimes precedes the development of T2-weighted lesions and lasts for 2 to 4 weeks. The new T2-weighted lesion has a fuzzy border and enlarges over a few weeks. After a period of

stabilization, the T2-weighted lesion regresses and becomes more sharply delineated from the surrounding white matter as edema resolves. Most of the time, a residual abnormality with increased T2 weighting and decreased T1-weighted signal remains, reflecting demyelination and gliosis. The MRI activity of disease, defined as either the number of new, recurrent, and enlarging lesions or the number of gadolinium-enhancing lesions, is much higher than the clinical activity. This may be either because of the involvement of asymptomatic areas of the CNS or because of a pathophysiological difference between symptomatic and nonsymptomatic lesions based on the presence or absence of axonal dysfunction.

There is only a poor correlation between disability and lesion load (volume of white matter abnormalities) determined by head MRI. Sometimes individuals have severe impairment and few abnormalities, and the converse may occur. This disparity is partially explained by variable spinal cord involvement, but a pathophysiological difference may account for some of the discrepancy.

MRI has become an important component of recent clinical trials. Because of the high sensitivity of MRI for disease activity, it is reasoned that periodic MRI can determine treatment efficacy much more quickly than monitoring relapse rate or disability level. Many studies have used MRI as a secondary outcome, and a few have used it as a primary outcome, a true surrogate marker of the main parameter of interest.

Additional MRI techniques have also proven useful in the diagnosis of MS. MRI of the spinal cord shows discrete lesions in about 80 percent of CD MS patients. Fluid attenuated inversion recovery eliminates the CSF signal from T2-weighted images and increases the contrast of lesions and sensitivity of both head and spine MRI. Short time-inversion recovery suppresses fat signal and is useful in detecting optic nerve lesions. Magnetization transfer imaging takes advantage of the macromolecular environment of protons and can discern early edematous lesions, which are frequently reversible, from chronic demyelinated and gliotic lesions that are nonreversible. MR spectroscopy is used to determine the biochemical changes that occur in lesional and nonlesional white matter of MS patients.

CSF evaluation remains a valuable diagnostic tool for MS. A lymphocytic pleocytosis occurs during acute exacerbations in about one third of patients, but this seldom

exceeds 50 cells. Total protein is often mildly elevated, and the proportion of gamma-globulin is high owing to the synthesis of immunoglobulins within the blood-brain barrier. The majority of CSF immunoglobulin is IgG, although IgM and IgA may also be elevated. Measures of intrathecal IgG production have been devised that are more useful than simple gamma-globulin levels. The IgG index and synthesis rate are elevated in 70 to 90 percent of CD MS patients and occasionally in other disorders (see later). Agarose gel electrophoresis, or the more sensitive isoelectric focusing of CSF proteins, often reveals discrete bands of immunoglobulin, each a monoclonal antibody. It is pertinent to compare serum and CSF banding patterns because peripheral monoclonal gammopathies may produce CSF bands. To reduce false-positive results, only unique CSF OCBs should be reported. Between 85 and 95 percent of CD MS patients have OCBs; however, early in the course they are not as prevalent. Once present, OCBs persist and the pattern does not vary, although new bands occasionally appear. Unlike subacute sclerosing panencephalitis, in which the majority of OCBs are antibodies specific for measles virus, the specificity of OCBs in MS is unknown.

The presence of OCBs does not necessarily imply MS, because up to 8 percent of non-MS CSF samples contain them.^[31] Other inflammatory or infectious illnesses are usually responsible for OCBs in non-MS patients, and in these instances they often do not persist. The presence of myelin components, antimyelin antibodies, and kappa light chains in CSF has also been used in the diagnosis of MS. However, the sensitivity and specificity of these products is less than that of OCBs.

Evoked potentials are summed cortical electrical responses to peripheral sensory stimulation that can be used to localize sites of pathology and measure conduction velocity along sensory pathways. Visual evoked potentials (VEP) and somatosensory evoked potentials (SSEP) may detect subclinical sites of demyelination, thus providing evidence of multifocality. Brain stem auditory evoked potentials (BAEP) are occasionally informative. More than 90 percent of persons with a history of optic neuritis have an abnormal VEP, and 85 percent of CD MS patients have abnormalities on VEPs even when the history of optic neuritis is absent. Slowed conduction is present on SSEP in nearly three fourths of patients with CD MS. BAEPs are the least sensitive, with abnormalities in approximately 50 percent. MRI has largely supplanted the use of evoked potentials in MS because of the greater sensitivity in the diagnosis and the detailed anatomical information it provides.

Management. There is no available prevention or cure for MS. Yet a number of therapies may hasten recovery from exacerbations, provide symptomatic relief of symptoms, maximize physical abilities, and prevent certain complications. In addition, treatments that alter the natural course of MS have become available and others are being developed. Methods of enhancing recovery are also being explored.

Acute Exacerbations. Corticosteroids are the most commonly used treatment for MS, although there have been few studies to address their efficacy. Adrenocorticotropic hormone (ACTH) was shown to speed recovery from an exacerbation but had no effect on the ultimate degree of recovery. Because of the unpredictable cortisone response to ACTH, oral prednisone and later intravenous methylprednisolone became the preferred treatments. The Optic Neuritis Treatment Trial verified that intravenous methylprednisolone but not prednisone increased the recovery rate and unexpectedly increased the time to the next relapse, thus delaying the diagnosis of CD MS.^[32] Moreover, the prednisone-treated group had twice as many recurrences. The reason for this unconfirmed finding and its relevance to those with definite MS are unknown. Nonetheless, it has affected the practice of treating acute MS exacerbations. The current recommendation is to treat disabling attacks with 500 to 1000 mg of intravenous methylprednisolone per day for 3 to 5 days with or without a short tapering dose of oral corticosteroids.

Because up to one third of patients do not have adequate recovery after a relapse despite the use of corticosteroids, other therapies are needed. Unfortunately, the only additional controlled clinical study to address this evaluated the combination of simultaneous ACTH and cyclophosphamide with true or sham plasma exchange.^[33] Although the group treated with plasma exchange was thought to recover faster, the benefit was marginal at best and this treatment program has found no clinical utility. Plasma exchange alone was found beneficial in some patients with severe inflammatory demyelinating episodes who had failed to improve with intravenous therapy with methylprednisolone,^[34] and a double-blind crossover study is in progress to confirm this finding.

Alteration of the Natural Course. The primary goal of drug treatment is to alter the natural course of the disease. In MS clinical trials, this means reduction in the frequency and severity of relapses, preventing the chronic progressive phase, and slowing the progression of disability. The activity of disease seen on MRI is often used as a secondary outcome. Many different immunosuppressive and immunomodulating therapies have been evaluated, and several other studies are in progress.

Cyclophosphamide is an alkylating agent that has indiscriminant cytotoxic effects on rapidly dividing cells, including lymphocytes, making it a potent immunosuppressant. Several studies have claimed a beneficial effect in both relapsing and progressive patients. Because one of the major studies included ACTH, intravenous methylprednisolone is sometimes given with the cyclophosphamide. Other trials have not found a favorable effect. Because of the inconsistent results, high potential for serious side effects, and adverse reactions, including hemorrhagic cystitis and malignancy, cyclophosphamide is not widely used. Some centers, however, use cyclophosphamide in patients with aggressive disease in whom more conventional treatments have failed.

Numerous studies have shown azathioprine, a purine analog antimetabolite, to have marginal efficacy in the treatment of MS. A meta-analysis of all blind, placebo-controlled studies confirmed a slight benefit of slowed progression and less frequent relapses.^[35] The toxicity of azathioprine and its slow onset of action have prevented its widespread use. Besides the liver toxicity and hematological effects, the induction of malignancies has been a concern. One retrospective study did not find an increased incidence

of cancer in MS patients treated with azathioprine, but this remains a potential risk.

Methotrexate is a folate antagonist that is effective in rheumatoid arthritis. Weekly low-dose oral methotrexate was found to delay upper extremity dysfunction in SP MS patients, although it had no effect on the more traditional measures of disability, including the Expanded Disability Status Scale (EDSS).^[36]

The use of cyclosporine in the treatment of MS has been evaluated in three clinical trials, none of which have demonstrated a convincing benefit. In addition, side effects such as hypertension and elevation of creatinine were fairly common. Cladribine is a nucleoside derivative that was found to decrease relapse rate and slow the progression in patients with SP MS in an initial investigation.^[37] Although cladribine was administered intravenously through a surgically implanted central venous line in that study, a large clinical trial is being done to determine whether the drug is effective when administered subcutaneously. The drug is better tolerated than other parenteral immunosuppressants, although bone marrow suppression is a risk.

Interferons are a class of peptides that have antiviral and immunoregulatory functions. A pilot study of interferon-gamma in MS was aborted after an increased

exacerbation rate was noted. In retrospect, this was not surprising because it is now known to be a proinflammatory, TH1-related cytokine that acts in part by increasing HLA type II expression. Interferon-alfa and interferon-beta have similar physiological actions and are part of the anti-inflammatory TH2 response. Interferon-beta 1b (Betaseron) was the first drug approved by the U.S. Food and Drug Administration (FDA) specifically for the treatment of MS. A large clinical study in RR MS patients demonstrated a reduction in the frequency of relapses by about one third with subcutaneous injection every other day.^[38] The severity of relapses was also lessened. Perhaps the most striking observation was its effect on MRI. The placebo-controlled group continued to accumulate white matter lesions, whereas patients in the high dose arm (8 million IU) had stabilization of their MRI and did not accumulate higher lesional volumes. No difference was found in the disability levels, however. Patients on a low dose of interferon-beta 1b actually did worse than placebo-treated patients on clinical measures, although there was a favorable effect on MRI behavior. This observation remains unexplained. Interferon-beta 1b is being further investigated in SP MS patients. Side effects include injection site reactions, flulike symptoms (low-grade fever, myalgias, headache; these lessen in frequency after treatment for a few months), mild liver enzyme elevation, and lymphopenia. Depression and attempted suicide were more common in the treated groups. One particularly disturbing result was the production of neutralizing autoantibodies in 38 percent of patients after 3 years of treatment. Not only do patients with these antibodies thereafter fail to respond to this drug, but there is also a concern that neutralizing antibodies may cross react with natural interferon-beta and interfere with its function. The long-term effects of these antibodies are unknown.

Another formulation of interferon-beta has been approved by the FDA. Interferon-beta 1a (Avonex) has the same amino acid sequence as natural interferon-beta and differs from interferon-beta 1b by one amino acid as well as by the presence of carbohydrate moieties. Once-weekly intramuscular interferon-beta 1a has been found to have effects similar to that of interferon-beta 1b in reducing the frequency of MS relapses.^[39] In addition, a favorable effect on disability was also demonstrated and side effects were less common. Neutralizing antibodies occurred half as often as with interferon-beta 1b. MRIs showed less enhancing lesions in the treated group but no difference in the change of lesional volume after 2 years. Duration of follow-up was, however, much less in the interferon-beta 1a study than in the interferon-beta 1b trial.

Copolymer 1 is a synthetic mixture of polypeptides produced by the random combinations of four amino acids that are frequent in MBP. After a preliminary study suggested efficacy, a randomized, double-blind, placebo-controlled, multicenter trial showed a 29 percent reduction in relapse rate and a mild positive effect on disability in RR MS patients.^[40] No MRI data have been presented.

Numerous additional therapies have been tested, and many others are undergoing evaluation. The antiherpesvirus drug acyclovir has been shown to reduce relapse frequency in a small prospective trial. Total lymphoid irradiation was found to slow the chronic progression of MS; but because this approach precludes the later initiation of immunosuppressant drugs and may be associated with a higher mortality rate, it is not widely used. Results of the initial small study of the immunosuppressant drug mitoxantrone seemed promising, but subsequent studies have found only modest effects. Monthly treatment with intravenous immunoglobulin in RR MS patients resulted in fewer and less severe relapses in addition to slowing the accumulation of disability in one small study. A unique mechanism of action is being explored with the use of oral myelin in a large phase III clinical trial. This trial tests the hypothesis that the oral administration of antigen may induce tolerance through either active suppression or anergy/deletion. Vaccination with CD52, CD4, irradiated MBP-specific CD4 cells, TCR variable beta 6, and variable beta 5.2 are under investigation in MS patients. Additional ongoing studies are investigating the potential role of sulfa-salazine and tacrolimus.

Symptomatic Treatment. Spasticity is common even in patients with only minimal weakness. It is usually prudent to begin treatment of mild spasticity with a stretching program. The addition of an evening dose of benzodiazepine may help relieve extensor spasms and clonus that may interfere with sleep. As spasticity worsens it becomes necessary to use baclofen. Doses should be escalated slowly to prevent the occurrence of overt side effects, and up to 120 mg/day may be required. Although baclofen is well tolerated in most patients, limiting side effects such as sedation and increased muscle weakness occur, and rarely a paradoxical increase in spasticity is noted. Liver enzyme elevation and nonconvulsive status epilepticus presenting as encephalopathy have also been reported in association with baclofen. Abrupt withdrawal of baclofen may result in hallucinations or seizures, making it necessary to taper doses. Despite symptomatic improvement, antispasticity measures may not increase function or independence. In paraplegic patients with severe spasticity and intolerance

to the required oral dose, intrathecal baclofen delivered by a subcutaneously implanted pump allows a much smaller dose and is often effective in alleviating intractable spasticity and may lessen urinary urgency. Tizanidine seems to be as effective as baclofen. Dantrolene has been used for spasticity, although the therapeutic window is small.

The treatment of fatigue is far from optimal, and medications are only partially effective. Amantadine at 100 mg twice per day is the standard initial treatment, although pemoline 37.5 mg daily is also superior to placebo. The stimulating effects of the selective serotonin reuptake inhibitors may also be somewhat effective in combating MS-related fatigue. Often, however, patients need to limit activities and schedule rest periods. Similarly, emotional incontinence may be amenable to a low dose of a tricyclic antidepressant.

Paroxysmal symptoms are highly responsive to medical treatment. A small dose of carbamazepine is often very effective. If not tolerated, several alternative medications may be tried, including phenytoin, acetazolamide, baclofen, and gabapentin. In addition, misoprostol has been claimed to be effective in MS-related trigeminal neuralgia. After about 1 month of treatment, periodic attempts at tapering off these medications is a reasonable approach because these symptoms usually remit. Seizures are treated no differently than in non-MS conditions. Heat sensitivity may require avoidance of precipitating activities, but this depends on the nature of symptoms and the situation in which they occur. If the precipitating activity cannot be avoided, a cooling jacket may be an option. A potassium channel blocker, 4-aminopyridine improves temperature sensitivity in some patients but occasionally causes seizures or disturbing paresthesias. Action tremor is a common disabling symptom. Unfortunately, it is often only marginally amenable to medical therapy. Clonazepam may afford some relief, but tolerance frequently develops, necessitating increasing doses. Isoniazid and carbamazepine have also been found marginally beneficial. One clinical trial showed ondansetron to reduce tremor-related disability. Anecdotal reports suggest that gabapentin may be partially effective. Improvements in stereotactic neurosurgery have made thalamotomy a legitimate option in those whose disability is mainly due to tremor and not ataxia.

Dysesthetic pains are difficult to control but sometimes respond to tricyclic antidepressants, carbamazepine, or baclofen. Gabapentin and tramadone may also be effective. Standard analgesics are not often useful in MS-associated pain, and narcotics should be avoided in the treatment of chronic pain.

Symptoms of a hyperreflexic bladder (urgency, frequency, and urge incontinence) are often manageable with anticholinergics such as oxybutynin, propantheline, or imipramine. A flaccid bladder can sometimes be aided by bethanechol, although intermittent catheterization is more often needed. Symptoms that suggest urinary retention (a feeling of incomplete emptying, frequency, hesitancy, or a need to apply pressure to the lower abdomen to urinate) should prompt evaluation with urinalysis and a post-void residual urine measurement. Residuals in excess of 15 ml are abnormal; and if they are above 50 ml, consideration should be given to urological consultation for more thorough investigation and to blood chemistries to determine urea and creatinine levels. Detrusor-sphincter dyssynergia, diagnosed by cystometry, is treated with anticholinergics, sometimes with the addition of an alpha-1 blocking agent (terazosin [Hytrin]) or intermittent catheterization. It is important to reassess bladder function periodically, and residuals should be monitored if there are any persistent changes in function or symptoms. Intermittent catheterization should be considered when post-void residuals reach 100 ml. A chronic indwelling urinary catheter should be avoided if reasonably possible. It is usually not necessary to use antibiotics prophylactically in the prevention of urinary tract infections. Urinary calculi may be prevented by acidification of the urine with cranberry juice. Constipation can usually be managed with bulk laxatives and stool softeners. More severe cases may require osmotic agents, bowel stimulants, anal stimulation, suppositories, or enemas. Bedridden patients may develop fecal impaction unresponsive to these measures and require manual disimpaction. Fecal incontinence can be minimized by adherence to a schedule for bowel movements.

It is pertinent to determine the precise nature of any sexual dysfunction in patients with MS. Physical difficulty from spasticity may be alleviated by premedication with baclofen, and a fast-acting anticholinergic such as oxybutynin may calm urinary urgency. Sexual dysfunction should not be automatically attributed to MS. It may be necessary to investigate hormonal levels and to obtain urological or gynecological consultation. Manual lubrication with gel is a ready solution to vaginal dryness. Erectile dysfunction may be treated by vacuum devices, intracavernous injections of papaverine (or combinations of papaverine, prostaglandins, and epinephrine; triple agent), or penile implant.

It is advisable for MS patients to attain good health habits, including proper diet and fitness. Smoking, excess alcohol, and obesity should be avoided. Exercise can help maximize function by increasing and maintaining joint mobility, strength, and stamina. This may in addition promote fitful sleep and possibly reduce the impact of fatigue. Physical and occupational therapy can play an important role in regaining independence. Canes, walkers, and wheelchairs or scooters may be needed to maintain safe mobility. Hand controls can be installed in automobiles for patients with lower extremity dysfunction. In debilitated, immobilized patients, periodic shifts in posture to change weight-bearing regions and air or water mattresses prevent bed sores. Passive range of motion exercises prevent contractures.

Enhancement of Recovery. The exact reason for persistent neurological deficits in MS is unknown. Primary demyelination, axonal dysfunction, extensive gliosis, or

axonal loss may all contribute. In the past it was thought that the CNS had no potential for remyelination. Pathological studies have suggested that limited remyelination does occur but is arrested for unknown reasons. Immunization with spinal cord homogenate was found to markedly enhanced central remyelination in an EAE model. Using the TMEV model (confirmed in EAE), Rodriguez identified two monoclonal autoantibodies that promote CNS remyelination.^[41] A preliminary study based on these studies found that intravenous immunoglobulin (IVIG) improved vision and VEP latencies in some MS patients with presumably

permanent visual impairment.^[42] Currently phase II trials are being done to determine if IVIG treatment can lead to functional improvement in patients with apparently irreversible weakness or optic nerve dysfunction.

Pregnancy. Before initiation of any drug in a woman of reproductive age, the potential for teratogenicity must be discussed. The treatment of acute exacerbations is unchanged during pregnancy, although one might have a higher threshold for treatment. Both corticosteroids and plasma exchange are relatively safe to use during pregnancy. None of the drugs used to alter the disease course, however, should be used during pregnancy, and they should be stopped if pregnancy occurs. The cytotoxic immunosuppressants have teratogenic effects, and interferon-beta induces spontaneous abortion in animals. The effects of many of the other drugs are unknown. It is best if these drugs are stopped several months before a planned pregnancy.

Prognosis and Future Perspectives. Because most information on the prognosis of MS is reported in terms of the EDSS, it is important to have some understanding of this scale. The EDSS is a 10-point scale with each increase representing worsening symptoms or function. The score is derived from severity scores in each of six systems as well as ambulation and work ability. A score of 0 means no signs or symptoms; 1 to 3 represent mild disability with no or minimal impairment of ambulation; 3.5 to 5.5 refer to moderate disability and impairment of gait; the need for a cane to walk one-half block (100 m) marks a score of 6; an EDSS of 8 refers to the need for a wheelchair and effective upper extremity function; an EDSS of 10 refers to death related to MS.

MS has a highly variable outcome, ranging from asymptomatic to fulminant with death ensuing in a matter of months. Autopsy series have estimated that unsuspected MS may occur in as many as 0.2 percent of the population. Even when symptomatic, MS may cause only nuisance symptoms. Benign MS, when defined as unrestricted ambulation or EDSS of 3 or less 10 years after onset, accounts for about one third of cases. However, many of these patients acquire more disability at a later time. When considering all patients with MS, Weinshenker found that 15 years after onset, 80 percent had EDSS worse than 3, 50 percent had reached EDSS of 6 or more, 10 percent were at EDSS 8, and 2 percent had died. The percentage of patients with initially RR MS who develop SP MS increases steadily with disease duration.^[43] At 10 years, 40 to 50 percent have continual deterioration; and after 25 years, approximately 80 percent have slow progression.

Natural history studies have identified several prognostic indicators that predict outcome to a limited extent. Factors associated with a better prognosis (slower accumulation of disability, longer time before chronic progression) include young age at onset, female gender, RR course (as opposed to PP MS), initial symptoms of sensory impairment or optic neuritis, first manifestations affecting only one CNS region, high degree of recovery from initial bout, longer interval between first and second relapse, low number of relapses in the first 2 years, and less disability at 5 years after onset (both EDSS and number of systems affected--sensory, motor, sphincter, brain stem, vision, cerebral). Despite the indolent nature, a PP course is the worst prognostic factor, with the median time to reach EDSS 6 of only 6 years, compared with approximately 20 years in RR patients. Men and patients with an older age at onset are more likely to have PP MS.

The survival of MS patients is only slightly below expected. Seventy-six percent of patients are alive 25 years after onset, which is 85 percent of that seen in age- and sex-matched controls.^[25] MS is rarely the direct cause of death, although respiratory failure from cervical myelopathy or extensive cerebral and brain stem demyelination and death occasionally occurs with acute or subacute exacerbations.^[46] Complications of MS such as pneumonia, pulmonary emboli, aspiration, urosepsis, and decubiti are responsible for 50 percent of deaths. Most of the other deaths are from heart disease, cancer, cerebrovascular disease, and trauma. Suicide is the only cause of death that is overrepresented among these cases. The suicide rate among MS patients may be as high as two to seven times that of non-MS persons.

The next decade may bring further delineation of susceptibility genes and possibly the mechanism by which they exert their actions. The virology of MS, including the possible role of human herpesvirus 6, will likely be further clarified. Persistence of additional viruses within the CNS may be discovered, adding complexity to this situation.

It seems clear that global immunosuppression is only marginally effective. Current studies concentrate on immune modulation by inhibiting or augmenting certain aspects of the immune response. The strategies employed include the following: induction of tolerance to MBP and other myelin components; reduction of T-cell subsets by the use of monoclonal antibodies, vaccination, or drugs; administration of anti-inflammatory (TH2) cytokines; inhibition of proinflammatory (TH1) cytokines; and blocking the trafficking of activated lymphocytes into the CNS.

NEUROMYELITIS OPTICA

Neuromyelitis optica (NMO) is an uncommon neurological illness characterized by the occurrence of optic neuropathy and myelopathy in close temporal relationship. The separation from MS has become questioned, owing to the frequent dissemination of lesions outside the optic nerves and spinal cord. Part of the difficulty lies with the broad, imprecise, and inconsistent definition. The names Devic's syndrome, Devic's disease, and NMO are often used interchangeably, although the first name encompasses all patients who fit the above definition and the second and third should only be used to refer to those patients presumed to have a distinct disorder. The term *opticospinal MS* is often used in the Far East to denote patients with exclusive or predominant involvement of optic nerves and spinal cord, encompassing most patients with Devic's syndrome.

Pathogenesis and Pathophysiology. Devic's syndrome may occur with ADEM, autoimmune disorders, MS, and possibly viral infections. Not surprisingly, the pathological descriptions are quite varied because these patients are invariably a heterogeneous group. Classically, acute spinal cord lesions demonstrate diffuse swelling and softening that extend over several levels or involve nearly the entire

cord in a continuous or patchy distribution. Acutely, there is destruction with dense macrophage infiltration involving white and gray matter, loss of myelin and axons, and lymphocytic cuffing of vessels. In chronic lesions, the cord is atrophic and necrotic, with cystic degeneration and gliosis. In the absence of perivascular cuffing, these extensive lesions resemble infarctions. The prominent spinal cord swelling in the confines of the restrictive pia presumably may raise intramedullary pressure, leading to the collapse of small parenchymal vessels, further propagating tissue injury. Proliferation of vessels with thickened and hyalinized walls similar to that seen after infarction or other extensive injury may occur.^[45] Less fulminant lesions commonly coexist and are much more typical of inflammatory demyelination. The optic nerves, chiasm, and occasionally cerebral hemispheres are involved in a similar fashion with either demyelinating lesions, necrotizing lesions, or both.

Epidemiology and Risk Factors. Devic's syndrome occurs in patients of varied ages (range, 1 to 73). The mean age at onset of monophasic Devic's syndrome is 27, whereas relapsing NMO (see later) tends to occur in an older age group (mean age at onset of 43). Monophasic Devic's syndrome affects males and females equally, whereas relapsing NMO affects females predominantly (F:M, 3.8:1). One third of patients have a preceding infection within a few weeks of neurological symptom onset. Most commonly this is a nonspecific upper respiratory tract infection, flu, or gastroenteritis. The most common specific infections preceding the development of Devic's syndrome are chickenpox and pulmonary tuberculosis. Devic's syndrome has also followed vaccination for swine flu and mumps. Only a few instances of the familial occurrence of Devic's syndrome have been reported, and in one of these families a unique mitochondrial mutation was found. Devic's syndrome is said to be more common in Japan and East Asia, although even there it is uncommon (less than 5 per 100,000).

Clinical Features and Associated Findings. Symptoms of optic neuritis and myelitis develop over hours to days and are often preceded or accompanied by headache, nausea, somnolence, fever, or myalgias. Continued progression of symptoms over weeks or months occasionally occurs. Most patients (greater than 80 percent) develop bilateral optic neuritis. Bitemporal or junctional field deficits, indicating chiasm involvement, are sometimes present early in the course of the optic neuritis. Visual loss is often accompanied by periocular pain, and myelitis onset is sometimes heralded by localized back or radicular pain. Lhermitte's sign is common. Severe degrees of neurological deficits are usual, and the degree of recovery is variable.

Patients who present with Devic's syndrome can follow one of several possible courses. Approximately 35 percent have a monophasic illness, 55 percent develop relapses nearly limited to the optic nerves and spinal cord (relapsing NMO or opticospinal MS), and rarely patients have a fulminantly progressive course without relapses or a course typical of MS.^[46] Relapsing NMO is often associated with autoimmune disorders, most commonly systemic lupus erythematosus. These patients also frequently have an elevated erythrocyte sedimentation rate and nonspecific elevation of autoantibodies, including antinuclear antibodies, anti-dsDNA, and antiphospholipid antibodies. Tonic spasms and neuropathic lower extremity pain are common sequelae to the spinal cord damage. Symptoms referable to brain stem lesions (nystagmus, ophthalmoparesis, vertigo) can occur in these patients as well.

Differential Diagnosis. The differential diagnoses for Devic's syndrome includes MS, ADEM, pulmonary tuberculosis, and viral infection (especially in the immunocompromised patient). In patients with an apparent affected family member, consideration should be given to mitochondrial disease. Relapsing NMO should raise the suspicion for associated autoimmune disorders. Because Devic's syndrome can occur in persons older than the age of 60, when an unrelated ischemic optic neuropathy could occur, and because isolated or recurrent myelopathy may precede the optic neuritis, additional consideration must be given to spinal cord compression, spinal cord tumor, and spinal arteriovascular malformation or dural fistula.

Evaluation. Imaging is needed to exclude structural lesions and provide information on the pathological process. Optic nerve or chiasm enlargement, T2-weighted signal changes, and enhancement may be seen on head MRI during the acute phase. Increased T2-weighted signal in the medulla is not uncommon and usually represents extension of high cervical lesions. Cerebral white matter lesions can be seen on head MRI in about 25 percent of cases. Spine MRI characteristically shows cord swelling, signal changes, and enhancement extending over several levels (Fig. 48-4). This appearance may resemble a spinal cord tumor, prompting consideration for biopsy. An occasional patient may need prone and supine myelography to exclude a spinal dural-based AVM. Laboratory investigations reveal an elevated erythrocyte sedimentation rate in one third, positive antinuclear antibodies in nearly one half, and occasionally other autoantibodies.^[47] It is reasonable to exclude syphilis, Lyme disease, and human immunodeficiency virus by laboratory testing. A chest radiograph helps to exclude pulmonary tuberculosis and sarcoidosis. CSF examination is an essential part of the evaluation for Devic's syndrome, and repeated studies are sometimes necessary to ensure that there is no infection in that the CSF findings are sometimes atypical for inflammatory demyelination. In contrast to MS, a minority of patients with Devic's syndrome (17 percent) have a normocellular CSF during the acute phase. A marked pleocytosis is often present, sometimes exceeding 100 cells. Moreover, neutrophils are commonly seen in CSF and may predominate, a situation virtually unknown in MS.^[46],^[47] The protein concentration is often very high and in 41 percent exceeds 100 mg/dl. Despite the intense inflammatory response, OCBs are conspicuously absent in the majority, being present in fewer than 20 percent of patients. CSF serology for the herpesvirus family (HSV types 1 and 2, varicella-zoster virus, Epstein-Barr virus, and cytomegaloviruses) is important, and polymerase chain reaction testing should be done in cases suggestive of viral infection (immunocompromised patients).

Management. Patients with acute or subacute Devic's syndrome often respond to corticosteroids (e.g., intravenous methylprednisolone). Limited experience suggest that they may respond to plasma exchange even when intravenous methylprednisolone does not produce significant improvement. Attempts at preventing relapses and the subsequent

Figure 48-4 Spine MRI of patients with relapsing NMCA. Sagittal T2-image of the cervical spine showing cord expansion and signal abnormalities extending through the cervical and upper thoracic. T1-weighted sagittal MRI showing cord swelling and extensive gadolinium enhancement from C1 to C7. Further enhancement is seen in the upper thoracic aC and D. Sagittal T2-weighted spine MRI showing a diffuse hyperintense lesion extending from T1 to the conus.

disability are often disappointing even with the use of immunosuppressive agents (e.g., azathioprine, cyclophosphamide).

Supportive care is a mainstay of management. Patients with Devic's syndrome are prone to many complications and require measures to prevent deep venous thrombosis and pulmonary embolism, urinary tract infection, decubiti, and contractures. Mechanical ventilation may be needed either temporarily or permanently. Patients with monophasic Devic's syndrome generally have simultaneous or rapid onset of the optic neuritis and myelitis (interval usually less than 1 month). Although some have significant residual disability, many recover remarkably and have little or no permanent deficits. A history of previous vague neurological symptoms or

definite demyelinating events is predictive of future relapses, either typical of MS or relapsing NMO. Those patients destined for recurrent myelitis and optic neuritis have a longer interval between the onsets of myelitis and optic neuritis. The vast majority of patients with relapsing NMO have very aggressive disease with frequent and severe exacerbations and a poor prognosis.

ISOLATED INFLAMMATORY DEMYELINATING CNS SYNDROMES

Region-restricted episodes of CNS inflammatory demyelination in persons without prior symptoms often represent the initial manifestation of MS, although some may be a forme fruste of ADEM (see later). The probability of recurrent demyelinating episodes has been the subject of several important investigations, and several clinical features and test results are of predictive value. Optic nerve, spinal cord, and brain stem are the most common sites of these recurrent monosymptomatic events, and the time profile follows that of MS relapses. The pathogenesis, pathophysiology, epidemiology, clinical features, associated disorders, differential diagnosis, evaluation, and management are the same as in MS and are discussed previously.

In these cases, the prognosis for visual recovery after each episode of optic neuritis is good and most patients regain normal visual acuity. Profound visual loss, recurrent optic neuritis, and age older than 35 are associated with a

higher risk for poor recovery. Investigators have concluded that recurrent multifocal demyelinating episodes, fulfilling the diagnostic requirements of CD MS, develop in 50 percent or more of patients after isolated optic neuritis when follow-up is extended beyond 20 years.^[48] Most of this risk is incurred within the first few years, although significant risk may continue into the fourth decade after the event. Children much more often develop simultaneous bilateral optic neuritis and have a lower risk for subsequent MS than adults. Factors that are associated with an increased risk of *developing* MS as a disseminated illness are the presence of venous sheathing, recurrent optic neuritis, family history of MS, white race, previous vague or nonspecific neurological symptoms, and the presence of OCBs, elevated IgG index, or IgG synthesis rate in CSF. Head MRI gives the most strongly predictive information. The relative risk of one or more cerebral white matter lesions, found in approximately 50 percent of optic neuritis patients, is 3 to 14. Of the 44 patients with monosymptomatic optic neuritis in one study, 82 percent of those with abnormal MRI fulfilled the diagnosis of MS within 5 years whereas only 6 percent of those with normal or nonspecific findings on MRI developed MS.^[49] The Optic Neuritis Treatment Trial also found an increased risk of MS in those with cerebral white matter lesions on MRI (27.7 percent of those with an abnormal head MRI vs. 9.3 percent of those with a normal head MRI after 3 years of follow-up).^[32] Both of these studies found that a higher number of lesions correlated with an even greater risk of MS.

The severity of acute transverse myelitis is inversely related to the risk of acquiring further symptomatic demyelinating lesions. Complete transverse myelitis with profound loss of motor, sensory, and sphincter function imparts a relatively low risk of 3 to 14 for the later diagnosis of MS. Partial transverse myelitis with preservation of significant motor function at peak is associated with a much higher incidence of MS. Head MRI further delineates the risk. In a study by Ford and associates, 11 of 12 patients with partial transverse myelopathy and cerebral white matter lesions on MRI developed MS within 3 years of follow-up whereas only 1 of the 3 patients with normal MRI progressed to MS.^[50] Excluding the 2 patients with complete transverse myelopathy in Morrissey's study, 59 percent of the patients with an isolated spinal cord syndrome and abnormal head MRI met the criteria for MS during a 5-year follow-up and 11 percent of patients with normal MRI had recurrences of multifocal demyelination.^[49]

Although monosymptomatic brain stem demyelination is not as common as either optic neuritis or acute transverse myelitis, similar conclusions have been reached. In the only study available, two thirds of these patients with cerebral white matter lesions detected on MRI developed MS within 5 years, compared with none of 5 patients with normal head MRI.^[49]

EXPERIMENTAL ALLERGIC ENCEPHALOMYELITIS

As mentioned earlier, there is no spontaneous animal model that closely resembles MS. EAE is the most widely studied animal model of this disease. EAE is an antigen-specific, T-cell-mediated autoimmune disease that can be induced in many species, although rat and mice models predominate in the literature. Acute EAE is a monophasic illness that more closely resembles ADEM. Chronic-relapsing EAE closely mimics the clinical course of MS with repeated clinical relapses from which the animal makes an incomplete recovery; some animals develop a slow progressive course after several relapses. Although there is considerable variability in the various EAE models, several closely parallel the pathological picture of MS with perivascular inflammation and primary demyelination initially and subsequent gliosis and axonal loss.

Studies in EAE have advanced our understanding of the various stages of disease initiation that may underlie the MS disease process, including the initial immune activation of T cells by encephalitogenic antigens and factors that influence T cell recognition; TCR restriction; the genetic influences on disease resistance, susceptibility, and recovery; T cell/macrophage interactions; the various roles of soluble mediators of inflammation (including TH1 and TH2 cytokines); factors regulating blood-brain barrier permeability; T cell/adhesion molecule interactions; factors influencing oligodendrocyte function and survival; and possible ways to reduce astrocytic proliferation and induce remyelination.

For decades, investigators have used EAE to screen for potentially effective therapies. Recent work has focused on the chronic-relapsing EAE model, extending the multitude of previous studies of immunosuppressive drug therapies. Current work includes strategies to enhance TH2 cytokine production and block TH1 cytokine function; therapies that target T-cell subsets, class II molecules of the major histocompatibility complex, and TCRs used for the recognition of encephalitogenic antigens (using monoclonal antibodies, altered peptide analogues, and T-cell vaccination studies that target TCR variable regions). EAE has been used to enhance understanding of the many possible mechanisms whereby interferons may influence immunemediated CNS injury and to explore the possibility that antigen-specific immunotherapy may ultimately be applicable to patients through either oral tolerance ("bystander suppression," anergy or clonal deletion) or with peptide analogues to encephalitogenic antigens.

Another widely studied animal model is Theiler's murine encephalomyelitis virus model. Intracranial inoculation with Theiler's virus leads to chronic infection and chronic inflammatory demyelination. Studies have shown that immune suppression ameliorates the pathological damage in this model, verifying that it is the immune response and not the viral infection that is responsible for the chronic demyelination. TMEV has been particularly useful in exploring a number of possible mechanisms of inducing remyelination in the setting of chronic demyelination. As outlined earlier, both polyclonal antispinal cord immunoglobulins and monoclonal antibodies directed against several protein antigens and chemical haptens have been shown to promote extensive CNS remyelination in TMEV. This work has led to two phase II clinical trials of human immunoglobulin in patients with optic neuritis and multiple sclerosis.

ACUTE DISSEMINATED ENCEPHALOMYELITIS

Acute disseminated encephalomyelitis is a monophasic inflammatory demyelinating disorder that characteristically begins within 6 weeks of an antigenic challenge such as infection or immunization. It occurs more often in the young and causes the rapid development of multifocal or focal neurological deficits. Perivenous inflammation, edema, and demyelination are the pathological hallmarks of ADEM, although these lesions commonly enlarge and coalesce, forming lesions pathologically indistinguishable from MS. Moreover, perivascular changes typical of ADEM are common in patients with MS. There is considerable overlap in the epidemiological, clinical, CSF, imaging, and pathological features between ADEM and MS, often making it difficult to distinguish between the two with reasonable confidence when encountering patients with a single demyelinating event.

Pathogenesis and Pathophysiology. ADEM closely resembles EAE both clinically and pathologically and is most likely due to a transient autoimmune response toward myelin. The occurrence of ADEM after vaccination with the rabbit spinal cord preparation of rabies virus led to the discovery of EAE. Infections and non-CNS-containing vaccinations may induce ADEM by molecular mimicry or by activating autoreactive T-cell clones in a nonspecific manner. Lymphocyte reactivity toward MBP has been identified in blood and CSF from patients with ADEM, but its absence in others indicates a role for other antigens.

Epidemiology and Risk Factors. ADEM can occur at any age but, perhaps because of the higher frequency of immunization and exposure to new antigens, it is most common during childhood. Unlike MS, both sexes are affected with equal frequency. No association has been noted with pregnancy.

ADEM has been reported to follow a number of different immunizations, usually within 6 weeks, including those for pertussis, diphtheria, measles, mumps, rubella, and influenza (postvaccination ADEM). However, the only epidemiologically and pathologically proven association is with rabies vaccination, which also causes demyelinating peripheral neuropathies. The original Pasteur rabies vaccine, prepared in rabbit spinal cord, was associated with an incidence of ADEM of approximately 1 per 3,000 to 35,000 vaccinations and is no longer in use. A later vaccine, made in duck embryo, which contains little neural tissue, carries a risk for ADEM of 1 per 25,000 vaccines. The use of human diploid cell lines, which contain no nervous system tissue, for the production of rabies vaccine has virtually eliminated the risk of ADEM. The association of bee stings with ADEM has also been reported.

Parainfectious ADEM usually follows onset of the infectious illness, often during the recovery phase, but because of the latency between pathogen exposure and illness it may precede clinical symptoms of infection or the two may occur simultaneously. The most commonly reported associated illness is a nonspecific upper respiratory tract infection. There have been a vast number of specific infections associated with ADEM, such as virus infections (including rubella, mumps, herpes simplex, varicella-zoster, Epstein-Barr, cytomegalovirus, influenza, and coxsackievirus) and infection with *Mycoplasma*, *Borrelia burgdorferi*, and *Leptospira*. Measles carries the highest risk for ADEM of any infection, occurring in 1 per 400 to 1,000 cases. Although ADEM has been reported in association with measles immunization, the risk is far lower than the risk of acquiring measles and its neurological complications.

Clinical Features and Associated Disorders. A prodrome of headache, low-grade fever, myalgias, and malaise often precedes the onset of ADEM by a few days. Neurological symptoms develop rapidly and are commonly associated with encephalopathy, stupor, coma, meningismus, and seizures. A variety of neurological manifestations may occur, reflecting the focal or multifocal involvement of brain, brain stem, cerebellum, optic nerves, and spinal cord. The mortality rate is generally 10 to 25 percent. Peak severity occurs within several days, and recovery may begin soon afterward. More than 50 percent of survivors have a marked recovery with no or minimal functional impairment. Occasionally, ADEM may evolve over a few months and there may be a second clinical deterioration or subacute progression for a time. In these unusual cases, the distinction from MS is difficult.

Differential Diagnosis. One of the primary concerns after a single demyelinating episode is whether other bouts can be expected (e.g., MS). Several features may tip the balance toward one or the other, but the proper diagnosis becomes apparent only with time. Classically, ADEM is characterized by the multifocal involvement at onset whereas MS often presents with monosymptomatic deficits such as optic neuritis. However, ADEM may cause unifocal symptoms and MS may present with multifocal CNS involvement, especially in children. The monosymptomatic deficits caused by ADEM are more commonly severe, such as bilateral optic neuritis and complete transverse myelitis. Although OCBs occur transiently in about one third of ADEM cases, their persistence implies a diagnosis of MS. The subsequent disappearance of OCBs, when performed by consistent techniques, is evidence against MS. The MRI appearance of these two disorders is often identical, ^[51] but the presence of basal ganglia or cortical lesions, or large globular white matter lesions, is more frequent in ADEM.

The fulminant development of ADEM is distinctive but not pathognomonic, because a rare form of MS known as Marburg's MS is also rapid in onset and often deadly. The appearance of brain stem, periventricular, and multiple, large cerebral white matter lesions and the presence of OCBs may distinguish Marburg's variant from ADEM.

On rare occasions, inflammatory demyelinating lesions may reach a large size and resemble tumors (especially lymphoma) on MRI, necessitating biopsy for clarification. There is usually one dominant lesion, but smaller separate lesions may be identifiable. These have been referred to as both ADEM and MS in the literature. The prognosis for recovery is often quite good, although approximately one third suffer subsequent attacks. Some develop typical MS, whereas others have recurring tumor-like lesions. The term *multiphasic ADEM* has been used when patients have large recurrences in the same location, and *relapsing ADEM* refers to recurrences at different sites. The relationship of these entities with MS is unclear.

Balo's concentric sclerosis refers to the pathological finding of alternating bands of demyelination and remyelination.

These patients typically have large lesions and subacute deficits similar to those described earlier. Typical demyelinating lesions commonly coexist, and rarely CD MS patients are noted to have similar-appearing lesions. The reason for this peculiar alternating pattern is unknown.

Schilder's myelinoclastic diffuse sclerosis is another rare condition that may be confused with ADEM or other demyelinating conditions. This is a progressive demyelinating disorder that usually begins in childhood. The features are often atypical and include dementia, aphasia, homonymous hemianopia, seizures, psychosis, elevated intracranial pressure, and the absence of OCBs. The most characteristic finding is the presence of two large, roughly symmetrical lesions on MRI, one in each hemisphere. The diagnosis is made by excluding the known inherited leukodystrophies, especially adrenoleukodystrophy.

Management. Treatment with intravenous methylprednisolone seems to halt progression and allow recovery to begin sooner, just as with MS. Plasma exchange can be tried in those with severe deficits and little response to corticosteroids.

Chapter 49 - Demyelinating Disorders of the Peripheral Nervous System

Robert W. Shields Jr
Asa J. Wilbourn

History and Definitions

Overview of Peripheral Nervous System Myelination and Electrophysiology

Acute Inflammatory Demyelinating Polyradiculoneuropathy (Guillain-Barre Syndrome)

Chronic Inflammatory Demyelinating Polyradiculoneuropathy

Monoclonal Gammopathies of Undetermined Significance

Multiple Myeloma

Osteosclerotic Myeloma

Waldenstrom's Macroglobulinemia

Motor Neuropathy with Multifocal Conduction Block

Reviews and Selected Updates

References

HISTORY AND DEFINITIONS

Waldrop, in 1834, reported a single patient who probably had acute inflammatory demyelinating polyradiculoneuropathy (AIDP), thereby providing the first clinical description of a demyelinating polyneuropathy. Landry, in 1859, described 10 patients who very likely had the same disorder; he recounted most of the clinical features now considered typical for AIDP. Guillain, Barre, and Strohl, in 1916, reported two soldiers who were recovering from rapidly evolving, principally motor polyneuropathies. They emphasized the loss of the deep tendon reflexes (DTRs) and the presence, on cerebrospinal fluid (CSF) examination, of an elevated protein level with a normal cell count (albuminocytological dissociation). Their paper probably has been the most influential of all the articles concerned with demyelinating neuropathies; from it the commonly used eponymic title for AIDP derives, that is, the Guillain-Barre syndrome, or GBS. Haymaker and Kernohan, in 1949, reviewed the pathology they had found in 50 fatal cases of AIDP. Their paper confirmed, both on a clinical and pathological basis, that Landry's ascending paralysis and GBS were, in fact, the same disorder. In 1955, Waksman and Adams first produced experimental autoimmune neuritis (EAN) by injecting peripheral nerve tissue, with adjuvants, into rabbits. In 1969, Asbury, Arnason, and Adams observed lymphocytic infiltration and segmental demyelination on pathological examination of spinal roots and nerves in all 19 patients they studied who had died of GBS, thus establishing a pathological link between GBS and EAN. [↩](#) [↪](#) [↩](#) [↪](#)

The first diagnostic criteria for AIDP were proposed in 1935. Several others have been proposed since then. Formulated in 1978 by Asbury, Arnason, Karp and McFarlin, the most widely used set resulted from a colloquium sponsored by the National Institute of Neurological and Communicative Disorders and Stroke; it was triggered by claims against the United States government for AIDP resulting from the 1976 swine influenza vaccination program. The electrodiagnostic (EDX) features of AIDP were first described in detail by Lambert and Mulder in 1964. [↩](#) [↪](#) [↩](#) [↪](#)

Osler and Targowla reported chronic progressive and relapsing forms of polyradiculoneuropathy in the 1890s. However, many of the clinical features of what is now termed chronic inflammatory demyelinating polyradiculoneuropathy (CIDP) were first catalogued by Austin in 1958. Austin's report triggered the widespread use of corticosteroids in patients thought to have this disorder. [↩](#) [↪](#) [↩](#) [↪](#) Nonetheless, there was no generally accepted clinical presentation for CIDP until 1975, when Dyck and co-workers established it as a distinct clinical entity, based on their review of 53 patients. [↩](#) [↪](#) Because the features of CIDP are relatively nonspecific, a number of polyneuropathies and polyradiculoneuropathies associated with specific diseases resemble, and may represent instances of, it.

OVERVIEW OF PERIPHERAL NERVOUS SYSTEM MYELINATION AND ELECTROPHYSIOLOGY

The peripheral nervous system (PNS) comprises less than 0.1% of all nerve tissue. The somatic PNS, when defined anatomically by the presence of Schwann cells, includes the primary roots, dorsal root ganglia, mixed spinal nerves, plexuses, nerve trunks, autonomic nervous system, and the third to twelfth cranial nerves. Peripheral nerve trunks are composed of a great number of axons, which are grouped into individual bundles or fascicles. These structures vary in number, depending on the nerve, its size, and the site at which it is studied. Schwann cells ensheath

every PNS axon nearly throughout their extent. Peripheral nerve fibers are divided into two groups, either myelinated and unmyelinated, depending on whether they have one, or several, axons per Schwann cell. In the human sural nerve, the ratio of unmyelinated to myelinated axons is approximately 3.7 to 1.

A myelinated peripheral nerve fiber consists of an axon and a series of Schwann cells located sequentially on its external surface. Each Schwann cell encircles the axon segment adjacent to it with a multilayered cell membrane structure, the myelin sheath. The short, constricted, myelin-free axon segment where consecutive Schwann cells abut each other is called the node of Ranvier. This region contains voltage-gated Na^+ channels. The myelin-coated axon segment between two nodes of Ranvier is an internode. Saltatory conduction is the characteristic means of impulse transmission along myelinated fibers. The myelinated axon is depolarized only at the nodes of Ranvier, thereby permitting it, compared with an unmyelinated fiber, to conduct much faster. Approximate linear correlations have been noted between myelin thickness and conduction velocity (CV). Myelinated motor axons conduct impulses centrifugally to the extrafusal muscle fibers, whereas myelinated sensory axons transmit impulses centripetally from the muscle spindles and Golgi tendon organs; they subservise the sensations of touch, pressure, and vibration.

Segmental demyelination (SD), or damage to the myelin sheath, can be either primary or secondary. With primary SD, only the myelin portion of the nerve fiber is affected; the axon is spared. Via different mechanisms, a number of processes can cause primary SD, including diphtheria toxin, lead salts, acute and chronic compression, and certain diseases, such as GBS. Nonetheless, both clinically and electrophysiologically, the demyelination that results is quantitatively the same. With secondary SD, damage to the myelin results from initial changes in the axon, typically consisting of chronic shrinking and atrophy. Axon atrophy with secondary SD occurs in some chronic polyneuropathies, for example, uremia. Pathophysiologically, whether it is primary or secondary, SD produces conduction abnormalities--slowing or block--as well as abnormal (ectopic) impulse generation. Clinically, these abnormalities can result in muscle weakness, impairment of large fiber sensory modalities, fasciculations, myokymia, cramps, and paresthesias.

The underlying pathology of a specific peripheral polyneuropathy frequently can be predicted by its EDX features. Based on these EDX features, most peripheral polyneuropathies can be divided into two types: (1) axonal degeneration or axon loss (frequently referred to as axonal) and (2) SD. Both familial and acquired polyneuropathies can be found in each group. For example, axon loss polyneuropathies include familial Charcot-Marie-Tooth, type II (Dyck classification) and acquired arsenic polyneuropathy, while SD polyneuropathies include familial Charcot-Marie-Tooth, type I, as well as acquired AIDP and CIDP. Most classifications make no distinctions between peripheral polyneuropathies and peripheral polyradiculoneuropathies, although often their clinical and EDX presentations differ from one another. All of the acquired disorders discussed in this section actually are polyradiculoneuropathies, regardless of the terminology used.

With axon loss polyneuropathies and polyradiculoneuropathies, the main EDX changes are (1) on nerve conduction studies (NCS), uniform reduction of amplitudes, ultimately culminating in unelicitable responses at all stimulation points, accompanied by no significant alterations in latencies or CVs, because they are being determined along surviving, unaffected axons; (2) on needle electrode examination (NEE), fibrillation potentials, accompanied by reduced motor unit potential (MUP) recruitment, if the motor nerve involvement is severe, and chronic neurogenic MUP changes, if the disorder is chronic.

With generalized SD disorders, the underlying pathophysiology may be conduction slowing, conduction block, or both, depending on the severity of involvement of the individual fibers. Whenever SD conduction slowing affects all, or nearly all, the large myelinated fibers to the same degree, then only the latencies and CVs are affected on NCS. The amplitudes and durations of the responses are unaltered. Alternatively, if conduction is slowed along different fibers to different degrees, then the NCS responses become dispersed, and as they do so, the amplitudes decrease (Fig. 49-1). With SD conduction block lesions, the NCS responses decrease in amplitude but are not dispersed (Fig. 49-2). However, SD lesions affect only a focal area of nerve, so the amplitudes on stimulating distal to that area (while recording still more distally) are unaffected, because conduction is being determined along a normal segment of nerve. On NEE, conduction slowing produces no changes, whereas conduction block, if severe, causes reduced MUP recruitment.

Some confusion exists regarding the pathophysiological and clinical correlations found with these two basic types of peripheral nerve lesions. Unelicitable responses and low-amplitude nondispersed responses are the NCS counterpart of weakness and of fixed sensory deficits, due to

Figure 49-1 Motor nerve conduction studies of the ulnar nerve in a patient with CIDP, recording from the hypothenar eminence with stimulation at (top trace), distal to the elbow(second trace), above the elbow(third trace), axilla (fourth trace) and at supraclavicular notch(bottom trace). With stimulation at more proximal sites, there is a cumulative effect of segmental demyelinating lesions, resulting in dispersion of the responses with conduction block.

Figure 49-2 Motor nerve conduction studies of the median nerve in a patient with motor neuropathy with multifocal conduction block, recording from the thenar eminence with stimulation (top trace) and above the elbow(bottom trace). A severe conduction block is noted in the segment of nerve between the two stimulating sites.

involvement of large myelinated fibers. They indicate that, regardless of cause, impulses are not able to traverse the nerve segments between the stimulation and recording sites. The only two pathophysiological processes that produce such NCS amplitude changes are axon degeneration and SD conduction block. In contrast, SD conduction slowing has very few clinical counterparts. If differential slowing is present, certain neurological examination techniques that require transmission of highly synchronized nerve volleys may be altered, for example, DTRs and vibratory sensation. However, SD conduction slowing generally does not produce clinical weakness when it affects motor axons. The fact that nerve impulses are reaching the muscle fibers a few milliseconds later than normal is of no significance.

Based on various EDX features, familial and acquired demyelinating disorders often can be differentiated from one another, and the acquired disorders can be subdivided into acute and chronic types. Familial SD polyneuropathies are length-dependent polyneuropathies and have predictable presentations that vary principally with the severity of the process. Some of their features are (1) NCS of the same type (i.e., motor or sensory) are affected earlier and more severely in the lower extremity than in the upper extremity; (2) in a given limb, the sensory NCS, compared with the motor NCS, tend to be involved earlier and more severely; (3) NCS of the same type, assessing nerve segments at approximately the same limb level, are affected to approximately the same degree; (4) NCS performed on corresponding nerves in contralateral limbs are affected equally; (5) along any specific nerve, conduction rate abnormalities are uniform; (6) late responses, H-responses and F waves, usually are unelicitable; (7) NEE abnormalities appear first and ultimately are most severe in the more distal lower extremity muscles.

In contrast to the familial demyelinating polyneuropathies, the acquired demyelinating disorders are all polyradiculoneuropathies. Nonetheless, at times they have an EDX presentation identical to that seen with the familial polyneuropathies, and in those instances, they cannot be distinguished from the familial types in the EDX laboratory. This most frequently occurs in patients with CIDP and with AIDP in the recovery stages. More often, however, the EDX findings with the acquired disorders deviate sufficiently from those listed earlier so that they can be recognized. This is particularly the case with AIDP relatively early in its course. There are several such variations: (1) nerves of the same type may show abnormalities that are more severe in the upper extremities than in the lower extremities, for example, the sural NCS may be normal, whereas the median sensory NCS may be grossly abnormal; this combination of changes virtually is never seen with a familial demyelinating polyneuropathy; (2) abnormalities may be focal or multifocal, rather than generalized, along a specific peripheral nerve; thus, a conduction block or focal slowing may be found only between the elbow and wrist segment of the median nerve, whereas it may be absent from more distal and more proximal segments or, conversely, progressive conduction blocks or progressive differential slowing may be found along a nerve; (3) nerves of the same type, in the same limb, at the same level, often show very dissimilar findings; (4) homologous nerves in contralateral limbs may be affected differently; (5) in a given limb, motor NCS may be more abnormal than sensory NCS; (6) H-responses and F waves may be variably affected; with acute disorders they may be abnormal when the standard NCS are normal, if the SD conduction changes are restricted to the proximal segments of the PNS; (7) on NEE, abnormalities may be found in any muscle, or they may be generalized, rather than manifesting a distal-proximal gradient. With acute SD polyradiculoneuropathies, conduction blocks often dominate the NCS, whereas with chronic SD polyradiculoneuropathies, conduction slowing typically is prominent. This chapter focuses on several acquired forms of neuropathies, most of which are

characterized by SD.

ACUTE INFLAMMATORY DEMYELINATING POLYRADICULONEUROPATHY (GUILLAIN-BARRE SYNDROME)

Until approximately a decade ago, GBS was considered to be a single clinical entity, a rapidly evolving sensorimotor polyradiculoneuropathy resulting from widespread demyelination in the PNS and due to inflammation. Consequently, GBS was viewed as synonymous with AIDP. However, it is now obvious that demyelination is only one of the causes for the combination of clinical features labeled GBS; different pathological processes can lead to the same clinical presentation (Table 49-1).^[13],^[14] In 1986, Feasby and co-workers reported that some patients who were considered to have GBS had axon loss rather than SD as their underlying pathophysiology; these cases have been labeled the acute axonal form of GBS.^[15] More recently, it has been appreciated that this subdivision must be further separated into two groups: the first with both motor and sensory fibers affected, labeled the acute motor-sensory axonal neuropathy pattern,^[16] and the second with only motor fibers affected, particularly at the root level, labeled the acute motor axonal neuropathy pattern or acute motor neuropathy.^[16],^[17] The following discussion reflects the prototype of GBS and these variations.

TABLE 49-1 -- ACQUIRED DEMYELINATING DISORDERS OF THE PERIPHERAL NERVOUS SYSTEM

Acute
Guillain-Barre syndrome
Acute inflammatory demyelinating polyradiculoneuropathy (AIDP)
Acute axon loss ("axonal") polyradiculopathy
Acute motor axonal neuropathy
Acute motor-sensory axonal neuropathy
Chronic
Chronic inflammatory demyelinating polyradiculopathy (CIDP)
Monoclonal gammopathies of undetermined significance (MGUS)
MGUS IgM neuropathy with anti-MAC, antibody
MGUS IgG, IgA, IgM neuropathy without anti-MAG antibody
CIDP with multiple myeloma
CIDP with osteosclerotic myeloma
CIDP with Waldenstrom's macroglobulinemia
Motor neuropathy with multifocal conduction block

Pathogenesis and Pathophysiology. All subdivisions of GBS appear to be autoimmune diseases resulting from aberrant immune responses against various components of peripheral nerve fibers. With AIDP, both humeral and cell-mediated factors are operative. Although the specific mechanisms of injury are unclear, the pathology that results is well documented, its hallmarks being inflammatory lesions, consisting of circumscribed areas containing lymphocytes, macrophages, and localized demyelination scattered throughout the PNS. The roots, plexuses, proximal nerve trunks, some cranial nerves, and autonomic fibers may be involved, often with a predilection, at least soon after onset, for the roots and distal peripheral nerve fibers. The myelin sheath is the specific target structure. Macrophages penetrate the basal lamina surrounding the axon, displace the Schwann cell from the myelin sheath, and then phagocytose the myelin lamellae.^[18] Pathophysiologically, these focal areas of demyelination result in conduction slowing or conduction block, depending on the severity of the process. Almost invariably, some axon loss also occurs but it is much less marked.^[11],^[12] With the acute axonal form of GBS, the roots are far more extensively affected than the peripheral nerves. Wallerian degeneration is prominent in the ventral roots alone with the acute motor axon neuropathy form, and in both the ventral and dorsal roots with the acute motor-sensory axonal neuropathy pattern. In those axons that have not undergone wallerian degeneration, macrophages are present within the periaxonal spaces, surrounding compressed but otherwise normal-appearing, axons. Just as AIDP has some minor associated axon loss, the acute axonal forms of GBS have some sparse SD present along surviving myelinated fibers: thus the lesions are "predominately" rather than "purely" axon loss in type.^[16] Pathophysiologically, the so-called acute axonal forms present as axon loss polyradiculoneuropathies affecting motor, or motor and sensory, fibers, depending upon the particular subgroup.^[16],^[16],^[17]

Epidemiology and Risk Factors. AIDP is a relatively rare disorder, having an average yearly incidence rate of 1 to 2 cases per 100,000 population. It occurs worldwide, affects all races, and attacks more males than females. Persons of any age are at risk, although the incidence is higher in the elderly. Most cases are sporadic, but clusters have been reported. Actual common-origin clusters typically derive from an obvious trigger factor, such as antirabies vaccination. Most studies have not reported a seasonal variation. Unlike the situation with CIDP, no clear relationship has been demonstrated between AIDP and human leukocyte antigen.^[2],^[3] The acute axonal form of GBS, at least in China, has many epidemiological features that differ from those described earlier. It occurs principally in epidemics, during the summer months, and typically affects children and young adults.^[15],^[16]

Antecedent events (so-called triggers) are associated with GBS in approximately 70 percent of cases. These usually occur 1 to 3 weeks before the onset of clinical symptoms, rarely as much as 6 weeks earlier. The one most often reported is a mundane upper respiratory infection. However, a great number of others have been described, although the linkage often has been inconclusive. Nonetheless, the evidence is rather convincing connecting a few vaccines (especially rabies), a few viral infections (particularly human immunodeficiency virus (HIV), Epstein-Barr, and cytomegalic inclusion virus), a few bacterial infections (especially *Campylobacter jejuni*), and even surgery, with bouts of GBS (Table 49-2). Increasing attention is being focused on *Campylobacter jejuni* infection, which clinically is manifested as a gastroenteritis.^[2],^[3],^[4] This particular bacterium appears to play a major role in the acute axonal form of GBS that occurs in epidemics in China.^[16],^[16] Fewer than 40 cases of GBS occurring during pregnancy have been reported. Apparently, this is an incidental co-existence, which can develop during any particular trimester. A few women have experienced GBS with successive pregnancies.^[2],^[4]

Clinical Features and Associated Disorders. The cardinal features of GBS are weakness, paresthesias, and diminished or absent DTRs.^[4] Most patients are essentially well and lack systemic symptoms, including fever, when their PNS symptoms begin. Often they have recently experienced one of the many antecedent events already described. The initial neurological symptoms vary from patient to patient. Distal, usually symmetrical paresthesias (so-called pins and needles) involving the toes, fingers, or both herald the onset of the disorder in at least 50 percent of patients. As the disease progresses, these paresthesias typically spread proximally but seldom extend beyond the ankles and wrists. Facial paresthesias, which are usually perioral, are less common. Weakness can be the presenting feature, but more often it is first noted a few days after

TABLE 49-2 -- ANTECEDENT EVENTS ASSOCIATED WITH GUILLAIN-BARRE SYNDROME

Viral	Bacterial
Influenza	<i>Campylobacter jejuni</i> *
Herpes	<i>Mycoplasma pneumoniae</i> *
Cytomegalovirus*	Spirochetal
Epstein-Barr virus*	<i>Borrelia burgdorferi</i>
Hepatitis	Vaccination
Human immunodeficiency viruso	Rabies (some strains)
Surgery	Vaccinia

*Stronger association.

the paresthesias begin. Typically, it begins in the lower extremities, especially in the proximal muscles so that patients may experience difficulty climbing stairs and rising from chairs for a day or two before they realize that they are ill. Weakness soon spreads (ascends) to the upper extremities. Less often, weakness begins simultaneously in the upper and lower extremities, with the lower extremities usually more severely affected. The progressive phase of the illness lasts from a few days to 3 to 4 weeks. Approximately 50 percent of patients reach the nadir of clinical function by 2 weeks and 80 percent by 3 weeks. The flaccid weakness that is ultimately present varies considerably in severity and distribution from one patient to another. However, it often is profound, involving all four limbs, the respiratory muscles, and the face. Facial diplegia, or bilateral facial weakness, is seen in approximately 50 percent of the patients. Occasionally, fasciculations are noted. Although the prominent features are motor in nature, pain that is deep, poorly localized, and sometimes accompanied by muscle cramping commonly occurs. Usually, it is most severe in the shoulder girdle, back, and posterior thighs and is notoriously more severe at night.

On clinical examination, one of the earliest findings is decreased or unelicitable DTRs. These may either precede or follow by a few days the demonstration of weakness on formal examination. Substantial sensory abnormalities are found infrequently, and contrast with the high incidence of sensory symptoms. Typically, vibration and proprioception, the sensory modalities mediated over large myelinated fibers, are the most severely affected. In some cases, profound proprioceptive loss results in sensory ataxia and pseudoathetosis. Generally, once symptoms have peaked, they persist unchanged for approximately 2 to 4 weeks (the so-called plateau phase) and then begin to recede in an extremely variable fashion from patient to patient.

Several atypical presentations or clinical variants of GBS have been described. The acute axonal form is more rapid in onset and more severe, and ultimate recovery is often poor. As noted earlier, this GBS subgroup is mainly responsible for the summer epidemics in China and is linked to a preceding *Campylobacter jejuni* infection. At present, it is not clear what percentage of sporadic GBS cases of this nature in North America are due to *Campylobacter jejuni*. The pure motor form, in which no sensory symptoms occur, is now known to be one of the presentations of the acute axonal variant. The Miller-Fisher syndrome consists principally of a triad of ophthalmoplegia, ataxia, and areflexia essentially occurring in isolation. The CSF protein usually is elevated, but the EDX findings are more suggestive of axon loss than SD. Miller-Fisher syndrome generally is a benign disorder and does not require specific immune therapy. Finally, a pure sensory form has been reported, although the diagnostic criteria for GBS proposed in 1978 exclude this variant.

With GBS, there is some overlap between antecedent events and associated conditions. GBS has been linked, often through single case reports, to a number of systemic diseases. However, for most of these cases, the relationship is more probably a chance association. There are a few exceptions. So many cases of GBS have occurred in patients with HIV infection that some type of cause-and-effect relationship seems very likely. Similarly, although the data are not as compelling, a link between Hodgkin's disease and GBS also appears to exist.

Differential Diagnosis. GBS is the most common type of rapidly evolving, generalized PNS disorder. Nonetheless, a great number of other disorders can be mistaken for it, particularly early in its course ([Table 49-3](#)). Ropper and co-workers, for example, list 50 entities that must be considered in the differential diagnosis of typical GBS. Certain preconditions must be met for many of these entities to be included. Thus, generally the patient must have recently traveled to various tropical regions for *fish* and *snake poisonings* to be considered; traveled to underdeveloped countries for *rabies*, *polio*, and *diphtheria* to be included; recently been in the woods in certain areas for *tick paralysis* or *Lyme disease* to be viable diagnostic possibilities; or been receiving *parenteral hyperalimentation* for hypophosphatemia to occur. Obtaining a detailed history and performing a careful physical examination will allow the correct initial diagnosis of GBS in most instances.

Transverse myelitis may superficially resemble GBS, particularly if spinal shock has occurred and the lower extremity DTRs are not able to be elicited. However, asymmetrical involvement, a definite sensory level, complete absence of upper extremity weakness, urinary incontinence, and CSF pleocytosis all speak against GBS. *Heavy metal intoxication*, principally subacute arsenic or acute thallium poisoning, can mimic GBS clinically; moreover, in the initial phase of arsenic poisoning, both the CSF and EDX findings may be identical to typical GBS. However, these disorders should be included in the differential diagnosis of GBS only if there were preceding bouts of gastroenteritis. Associated central nervous system involvement is also common, particularly with thallium poisoning, and sometimes more than one person is affected simultaneously, strongly suggesting a common source. *Vasculitic neuropathies* occasionally are mistaken for GBS. However, systemic signs, including fever, are common; the sensory and motor involvement in the limbs usually is both distal in location and asymmetrical; cranial nerve involvement, respiratory complications, and sphincter dysfunction are uncommon. Moreover, the CSF typically is normal (except with systemic lupus erythematosus) and EDX studies reveal changes suggestive of axon loss, rather than SD. *Acute intermittent porphyria*

TABLE 49-3 -- DIFFERENTIAL DIAGNOSIS OF GUILLAIN-BARRÉ SYNDROME

Hysteria/conversion reaction	Hexacarbons
Malingering	Diphtheria
Brain stem infarction	Drugs
(Locked-in syndrome)	Lyme disease
Acute myelopathies	Critical illness
Poliomyelitis	Vasculitis
Rabies	Neuromuscular transmission disorders
Enteroviruses	Botulism
Necrotic	Tick bite paralysis
Transverse	Myasthenic syndrome
Focal compression	Myasthenia gravis
Cauda equina lesions	Snake venom
Peripheral neuropathies	Sea urchin venom
Heavy metals; arsenic; thallium, gold	Hypermagnesemia
	Muscle disorders
Alcohol	Hypokalemia
Organophosphates	Hyperkalemia

can produce a PNS disorder that can be mistaken for GBS. However, its evolution is usually longer and abdominal pain, constipation, and altered mental status are almost constant findings. The motor deficits often begin in the upper extremities; the Achilles DTRs may be preserved; sensory loss often is proximal; and seizures may occur. Moreover, the CSF protein typically is normal, and the EDX studies demonstrate axon loss rather than SD. Finally, both porphobilinogen and alpha aminolevulinic acid are excreted in the urine in increased amounts during attacks of acute intermittent porphyria. *Botulism* in adults, nearly always foodborne, has a clinical presentation that resembles that of GBS. However, frequently several cases occur simultaneously, excluding sporadic GBS from consideration. Even with single cases, immediately preceding gastrointestinal symptoms are prerequisite, and constipation often is prominent throughout the course. Blurred vision, dry mouth, ptosis, and dilated pupils that poorly respond to both light and accommodation are very common. Weakness descends from the bulbar region, so that neck weakness and respiratory muscle weakness may be far more prominent than limb weakness. Other features include rare sensory loss and a normal CSF. EDX changes include motor unit disintegration, affecting the motor amplitudes on NCS and highly polyphasic, disintegrated MUPs, usually with fibrillation potentials, on NEE. Finally, early in its course GBS can be mistaken for a functional disorder, for example, hysteria. Most neurologists can recount situations in which patients were released from emergency rooms with hysterical symptoms, only to be admitted to an intensive care unit a few days later, receiving treatment for GBS. This most often occurs whenever the patients have a history of psychiatric illness; the patients' sensory complaints can be mistaken for those caused by hyperventilation; weakness is at an early stage, so that gait disturbances are present but limb strength seems intact on formal testing; and before the DTRs are lost.

Evaluation. Routine hematology studies usually are normal. The two critical laboratory studies are CSF analysis and EDX examination. CSF that contains increased protein concentration with a normal cell count--albuminocytological dissociation--has been considered one of the diagnostic findings in the GBS since Guillain, Barre, and Strohl's original 1916 report. Elevated CSF protein, typically ranging from 46 to 300 mg/dl, is seen in most patients, particularly after the first week of illness. Conversely, the CSF cell count usually remains normal, although it may be elevated (greater than 10 mononuclear leukocytes per cubic millimeter) in patients whose GBS is superimposed on acquired immunodeficiency syndrome (AIDS) or Lyme disease. In approximately 10 percent of patients with GBS, usually those with mild cases, elevated CSF protein cannot be found, even with repeated sampling during the course of the illness. On EDX examination, very often changes strongly suggestive of SD, such as conduction block, differential slowing, or focal slowing, are seen on assessment of one or more often several nerves; generally, these changes are much more apparent on motor NCS than sensory NCS. Moreover, patterns of abnormalities suggestive of an acquired SD polyradiculoneuropathy, such as upper extremity sensory NCS responses that are unelicitable or of low amplitude while normal in the lower extremity, often are found. Unfortunately, both the CSF analysis and EDX studies are generally least helpful for diagnosis during the very initial phase of the illness, which is precisely the period when a definite diagnosis is being sought so that specific treatment can be initiated. Thus, during the first several days of the illness, in many patients the CSF protein is not elevated and the EDX studies are normal, or are abnormal but nondiagnostic.^[11], ^[12] One very common misconception regarding the EDX studies is that substantial slowing of motor CVs is a typical finding with early GBS. In fact, such NCS slowing seldom is seen during that stage of GBS; it is far more commonly found in the late plateau or recovery stages, when it is unneeded for diagnosis.

Management. There is no known prevention for sporadic GBS, although those persons who previously had a bout after immunization should avoid future immunizations, if at all possible.^[1] In contrast, whenever GBS occurs in epidemic form, as it does in China and other underdeveloped countries, its incidence may be reduced by improved public health measures.

The treatment of GBS has two components: (1) supportive care and (2) specific therapy. Supportive care remains the cornerstone of therapy, because most patients recover function if they advance past the acute phase of the illness. The major reduction in deaths from GBS over the past few decades has been due to advances in supportive care, particularly in mechanical ventilation.^[2] ^[3] ^[4]

Most authorities recommend that patients with suspected GBS be hospitalized, regardless of how mild their disorder appears initially. This is because instances of rapid deterioration occurring over a brief period of time, leading to respiratory failure, have been reported. Once they are hospitalized, patients must be assessed and monitored to avoid the major life-threatening complications of GBS, including respiratory failure, dysautonomia, and venous thromboembolism. Respiratory compromise is the most serious complication and is the most common. It is responsible for most intensive care unit (ICU) admissions, and this occurs in approximately 30 percent of GBS patients who are hospitalized. Weakness of the respiratory muscles, particularly the diaphragm, is most often responsible for respiratory failure. Other factors include weakness of various bulbar-innervated muscles and pulmonary complications, including atelectasis, pneumonia, and pulmonary embolism.^[2] ^[3] ^[4] ^[19] Respiratory function can be assessed with arterial blood gas analysis and peak expiratory flow pressure measurements. Vital capacity measurements provide the most useful information regarding the degree of respiratory compromise.^[2], ^[20] Respiratory function must be monitored closely. Generally, intubation is required whenever the vital capacity falls to 15 ml/kg. Intratracheal intubation is complicated in patients with GBS because of (1) dysautonomia, which can result in marked hypotension, arrhythmias, and sudden death due to various drugs and to airway manipulation; and (2) hyperkalemia, induced by succinylcholine, which can cause arrhythmias and cardiac arrest. Tracheotomies usually are not performed unless airway assistance is still needed at the end of the second week of the illness.^[20]

Dysautonomia occurs to some extent in the majority of GBS patients but more frequently and more severely in those with respiratory failure and severe motor deficits. Severe paroxysmal hypertension, orthostatic hypotension,

and various cardiac arrhythmias are all complications that may prove difficult to manage.^[19] Pulmonary embolism occurs in about 5 percent of patients immobilized with GBS, typically after the second week of immobilization. In one series, it was responsible for approximately 28 percent of deaths. Preventive measures include subcutaneous heparin--switched to Coumadin if patients are long-term--and intermittent calf pneumatic compression devices.^[2] ^[3] ^[4] ^[19] Other complications are urinary tract infections and gastrointestinal disorders, including bleeding secondary to stress ulcers and erosive gastritis, ileus, and fecal impaction. Hyponatremia can develop, usually in ventilated patients and due to inappropriate release of antidiuretic hormone. This electrolyte imbalance responds to fluid restriction.^[4], ^[19], ^[21]

Two non-life-threatening complications of GBS that require attention are pain and psychological trauma. To treat pain, a number of medications have been used with varying success. These include analgesics such as aspirin and narcotics. However, narcotics must be given with caution because they tend to exacerbate respiratory failure and to produce ileus. Antidepressants and anticonvulsants generally have not been effective. A few reports have described sustained pain relief for a few days following a single IM injection of 40 to 60 mg of methylprednisolone. Simple physical measures, such as the application of cold or hot packs, gentle massage, or repositioning with the limbs in slight flexion, may bring pain relief.^[19] The psychological stress on essentially paralyzed GBS patients must also be appreciated. Their fears and concerns, particularly regarding recovery potential, must be addressed throughout all phases of the illness.^[19], ^[21]

The specific treatment of choice for GBS since 1978 has been plasmapheresis. It can be beneficial in patients of all ages, although there are only anecdotal reports, rather than large-scale studies, to support its value in children with GBS. Also, pregnancy is not a contraindication to plasmapheresis; at least two pregnant women have been treated with this method without incident.^[4] Although plasmapheresis has no effect on either mortality or relapse rates, measurable objective improvement occurs in nearly every other aspect of their disorder, in at least 50 percent of treated patients. Thus, compared with nontreated patients, improvement begins earlier in the course and is appreciably better at 1 month after onset. With plasmapheresis, less mechanical ventilation is required, and both ICU and hospitalization time is decreased. To be effective, plasmapheresis must be instituted early in the course of the disorder, preferably within the first week. The precise regimen has not been established, although most investigators have used 150 to 250 ml/kg over 7 to 10 days of treatment.^[2] ^[3] ^[4] The drawbacks of plasmapheresis include its expense and rare complications such as hypotension and sepsis. There is a risk of acquiring viral infections, such as hepatitis and possibly AIDS, if fresh frozen plasma is used as the replacement fluid. (Plasma appears to offer no benefit over albumin with saline.^[4])

Some preliminary studies using intravenous immunoglobulin (IVIg) treatment for GBS have produced encouraging results. This mode of treatment has advantages over plasmapheresis in regard to its being simpler to administer and costing slightly less. However, the transmission of viral infections, including AIDS, is a significant concern, because IVIg is made from plasma pooled from thousands of donors.^[4] Both corticosteroids, in conventional doses, and adrenocorticotrophic hormone (ACTH) have proved to be ineffective in the treatment of GBS. In fact, a few studies have suggested that ACTH is actually detrimental.^[2], ^[4] High-dose corticosteroids could conceivably be of benefit, but there are potential complications, particularly bowel perforations and serious infections. Nonetheless, if they are shown to be effective, they will be very appealing treatment options compared with plasmapheresis, because of their being relatively inexpensive and easy to administer.^[4]

During the first two trimesters of pregnancy, the management of women with GBS is identical to that of nonpregnant patients in regard to both supportive care and specific therapy. During the third trimester, owing to increased respiratory demand, supportive care becomes crucial, because the risk of respiratory failure increases, culminating during delivery. Adequate ventilation must be ensured during this period. Owing to an increase in premature labor and delivery, a perinatal infant mortality rate of approximately 10 percent mars late pregnancy complicated by GBS.^[4] GBS is not considered an indication for cesarean section, and infants do not acquire GBS, even transiently, from their affected mothers.^[2], ^[4]

Prognosis and Future Perspectives. Even as late as 1953, Guillain always contended that GBS was an inherently nonfatal disorder, a benign disease that left little, if any, residual effects. Such optimism is not supported by many series published over the past 30 years. Excluding those with mild disease, most patients are hospitalized for at least 1 month and often considerably longer, particularly if mechanical ventilation is required. Overall, approximately 5 percent of patients die; mortality rates of 15 to 20 percent have occurred in ICUs, most often from adult respiratory distress syndrome. Approximately 75 percent of patients recover without serious neurological residuals, and recovery typically ensues over the 6 to 12 months after onset and is usually maximal by 18 months after onset. Some patients may be left with persistent minor weakness, paresthesias, or sensory loss.^[4] Approximately 7 to 15 percent of patients have permanent, substantial neurological sequelae, for example, bilateral footdrop, intrinsic hand muscle weakness and wasting, sensory ataxia, or burning dysesthesias. Only a very few, however, are permanently bedridden by the disorder.^[2] ^[3] ^[4] Several factors during the acute phase of the illness have been linked to subsequent poor recovery. These factors include older patient age (particularly age 60 or older); rapid, early evolution, leading to quadriparesis within a week; and very low motor NCS amplitudes on distal stimulations early in the course of the disease (suggesting severe axon loss, but equally consistent, at least theoretically, with severe distal SD conduction blocks). The latter has proved to be the single most reliable outcome predictor.^[12] Not surprisingly, most of the prognostic factors listed merely indicate that a poor long-term prognosis is directly related to the severity of the acute episode.

As the past decade has illustrated, much is yet to be learned about GBS. What is the exact initiating mechanism for demyelination with AIDP? ^[18] How frequently does *Campylobacter jejuni* infection serve as the antecedent event with GBS, and exactly how does it cause the disorder?

Unlike certain other known triggers, for example, cytomegalovirus, *Campylobacter jejuni* rarely invades PNS tissue directly, so the possibility that GBS results from various PNS structures being injured as a bystander when the immune system attacks a virus within the PNS is untenable.^[14] Is the acute axonal form of GBS seen in North America and Europe typically caused by *Campylobacter jejuni* infection? These questions are of much more than academic interest, because the answers to them can play a significant role in treatment, and possibly prevention, of this disorder.

[PreviousNext](#)

CHRONIC INFLAMMATORY DEMYELINATING POLYRADICULONEUROPATHY

Pathogenesis and Pathophysiology. CIDP is an apparent immune-mediated disorder of the PNS. The term CIDP was coined to emphasize that the disorder is a chronic process that results in demyelination as well as an inflammatory cell response in peripheral nerves and spinal nerve roots; typically, there is a mononuclear cell infiltration involving the endoneurium and epineurium of peripheral nerve fibers.^[22] The predominant pathological feature is SD, although usually there is some degree of axon loss as well ([Figs. 49-3](#) and [49-4](#)). These pathological changes have been found to involve roots, plexuses, proximal nerve trunks, and occasionally, cranial nerves and sympathetic trunks, as well as some autonomic nerves.^[23] The predilection for CIDP to involve roots and proximal nerve trunks is responsible for the prominent proximal weakness that may be encountered in this disorder and helps distinguish it from most other generalized polyneuropathies. The predominant involvement of myelin in CIDP results in a characteristic pattern of findings on EDX testing, including

Figure 49-3 Electron microscopy of sural nerve in CIDP. A normal myelinated fiber(*left*) adjacent to a myelinated fiber that has thin and partially absent myelin(*right*).

Figure 49-4 Teased nerve fiber preparation showing segmental demyelination in a sural nerve in CIDP.

slowed nerve CV and conduction block; the latter process correlates with the clinical deficits. Also, the distinctive distribution of NCS abnormalities that may occur with acquired SD polyradiculopathies (already described) is often seen.^[1c]

The evidence that CIDP is immune mediated is compelling although still somewhat inconclusive. In many respects, it is similar to the evidence advanced for AIDP being an immune-mediated disorder. The onset or relapses of CIDP on occasion seem to be triggered by a preceding event, such as an infection or vaccination that could initiate an immune-mediated response. In addition, most patients with CIDP respond to corticosteroids and other immunosuppressants, plasma exchange, and IVIg, therapies designed to treat immune-mediated disorders. Furthermore, CIDP shares many clinical and pathological features with experimental models of immune-mediated peripheral neuropathy, particularly EAN. This has led to speculation that the pathogenesis of CIDP is similar to that of AIDP and EAN. Lastly, the presence of immune-effector cells and the deposition of antibody and complement on myelinated fibers is impressive but indirect evidence of an immunemediated process in which both cellular and humoral immune systems are operative.^[24]

A disorder clinically similar to CIDP but with pathological and EDX features, indicating an axon loss process, has been reported.^[23] Whether this actually represents a so-called axonal form of CIDP similar to the axonal form of GBS remains to be established.

Epidemiology and Risk Factors. The age of onset of CIDP has been reported to range from 1 year through the eighth decade or later, with a mean in the fourth decade. Both sexes are affected, although there is a slight male predominance. With the mean age of onset being in the fourth decade, women of childbearing age may develop CIDP. Furthermore, there is evidence that the disorder may relapse or worsen during pregnancy and in the postpartum period.^[25] Patients with certain histocompatibility antigens have an increased risk of developing CIDP. In

particular, there is an increased incidence of histocompatibility locus antigens AW30, AW31, A1, B8, and DR w3. Furthermore, CIDP, GBS, and multiple sclerosis have all been associated with the presence of the M3 allele of the alpha-1 antitrypsin system located on chromosome 14.^[3]

Clinical Features and Associated Disorders. By definition, CIDP is a chronic disorder that typically evolves slowly, almost always requiring a period of 8 weeks or longer for symptoms to reach their peak, and they typically do so over many months. CIDP can follow either a slowly progressive monophasic course, which occurs in approximately two-thirds of patients, or a cyclical relapsing course seen in the remainder.^[3],^[26]

The symptoms of CIDP can be variable, but usually weakness tends to predominate over sensory symptoms.^[3],^[22] The distribution of weakness often conforms to a typical peripheral neuropathy pattern of symmetrical involvement, with the lower extremities being affected more than the upper extremities and distal muscles being affected more than proximal muscles. However, in many patients, the weakness is asymmetrical, and in others, it is more prominent proximally. The degree of weakness varies markedly from patient to patient. In the majority of patients, it is mild to moderate in degree, but rarely, the weakness can be severe and generalized, sometimes associated with respiratory failure necessitating ventilatory support. Muscle cramping and fasciculations are infrequent symptoms.^[3],^[22],^[23]

Sensory symptoms are usually confined to mild paresthesia or modest sensory loss. However, in those patients with chronic progressive courses, sensory symptoms may become more prominent. In addition to numbness and paresthesia, pain sometimes is reported, although this occurs in less than 20 percent of patients. Very infrequently, CIDP may present with predominate sensory symptoms, including numbness, paresthesia, and sensory ataxia. In a subset of these patients, this PNS disorder appears essentially confined to sensory fibers, prompting speculation that the apparent immune-mediated response is directed at a unique antigen in the myelin of sensory fibers. However, in most instances in which the disorder begins as a sensory neuropathy, it later evolves to a more typical pattern of sensory and motor involvement. On occasion, the cranial nerves may be affected, causing symptoms of diplopia, facial weakness or numbness, dysarthria, and dysphagia. Autonomic symptoms are uncommon, although incontinence and erectile impotence have been reported.^[3],^[22],^[23]

The physical signs noted in CIDP reflect the clinical symptoms. Distal symmetrical weakness, with the lower extremities more severely affected than the upper extremities, is the rule. However, asymmetrical involvement and more prominent proximal involvement can occur, and they serve as important clinical clues to the diagnosis of CIDP. Generalized hyporeflexia or areflexia is characteristic. Sensory loss often conforms to a distal to proximal gradient, in the so-called stocking-glove pattern, with all modalities affected to a nearly equal extent. Occasionally, sensory ataxia may be observed. Cranial nerve findings may include signs of facial, bulbar, and neck weakness. Papilledema is an unusual clinical feature, and its precise pathophysiology is unclear. It has been attributed to altered resorption of CSF over the arachnoid villi due to elevations of CSF protein or to increased intracranial pressure.^[3] Rather rare clinical features include pupil abnormalities consistent with parasympathetically denervated pupil, Horner's syndrome, and postural or cerebellar-type tremors.^[26] Occasionally, hypertrophied nerves may be palpated in patients with very chronic CIDP. Rarely, the spinal nerve roots may be hypertrophied to such an extent that they act as masses, compressing the spinal cord and may produce a syndrome of spinal cord compression.^[26]

Some patients with CIDP have abnormalities on MRI scans of the head that are considered to be consistent with multiple sclerosis.^[27] Whether these isolated patients represent the coincidental occurrence of two disorders or whether an immune-mediated disorder of both central and peripheral myelin is operative remains unclear.

There is no conclusive evidence that CIDP patients have a higher incidence of other medical conditions, including autoimmune disorders. However, associated disorders, including systemic lupus erythematosus, Hashimoto's thyroiditis, thyrotoxicosis, chronic active hepatitis, inflammatory bowel disease, urticaria, eczema, and psoriasis do occur in some CIDP patients.^[3] A CIDP-like disorder may occur in the setting of monoclonal gammopathies of uncertain significance (MGUS), as well as with multiple myeloma, osteosclerotic myeloma and other lymphoproliferative disorders. These disorders are discussed as distinct entities in the following sections.

Differential Diagnosis. On purely clinical grounds, CIDP may be confused with a wide variety of chronic sensorimotor polyneuropathies, including those related to diabetes, uremia, hypothyroidism, acromegaly, toxins, and alcoholic-nutritional mechanisms. Although CIDP may produce distinguishing clinical features, such as predominant motor symptoms and signs, asymmetrical involvement, proximal motor involvement, and cranial nerve symptoms and signs, the paramount factor in separating CIDP and related disorders from the rather large group of nonspecific, chronic axon loss sensorimotor polyneuropathies is the presence of acquired SD features on EDX testing. Thus, EDX evaluation is the key step in identifying the acquired SD polyneuropathies, including CIDP. The differential diagnosis of this category includes not only CIDP but the CIDP-like disorders that may be associated with multiple myeloma, osteosclerotic myeloma (including the POEMS syndrome, an acronym which stands for polyneuropathy, organomegaly, endocrinopathy, M-protein, and skin changes), MGUS, and Waldenstrom's macroglobulinemia. These disorders may be distinguished from CIDP by the presence of an M-protein in the serum or urine, the presence of lytic or sclerotic lesions on skeletal bone survey, or both. A disorder essentially identical to CIDP can result from HIV infection. Consequently, testing for HIV is indicated in patients at risk. CIDP may be a presenting feature of HIV infection, preceding seroconversion for up to 6 months. For this reason, repeating HIV testing 6 months after the onset of a CIDP-like disorder is appropriate in patients at risk.

Familial hypertrophic polyneuropathies that produce EDX features of SD along with axon loss may sometimes be confused with CIDP. With the familial disorders, a

positive family history typically is recorded, but in some instances, it is not. CIDP can usually be distinguished on clinical grounds by its more rapid tempo of evolution and

a cyclical or relapsing course. The EDX findings may also be helpful in differentiating CIDP from these disorders. In the familial disorders, the SD features on NCS tend to be symmetrical, with uniform involvement of all nerves. Focal conduction block and focal conduction slowing usually are not observed. Despite these numerous distinguishing features, occasionally it still may be difficult to distinguish a long-duration CIDP from a familial hypertrophic SD polyneuropathy. In such circumstances, a trial of therapy is usually indicated.

On occasion, CIDP may be difficult to differentiate from AIDP. Patients with more subacute courses of CIDP have been described, and sometimes CIDP may begin with a relatively acute onset. Over time, CIDP usually declares itself by a typical chronic relapsing course or a more slowly progressive monophasic course. The distinction between AIDP and CIDP is significant because the ultimate course, prognosis, and treatment are different. ^[23], ^[24]

Evaluation. As noted earlier, the performance of a comprehensive EDX evaluation to uncover findings consistent with acquired SD is key in the evaluation and diagnosis of CIDP and related disorders. These EDX findings clearly distinguish CIDP and related disorders from the vastly more common group of clinically similar axon loss sensorimotor polyneuropathies.

The general laboratory features of CIDP are relatively nonspecific and are not particularly useful in confirming the diagnosis. Routine laboratory tests typically are normal. The CSF protein, however, is frequently elevated to a moderate degree; in one series, it ranged from 23 to 600 mg/dl with a mean of 138 mg/dl. Nonetheless, it should be emphasized that in 10 percent of patients with CIDP, the CSF protein may be normal. ^[1] Even sural nerve biopsies generally do not provide specific or diagnostic features, although in the majority of patients they will document the presence of inflammation and demyelination, two features that characterize CIDP. However, these findings are not pathognomonic. Furthermore, the sural nerve biopsy may be normal in nearly 25 percent of patients. ^[22] It is important to appreciate that a normal CSF protein and sural nerve biopsy are not necessarily inconsistent with the diagnosis of CIDP. On the other hand, a normal EDX examination essentially excludes this diagnosis.

The critical component in the evaluation of a patient with suspected CIDP is to exclude the CIDP-like disorders. This requires careful screening of the serum and urine for the presence of M-proteins. Because a small amount of M-protein may still be undetected by routine serum protein electrophoresis testing, the search for M-protein should include an assessment incorporating immunoelectrophoresis or immunofixation techniques. The presence of an M-protein in the setting of a CIDP-like disorder may signify a polyneuropathy associated with multiple myeloma, osteosclerotic myeloma, MGUS, Waldenstrom's macroglobulinemia, or another lymphoproliferative disorder. Also, a skeletal x-ray study is indicated, because a significant percentage of patients with osteosclerotic myeloma may not disclose an M-Protein on immunofixation. HIV testing should also be performed in all patients at risk with a CIDP-like disorder.

Management. CIDP is a very treatable disorder, with most patients showing favorable responses to one of the many therapeutic modalities available. Some of the earliest reports of CIDP indicated that it was often steroid responsive. ^[23] Subsequently, a controlled clinical trial clearly established the value of corticosteroids in the treatment of CIDP, regardless of whether the course was monophasic and progressive, or cyclical and relapsing. ^[28] Other forms of immunosuppression, including azathioprine and cyclophosphamide, also have been reported to be effective therapies for CIDP, but none has been confirmed by a randomized or controlled trial. In addition, plasma exchange therapy and IVIg are efficacious and of comparable value in the treatment of CIDP. ^[29], ^[30]

When constructing a treatment plan for patients with CIDP, it is important to balance clinical symptoms against the risks and potential benefits of the therapy. Clearly, patients with rather modest or minimal symptoms may not require treatment. Instead, they should be followed and observed closely. However, in those with a progressive course or with substantial clinical symptoms, treatment may begin with IVIg, plasma exchange therapy, or corticosteroids. Although both IVIg and plasma exchange are relatively expensive therapeutic modalities, either is justified as an initial treatment. Their advantage is that they obviate the need for chronic corticosteroid or other immunosuppressant treatment, and thus avoid the associated side effects and complications of these therapies. Both IVIg and plasma exchange are comparable in efficacy and expense. Nonetheless, IVIg may have certain advantages over plasma exchange. It may require fewer treatments, it is somewhat less invasive, and it may be administered at home. It is imperative, however, that patients considered for IVIg therapy be assessed for IgA deficiency, because anaphylactic reactions have occurred following the administration of IVIg in patients with IgA deficiency. Furthermore, caution should be exercised in administering IVIg to patients who have underlying renal dysfunction, because the risk of renal failure is increased following IVIg treatment. Traditionally, IVIg therapy is administered at a dose of 400 mg/kg/day over 5 consecutive days. ^[24] An alternative recommendation is to use IVIg at 400 mg/kg/day once per week over 6 to 8 consecutive weeks. ^[26] Plasma exchange therapy requires expertise in its use and is clearly more technically demanding than is IVIg treatment. Plasma exchange usually is administered twice weekly for the first 3 weeks and then once or twice weekly for an additional 3 weeks. ^[23] Patients typically respond to IVIg or plasma exchange within the first several weeks of treatment and may demonstrate sustained improvement for many weeks or months. Relapses may require periodic isolated treatments with a single dose of IVIg or single plasma exchange. If a patient responds successfully to infrequent booster treatments of either IVIg or plasma exchange, it is reasonable to maintain this form of treatment rather than adding corticosteroids or other immunosuppressants.

In patients who are not candidates for either IVIg or plasma exchange, or in whom responses are not satisfactory, chronic immunosuppressive therapy must be considered. Corticosteroids typically are used at relatively high doses initially and then slowly tapered while monitoring the clinical response. Most patients who respond will do so during their first few months of treatment. In those patients who cannot tolerate corticosteroids and in those who do not

obtain a satisfactory clinical response to them, a trial of other immunosuppressants, including azathioprine or cyclophosphamide, may be a reasonable alternative. ^[23]

In addition to these various immunosuppressive therapies, patients should undergo a thorough physical therapy assessment to determine if they require aids to ambulation, including orthotic devices such as ankle-foot-orthosis for footdrop. Other physical therapy modalities, including stretching and range of motion exercises, may be helpful while a patient is responding to medical therapy.

Prognosis and Future Perspectives. The prognosis is favorable for most patients with CIDP who are properly diagnosed and treated. In one large group of patients whose disease-duration averaged 5.7 years and who were followed for a minimum of 24 months, nearly 40 percent were asymptomatic and nearly 50 percent had either minor symptoms that did not have any impact on their level of function or had only very modest restrictions in lifestyle. ^[31] Future research objectives will focus on the specific immune-mediated mechanisms and pathophysiology of CIDP. From a purely clinical perspective, further trials are needed to better define optimal therapeutic protocols using the modalities that have already proved effective, including IVIg, plasma exchange, and corticosteroids.

MONOCLONAL GAMMOPATHIES OF UNDETERMINED SIGNIFICANCE

Pathogenesis and Pathophysiology. A heterogeneous group of peripheral neuropathies has been associated with the presence of an MGUS. However, the precise relationship of the monoclonal (M-) protein to the peripheral nerve disorder remains unclear. By definition, MGUS indicates the presence of an M-protein of less than 3 g/dl in concentration, with less than 5 percent plasma cells in bone marrow, none or only a very small amount of M-protein in the urine, and the absence of other abnormalities, including lytic or sclerotic bone lesions, anemia, hypercalcemia, and renal insufficiency. Furthermore, the M-protein should remain at stable and low concentrations over time.^[32] The natural history of MGUS indicates that with advancing time specific hematological and lymphoproliferative disorders, such as multiple myeloma, Waldenström's macroglobulinemia, amyloidosis, and lymphoma, may develop. Nevertheless, most patients who undergo a comprehensive evaluation for an M-protein in their serum ultimately will have it attributed to MGUS. MGUS is rather common, occurring in up to 1.7 percent of patients older than age 50 and in 3 percent of patients older than age 70.^[32]

Acquired SD polyneuropathies with features similar to that of CIDP have been observed in MGUS with IgG, IgA, and IgM M-proteins. These observations, coupled with the response of these disorders to the typical therapeutic interventions used for CIDP, have fostered the belief that these disorders are also immune mediated. However, the only strong evidence to support this theory is found in the MGUS neuropathy associated with IgM M-protein. In this disorder, the M-protein binds and reacts to myelin and to an oligosaccharide determinant that is shared by the myelin glycoproteins myelin-associated glycoprotein (MAG) and P₀, and the glycolipids sulfated glucuronyl paragloboside (SGPG) and sulfated glucuronyl lactosaminyl paragloboside (SGLPG).^[33] Approximately 50 percent of patients with IgM MGUS neuropathy have anti-MAG antibodies. Many of these patients demonstrate specific clinical and EDX features that distinguish them from the more heterogeneous group of polyneuropathies associated with MGUS. The finding of deposits of anti-MAG M-protein and complement on affected myelin sheaths, the presence of widening of myelin lamellae at the sites of antibody deposition, and the experiments that document the development of polyneuropathy in animals following passive transfer of patients' serum support the concept that the IgM M-protein with anti-MAG activity plays an important pathogenetic role in the development of the polyneuropathy.^[33] Other observations, however, have detracted from this theory, including the fact that the concentration of the IgM M-protein may not always correlate with the severity of the polyneuropathy nor with the clinical response after treatment.^[34]

Similar to CIDP, the demyelinating polyneuropathy associated with MGUS typically produces physiological alterations suggestive of an acquired SD polyradiculoneuropathy, often accompanied by a modest degree of axon loss. MGUS can also produce a pure axonal sensorimotor polyneuropathy.^{[33], [34]}

Epidemiology and Risk Factors. MGUS polyneuropathy tends to occur later in life than CIDP, with the mean age of onset in the mid to late sixth decade. In most large series, a distinct male predominance is noted. There are no other particular risk factors, and MGUS neuropathy seldom occurs in women of childbearing age.^{[33], [34]}

Clinical Features and Associated Disorders. In general, the MGUS polyneuropathies associated with IgG, IgA, and IgM without anti-MAG activity conform to a symmetrical sensorimotor polyneuropathy that shares many clinical features with CIDP including predominant proximal weakness. Nonetheless, there may be some differences. Sensory symptoms usually are more prominent than in CIDP. In addition, the initial phase of the disorder often progresses much slower than it does in CIDP, and the course is less likely to be cyclical or relapsing. Also, cranial nerve involvement and autonomic involvement are rare. Nevertheless, clinical syndromes indistinguishable from CIDP may be seen with MGUS polyneuropathy.

The clinical syndrome seen with MGUS IgM polyneuropathy associated with anti-MAG antibodies appears to differ from that seen both with CIDP and with MGUS polyneuropathy associated with IgG, IgA, and IgM without anti-MAG activity.^[34] With this disorder, sensory symptoms may be even more prominent and can be the initial presenting feature. Typically, progressive sensory impairment is followed later by motor involvement. Sensory ataxia, particularly affecting the gait, is a common finding, as are tremors of the upper extremities that resemble essential tremor.^[35] Similar to the other MGUS polyneuropathies, the clinical features tend to progress more slowly and are less severe than the initial symptoms associated with CIDP. Moreover, relapsing and cyclical courses are not seen, and cranial nerve or autonomic involvement rarely are encountered.

1001

There is no definitive evidence that other disorders, particularly other immune-mediated disorders, are present to a greater extent in patients with MGUS polyneuropathy. It should be emphasized, however, that the diagnosis of MGUS depends on the stability of the M-protein concentration. Because a significant number of patients with MGUS will later develop malignant forms of monoclonal gammopathy, these patients require repeated evaluations and monitoring of the M-protein over time.

Differential Diagnosis. The differential diagnosis of MGUS polyneuropathy producing acquired SD changes on EDX examination is identical to that of CIDP. It is key to exclude the other causes for monoclonal gammopathy, including multiple myeloma, isolated plasmacytoma, Waldenström's macroglobulinemia, osteosclerotic myeloma (including the POEMS syndrome), heavy chain diseases, malignant lymphoma, and amyloidosis. It should also be noted that MGUS polyneuropathy may manifest as an axon loss polyneuropathy and, consequently, should be included in the differential diagnosis of axon loss sensorimotor polyneuropathy discussed elsewhere.^{[32], [33], [34]}

Evaluation. The EDX examination shows changes suggestive of a chronic, acquired SD polyradiculoneuropathy. Searching for an M-protein is an important component in the evaluation of any patient with a significant sensorimotor polyneuropathy. As noted earlier, if the serum protein electrophoresis is negative or unrevealing, additional testing should be performed using immunoelectrophoresis or immunofixation techniques. These methods are more sensitive in detecting small amounts of M-protein that may be important in the identification of MGUS polyneuropathy.^[32] Once an M-protein is detected in the setting of a sensorimotor polyneuropathy, a careful evaluation must follow to assess for a lymphoproliferative disorder. This evaluation typically entails routine laboratory studies to assess for anemia, hypercalcemia, and renal insufficiency. In addition, M-protein should be sought in the urine, and a skeletal bone survey should be obtained to assess for multiple myeloma, isolated plasmacytomas, or osteosclerotic changes typical of osteosclerotic myeloma. Although radionuclide bone scans may be valuable in this assessment, the skeletal plain x-ray study is more sensitive for the detection of osteosclerotic lesions. A bone marrow aspirate should also be performed. HIV testing also should be performed in patients at risk, with guidelines similar to those noted for CIDP.

Routine laboratory studies in MGUS polyneuropathy typically are unremarkable. The CSF protein is consistently increased in a fashion similar to that seen with CIDP. Sural nerve biopsy may also disclose features of inflammation and SD with some axon loss, which are very similar to the pathological changes noted in CIDP. None of these findings, however, is specific for MGUS polyneuropathy, and none serves to differentiate it from CIDP and other related disorders.

Because MGUS polyneuropathy associated with IgM and anti-MAG antibodies may represent a clinically distinct disorder, patients with IgM M-proteins should be screened for anti-MAG activity. This is sometimes performed in conjunction with assessment for anti-SGPG and anti-SGLPG antibodies. There is some evidence to suggest that this subset of MGUS polyneuropathies can be distinguished from CIDP and other MGUS polyneuropathies by its EDX features: the absence of substantial conduction block, and the prominent slowing of sensory and motor nerve conduction in the distal nerve segments.^[36]

Management. The data regarding benefits of therapeutic intervention with steroids, immunosuppressants, plasma exchange, and IVIg are largely anecdotal but tend to indicate that MGUS polyneuropathy responds in a fashion similar to CIDP.^[34] A controlled trial of plasma exchange did disclose efficacy in MGUS polyneuropathy but appeared to demonstrate greater improvement in polyneuropathies associated with IgG and IgA M-proteins compared with those associated with IgM M-proteins.^[37] Although convincing data are lacking, there is general agreement that these patients should be treated following the same guidelines used for CIDP. However, because MGUS polyneuropathy tends to be a more slowly progressive disorder than CIDP, it may be more difficult to define a precise threshold when treatment is indicated. Furthermore, treatment must be aggressive and sustained to provide ample time to observe a clinical response.

Prognosis and Future Perspectives. In comparison to CIDP, the prognosis in patients with MGUS polyneuropathy as a group may be less favorable. Despite the fact that the initial severity of weakness and sensory impairment is considerably less in MGUS polyneuropathy compared with cyclical relapses of CIDP or to the peak of a monophasic course of CIDP, MGUS polyneuropathy tends to be slowly progressive and ultimately, if the condition is left untreated, may result in more severe clinical deficits and disability.^[37] Also, MGUS polyneuropathy, overall, is somewhat less responsive to therapy than CIDP. Patients with MGUS polyneuropathy who have prominent features of acquired SD on EDX testing appear to have the greatest chance for significant improvement following therapeutic intervention. Those patients with IgM anti-MAG polyneuropathy may be less responsive to plasma exchange and other interventions. In a study of 25 treated patients with MGUS polyneuropathy who had a mean duration of illness of 6.6 years and were followed for a minimum of 24 months, 12 percent were asymptomatic and another 60

percent had either minimal, nondisabling symptoms or minor symptoms that caused only modest restrictions in their lifestyle. [31]

Very fundamental nosological issues regarding MGUS polyneuropathies need to be clarified. Does the presence of an M-protein in the setting of a SD polyneuropathy mimicking CIDP indicate a separate and distinct clinical entity? What is the pathogenetic role of the M-protein in the genesis of MGUS polyneuropathy? Is the subset of MGUS polyneuropathy associated with IgG and IgA M-proteins distinct clinically and pathogenetically from that associated with an IgM M-protein? More specifically, does the presence of anti-MAG antibodies in IgM MGUS polyneuropathy signify a distinct clinical and pathogenetic disorder that can be separated from CIDP and the other MGUS polyneuropathies? And finally, what are the natural histories of these disorders and what represents optimal therapies for the various types of MGUS polyneuropathy?

[PreviousNext](#)

MULTIPLE MYELOMA

Pathogenesis and Pathophysiology. Multiple myeloma is a hematological disorder characterized by a proliferation

of a single clone of plasma cells that produces a specific immunoglobulin. This disorder may affect patients between the ages of 40 and 70, but the peak incidence is in the seventh decade. Multiple myeloma typically causes bone pain, general fatigue, and weakness, and is often accompanied by anemia, chronic renal failure, and hypercalcemia. Over 99 percent of patients will have an M-protein detected in the serum or urine on immunoelectrophoresis or immunofixation.^[32] Skeletal bone surveys reveal osteolytic or rarely osteoblastic lesions in approximately two thirds of patients. The diagnosis can be established by bone marrow aspiration, which documents prominent collections of immature plasma cells.

Peripheral neuropathy is a rare complication of multiple myeloma, and when present, it is more likely due to associated amyloidosis than a remote effect of the multiple myeloma. However, an axon loss polyneuropathy as well as an acquired SD polyneuropathy may occur as a remote effect. The precise pathogenesis of the polyneuropathy is unknown, but mechanisms similar to those proposed for MGUS polyneuropathy may be operative.

Epidemiology and Risk Factors. Patients with polyneuropathy secondary to multiple myeloma tend to present at a younger age than patients with multiple myeloma without polyneuropathy.^[38] Most reports indicate a rather prominent male predominance. In the majority of patients the polyneuropathy is the presenting sign of the multiple myeloma and, in fact, may predate the diagnosis of multiple myeloma for many months or years. It is extremely rare for multiple myeloma to affect women of childbearing age, and thus there is no known influence or risk associated with pregnancy.

Clinical Features and Associated Disorders. Multiple myeloma typically produces a chronic, slowly progressive, symmetrical, sensorimotor polyneuropathy. However, in some patients, a more rapid evolution may occur in which motor weakness is prominent and which may result in quadriparesis with respiratory involvement. Rarely, cranial nerve involvement, characterized by facial weakness or ophthalmoplegia, may be observed. Generalized hyporeflexia or areflexia is a common finding. Autonomic involvement seldom occurs, and when present in a patient with multiple myeloma, it raises the more likely possibility of an underlying amyloid neuropathy.

There are no disorders that are directly associated with the polyneuropathy secondary to multiple myeloma. However, the clinical disorders that often accompany multiple myeloma may be present. These include metabolic abnormalities such as anemia, leukocytosis, thrombocytosis, hypercalcemia, hyperuricemia, and chronic renal failure. Amyloidosis is also a common associated disorder, which may produce a polyneuropathy with prominent small fiber involvement characterized by burning dysesthesia and pain as well as by generalized dysautonomia. Involvement of bone marrow by multiple myeloma may result in compression fractures of the spine, which, in turn, may cause compressive myelopathy, compressive radiculopathies, or both.

Differential Diagnosis. The differential diagnosis of an acquired SD polyneuropathy occurring in the setting of multiple myeloma is identical to that already described for CIDP. In particular, the presence of an M-protein and an acquired SD polyneuropathy requires a careful, methodical evaluation for multiple myeloma, osteosclerotic myeloma, lymphoma, macroglobulinemia, and MGUS. HIV testing should be performed in patients at risk.

Evaluation. The EDX examination shows evidence of a chronic, acquired SD polyradiculoneuropathy. The presence of an M-protein in the serum or urine occurs in nearly all patients. General laboratory studies in multiple myeloma may sometimes disclose evidence of anemia, chronic renal failure, hypercalcemia and occasionally hyperuricemia, leukocytosis and thrombocytosis. Skeletal survey may disclose osteolytic or occasionally osteoblastic lesions in approximately two thirds of patients. However, the diagnosis of multiple myeloma is made on bone marrow aspiration, which demonstrates increased numbers of immature plasma cells in the bone marrow. As noted earlier, the presence of a polyneuropathy in a patient with multiple myeloma is more likely to be due to amyloidosis. Confirmation of systemic amyloidosis with appropriate biopsy of such tissues as the rectal mucosa or abdominal fat pad may be helpful; however, sural nerve biopsy for amyloid may provide definitive evidence of amyloidosis as the mechanism of the underlying polyneuropathy. Amyloid neuropathy can be distinguished from polyneuropathy associated with multiple myeloma by EDX testing, which typically discloses changes of axon loss rather than demyelination.

Management. The treatment of acquired SD polyneuropathy caused by multiple myeloma consists of optimal treatment of the myeloma. This usually involves chemotherapy, typically with steroids and melphalan. In some patients, as the multiple myeloma clinically improves with treatment, the polyneuropathy does also. In others, however, the polyneuropathy may persist or worsen despite successful treatment of the multiple myeloma. In patients with isolated plasmacytoma, local surgery or radiation therapy may result in satisfactory improvement in the polyneuropathy.^[39]

Prognosis and Future Perspectives. The published data are insufficient to define clearly the specific prognosis of acquired SD polyneuropathy occurring in the setting of multiple myeloma. Obviously, patients with associated systemic amyloidosis have a poorer prognosis than patients with polyneuropathy due solely to the remote effect of multiple myeloma.^[34]

Much is yet to be learned regarding the pathogenesis of the polyneuropathies associated with multiple myeloma. In particular, the role of the M-protein in their pathogenesis and the possibility of an immune-mediated pathophysiology needs to be carefully explored. However, owing to their rare occurrence, it has been difficult to amass enough clinical experience to define properly the clinical and pathogenetic mechanisms of these heterogenous disorders.

OSTEOSCLEROTIC MYELOMA

Pathogenesis and Pathophysiology. Osteosclerotic myeloma may be considered a rare variant of multiple myeloma, comprising only 3 percent of all patients with myeloma. Many of the typical features of multiple myeloma, including anemia, hypercalcemia, chronic renal failure,

fatigue, weakness, and bone pain, are rare or at least uncommon in osteosclerotic myeloma. Furthermore, the level of M-protein is lower, and there are fewer plasma cells in the bone marrow. In contrast to multiple myeloma, however, an associated polyneuropathy is relatively common in osteosclerotic myeloma, occurring in over 50 percent of patients.^[34] Furthermore, the polyneuropathy associated with osteosclerotic myeloma may frequently be a component of the so-called POEMS syndrome.^[35]

The precise pathophysiology of the polyneuropathy associated with osteosclerotic myeloma and the multi-organ features of POEMS syndrome is unknown. It is likely that the plasma cells secrete an immunoglobulin or some other substance that may cause both the polyneuropathy and the other systemic features of POEMS syndrome.^[35]

Epidemiology and Risk Factors. Patients with polyneuropathies secondary to osteosclerotic myeloma typically range in age from the late fourth decade through the seventh decade with a mean age in the late fifth decade. There is a rather prominent predilection for the disorder to occur in males. For the above-mentioned reasons, it would be exceedingly rare for this disorder to occur in women of the childbearing age.

Clinical Features and Associated Disorders. The clinical features of polyneuropathy associated with osteosclerotic myeloma typically conform to those of a rather chronic, progressive sensorimotor polyneuropathy. In the majority of patients, the polyneuropathy progresses to the point of rather remarkable weakness involving proximal as well as distal muscles, and may result in significant disability. Typically, weakness is a more prominent symptom than sensory impairment. Autonomic symptoms are rare, and cranial nerve involvement is absent except for instances of papilledema. General systemic symptoms of bone pain, fatigue, and weakness typical of multiple myeloma usually are not seen.^[35]

The neurological examination typically discloses prominent weakness that is worse distally but with occasional proximal involvement. Sensory loss is less prominent and tends to affect the large fiber modalities of touch pressure, joint position sense, and vibratory sensation more so than smaller fiber modalities of pain and temperature. Papilledema may be seen in up to 50 percent of patients.^[35]

One or more additional features of the POEMS syndrome often are observed, but in many cases, these are not prominent and must be carefully sought. Hepatomegaly may be found in up to 50 percent of patients, whereas lymphadenopathy and splenomegaly are less common. Manifestations of endocrinopathy include diabetes mellitus, hypothyroidism, impotence, gynecomastia, testicular atrophy, amenorrhea, hyperprolactinemia, and hyperestrogenemia. Skin changes include hyperpigmentation, thickening of the skin, hypertrichosis, skin angiomas, clubbing, and white nails. Some skin changes are suggestive of scleroderma. Peripheral edema, ascites and pleural effusions may also be seen. POEMS syndrome, sometimes referred to as Crow-Fukase syndrome, is not unique to osteosclerotic myeloma. It has been observed in multiple myeloma, Waldenström's macroglobulinemia, and angiofollicular lymph node hyperplasia, also referred to as Castleman's disease.^[35]

Differential Diagnosis. In nearly all patients with polyneuropathy associated with osteosclerotic myeloma, the diagnosis is made during a comprehensive evaluation for a cryptogenic polyneuropathy. The findings on EDX examination of features consistent with an acquired SD polyneuropathy provide the differential diagnosis of CIDP and the related disorders, as noted earlier. Furthermore, the presence of an M-protein necessitates a hematological evaluation, which encompasses skeletal bone study and bone marrow aspirate. Careful attention to the possibility of the systemic features of the POEMS syndrome can yield important clues to the diagnosis of polyneuropathy associated with osteosclerotic myeloma.

Evaluation. Typically, the fact that there are EDX changes suggestive of an acquired SD polyradiculoneuropathy will already have been determined. The M-protein associated with osteosclerotic myeloma is usually IgG or IgA and is almost always of the lambda light chain type.^[34] The concentration is typically low and rarely more than 3 g/dl, the usual range seen in multiple myeloma. An important point is that approximately 25 percent of patients with osteosclerotic myeloma may not have an M-protein detected in the serum or urine.^[34] Thus, to evaluate a patient properly for this disorder, a skeletal survey is essential to uncover osteosclerotic lesions, the hallmark of the syndrome. These lesions typically involve the spine, pelvis, ribs, and proximal long bones of the limbs; occasionally they are not prominent and may be misinterpreted as benign bone sclerosis. Usually, the bony lesions show both osteosclerotic and lytic changes--sometimes they have the appearance of an osteosclerotic rim around a lytic lesion. The CSF usually is normal, except for an elevation of protein comparable to that noted in CIDP. EDX studies show features of an acquired SD polyneuropathy, although in some patients, axonal degeneration may be prominent. Sural nerve biopsies typically show combinations of both axon loss and segmental demyelination with occasional small foci of inflammatory cell infiltrates in the perivascular epineurium. Bone marrow aspirate usually discloses less than 5 percent of plasma cells. Routine laboratory studies most often are unrevealing, although thrombocytosis may be observed in nearly half of patients, with other features, including leukocytosis and polycythemia, present in a smaller number of patients.

Management. Patients with solitary osteosclerotic lesions appear to have the very best response to therapy. Local radiation of single or multiple lesions may result in substantial improvement in the polyneuropathy in the majority of patients. In patients with multiple osteosclerotic lesions, chemotherapy may result in improvement and stabilization of the polyneuropathy, although the responses appear to be less satisfactory than in those with isolated osteosclerotic lesions.

Prognosis and Future Perspectives. The polyneuropathy associated with osteosclerotic myeloma tends to be slowly progressive and may produce rather prominent generalized weakness and considerable disability, including wheelchair or bed confinement. The majority of patients with isolated osteosclerotic lesions respond to treatment, demonstrating stabilization, if not improvement, of their polyneuropathies. Patients with multiple osteosclerotic lesions do not respond as well.

Future research into this entity must provide a unifying pathophysiology that can explain the multisystem involvement

of the POEMS syndrome. The pathogenetic role of the M-protein lambda light chain is a likely candidate for further study. From a clinical viewpoint, a more systematic study of the optimal mode of therapy is needed. However, the relatively rare occurrence of this entity will make it difficult to perform controlled therapeutic trials.

WALDENSTROM'S MACROGLOBULINEMIA

Waldenstrom's macroglobulinemia is a chronic lymphoproliferative disorder characterized by a clonal proliferation of B lymphocytes or lymphoplasmacytic cells in bone marrow or in lymph nodes, or both and a high concentration of monoclonal IgM M-protein, typically exceeding 3 g/dl. In addition to the clinical features caused by the circulating macroglobulin, including hyperviscosity syndrome and cryoglobulinemic features, a polyneuropathy occurs in approximately one third of patients.^[34] Half of all those with polyneuropathy are positive for anti-MAG antibodies.^[34] In this latter group of patients, the pathophysiology of the polyneuropathy may be similar to that seen with MGUS IgM anti-MAG positive polyneuropathy. However, a more heterogeneous group of polyneuropathies, predominantly axon loss in type but occasionally demyelinating, may be encountered in those patients who are anti-MAG negative, similar to what is observed in the other IgM MGUS polyneuropathies. The pathophysiology of these polyneuropathies also is similar to that noted for the MGUS polyneuropathies without anti-MAG activity. Waldenstrom's macroglobulinemia tends to occur in the middle to older age groups, with a mean age of onset in the early seventh decade, and there is a slight male predominance. The late age of onset essentially precludes it occurring in pregnant women.

The clinical features of the demyelinating polyneuropathy associated with macroglobulinemia and anti-MAG activity is essentially identical to that noted in MGUS IgM anti-MAG-positive patients.^[34] The disorder typically is a chronic sensorimotor polyneuropathy with prominent sensory involvement, including sensory ataxia. Other peripheral nerve syndromes may occur in macroglobulinemia, however, including asymmetrical mononeuropathy associated with cryoglobulinemia and a rather typical amyloid polyneuropathy. A hyperviscosity syndrome may occur in 15 percent of patients with macroglobulinemia, usually in the setting of an underlying lymphoma.^[40] This syndrome produces a wide spectrum of symptoms including general fatigue, blurred vision, and dizziness. Blurred vision may be secondary to distended retinal veins, retinal hemorrhages, and papilledema. Easy bleeding of mucous membranes is also observed and usually is due to abnormal platelet function induced by the IgM M-protein. In addition, the IgM M-protein may function as a cryoglobulin and contribute to other systemic symptoms, including renal disease, altered liver function studies, arthralgia, Raynaud's syndrome, and cryoglobulinemic neuropathy.^[40] Moreover, a chronic hemolytic anemia occurs in approximately 10 percent of patients. Nearly one third of patients have lymphadenopathy or splenomegaly.

The presence of a high concentration of IgM M-protein in the context of an acquired SD polyneuropathy requires a careful evaluation for lymphoproliferative disorders. This usually necessitates skeletal bone survey to assess for multiple myeloma and osteosclerotic myeloma as well as bone marrow aspiration. The presence of lymphadenopathy and organomegaly coupled with the other systemic features of macroglobulinemia provide the key clinical clues to the diagnosis.

Evidence of an acquired SD polyradiculoneuropathy should be found on EDX studies. The evaluation of patients with IgM M-protein and acquired SD polyneuropathy is identical to that described for MGUS polyneuropathy. Testing for anti-MAG activity is essential to identify the subset of patients with macroglobulinemia who may have a more specific immune-mediated disorder. Results of nerve biopsies and CSF analysis are similar to those seen in MGUS IgM anti-MAG polyneuropathy. Routine laboratory studies in patients with macroglobulinemia often disclose anemia, monoclonal blood lymphocytosis, and Bence Jones proteinuria as well as elevated serum beta-microglobulin in nearly half of patients. Also, the presence of cryoglobulins is not an uncommon finding. Diagnosis is confirmed by the presence of a high concentration of IgM M-protein in the setting of underlying lymphoma characterized by infiltration of bone marrow, lymph nodes, and spleen.

Waldenstrom's macroglobulinemia typically is treated with combinations of chemotherapy and plasmapheresis. Chemotherapy for underlying lymphoma often incorporates a combination of an alkylating agent and a glucocorticoid. Plasma exchange often is recommended for patients who develop polyneuropathy and in those with clinical features of hyperviscosity syndrome and cryoglobulinemia.^[40] Waldenstrom's macroglobulinemia is a serious disease with a median survival time of approximately 4 years. Therapeutic intervention with chemotherapy and plasmapheresis may be helpful in stabilizing or improving the associated polyneuropathy.

MOTOR NEUROPATHY WITH MULTIFOCAL CONDUCTION BLOCK

Pathogenesis and Pathophysiology. Motor neuropathy with multifocal conduction block (MNMCB), sometimes referred to as multifocal motor neuropathy with conduction block, is a rare disorder that is characterized by asymmetrical motor weakness and EDX features of acquired SD lesions affecting one or more localized segments of motor nerve fibers. Its pathogenesis is unknown but an immune-mediated mechanism is supported by pathological features of inflammatory demyelinating changes, favorable clinical response to immunosuppressant and immune-modulating therapies, and many striking similarities with CIDP.^[41] Pathological features include demyelination, occasionally with evidence of remyelination in the form of onion bulb formation, and perivascular inflammatory infiltrates, primarily of lymphocytes. These changes have been observed in cranial nerves as well as in proximal and distal segments of peripheral nerves examined at autopsy.^[42]

Although motor fiber involvement is responsible for most of the clinical and EDX features, similar pathological changes of demyelination with inflammation also have been reported in sensory nerves, including sural nerve specimens examined at nerve biopsy. Reflecting this, occasionally sensory NCS abnormalities are seen.

Antibodies to the GM₁ ganglioside have been reported in a high percentage of patients with MNMCB.^[41] This factor has led to the concept that these antibodies are playing a pathogenetic role in this disorder. However, direct evidence in support of this proposal is lacking.^[43] Furthermore, the presence of anti-GM₁ antibodies is relatively nonspecific, because they can be found in a wide range of other neuromuscular disorders. Very high titers of GM₁ antibody appear to have greater specificity for lower motor neuron syndromes, including MNMCB.^[44] Nonetheless, patients with MNMCB who do not have antibodies to GM₁ still respond to immune-modulating therapies. This field is rapidly evolving. It is possible that the presence of antibodies to GM₁ and other antigens may eventually prove more useful in the diagnosis of lower motor neuron syndromes, including MNMCB.^[44]

Epidemiology and Risk Factors. MNMCB is a rare disorder. The age of onset spans many decades, from the teen-age years through late adult life, but the condition tends to begin in young adults. There is a slight male predominance. There is no known predilection for this disorder to affect women during pregnancy or to worsen during pregnancy or in the postpartum period.

Clinical Features and Associated Disorders. MNMCB characteristically is a progressive disorder that causes multifocal and asymmetrical weakness and occasionally muscular atrophy accompanied by cramps and sometimes fasciculations.^[41] This disorder often begins in the upper extremities, and although it may spread to involve the lower extremities, it may remain localized to or more prominent in the upper extremities throughout its course. Whereas some weakened muscles may be atrophic, other involved muscles may be of normal bulk despite chronic weakness, a clinical sign suggesting that SD conduction block is the mechanism of weakness rather than axon loss. Cranial nerve involvement is uncommon, although atrophy and weakness of the tongue and other bulbar symptoms and signs have been noted. Even though the condition predominately affects motor function, most patients will eventually experience sensory symptoms, including a sense of numbness or tingling, often in the absence of objective sensory loss. Sensory symptoms and signs are most common in patients with longstanding MNMCB. The DTRs frequently are absent or depressed in the distribution of the affected nerves, but surprisingly, they are sometimes preserved.

MNMCB typically follows a very chronic indolent course that may span many years. On occasion, the disease appears episodic, with patients having a stable nonprogressive course lasting many months or years before another episode develops. Alternatively, some patients have a more subacute course that may lead to rather prominent widespread weakness and disability over several months. Rare instances of central nervous system involvement have been reported in patients with typical MNMCB. However, these clinical features are usually modest and seldom resemble the combined features of upper and lower motor neuron disease noted in amyotrophic lateral sclerosis (ALS).^[41]

Differential Diagnosis. Many of the clinical and EDX features of MNMCB bear a close similarity to CIDP and related disorders. In fact, MNMCB has been regarded by some as a variant of CIDP.^[41] Thus, patients presenting with predominately motor weakness accompanied by EDX features of acquired SD need to be assessed for the same conditions included in the differential diagnosis of CIDP. In addition, some patients with MNMCB may superficially resemble patients with motor neuron disease or ALS. Usually, MNMCB can be differentiated from these disorders by its more chronic and indolent course, the absence of upper motor neuron symptoms and signs, and most important, the presence of acquired SD features on EDX testing.

Evaluation. Because MNMCB may represent a variant of CIDP, it is important to evaluate patients with MNMCB in the same fashion as patients with possible CIDP. A careful search for an M-protein, skeletal bone survey for osteosclerotic or osteolytic lesions, and HIV testing in patients at risk should be considered in patients with clinical features suggesting MNMCB. The CSF is usually normal in all aspects, including its protein content, thereby signifying the predilection of MNMCB to involve peripheral nerves rather than spinal nerve roots. The majority of patients with MNMCB will have high titers of anti-GM₁ antibodies. As noted earlier, the presence of the anti-GM₁ antibody is not specific to MNMCB and is not required for the diagnosis. The EDX features of this disorder provide its laboratory confirmation: They disclose evidence of multifocal conduction block, generally confined to motor fibers (see [Fig. 49-2](#)). Typically, the lesion sites are not common locations for entrapment or compressive neuropathies, for example, a focal conduction block may be found along the ulnar nerve in the forearm, rather than at the elbow.

Management. Because MNMCB is a rare disorder, the data are limited regarding the efficacy of the various available treatment modalities. Anecdotal reports suggest that prednisone, azathioprine, and plasmapheresis rarely are effective. However, both IVIg and high-dose intravenous cyclophosphamide may be of benefit.^{[41], [45]} Clearly, IVIg is the preferred treatment over IV cyclophosphamide, owing to the greater risks and complications of the latter drug. In a fashion similar to CIDP, IVIg may be administered periodically to maintain clinical improvement. It should be emphasized that the treatment of MNMCB must be individualized. Many patients with MNMCB, for example, have very modest clinical symptoms that persist unchanged for many years. The appropriate management of such patients may be observation alone rather than have them undergo the risk and expense of IVIg or cyclophosphamide treatments.

Prognosis and Future Perspectives. The rarity of this disease and its relatively recent initial description in 1982 are factors that limit experience with its natural history. Nevertheless, most patients with MNMCB seem to display a chronic, slowly progressive or stable course over many years. With the advent of IVIg treatment as well as intravenous cyclophosphamide, it is likely that in many patients the disorder can be stabilized, resulting in modest, if any, disability.

Key fundamental issues to be resolved regarding MNMCB include its precise pathophysiology, including the role of anti-GM₁ antibodies and its relationship to CIDP. From a clinical perspective, more experience is required to better formulate optimal therapeutic interventions.

Chapter 50 - Autoimmune and Inflammatory Disorders

Russell Bartt
Kathleen M. Shannon

History and Definitions

Inflammatory Vasculopathies; Arteritis

Extracranial Granulomatous Arteritis (Giant Cell "Temporal" Arteritis)

Intracranial Granulomatous Arteritis or Primary Angiitis of the Central Nervous System

Takayasu's Arteritis

Polyarteritis Nodosa, Churg-Strauss, and Overlap Syndromes

Wegener's Granulomatosis

Vasculitis Associated with Antiphospholipid Antibodies

Thromboangiitis Obliterans (Buerger's Syndrome)

Connective Tissue Diseases

Rheumatoid Arthritis

Systemic Lupus Erythematosus

Progressive Systemic Sclerosis

Mixed Connective Tissue Disease

Sjogren's Syndrome

Other Autoimmune Conditions

Myasthenia Gravis

Dermatomyositis and Polymyositis

Eosinophilic Myositis and Related Syndromes

Inclusion Body Myositis

Behcet's Disease

Reviews and Selected Updates

HISTORY AND DEFINITIONS

Pathological disorders mediated by immune processes directed against autologous tissues were first recognized in the early 1900s by Erlich, who used the term "horror autotoxicus" to describe this phenomenon. The first descriptions of necrotizing arteritis appeared in an 1852 treatise on aneurysms by Karl Rokitansky. ^[1] In 1866, the term periarteritis nodosa was used to describe a single patient with a typical histologic appearance of necrotizing arteritis. ^[1] Most of the descriptions evolved in the 1940s and 1950s by people such as Jacob Churg and Friedrich Wegener. With few exceptions, these syndromes continue to be defined by the classic pathological appearance.

The ability of the immune system to differentiate between one's body and a wide variety of potential pathogens and toxins is remarkable. Under normal circumstances, the immune system may react against certain of its own tissues such as neoplasms and senescent red blood cells. While extensive growth in immunology has led to a better understanding of the pathophysiology of these diseases, often the etiology remains obscure.

Lymphocytes recognize foreign antigens through receptors on their surface, and the differentiation between self and nonself is essential to normal function. Several factors may account for this ability to avoid self-reactivity: self-directed T-lymphocytes may be deleted from the repertoire at an early age; self-antigens may not be presented to the lymphocytes in such a way as to induce an immune response; self-antigens may be in "immunologically privileged" tissues, which are not routinely exposed sufficiently to the circulating lymphocytes; or self-response may be downregulated by other components of the immune system. ^[2] It is believed that evasion of these mechanisms leads to autoimmune disease by one of the following pathways: (1) normal regulatory control to a given self-antigen may be lost or bypassed; (2) self-antigens may express major histocompatibility complexes II (MHC-II), normally present only on immunologically competent cells; these self-tissues may then present antigens to lymphocytes; or (3) a foreign antigen with a similar molecular structure may mimic a self-antigen and result in cross-reactivity. ^[2]

The autoimmune response may be directed at a relatively specific tissue antigen such as the acetylcholine receptor in myasthenia gravis (organ-specific response). Alternatively, the self-antigen may be in many tissues and be relatively nonorgan-specific, causing diseases such as systemic lupus erythematosus.

Vasculitis is a common manifestation of a diverse group of diseases. Though they may result from etiologically and pathogenetically different diseases, all share the pathological finding of inflammation of the vessel wall. Tissue injury results from the occlusion of inflamed vessels. Vasculitides can be organized by the size of the vessels involved (e.g., large, medium, or small vessel vasculitis shown in [Fig. 50-1](#)) or by the predominant cell type involved, as discussed below. ^[1]

For *neutrophil-predominant vasculitis* to occur, an inflammatory stimulus must perturb the homeostasis of circulating leukocytes and endothelial cells. Adhesion to certain areas of the vasculature is induced by cytokine-stimulated expression of adhesion molecules (e.g., ICA-1, VCAM-1).

1998

Figure 50-1 Classification of the vasculitides by vessel size (Adapted from Jennette JC, Falk RJ: Clinical and pathological classification of ANCA-associated vasculitis: What are the controversies? Clin Exp Immunol 1995; 101[Suppl 1]:18-22.)

In severe inflammation, there is mural necrosis with rupture and hemorrhage, or leakage of plasma factors into tissues where soluble coagulation factors contact inflammatory debris causing fibrinoid necrosis.

Mononuclear-predominant vasculitis (lymphocytes, monocytes, macrophages) can occur as a discrete entity or can evolve from neutrophil-predominant vasculitis. Unlike neutrophils, monocytes have a regulatory role as well as an effector role in inflammation. Therefore, the histological demonstration of T-lymphocytes does not prove that the process is mediated by a T-lymphocyte immune response. Mononuclear-predominant vasculitis is seen in giant cell arteritis, Takayasu's arteritis, and primary angiitis of the central nervous system.

Immune complex vasculitis results from deposition of heterologous or autoantigen immune complexes in vessel walls either from the circulation or by in situ formation. Most circulating immune complexes are cleared from the circulation without causing vascular inflammation. Molecular size and electrical charge influence the ability to survive in the circulation and deposit in vessel walls. Medium-sized cationic particles are the most pathogenic.

Antineutrophil cytoplasmic antibodies (ANCA) are associated with some vasculitides that involve small vessels including epineural vessels. It is not known if ANCA cause the vasculitis or are an epiphenomenon. Peripheral neuropathies are frequently encountered in ANCA vasculitides, but it is unclear how many neuropathies are ANCA-associated.

Infections can cause vasculitis by direct effects of the agents themselves and by the immune-mediated response. Infectious vasculitides will not be covered in this chapter.

Connective tissue diseases as a whole are syndromes with immunological reactivity to various tissue components. Clinically, however, there may be overlap with other autoimmune conditions. Tissue components of the vasculature may be involved, and a vasculitis may dominate the clinical picture. This is demonstrated by the frequent occurrence of mononeuritis multiplex in the connective tissue diseases, as a result of peripheral nerve ischemia secondary to inflammation of the vasa nervorum.

Other autoimmune conditions are not targeted at the vessels but are part of a connective tissue syndrome. Those disorders affecting the neurological system, are discussed in the last section of this chapter.

INFLAMMATORY VASCULOPATHIES; ARTERITIS

Extracranial Granulomatous Arteritis (Giant Cell "Temporal" Arteritis)

Pathogenesis and Pathophysiology. Giant cells are the pathological hallmark of this large-vessel, T-cell mediated vasculitis. CD4 cells aggregate with a response centered on the internal elastic lamina. These cells may contain elastic fiber fragments. Giant cell arteritis (GCA) affects the aorta and its branches, including the cervicocephalic arteries (carotid and vertebral), reflecting its predilection for the internal elastic lamina. Intracranial arteries are usually not involved, although proximal branches of the internal carotid artery have been lesioned. The superficial temporal artery and intraorbital branches of the carotid artery are involved in many cases. Vertebral arteries may be affected in very severe cases, though basilar artery involvement is rare. Aortic rupture can also occur. There is an overlap between GCA and polymyalgia rheumatica (PMR).

Epidemiology and Risk Factors. Age is a strong risk factor for disease. Maximum incidence is in the 70s with

the median age of onset being 75, and virtually no cases in the population less than 50 years of age. Overall, women have a higher age-adjusted incidence than men, 16.5 versus 5.7 per 100,000 per year of the U.S. population aged 50 and older. The incidence rate reported has increased each decade from the 1950s into the 1970s. Additionally, the number of negative biopsies in cases suspected of having GCA has also increased. As opposed to an actual increase in the disease, an explanation for these findings may represent better identification of potential cases as a result of heightened awareness of the disease. There has been a tendency to reclassify cases of PMR to GCA when the disease has been more aggressive, accompanied by visual symptoms or headache, or was relatively resistant to low-dose corticosteroid therapy.

Clinical Features and Associated Disorders. GCA was first described in 1890, but was best described in 1932 as giant cell inflammation of the temporal artery with a systemic syndrome of fever, anorexia, weight loss, fatigue, and anemia. PMR was described as an illness of the elderly with proximal muscle pain and stiffness along with a systemic syndrome. PMR was felt to be a variant of rheumatoid arthritis, with synovitis but without rheumatoid factor. In time it became clear that there was overlap between GCA and PMR. However, the greater sensitivity of PMR to steroids contributed to continued separation of the two syndromes. Most likely, both are part of a spectrum of disease characterized by variable degrees of synovitis and arteritis related to a common yet unknown etiopathogenic agent. PMR occurs in 58 percent of patients with GCA and is the initial symptom in 25 percent. Criteria for the diagnosis of GCA and PMR are listed in [Table 50-1](#).

Pain is commonly experienced by patients with GCA. Headache, sometimes with scalp tenderness, occurs in 72 percent of patients and is present in 33 percent at the time of diagnosis. Jaw claudication is an occasional feature. Neck or back pain is present in 25 percent of patients with GCA who do not have PMR.

Vascular disease may manifest in several ways. Bruits may be audible over involved arteries. Carotid bruits occur in 10 to 20 percent and are frequently bilateral. Claudication or upper limb bruits occur in approximately 60 percent of patients, and about 40 percent of patients with carotid bruits will have some ischemic brain or eye complication. However, permanent visual loss and stroke occur with about the same frequency regardless of the presence of bruits. About 4 percent of patients with GCA will experience a transient ischemic attack (TIA) or stroke ([Chapters 22](#) and [45](#)). The proportion of such events occurring in the vertebrobasilar circulation is greater in GCA patients than that seen in the general stroke population. Within the vertebrobasilar system, these events may not respect distinct vascular territories. There are some reports of myelopathy in GCA presumably from vertebral or anterior spinal artery involvement.

The risk of blindness remains poorly defined in GCA and PMR. Overall, eye findings occur in 8 to 23 percent of people with GCA. Amaurosis fugax occurs in 10 to 12 percent. Anterior ischemic optic neuropathy (AION) results from posterior ciliary and, less frequently, retinal arteritis. Occasionally, the findings are entirely retrobulbar. However, acute optic disc edema followed by the development of optic pallor over 2 to 4 weeks may be seen. Diplopia is seen in 2 to 14 percent of patients, usually related to extraocular muscle dysfunction, but rarely as a result of brain stem disease. Clinical findings may fluctuate daily as a characteristic feature.

Vertigo or unilateral hearing loss may rarely be the result of an infarct of the vestibulocochlear nerve. Other cranial nerves, such as the fifth, seventh, or twelfth, have been affected in isolation or as part of a mononeuritis multiplex. Occasionally, other cranial neuropathies have occurred causing facial pain, hemianesthesia of the tongue or lingual paralysis.

Peripheral nerve disorders are common in many of the vasculitides. Involvement of the vasa nervorum may result in a mononeuritis multiplex. Many areas of involvement of peripheral nerves may overlap, suggesting a distal symmetrical polyneuropathy.

Although myalgia is a common symptom and localized inflammation has been described in patients with GCA, inflammatory myositis is not a recognized feature of the illness. Myopathy in GCA usually results from corticosteroid use (see Management).

Differential Diagnosis. Numerous symptoms occur in GCA that are not specific for the condition. Certainly, the population that is at the greatest risk for the development of GCA is also at risk for atherosclerotic vascular disease. This situation presents problems in evaluating individual patients as well as interpreting the literature. The presence of constitutional symptoms such as weight loss and fevers and an elevated sedimentation rate, with or without a pain syndrome, should raise GCA as a serious consideration.

Evaluation. The examination in suspected GCA should

TABLE 50-1 -- CRITERIA FOR THE DIAGNOSES OF GIANT-CELL ARTERITIS AND POLYMYALGIA RHEUMATICA

Giant-Cell Arteritis (must meet all 5 criteria)	Polymyalgia Rheumatica (must meet all 7 criteria)
1. Confirmatory biopsy	1. Shoulder/pelvic girdle muscle pain
2. Tenderness to palpation ± pulselessness in temporal artery	2. Morning stiffness
3. Any or all of: visual disturbance temporal or occipital headache jaw claudication	3. Duration of symptoms for at least 2 weeks
4. Westergren ESR >30 mm/hr OR C-reactive protein >6 µg/ml	4. Absence of true arthritis
5. Prompt response to steroid therapy	5. Absence of objective signs of muscle disease
Duration of symptoms for at least 2 weeks	6. Westergren ESR >30 mm/hr OR C-reactive protein >6 µg/ml
	7. Prompt response to steroid therapy

Modified from De Silva M, Hazelman BL: Azathioprine in giant cell arteritis/polymyalgia rheumatica: a double blind study. *Ann Rheumatol Dis*, 1986, 45:136-138.

include inspection, auscultation, and palpation of extracranial arteries. Blood pressure in both arms should be assessed for asymmetry. Routine bloodwork commonly shows anemia. Serologic evaluation, including erythrocyte sedimentation rate (ESR), and C-reactive protein assessment are necessary. Abnormalities of the temporal artery may be apparent on color duplex ultrasonography. Characteristic signs include a dark halo around the arterial lumen, and stenoses or occlusions of temporal artery segments. Angiography may demonstrate segmental stenosis or occlusion of the temporal artery. Superior temporal artery angiography is less reliable than biopsy. Biopsy of the superficial temporal artery may show giant cells, but several sections usually need to be examined.

Management. Early studies evaluating steroid efficacy were flawed and some do not reach statistical significance by today's standards. Overall, however, there appears to be a modest beneficial effect of high-dose steroids consistent with the understanding of the effect of steroids on other vasculitic syndromes. The

prevention of blindness is considered worth the approximately 50 percent risk of adverse effects (symptomatic vertebral collapse in 26 percent, myopathy 17 percent) from steroid therapy. Prednisone remains the mainstay of treatment with initial dose of 40 to 60 mg/d and treatment over the next few years. Tapering should be done slowly. In the rapidly deteriorating patient or one with a neurologic syndrome, IV methylprednisolone can be used, typically 1 g/d divided into 2 to 4 doses. No well-controlled trials have examined differences in dosing regimens. If relapse occurs while tapering, then the target dose to taper to should be higher than the dose at the time of relapse. ESR monitoring is very helpful in determining relapses and responses to dose changes.

A number of other immunosuppressives have been used, including azathioprine, methotrexate, dapsons, and cyclophosphamide, with inconsistent results. Cyclophosphamide may be the most consistently effective. Azathioprine was compared in a double-blind fashion to placebo in GCA patients already taking prednisone. Because the immunosuppressive effect of azathioprine is delayed, a statistically significant difference in prednisone dose was reached only after 1 year of therapy.

Prognosis and Future Perspectives. Although GCA can cause death, stroke, or myocardial infarction, the survival of GCA patients does not significantly differ from that of age matched controls. In a series of 21 GCA patients who died, in only one case was the cause of death attributed to GCA. Catastrophic neurologic sequelae such as blindness and stroke are uncommon and have been lessened in frequency by the use of steroids.

Intracranial Granulomatous Arteritis or Primary Angiitis of the Central Nervous System

Pathogenesis and Pathophysiology. This disorder has carried a number of names, including noninfectious granulomatous angiitis with a predilection for the CNS, granulomatous angiitis of the CNS (GACNS), primary angiitis of the CNS (PACNS), and vasculitis confined to the CNS. First described in 1959, very few cases were described antemortem until the widespread availability of angiography in the 1960s. The term PACNS is most appropriate because it requires the absence of a systemic disease, but does not require the presence of granulomatous lesions. Pathologically there are monocytes/histiocytes, lymphocytes, and plasma cells infiltrating the walls of small arteries, particularly in the leptomeninges. In 85 percent of cases, multinucleated giant cells are seen among the inflammatory cells. Small leptomeningeal arteries are preferentially affected, although occasional involvement of the internal carotid and vertebral arteries is seen. Numerous small foci of infarction are common, but there may be large areas of ischemia, sometimes with superimposed hemorrhage. Unlike polyarteritis nodosa, there is no predilection for the branching points of arteries. The etiology is unknown but there is growing speculation of a viral cause. There is no evidence that the disease is mediated by immune complexes, although there may be a direct immune interaction at the level of the vessel wall.

Epidemiology and Risk Factors. Most patients are young or middle-aged (range 3 to 74 years). In the literature, and among biopsied cases, males predominate, although among biopsied cases, there is a female predominance of 2:1. The majority of cases do not have any identifiable preexisting condition.

Clinical Features and Associated Disorders. Typically, the patient has a headache of gradual onset and a diffuse encephalopathy or dementia. Later, focal neurological signs develop. In one large review of 108 cases (including 99 from the literature), 53 percent of cases presented with both focal and diffuse findings, 32 percent with focal findings only, and 11.1 percent with diffuse findings only (Table 50-2). Headache is the most common presenting symptom and is often associated with nausea and vomiting. Occasionally, cranial neuropathies, cerebellar dysfunction, and cauda equina syndromes have been the initial symptoms. Isolated cord involvement has been noted in a few patients. The syndrome may be acute or insidious, and may fluctuate with periods of apparent remission. Systemic symptoms like fever, weight loss, arthralgias, and myalgias are typically absent, and when present suggest an alternative diagnosis.

It has been proposed that PACNS may fall into subgroups by clinical criteria. According to these criteria, "true" PACNS lasts longer than 3 months, is characterized by focal and diffuse neurological dysfunction, and is associated with typical biopsy findings. The cerebrospinal fluid (CSF) is abnormal with a picture suggesting chronic meningitis. The outcome is poor if untreated. A more "benign angiopathy" of the CNS has an acute onset, normal CSF analyses, primary diagnosis by angiography, and a benign clinical course. Postpartum cerebral angiopathy has been described in women in the immediate postgravid state. There are eight well-documented cases in which headaches, nausea, vomiting, focal CNS signs, and abnormal CSF developed in women who showed no signs of toxemia or hypertension. Cerebral angiography showed alternating areas of stenosis and ectasia with "sausaging" of multiple vessels. Normalization of angiography changes demonstrated by serial studies over 4 weeks suggests that the basis of the arteritis is at least in part vasospastic. The

TABLE 50-2 -- CLINICAL FEATURES OF PRIMARY ANGIITIS OF THE CENTRAL NERVOUS SYSTEM

. strength of the relationship between this condition and PACNS remains unclear. PACNS associated with immunosuppressive illness represents a small subset of these cases, which include lymphomas, leukemias, myeloproliferative disorders, immunosuppressive therapy for inflammatory bowel disease or following renal transplant, and HIV. These are unique cases in which the immunosuppressed state may appear crucial to susceptibility to the condition.

Differential Diagnosis. Other small-vessel vasculitides such as Wegener's granulomatosis have presented as temporal or CNS vasculitis. Pulmonary lesions should be helpful in this differential. GCA occurs in an older population than PACNS. Those patients with PACNS affecting large and small arteries are older than those with small vessel involvement alone. Immunologic or epitope changes may be related to age. Infections and more systemic forms of vasculitis need to be considered in the differential diagnosis of PACNS. Tuberculosis and other mycobacteria, meningovascular syphilis, fungal infections, hepatitis B, and herpes ophthalmicus are other possibilities. Drugs, particularly stimulants, can cause a vasculitis. Noninflammatory vasculopathies such as fibromuscular dysplasia and moyamoya may be considered and these diagnoses are best addressed by angiography.

Evaluation. Most important in the diagnosis of PACNS is appropriate clinical suspicion. The ESR is elevated in 66 percent of the patients, on average 44 mm/hr, ranging up to 116 mm/hr. The ESR may be more helpful to exclude a systemic vasculitis than to include a CNS vasculitis.

CSF should be examined if the diagnosis of PACNS is considered. The CSF is abnormal in 81 percent of those examined. Mixed or lymphocytic pleocytosis is present in 68 percent, ranging up to 330 cells/hpf. Seventy percent have elevations of CSF protein averaging 118 mg/dl, but ranging up to 825 mg/dl. Serial lumbar punctures in the same patient may show spontaneous fluctuations in pleocytosis and protein. An abnormal electroencephalogram is 81 percent sensitive, and diffuse slowing is the most common finding. Focal slowing or sharp wave discharges are noted on occasion. CT brain scans have disparate findings, showing infarcts, low-density lesions, or gyriform enhancement. MRI may show focal areas of infarction in multiple vascular territories. Normal MRI scans are rare, but have been seen in some biopsy-proven cases.

In patients with angiograms, "classic arteritis" is seen in 65 percent, and less specific abnormalities in 19 percent. Thirteen percent of angiograms are normal. High-resolution film magnification is preferred to digital subtraction angiography in its ability to resolve changes in small-caliber vessels. The "arteritic" appearance of vasculitis is not completely specific and has been seen in vasculopathies due to other causes such as atherosclerosis, infection, and drugs and toxins. Considered in the context of the patient's age, clinical syndrome, laboratory and CSF studies, angiography remains very helpful in establishing the diagnosis short of biopsy.

If the angiogram is normal or atypical, leptomeningeal and cortical biopsy should be performed. Owing to the focal nature of the lesions, there is significant risk for

sampling error. In a series of 108 cases (including 99 from the literature), the yield of leptomeningeal and cortical tissue was 87 percent and 57.9 percent, respectively. In 43 pathologically confirmed cases, 11 premortem biopsies were false negatives (diagnostic sensitivity 74.4 percent). In five cases, other abnormalities, such as lymphocytic or granulomatous meningitis, necrosis and infarct were seen. ^[10]

Because of the false-negative rates in biopsy and angiography, decisions about diagnosis and monitoring of treatment must be tailored to the individual case and incorporate as much clinical and laboratory information as possible. However, highly toxic therapy should not be considered unless cerebral and leptomeningeal biopsy has been performed. ^[9]

Management. There are no controlled treatment trials to date. High dose (60 to 80 mg/day) prednisone combined with a calcium channel blocker is recommended. With good clinical response, tapering in a few months' time is reasonable. If lack of response or recurrence develops, oral cyclophosphamide (1 to 2 mg/kg/d) should be added and continued for 6 to 12 months until all signs of disease have disappeared. Angiography can be used to reassess disease activity, and repeated biopsies may be needed in some cases. ^[10] The rationale for treatment of PACNS is summarized in [Table 50-3](#). Postpartum cerebral angiitis should be treated with a short course of high-dose steroids and calcium channel blocker. ^[10]

Prognosis and Future Perspectives. The prognosis in PACNS is guarded; outcome depends on the severity of the disease and the response to the treatments described above. The prognosis is favorable in young women with "benign angiopathy" or "postpartum angiopathy," and poorer in those with "true" PACNS.

Considerable work remains to be done to further the understanding of the etiology, pathogenesis and pathophysiology,

clinical subtypes, optimal treatment, and the long- term outlook of the disorder.

Takayasu's Arteritis

Pathogenesis and Pathophysiology. Takayasu's arteritis (TA), first described by Takayasu and Onishi in Asian patients with absent limb pulses and retinopathy, ^[13] is now well recognized in Western countries as well. The burden of disease is in the aorta and its main branches with symptoms attributable to vascular compromise or a systemic immune response. In tissue specimens, giant cells are seen invading the media and adventitia of affected vessels.

There are a number of changes that suggest an immunopathogenesis, including hypergammaglobulinemia, increased ratio of CD4 to CD8 cells in the periphery, circulating immune complexes, anti-aortic antibodies, and a positive rheumatoid factor. Nearly half of Japanese patients have statistically significant associations with Bw52 or DR12. The immunogenetics of TA are less well defined in Western patients. ^[14] It is currently believed that in a genetically predisposed individual and in a conducive hormonal milieu, exposure to an unknown antigen precipitates an uncontrolled, inflammatory immune response that primarily targets large vessels. ^[15] Because of descriptions occurring in India where tuberculosis is endemic, a relationship between TA and tuberculosis infection was briefly considered, but later abandoned. ^{[13], [14]}

Epidemiology and Risk Factors. Despite increased ascertainment, TA remains rare in the Western Hemisphere (2.6 cases/million). The ratio of women to men is about 8.5:1, and TA is more common in lower socioeconomic classes. ^[13] In a prospective study of 60 patients, in which 45 were followed for 6 months to 20 years (median 5.3 years), mean age of onset was 21 years. ^[14] If only Western cases are considered, the mean age of onset is 41 years. ^[15] Within the United States, the racial makeup of cases largely reflects the relative proportions of ethnic groups among U.S. residents, except that Asians account for an unusually large number of cases (10 percent of cases versus 2.9 percent of the U.S. population). ^[14] There are occasional reports among family members suggesting a possible genetic component. Associations between TA and various other autoimmune diseases have been reported. ^[15]

Clinical Features and Associated Disorders. Although early descriptions suggested that TA had a triphasic course with early systemic complaints followed by symptoms related to vascular inflammation and finally sequelae of vascular stenoses, this pattern is not universal. In addition, the clinical manifestations of TA may differ depending on geographical region. Aortic arch disease predominates in Japanese patients, and thoracic and abdominal aortic disease predominates in Thailand, Mexico, and India. Within a given vascular territory, the presence of symptoms depends largely on the extent of collateral circulation to involved organs. For example, gastrointestinal symptoms are rare even though stenoses and mesenteric vessel occlusions are common. ^[13]

In the 60-patient series cited above, all had vascular symptoms or signs. ^[15] Eighty percent of patients had bruits, most in the carotid arteries. Carotodynia was present in 32 percent of the series. Elevated blood pressure occurred in 33 percent mostly owing to lesions of the renal arteries or descending aorta. Asymmetrical blood pressures were present in 50 percent of the patients, a finding suggesting that four extremity blood pressures can be used in diagnosis and in clinical follow-up. Diminished or absent extremity pulses occur in over half of the patients with TA. HLA- Bw52 has been associated with an increased risk of aortic valve insufficiency and a worse prognosis in Japanese patients. ^[14]

Among the 60 patients cited above, nervous system symptoms occurred in over half. Fifty-seven percent of those with vertebral artery involvement and 23 percent of those without vertebral artery involvement experienced lightheadedness or dizziness. TIA and stroke each occurred in 5 of the 60 patients. These events are presumably related to artery-to-artery or cardiogenic emboli. Visual disturbances affected one third of the patients, most of whom had carotid or vertebral artery involvement. These visual disturbances are almost always bilateral; however, monocular blindness did occur in one patient. ^[14] Pregnancy does not appear to potentiate disease activity, and there is no difference in fertility rates, C-section rates, or neonatal death among TA patients when compared with the general population. ^[13] It is recommended that those who wish to become pregnant do so during an inactive disease phase. Because of increased cardiovascular demands, the third trimester may be most difficult for these patients. Aortic regurgitation or heart failure may develop, and hypertension may be a problem even in the absence of preeclampsia. Typically, these problems abate after delivery. ^[13] Moderate doses of corticosteroids have not had significant effects on the fetus. ^[15]

Differential Diagnosis. Diagnostic criteria for TA are shown in [Table 50-4](#). ^[13] Other causes of large vessel disease should be entertained. Possible causes of inflammatory aortitis include syphilis, tuberculosis, systemic lupus erythematosus and giant cell arteritis. Developmental abnormalities such as Ehlers-Danlos syndrome and Marfan's syndrome can give an abnormal appearance to the aorta and be misleading. Aortic abnormalities can also occur as the result of radiation fibrosis, neurofibromatosis, and ergotism.

Evaluation. ESR >20 mm/hr (>40 mm/hr during pregnancy)

TABLE 50-4 -- CRITERIA FOR THE DIAGNOSIS OF TAKAYASU'S ARTERITIS

ONSET OR WORSENING OF TWO OF THE FOLLOWING:

- Unexplained systemic illness (fever or musculoskeletal complaints)
- Increased sedimentation rate
- Features of vascular ischemia or inflammation
- Claudication

Diminished or absent pulse
Asymmetric blood pressure (arms or legs)
Bruit
Vascular pain
Typical angiographic features

Modified from Kerr GS: Takayasu's arteritis. *Curr Opin Rheumatol* 1994; 6:32-38.

is considered by most to be an indicator of active disease.^[13] In one series, ESR was elevated in 72 percent during active disease, and 44 percent during clinical remission.^[14] The correlation between ESR and biopsy evidence of disease activity is poor. As many as 42 percent of patients with normal ESR have active lesions on biopsy.^[14] Repeated ESR evaluations over time may be the most useful as an indicator of relative disease activity in a given patient. Other markers of disease activity, including endothelin-1, von Willebrand's factor, and factor VIII antigen, have not been well evaluated.^[15] The disease is presumed to be inactive when there is an absence of clinical features, the sedimentation rate is normal, and the angiogram is unchanged. Unfortunately, the correlation between ESR and biopsy evidence of disease activity is poor.^[16] The ESR may be most useful as an indicator of relative disease activity in a given patient.

Noninvasive tests have been used as diagnostic aids. Ultrasonography and MRI have been used with varying results, but nothing yet has the sensitivity and specificity of an angiogram.^[15] Angiography is considered the diagnostic gold standard but carries the risks of an invasive procedure and the risk of rupture of diseased vessels. An angiogram does not differentiate between acute and chronic lesions, however, and cannot assess disease activity. In one series, the disease burden was distributed as follows: aortic lesions 65 percent, carotid 58 percent, renal 38 percent, and vertebral 35 percent. Long stenotic lesions were seen in 98 percent of patients. Aneurysms were seen in 27 percent of patients, and were present in 5 percent of carotid and 2 percent of vertebral arteries.^[14]

Management. Glucocorticoids are the mainstay of therapy. Other immunosuppressive therapies are used for patients who fail to respond to steroid therapy or who relapse during steroid withdrawal. Azathioprine is frequently used, and cyclophosphamide has been used with some success. Methotrexate appears to be relatively well tolerated and is beneficial in helping patients successfully taper steroids or avoid relapse.^[17] Beta noradrenergic blockers and angiotensin converting enzyme (ACE) inhibitors can be used to treat hypertension due to vascular stenosis that is not surgically correctable. ACE inhibitors must be used with caution in patients with bilateral renal artery stenosis. Although effective for heart failure, vasodilators are not helpful in patients with renal artery stenosis.^[15] Antiplatelet therapy is probably not indicated to prevent thrombotic events, since native-vessel thrombosis is not a common feature.

Surgical treatment has an auxiliary role, since renal artery stenosis with severe hypertension is common. Percutaneous coronary transluminal angioplasty (PCTA) successfully restores patency in as many as 80 percent of these patients. Bypass surgery can be done for repeated PCTA failure. Bypass of carotid arteries from the ascending aorta can be done as well. In general, success of bypass surgery is improved during disease inactivity (88 percent versus 53 percent).

Prognosis and Future Perspectives. Most patients experience morbidity from TA or the treatment of the disease. Five- to 10-year survival rates are in the range of 80 to 97 percent. Myocardial infarction, stroke, cardiac failure, aneurysmal rupture, and renal failure are causes of death.^[9]

In the future, more accurate noninvasive diagnostic tools including vascular imaging and serum markers for disease activity will likely improve the accuracy of TA diagnosis. Safer and more efficacious immune modulating therapies are also needed based on a better elucidation of the etiopathogenesis of the disorder.

Polyarteritis Nodosa, Churg-Strauss, and Overlap Syndromes

Pathogenesis and Pathophysiology. Classic polyarteritis nodosa (PAN) is a necrotizing, nodular vasculitis that preferentially affects medium and small arteries, and sometimes arterioles. The pathophysiology is believed to be deposition of immune complexes in the involved arteries. PAN is associated with a number of infections, particularly hepatitis B, tuberculosis, and streptococcus. In those cases associated with hepatitis B, hepatitis B surface antigen IgM, and complement can be demonstrated in the vasculitic lesions. In most cases, however, no association with an infectious agent can be demonstrated.^[17]

Churg-Strauss syndrome (CSS), also known as allergic angiitis and granulomatosis, is a systemic vasculitis marked by systemic hypereosinophilia and multiple organ involvement, which usually includes asthma. These signs and symptoms are somewhat distinctive and serve to reduce confusion with the other vasculitides. Pathological features include a necrotizing vasculitis affecting small or occasionally medium-sized arteries and veins, eosinophilic infiltration, and extravascular granulomata.^[18]

Microscopic polyangiitis (MPA) is similar to PAN but is characterized histologically by involvement of arterioles, capillaries, venules, and rarely medium-sized arteries.^[17] Polyarteritis nodosa and microscopic polyangiitis overlap considerably, and the American College of Rheumatology criteria for diagnosis do not distinguish between the two entities.^[17]

Epidemiology and Risk Factors. PAN occurs from infancy to old age with peak incidence in the fifth and sixth decades of life and an estimated male to female ratio of 2.5:1. In a series of patients with CSS, the mean age of diagnosis was 49.7 years (range 17 to 75 years), and women were affected more often than men.^[19] MPA, considered an

104

overlap syndrome, shares the epidemiology of PAN, and an incidence separate from that of PAN is difficult to discern.

Clinical Features and Associated Disorders. Patients with PAN typically present with systemic signs and symptoms including weakness, leg and abdominal pain, and fever. Arthralgias and hypertension are often present. Maculopapular or nodular skin rash is common, as is livedo reticularis. Cardiac symptoms result from hypertension, pericarditis, or coronary vasculitis, and pulmonary involvement is atypical. The CNS is rarely involved, but stroke, delirium, seizures, and myelopathy have been reported.^[19],^[20] Disease affecting the peripheral nervous system (PNS) is common in PAN and usually appears in the pattern of mononeuritis multiplex or asymmetrical polyneuropathy.^[21]

CSS usually begins with upper respiratory symptoms such as sinusitis and rhinitis. Symptoms of systemic vasculitis involving skin, heart, and peripheral nerves follow. In a series of 42 patients with CSS, 62 percent had nervous system involvement, almost entirely restricted to PNS. Mononeuropathy multiplex (58.6 percent), distal symmetrical polyneuropathy (24.1 percent), asymmetrical polyneuropathy (3.5 percent), and one patient with a lumbar radiculopathy (3.5 percent) were included. Three of the patients in the series (10.3 percent) had cerebral infarctions.^[19] Inflammatory myopathy has also been described in other series.

Little information is available on pregnancy and vasculitis. One woman with CSS worsened with two pregnancies, then died of cardiac disease during her third. Another woman had symptom remission during pregnancy. MPA has rapidly progressive glomerular nephritis (RPGN) as one of its major characteristics. The clinical outcome can be poor with chronic renal failure. Relapses may be more common than in PAN.^[17] In MPA, peripheral neuropathy occurs in only 10 to 20 percent of patients.^[17]

Differential Diagnosis. Nonspecific systemic symptoms at presentation may lead to consideration of infection, neoplasm, or connective tissue disease.^[22] The presence of mononeuritis multiplex strongly suggests vasculitis. In the absence of organ system involvement, other than the CNS, the differential diagnosis rapidly expands to include virtually any vasculopathy, inflammation, or infectious disease. In the appropriate clinical setting, particularly with perinuclear antineutrophil cytoplasmic antibody (pANCA) positivity, the diagnosis may be made clinically without need for tissue diagnosis.^[18]

Evaluation. The ESR is typically elevated in PAN patients, averaging 60 mm/hr.^[21] Other laboratory studies may show leukocytosis, anemia, thrombocytosis, and abnormal urinary sediments. Hepatitis B surface antibody is seen in a subset of patients. pANCA is detected in almost 20 percent of PAN patients, and it has been suggested that these pANCA-positive PAN patients may actually have MPA.^[1]

Electromyography and nerve conduction velocity studies demonstrate chronic partial denervation, impaired motor and sensory nerve conduction, and sometimes conduction block due to focal ischemic lesions.^[21] Sural nerve biopsies in patients with peripheral neuropathy demonstrated pathological findings in 30 of 34 patients,

showing vasculitis of epineural arterioles, resulting in a central fascicular pattern of nerve damage.^[21] In suspected cases of PAN- associated myopathy, muscle enzymes, EMG, and biopsy are diagnostic.^[23] Biopsy of symptomatic tissues such as peripheral nerve and skin may also be diagnostic. CSF may also be helpful in detecting CNS involvement with lymphocytosis and elevated protein. MRI imaging is nonspecific but helpful in localizing involvement in the CNS. Angiography establishes the diagnosis in about 80 percent of patients, demonstrating aneurysms and changes in blood vessel caliber or stenotic lesions.^[17]

In CSS, eosinophilia in the peripheral blood (defined as greater than $1.5 \times 10^9/L$) is very helpful in leading toward a correct diagnosis.^[18] In the clinical setting of peripheral eosinophilia, asthma, and findings typical of vasculitis or multiple necrotizing cutaneous lesions, the diagnosis can be made without biopsy,^[18] although other hypereosinophilic syndromes discussed later in this chapter must also be considered. Approximately 70 percent of CSS patients are pANCA-positive.^[1]

MPA may cause mononeuritis multiplex without other defining disease features, and evaluation of the PNS as described above is essential.^[21] Skin lesions, when present, provide a convenient means of tissue diagnosis with minimal risk. Even in the presence of CNS vasculitis, visualization of arteritis by angiography is usually impossible because the involved vessels are smaller than 700 μm in diameter.^[24] MPA is the vasculitis most closely associated with pANCA, and 50 to 90 percent of patients are pANCA- positive.^[1]

Management. Glucocorticosteroids are the mainstay of immunosuppressive therapy for all of the vasculitides. In PAN and MPA, prednisone 1 mg/kg daily (possibly higher), in divided doses, should be given until inflammatory features are controlled. Prolonged treatment may be required, and the lowest effective dose should be sought on an alternate-day regimen.^[25] Retrospective trials of cytotoxic agents have suggested efficacy but other studies report no added benefit.^[25] Nonetheless, if steroids are not effective or organ system damage is progressive, cyclophosphamide, at doses of 2.5 to 3.5 mg/kg/d, or another cytotoxic agent should be used.^[25] Antiviral agents, such as vidarabine, have been reported to be successful in cases of hepatitis B- associated PAN.^[25] Antiplatelet agents such as aspirin should be used throughout the course of treatment, due to a potential platelet aggregating effect of steroids in vasculitis patients.^[25]

CSS is managed in the same fashion as PAN and MPA but CSS patients are more responsive to initial treatment with steroids and less often require cytotoxic treatment.^[25] In a series of 29 CSS patients, only 2 required cytotoxic therapy in addition to steroids.^[18]

Prognosis and Future Perspectives. Prior to immunosuppressive therapy, patients with systemic vasculitides had a 5-year survival rate of about 13 percent.^[21] Most deaths were attributed to renal or pulmonary failure with vascular events in the gastrointestinal tract or CNS comprising the rest. Since the use of steroids, the five-year survival has improved to about 47 to 57 percent, although older patients have a worse outcome.^[21]

With PNS involvement, if inflammatory features respond to treatment, there is often an improvement in the neuropathy.^[21] All the 29 patients with CSS in the Mayo Clinic series

1015

received steroid therapy and 10 patients had improvement of their neurologic syndrome. In the mean follow-up of 3.9 years, four patients died, one from a cerebral infarct.^[17] With MPA, the clinical outcome can be poor with chronic renal failure. Relapses may be more common than in PAN.^[17]

Wegener's Granulomatosis

Pathogenesis and Pathophysiology. The almost universal involvement of the upper or lower airway in Wegener's granulomatosis (WG) has led to a theory that the condition results from exposure to an inhaled antigen with resultant granulomatous inflammation and altered immunoreactivity.^[26] Cell-mediated immunity and immune complexes are felt to play significant roles. There may be genetic or other predisposing host factors. A strong association with cytoplasmic antineutrophil cytoplasmic antibodies (cANCA) suggests a pathogenic role. It has been shown in vitro that cANCA causes neutrophils to undergo a respiratory burst and degranulation, releasing toxic superoxides.^[27] However, there is no direct evidence to confirm that it is an etiologic factor in WG.

Epidemiology and Risk Factors. The incidence of WG in the United States is about 1 in 30,000. Among 180 patients referred to the National Institute of Allergy and Infectious Diseases, 97 percent with WG were white with equal numbers of men and women. The mean age was 41 years (range 9 to 79 years) and 15 percent were less than 19 years of age.^[28] The ease of identification of the disorder with cANCA has increased disease ascertainment.

Clinical Features and Associated Disorders. Criteria for the diagnosis of WG are listed in [Table 50-5](#).^[29] Ninety percent of patients with WG have upper and/or lower airway symptoms. Median duration of these symptoms at the time of diagnosis is 4.7 months. Nasal, sinus, and ear abnormalities are seen at presentation in 73 percent and during the illness in 92 percent. Lung disease develops in 85 percent of cases over the course of the illness, although it is asymptomatic in one third of cases. Eighteen percent of patients present with asymptomatic glomerulonephritis and 77 percent of patients develop glomerulonephritis, usually within the first two years of disease onset.^[28]

Nervous system involvement is rare at initial presentation but mononeuritis multiplex develops eventually in 15 percent of patients. Central nervous system involvement occurs in 8 percent of patients and includes stroke, cranial nerve abnormalities, and diabetes insipidus.^[28] In literature series, neurologic involvement with WG occurs in 22 to 54

TABLE 50-5 -- CRITERIA FOR THE DIAGNOSIS OF WEGENER'S GRANULOMATOSIS

TWO OR MORE OF THE FOLLOWING:

- Purulent or bloody nasal discharge or oral ulcers
- Radiographic evidence of nodules, fixed infiltrates, or cavities
- Microscopic hematuria
- Biopsy evidence of granulomatous inflammation

Modified from Nishino H, DeRemee RA, Rubino FA, Parisi JE: Wegener's granulomatosis associated with vasculitis of the temporal artery: report of five cases [see comments]. *Mayo Clin Proc* 1993; 68:115-121.

percent of patients. Virtually any portion of the neuraxis can be affected, but the most common manifestation is peripheral neuropathy, particularly mononeuropathy multiplex.^[30]

Headache in WG is due to sinusitis, pachymeningitis, or cerebral vasculitis. Multiple forms of cranial nerve problems occur. Exophthalmos, ophthalmoplegia, and optic nerve involvement due to granulomatous involvement may be a presenting symptom of WG.^[28] Ocular symptoms are present in 15 percent of patients at onset and 52 percent of patients during the disease course. The most helpful diagnostic finding is proptosis (2 percent at onset, 15 percent overall), since it is highly suggestive of WG when associated with upper or lower airway disease. Proptosis is usually painful and leads to visual loss owing to anterior ischemic optic neuropathy in about half of affected patients. Extraocular muscle entrapment can cause diplopia.^[28] Recurrent serous or suppurative otitis media may cause partial (33 percent) or total unilateral (1 percent) or bilateral (1 percent) hearing loss.^[28] Multiple cranial neuropathies rarely occur as a result of pachymeningitis.^[28]

Intracranial vasculitis, cerebritis, and meningitis are uncommon.^[26] Because the small vessels are typically involved in WG, angiography is usually normal.^[26] PNS involvement can take several forms. Mononeuritis multiplex is a frequent neurologic complication (as in PAN and MPA) and the most suggestive of vasculitis as an etiology.^[26] Asymmetrical peripheral neuropathy and distal symmetrical polyneuropathy also occur.^[21] Although myalgias and arthralgias are frequent complaints in WG, myopathy is a relatively uncommon manifestation.^[26] In general, pregnancy adversely affects clinical signs.^[32]

Differential Diagnosis. Constitutional symptoms such as fever and weight loss occur to varying degrees and may initially lead the diagnostic evaluation toward chronic infection or malignancy. In those patients with clinical involvement of the orbit or retro-orbital space, malignancy and endocrinopathies are likely considerations. When symptoms are isolated to the respiratory tract, diagnoses of recurrent infection or allergy are common. In patients with milder disease, diagnosis may be delayed up to 5 to 15 years after the initial symptoms.^[28]

Evaluation. Routine blood studies show leukocytosis and normochromic normocytic anemia in most and thrombocytosis in many patients. ESR averages 71 mm/hr

(range 17 to 140) and correlates well with disease activity before treatment in 80 percent of patients. ^[28]

The high specificity of cANCA for Wegener's and its limited variants has been confirmed in large studies. In the appropriate clinical setting a positive cANCA may obviate the need for tissue diagnosis. A negative cANCA, however, does not exclude the possibility of WG. The sensitivity depends on extent and activity of the disease process. There is greater than 90 percent sensitivity in the systemic vasculitic phase of disease, but only 65 percent in patients with predominantly granulomatous disease limited to the upper and lower respiratory tract. In patients with no active disease, the sensitivity is about 30 percent. ^[33]

In patients with CNS manifestations of the disease, MRI is a valuable initial step in evaluation. T2-weighted sequences and gadolinium-enhanced images are most sensitive to ischemic changes secondary to vasculitis. ^[24] When

clinical suspicion of CNS vasculitis is high, angiography and biopsy should be pursued despite a normal MRI. ^[24] Because the size of vessels involved in CNS WG is small, the greatest utility of angiography may be the exclusion of other vasculitides or nonvasculitic vascular disease. ^[24], ^[26]

Open lung biopsy is positive greater than 90 percent of the time, while bronchoscopy-directed biopsy shows vasculitis in only 7 percent. The typical appearance is that of a granulomatous vasculitis with necrosis, giant cells, and microabscesses. ^[28]

Management. Treatment study includes prednisone (1 mg/kg/d) and oral cyclophosphamide (2 mg/kg/d). Fulminant disease is treated with more aggressive cyclophosphamide (up to 5 mg/kg/d) with subsequent doses based on white cell counts. According to response, doses are adjusted to eliminate prednisone and maintain patients on cyclophosphamide alone. Then cyclophosphamide is tapered until disease recurrence or discontinuation. Using this regimen, 75 percent remit completely and an additional 16 percent have marked improvement. Eight percent of patients have seemingly intractable disease, but achieve remission in up to 4 to 6 years. Remission is achieved at least once in 96 percent of patients. However, 46 percent of patients have at least one relapse and 44 percent have relapses of more than five consecutive years' duration. ^[28] Methotrexate may be of some value in patients with milder disease or cyclophosphamide intolerance. ^[29]

The role of serial cANCA titers in determining the risk of relapse in treated patients is unknown, and it is premature to recommend altering immunosuppressive therapy in response to a changing titer. ^[33]

Prognosis and Future Perspectives. The disease and its treatment carry significant morbidity. Cushingoid features are universal among steroid-treated patients. With cyclophosphamide, there is a 2.4-fold overall increase in the rate of malignancies, including a 33-fold increase in bladder and 11-fold increase in lymphoma, compared with rates of the national cancer registry for a similar cohort. Serious infections occur in half of the patients with a rate of 0.11 infections per patient year. The mortality rate is 20 percent; more than 50 percent of the deaths are attributed to active disease or treatment-related complications. Renal disease, coronary disease, infection, malignancy, and combined renal and pulmonary disease are contributory. ^[28]

Vasculitis Associated with Antiphospholipid Antibodies

Pathogenesis and Pathophysiology. Antiphospholipid antibodies (aPL) are a heterogeneous family of antibodies of the IgG, IgM, or mixed classes with varying cross-reactivities. Antibodies within this family include anticardiolipin antibodies, antibodies responsible for the false-positive Venereal Disease Research Laboratory (VDRL) serology and the lupus anticoagulant. Antiphospholipid antibodies may be detected in a number of clinical settings. Normal elderly may have aPL of unclear significance. They may be seen in patients treated with phenothiazines, antiarrhythmics, and anticonvulsants, or in the context of infections or malignancy. Antiphospholipid antibodies are commonly seen in patients with systemic autoimmune disorders such as systemic lupus erythematosus. The primary antiphospholipid antibody syndrome comprises recurrent venous or arterial thrombosis, fetal loss, thrombocytopenia and positive results on serological tests for lupus anticoagulant or anticardiolipin antibodies. ^[34]

The nervous system antigen targeted by aPL has not been identified. All cell membranes contain phospholipids, though they are generally protected from the immune system by the bilayer membrane structure. The ability to form antiphospholipid antibody may depend on an induced conformational change in membrane structure and interaction with co-factors. Certain known vascular risk factors such as diabetes, hypertension, cigarette smoking, and lipid disorders may trigger the conformational change, exposing the vascular endothelium to the immune system. Old age, smoking, and diabetes mellitus may elevate glycoprotein co-factors such as beta 2 glycoprotein I (beta2-GPI). This co-factor normally inhibits the intrinsic coagulation pathway and adenosine diphosphate (ADP)-mediated platelet aggregation; interference with its action may promote thrombosis and platelet aggregation. ^[35] In addition, aPL may interact with natural anticoagulants such as placental anticoagulant proteins, plasminogen activators, and proteins C and S. These antibodies may also provoke complement activation or may interfere with the function of prostaglandin I₂. Although the exact mechanism or mechanisms remain ill-defined, the preponderance of evidence is that aPL cause an autoimmune-mediated prothrombotic state. ^[34]

Pathologic examination of affected cerebral and carotid arteries shows a noninflammatory vasculopathy with fibromuscular dysplasia, fibrin thrombi, and widespread obstruction by a proliferation of intimal fibrous tissue or myointimal cells. In later stages, fibrous webs may form across arterial lumens. ^[36], ^[37]

Epidemiology and Risk Factors. The frequency of aPL depends heavily on the population being studied. A review of a number of studies suggests that aPL can be detected in 2 to 12 percent of the normal population, 10 to 26 percent of patients with first stroke, 10 to 40 percent of women with recurrent fetal loss, and 40 to 50 percent of patients with systemic lupus erythematosus. ^[34] In a prospective study of 147 people with aPL and thromboses within or outside the nervous system, a number of concomitant risk factors for thrombosis were identified in 76 percent. These included pregnancy, hypertension, hyperlipidemia, and diabetes. ^[38]

Clinical Features and Associated Disorders. The complications of aPL fall into four classes: peripheral venous thrombosis and pulmonary embolism (type I), coronary or peripheral artery thrombosis (type II), cerebrovascular or retinal vessel thrombosis (type III), and mixtures (type IV). ^[39] Nervous system abnormalities associated with aPL include cerebral or spinal arterial or venous infarction, chorea, hemidystonia, seizures, migraine, Guillain-Barre syndrome, transient global amnesia, motor neuron disease, myasthenia gravis, and behavioral abnormalities like affective disorder or dementia. ^[34], ^[40], ^[41], ^[42], ^[43], ^[44] Several clinical features of transient focal neurological events in aPL-positive patients distinguish these individuals from their aPL-negative cohort. Amaurosis fugax and episodes of unilateral paresthesias without headache and without a family history of migraine suggest aPL positivity in young persons. ^[45]

The risks associated with aPL in otherwise healthy persons are ill-defined. Clearly, patients with aPL and a single thrombotic event are at greater risk of subsequent thrombotic events. However, the risk of primary thrombotic events in otherwise healthy persons with aPL remains poorly understood.

Differential Diagnosis. The primary aPL syndrome must be distinguished from other causes of atherosclerotic and nonatherosclerotic vascular disease. Other connective tissue diseases such as systemic lupus erythematosus (SLE) or aPL associated with exposure to inciting drugs can be discerned using history, physical examination, and laboratory tests. An analysis of 1,000 patients with SLE from the medical literature yielded an average frequency of 34 percent for the lupus anticoagulant and 44 percent for anticardiolipin antibody. ^[46] Within the context of SLE, the presence of antiphospholipid antibodies is highly correlated with a history of thrombosis, neurological disorders, and thrombocytopenia.

Evaluation. The diagnosis of primary antiphospholipid syndrome rests on the demonstration of antiphospholipid antibodies (anticardiolipin antibodies, lupus anticoagulant, or false-positive serologic test for syphilis) in a person with a characteristic syndrome. Associated connective tissue diseases such as SLE and Sjogren's syndrome should be excluded with appropriate clinical investigation and autoantibody studies. Patients with central nervous system focal events should be evaluated using magnetic resonance imaging, and scans may demonstrate large infarcts or hyperintense white matter abnormalities. ^[47]

Management. The management of aPL employs antithrombotic agents and immunosuppression. However, there are no prospective controlled data that support a given course of therapy. Young patients with thrombotic events and aPL are generally treated with antithrombotics (warfarin, subcutaneous heparin, low-molecular-weight heparin, and antiplatelet therapy). In a prospective study of 147 patients with aPL and an index nervous system lesion or evidence of thrombosis, anticoagulation using warfarin to an international normalized ratio (INR) of greater than 3 (with or without aspirin) was superior to less aggressive warfarin therapy (with or without aspirin), aspirin alone, and no therapy. ^[38] The highest risk of recurrent thrombosis in this study was within 6 months of discontinuation of

warfarin, suggesting the need for chronic therapy.^[38] There remains no consensus, however, on the nature and duration of optimal anticoagulation. Corticosteroid and other immunotherapies in the aPL syndrome are also controversial. The titers of aPL may be reduced with effective doses of immunosuppressants or with plasmapheresis, but the clinical efficacy of these modalities in the prevention of recurrent thrombosis is unknown.^[48] Intravenous immune globulin (IVIg) infusions, usually with concomitant corticosteroids and antithrombotic therapy, have successfully prevented fetal loss in women with aPL and recurrent fetal loss. However, there are no reliable data in women with nervous system thrombosis and the association of IVIg therapy and thrombotic events in other nervous system conditions warrant caution in the use of this technique. More definitive recommendations are likely to result from prospective trials of various therapies in aPL-positive patients with stroke.^[34], ^[49]

Prognosis and Future Perspectives. Patients with the highest titers of IgG antiphospholipid antibodies have a relatively high risk of recurrent thrombotic events, especially stroke, deep venous thrombosis, and spontaneous abortion. Patients with aPL and cerebral thrombosis face a recurrence risk up to 20 percent per year for TIA or stroke and 56 percent per year for noncerebral thrombosis.^[34] While the risks associated with aPL seem well-defined among patients with systemic lupus erythematosus or those who have had thrombotic events, the prognostic import of a finding of isolated aPL remains obscure.

Thromboangiitis Obliterans (Buerger's Syndrome)

Pathogenesis and Pathophysiology. Discovered in 1879 and described in 1908, Buerger's disease or thromboangiitis obliterans (TO) is an uncommon vasculitis of the small and medium-sized distal arteries and veins and almost exclusively affects cigarette smokers. There was confusion about the existence of TO for many years. The better classification of other vasculitides and the development of angiography have led to the identification of TO as a separate condition.

Almost all cases of TO have occurred in tobacco users, suggesting that the inflammatory response may be allergic. Smokers with and without TO demonstrate a similar cellular immune response to a purified tobacco glycoprotein.^[50] Anticollagen antibodies and cellular immune reactions to type I and III collagen are present in patients with TO. Other potential mechanisms involved include a derangement of the endothelial cell, which could be the result of decreased plasminogen activator inhibitor 1 release.^[50] There are reported familial occurrences that raise the question of a genetic susceptibility, and an increased association with HLA-A9 and HLA-B5 has been demonstrated in some with the disease. Some cases have occurred in association with other disorders such as IgA nephropathy, hypereosinophilia, and with positive serologic tests for rickettsial organisms. It has also been proposed that the abnormality may be a hypercoagulable state with secondary inflammation. However, the exact pathogenesis remains somewhat elusive.

Pathological findings are not routinely reported since most of the surgeries are performed on limbs with severe ischemia.^[50] Three stages of pathological changes have been identified. Initially, non-necrotizing panarteritis occurs with preservation of vascular wall architecture. The media and internal elastic lamina remain intact, a finding that differentiates TO from other vasculitides where there is destruction of the elastic lamina. Infiltrates of inflammatory cells and granulomas in the thrombus differentiate the occlusive lesions of TO from atherosclerosis where thrombi are composed of only fibrin, red blood cells, and platelets. Intrathrombotic granulomas are a distinctive hallmark of TO. Following this development, there is organization of the thrombus, with the type of inflammatory cells involved changing from neutrophils to lymphocytes and occasionally with eosinophils. Lastly, recanalization occurs with evidence of perivascular fibrosis. Aneurysms are an uncommon finding because the vascular wall remains intact.

Epidemiology and Risk Factors. TO typically occurs in young smokers. The incidence is approximately 8 to 12/ 100,000 in the general population, thereby representing less than 1 percent of all patients with vascular disease. According to a report from the Mayo Clinic, there has been a 10-fold decline in U.S. case incidence from 1947 to 1986. Japan, Eastern Europe, Southeastern Asia, and Israel have not shown similar declines.^[50] The median age of onset is 34.5 years of age. All are tobacco users. Men are affected about three times as often as women, but this ratio varies in different countries in relation to the gender predominance of smokers.^[50]

Clinical Features and Associated Disorders. Clinically, intermittent claudication begins in the feet and involves the legs more proximally as the disease progresses. The arms become affected in 90 percent of cases. Large arteries are rarely involved. Symptoms include ischemic pain at rest in 80 percent, claudication in 60 percent, and Raynaud's phenomenon in 35 percent of patients. Common signs are ischemic ulcers in 75 percent and distal gangrene in 80 percent.^[50], ^[51] The neurologic consequences of TO are sensory symptoms, which occur in 69 percent of patients.^[50] Sensory polyneuropathy may be secondary to severe ischemic changes or to fibrous encasement of distal neurovascular bundles.^[50]

Differential Diagnosis. Differential diagnoses include other vasculopathies and autoimmune diseases such as systemic lupus erythematosus, scleroderma, polyarteritis nodosa, antiphospholipid antibody syndrome, GCA or TA. Other conditions such as pseudoxanthoma elasticum and Ehlers-Danlos may be considered as well. It is important to exclude proximal sources of emboli and atherosclerosis.^[50]

Evaluation. The ESR is abnormal in only 15 percent of patients. Angiography demonstrates involvement of small and medium-sized vessels with segmental occlusions and collateral vessels in the distal vessels of the feet and hands.^[50] The absence of lesions proximally strongly favors the diagnosis of TO.

Management. It is imperative that the patient discontinue tobacco exposure. Forty-two percent of patients who continued smoking after the diagnosis required amputation, whereas only 5 percent of those who ceased smoking underwent amputation. The use of anticoagulants and antiplatelet agents may be beneficial on occasion, although the results of medical therapy have been generally poor. Ilprost, a prostacyclin analog, improves leg pain in 35 percent and heals ulcers in 22 percent of patients. Despite clear evidence of inflammation, corticosteroids have not been of benefit.

Prognosis and Future Perspectives. Twenty percent of patients require limited resection of the toes or feet, and another 20 percent have a proximal, below-the-knee amputation. Only 6 percent of patients require finger or upper extremity amputation. The sensory changes parallel the course of the vascular disease and stabilize if the ischemic changes are controlled. Survival rates at 5 and 10 years approach that of the normal population.

CONNECTIVE TISSUE DISEASES

Rheumatoid Arthritis

Pathogenesis and Pathophysiology. Rheumatoid arthritis (RA) is an immune complex disease. The most important autoantibody in RA is the rheumatoid factor, an antibody, usually of the IgM or IgG class, which reacts with immunoglobulins. The original triggering mechanism may be exposure to a microbial antigen. Autoantibodies to other cellular antigens such as histones, single-stranded DNA, filaments, collagen, and nuclear antigens have been described. Immune complexes composed of IgG combined with IgM or IgG anti-IgG antibodies cause inflammation of the synovium in the joints. Although the largest and most pathogenic immune complexes are found in the joints, others can be detected in the blood of patients with extra-articular manifestations such as vasculitis.

Epidemiology and Risk Factors. Rheumatoid arthritis is a chronic multisystem disease that affects 1 to 2 percent of the population. Disease onset is between 35 and 50 years of age in 80 percent of cases. Women account for 75 percent of cases. An increased risk in nulliparous women and a putative protective effect of oral contraception suggest a hormonal role in disease expression. Although there is a genetic predisposition to developing the disorder, genetic factors probably account for only about 30 percent of the risk of developing RA.

Clinical Features and Associated Disorders. The onset of RA is typically insidious, with prodromal malaise, fatigue, and generalized weakness. Characteristic symmetrical polyarthritis develops within weeks to months. Articular signs and symptoms preferentially affect the cervical spine and the metacarpophalangeal, proximal interphalangeal, wrist, elbow, knee, ankle, forefoot, and subtalar joints. Progression of joint disease leads to bony erosion and joint deformity. Extra-articular manifestations including rheumatoid nodules in subcutaneous, cutaneous, connective, and pulmonary tissues, pleuritis, interstitial fibrosis, pneumonitis, and pericardial effusions tend to occur in patients with high levels of circulating rheumatoid factor. Felty's syndrome (rheumatoid arthritis, splenomegaly, neutropenia, anemia, and thrombocytopenia) is seen in some patients with long-standing disease.

A few patients develop systemic vasculitis heralded by the development of ischemic skin lesions, mononeuritis multiplex, or documented visceral vasculitis. Although this syndrome is usually seen in men who have had RA for more than 10 years, it may be seen in women at disease presentation.

Neurological manifestations occur in patients with moderate to severe RA. They may be caused by direct effects of the disease process or secondary effects from bone or joint involvement. Rheumatoid nodules frequently form in the dura mater, where they tend to be asymptomatic except in cases of extensive involvement with pachymeningitis. The occurrence of symptomatic CNS vasculitis is rare, even in the setting of active systemic vasculitis. Clinical signs of rheumatoid CNS vasculitis include seizures, dementia, hemiparesis, cranial nerve palsy, blindness, hemispherical dysfunction, cerebellar ataxia, and dysphasia. Pathologic examination reveals chronic perivasculitis, transmural chronic inflammatory cell infiltration, intimal collagen proliferation with luminal narrowing, and fibrinoid necrosis of the media of small arteries. Changes in the articular architecture of the cervical spine may produce CNS dysfunction at the cervicomedullary junction or spinal cord level. Significant disease of the cervical spine is present in

109

up to 70 percent of patients with advanced disease. The major changes in the cervical spine include vertebral body erosion and collapse, rheumatoid discitis, dural thickening and fibrosis with spinal cord compression, and most commonly atlantoaxial subluxation. Subluxation of C1 on C2 may be in the anterior, posterior, or vertical directions, or there may be multiple cervical subluxations resulting in a "staircase appearance" of the cervical spine. Cervical subluxation is often asymptomatic. In patients who are symptomatic, the most striking features are myelopathic. However, other symptoms have been reported, including occipital headache and obstructive hydrocephalus. Brain stem syndromes result from pseudoaneurysm of the vertebral artery, direct compression of the medulla by eroded, displaced odontoid fragments, and rheumatoid granulomata. Neurological manifestations more commonly result from intermittent or sustained anterior cord compression, sometimes complicated by compression-induced ischemia in the distribution of branches of the anterior spinal artery. Most patients with radiographic evidence of subluxation are asymptomatic. Common symptoms and signs include neck pain, weakness affecting arms before legs, flexor spasms, sphincter disturbances, paresthesias, hyperreflexia, and sensory changes.

Peripheral nerve disease in RA results from nerve entrapment, segmental demyelination, or vasculitic involvement of the vasa nervorum. Entrapment or compression of peripheral nerves occurs in 45 percent of patients and affects the median, ulnar, posterior interosseous, tibial, common peroneal, or posterior tibial nerves. Other patterns of neuropathy seen in RA are distal sensorimotor or sensory polyneuropathy and mononeuritis multiplex. Vasculitic changes underlie all types of noncompressive neuropathies in RA. Myositis may be seen but is not usually a prominent feature of the disorder.

Differential Diagnosis and Evaluation. RA must be distinguished from degenerative osteoarthritis and from deforming inflammatory arthritis associated with other connective tissue disorders. The diagnosis of RA is based on a clinical picture of symmetrical polyarthritis, radiological confirmation of joint erosion, and the demonstration of antibodies including RF by immunologic tests. CNS signs should be explored using magnetic resonance imaging studies of the brain and spinal cord as clinically indicated. Electromyography is useful in the differentiation of various peripheral nerve syndromes.

Management. The treatment of RA is generally divided into first, second, and third line therapies. First line therapy for joint disease employs nonsteroidal anti-inflammatory drugs. Second line therapies include gold, D-penicillamine, sulfasalazine, and hydrochloroquine. Third line agents include corticosteroids and cytotoxic agents. Rheumatoid vasculitis with central or peripheral nervous system manifestations should be treated as any other systemic vasculitis using immunosuppression with corticosteroids and cytotoxic agents. The role of other immunotherapies such as plasmapheresis or intravenous immunoglobulin is not known. The prognosis is similar to that of systemic necrotizing vasculitis. Cervical subluxation should be treated conservatively with analgesics, muscle relaxants, and neck immobilization. Protection from inadvertent and iatrogenic trauma is essential. Patients with severe vertebral displacement and marked or progressive myelopathy should be considered for surgical fixation.

Prognosis and Future Perspectives. RA is a chronic disease, and the remission rate over 10 years is less than 10 percent. RA is associated with excess mortality, with a three-fold increase in the risk of death. Causes of death attributable to the disease process include infection and renal disease whereas those likely related to treatment are gastrointestinal disorders. Vasculitic peripheral neuropathy often improves, but the survival of patients with systemic rheumatoid vasculitis is poorer than others with RA. Atlantoaxial subluxation is most often clinically static, and surgical fixation is not necessary in the majority of cases.

Systemic Lupus Erythematosus

Pathogenesis and Pathophysiology. Systemic lupus erythematosus (SLE) is defined by its clinical features and the almost invariable presence of autoantibodies directed against certain components of cell nuclei. The immunological features of SLE are the lupus erythematosus cell, antinuclear antibodies, immune complexes, complement activation, tissue deposition of immunoglobulins and complement, and other autoantibodies. A nonspecific B-cell polyclonal activation may be responsible for the initiation of the disease; however, evidence of antigen-specific activation of antibody production also exists. Both of these mechanisms likely operate simultaneously to bring about manifestations of the disease. Additionally, the linkage of certain antibodies with particular human leukocyte antigen (HLA) loci and a 30 to 50 percent coincidence of SLE in monozygotic twins suggest a genetic factor in the pathogenesis of the disease.

Tissue damage results from both immune complex mediated vasculopathy and direct effects of antibodies reacting with cell-surface or serum components. The clinical manifestations of SLE include those that result from immune responses as well as those that result from organ damage (e.g., uremia). A number of drugs including procainamide, hydralazine, chlorpromazine, methyl dopa, antibiotics, and anticonvulsants can produce a lupus-like syndrome. Some of these drugs induce

the formation of histone-dependent ANA, and the syndromes usually abate with cessation of the drug. Drug-induced lupus is milder than idiopathic SLE and does not cause renal or CNS disease.

Epidemiology and Risk Factors. SLE is prevalent but varies throughout the world. In North America and northern Europe, the incidence is about 1 in 2500. There appears to be a higher incidence in Hispanics and African-Americans and a tendency toward more severe disease; however, based in part on socioeconomic factors, a potential ascertainment bias exists. There is a predominance of disease in women, with an incidence of 1 in 700, particularly among African-Americans, with an incidence of 1 in 245. The incidence in children and older adults is about 1 per 100,000. [68] Environmental risk factors have been implicated, including exposure to ultraviolet light, viral infection, and physical or emotional stress.

Neurological events are common in SLE. In one series,

TABLE 50-6 -- CRITERIA FOR THE DIAGNOSIS OF SYSTEMIC LUPUS ERYTHEMATOSUS

Criterion	Definition
Malar rash	Fixed erythema, flat or raised, over the malar eminences, tending to spare the nasolabial folds
Discoid rash	Erythematous raised patches with adherent keratotic scaling and follicular plugging; atrophic scarring may occur in older lesions
Photosensitivity	Skin rash occurring as a result of exposure to sunlight, by patient history or physician observation
Oral ulcers	Oral or nasopharyngeal ulceration, usually painless, observed by a physician
Arthritis	Nonerosive arthritis involving two or more peripheral joints, characterized by tenderness swelling, or effusion
Serositis	Pleuritis--convincing history of pleuritic pain or rub heard by a physician or pleural effusion OR Pericarditis--documented by electrocardiogram or rub or evidence of pericardial effusion
Renal disorder	Persistent proteinuria \geq 0.5 g per day or greater than 3+ if quantitation not performed OR Cellular casts--may be red cell, hemoglobin, granular, tubular, or mixed
Neurological disorder	Seizures--in the absence of offending drugs or metabolic derangements OR Psychosis--in the absence of offending drugs or known metabolic derangements
Hematological disorder	Hemolytic anemia--with reticulocytosis OR Leukopenia--less than 4000/mm ³ on two or more occasions OR Lymphopenia--less than 1500/mm ³ on two or more occasions OR Thrombocytopenia--less than 100,000/mm ³ in the absence of offending drugs
Immunological disorder	Positive LE cell preparation OR Anti-DNA: antibody to native DNA in abnormal titer OR Anti-SM: presence of antibody to Smith nuclear antigen OR False-positive serologic test for syphilis known to be positive for 6 months and confirmed by <i>Treponema pallidum</i> immobilization or fluorescent treponemal antibody absorption test
Antinuclear antibody	An abnormal titer of antinuclear antibody by immunofluorescence or equivalent assay at any point in time and in the absence of drugs known to be associated with drug-induced lupus syndrome

Modified from Tan EM, Cohen AS, Fries JF, et al: The 1982 revised criteria for the classification of systemic lupus erythematosus. *Arthritis Rheum* 1982; 25:1271-1277.

91 patients were followed for 599 patient years. In 25 percent of the 288 hospital admissions, neurological problems were primary or secondary reasons for admission. Only 14 percent had no symptoms or signs attributable to nervous system disease. [69]

Clinical Features and Associated Disorders. SLE has diverse clinical manifestations that can affect virtually every organ system. A number of the common manifestations are not specific to SLE. Criteria for the diagnosis of SLE are listed in [Table 50-6](#). [70]

The criteria for the diagnosis of neurological SLE are the presence of psychosis or seizures in the absence of offending drugs or known metabolic disturbance such as uremia or severe electrolyte imbalance. The term CNS- SLE or neuropsychiatric lupus has been used to describe collectively the neurological or behavioral events in patients with SLE. The neurological complications of SLE extend beyond this oversimplification, and there are often multiple factors related and unrelated to the disease that contribute to neurological dysfunction.

A few studies have looked specifically at the neurologic and behavioral events in SLE. [69], [71] Seizures represent approximately 25 percent of the neurologic problems in patients with SLE and may occur at times of disease inactivity. [72] In most cases, the genesis of seizures was multifactorial and included preexisting epilepsy, trauma, azotemia, systemic infection, meningitis, or stroke. About 30 percent of patients with SLE and seizures have no other predisposing features. [69] Seizures are positively associated with coagulopathy and stroke, and negatively associated with cardiac disease. [69]

Stroke accounts for 15 to 20 percent of neurologic events in SLE, and is a significant cause of morbidity. [69] Although stroke was as likely to occur during disease inactivity in the study by Kaell, 86 percent of another series of patients with large vessel occlusive disease stroke had active SLE at the time of the stroke. [71], [72] In more than half the cases, strokes are multiple, although earlier strokes may have been asymptomatic. [72] Headache heralded ischemic stroke in 60 percent of cases in one series. [71] Strokes may result from emboli, coagulopathy, atherosclerotic disease, or arterial dissection. [72] Libman-Sacks valvular disease or ventricular dysfunction may be identified in some patients. Valvular vegetations on postmortem examination can be found despite a normal echocardiogram. [71]

aPL such as anticardiolipin antibody and lupus anticoagulant may play a significant role in many of the thrombotic events in SLE. [71] Statistically, the presence of these antibodies significantly raises the incidence of primary stroke; the recurrence rate among aPL-positive SLE patients with prior stroke exceeds 50 percent. [69] aPL in patients with SLE are more likely to be associated with valvular and other cardiac disease. [71] Vasculitis is a rare cause of CNS dysfunction in SLE. [69], [71] Long-term corticosteroid treatment may play a role in premature cerebral and coronary atherosclerotic disease, which may contribute to stroke risk. [71] Hemorrhagic stroke occurs less commonly but frequently results in coma or death. [69]

Behavioral changes occur for a variety of reasons and represent at least one third or more of the neurological complications seen with SLE. Psychosis, delirium, altered alertness, disorientation, suicide attempts, and behavioral outbursts account for most cases. [69] Steroids are rarely implicated as a cause of behavioral change. Systemic or CNS infections are involved in many cases and may be fatal. [69] Opportunistic infections, including cytomegalovirus, aspergillus, listeria, and strongyloides stercoralis are common, and the CSF may not show inflammatory changes in the presence of infection. [69], [72]

Chorea has been described in patients with SLE and may be associated with the presence of antiphospholipid antibodies in the absence of a radiographic lesion in the basal ganglia.^[69] PNS abnormalities are less common than in other collagen vascular disorders, occurring in 2 percent to 21 percent of cases.^[73] A predominantly distal, axonal sensorimotor polyneuropathy is more common than mononeuritis multiplex.^[73]

Pregnancy in patients with active disease, particularly with nephritis and hypertension, is associated with a substantial risk of disease exacerbation and injury to the fetus. The presence of aPL has been associated with both stroke and second trimester abortion.^[68],^[71] For patients in remission, however, the risks during pregnancy are similar to those of unaffected patients.^[68]

Differential Diagnosis. The diagnosis of SLE is largely dependent on demonstrating a constellation of relatively specific findings in order to differentiate it from other systemic diseases. In approaching a patient with a given neurological syndrome, the differential diagnosis is generated by the predominant clinical picture, but SLE should always be kept in mind in a patient with CNS or PNS problems and dermatological or renal disease.

Evaluation. Various techniques can detect serum immune complexes, but the presence or quantity of the complexes is not specific to SLE. The most common antibody in SLE is the antinuclear antibody that stains homogeneously on immunofluorescence and is directed against nucleosomal DNA histone complexes. Over 95 percent of SLE patients have ANA antibodies in significant titers. Normal ANA titers are strong evidence against the diagnosis. Antibodies to native or double-stranded DNA and Sm, a ribonuclear protein antigen, are more specific than other antinuclear antibodies for the diagnosis of SLE.^[68]

Depressed serum complement levels are useful though not specific in recognizing disease activity and risk for renal and CNS involvement in SLE. Levels should be assessed during disease inactivity for comparison, and routine levels can serve as a guide for treatment. The aPL anticardiolipin antibody and lupus anticoagulant can be directly assessed in the serum.^[71]

CSF studies in SLE are nonspecific. Pleocytosis, elevated protein, and oligoclonal bands do not consistently correlate with the clinical syndrome or its severity.^[68] CSF may be helpful in identifying the responsible pathogen in CNS infection, but is not entirely sensitive.^[68] Electroencephalography (EEG) may be useful in a certain number of cases. The most common finding is generalized or focal slowing, and focal epileptiform discharges are seen in patients with seizures. The demonstration of a normal EEG may be useful in differentiation of psychosis and delirium.^[68]

MRI and CT scans are valuable in detecting strokes in this population. MRI has also demonstrated reversible changes suggesting breakdown of the blood-brain barrier in association with seizures or headaches.^[69]

There are no accepted criteria for the diagnosis of CNS- SLE.^[69] Of the diagnostic tests such as antineuronal antibodies, CSF-guanine levels, nuclear imaging, CT or MRI, or CSF oligoclonal bands, none has proven to be a single index of nervous system involvement.^[72]

Management. Many patients with mild symptoms such as myalgias, arthralgias, low-grade fevers, or arthritis can be managed with nonsteroidal anti-inflammatory medications. Some patients with skin rash and mucositis are effectively managed with antimalarial medications.^[68] When end organs are jeopardized, glucocorticoid therapy is indicated, and prednisone at an initial dose of 60 mg/d is usually sufficient.^[68] Treatment response can be followed clinically and serologically. Because there are no clear guidelines for the steroid management of SLE, the risks of steroid therapy should be weighed against the more immediate risks of the disease activity.

Treatment of the central nervous system complications of SLE depends on the pathogenic factors involved. Antithrombotic therapy with antiplatelet agents or anticoagulants is probably required for patients with aPL-associated vascular events, but this treatment has not been proven.^[69],^[71] Increased doses of corticosteroid may be of benefit if there are significant levels of aPL.^[71] Diffuse CNS involvement, mononeuritis multiplex, or findings suggestive of a vasculitis, are best treated with corticosteroids; cytotoxic agents may be of additional benefit, although this has not been well demonstrated.^[68] There are no specific guidelines for therapy during pregnancy. However, anticoagulation is probably indicated for pregnant SLE patients with aPL.^[68]

Prognosis and Future Perspectives. Although the natural history is highly variable, the 10-year survival rate approaches 90 percent. Patients with nephritis and systolic hypertension have a significantly worse prognosis.^[68] Although acutely dangerous, seizures and psychosis are generally associated with good long-term recovery.^[72] Patients with neurological episodes with more than one potential etiological factor such as hypertension, uremia, infection, drug abuse, and electrolyte abnormalities are more likely to recover significant function than those experiencing primary SLE-related events.^[72] Stroke and systemic infection carry a relatively poor short-term outcome.^[69],^[71]

Additional investigation of mechanisms involved in the generation of SLE-induced organ damage will serve to direct future therapies. Of relevance to SLE and other autoimmune diseases are therapies that may eliminate specific autoantibodies involved in the pathogenesis of the disease such as anti-idiotypic antibodies and sensitization of T cells against specific autoantibodies.

Progressive Systemic Sclerosis

Pathogenesis and Pathophysiology. Progressive systemic sclerosis (PSS) is a condition associated with thickening of the skin and tethering to subcutaneous tissues as well as smooth muscle atrophy and fibrosis of internal organs such as the gastrointestinal tract, lungs, heart, and

kidneys. The disorder is characterized pathologically by increased collagen deposition and perivascular inflammation in the skin, subcutaneous tissues, and internal organs.

Antinuclear antibodies are typically found, usually in a nucleolar pattern; antibodies to Scl-70, a soluble nuclear antigen, are specific, though insensitive. The demonstration of antibodies to smooth muscle and cytotoxicity to cultured endothelial cells suggests that autoimmunity plays a role in pathogenesis. The etiology of PSS is unknown, but glandular inflammatory processes appear to be related to cell-mediated immunity or to antibody-mediated cytotoxicity rather than to immune complex deposition.^[64] Immune complex disease appears to be responsible for rare cases of associated vasculitis.

Epidemiology and Risk Factors. The incidence of PSS ranges from 0.6 to 2.3 per million.^[74] Women, usually between the ages of 40 and 60 years, are affected three times as often as men. The association with certain HLA class II antigens suggests a hereditary predisposition.

Clinical Features and Associated Disorders. Some patients have a relatively benign form of the disorder limited to cutaneous changes in the distal extremities. In the generalized form of the illness, cutaneous abnormalities may predominate, but systemic symptoms, including generalized malaise, are common. Vascular changes in the hands progress from Raynaud's phenomenon to frank necrosis and induration and fibrosis of the skin (sclerodactyly) with atrophy of the underlying muscle. Rigidity of ligamentous tissue in the inner ear leads to conductive hearing loss. There may be fibrotic changes in the myocardium, pericardium, pleura, or lung. Glomerulonephritis with renal crisis is a frequent cause of morbidity and mortality. Mucosal gastrointestinal lesions occur, preferentially in the distal esophagus. Keratoconjunctivitis, lens subluxation, and cataracts are typical ocular signs, and musculoskeletal changes, including atrophy and osteolytic lesions, joint symptoms, and myopathy occur in 50 percent of patients.^[73]

The frequency of nervous system involvement varies; in one series of 727 patients, 6 had nervous system changes.^[75] In a more recent report of 48 patients, 56 percent had neurologic disturbances.^[73] Electrophysiologic studies suggest subclinical nervous system dysfunction in many asymptomatic patients.^[76]

Although rare, CNS disease has been reported. It may present as global cognitive decline or as a focal lesion. Encephalopathy, migraine, psychiatric changes, seizures, and focal neurologic deficits have been reported.^[73],^[77] Three cases with presumed cerebral arteritis have been reported, one a reversible encephalopathy with angiographic evidence of vasculitis, one with hemiplegia and aphasia with angiographic evidence of vasculitis, and one with right thalamic hemorrhage.

Trigeminal neuropathy is a frequent presenting feature of PSS, and is the most common cranial neuropathy found in the disorder. It develops insidiously or acutely and affects primarily the central part of the face. Pain is common and may resemble that of tic douloureux.^[76] Median and ulnar entrapment neuropathies have been

reported in up to 20 percent and distal polyneuropathy in up to 15 percent of patients.^[78] Most peripheral neuropathies can be ascribed to metabolic and nutritional factors. However, some cases of sensorimotor neuropathy occurring before the onset of other symptoms or very early in the disease course suggest that PSS may be etiological. In addition, a prospective evaluation of 29 patients with limited or widespread systemic sclerosis demonstrated raised tactile thresholds in 28, suggesting that subclinical peripheral nerve dysfunction is common in the disorder.^[79] Autonomic neuropathy is common,^[80] and recent evidence suggests that gastrointestinal dysmotility may be related to a neuropathic process.^[81] EMG in most cases of sensorimotor neuropathy reveals axonopathy, and histological features include collagenous infiltration of the peripheral nerves and the adventitia of vasa nervorum. Low-grade distal nerve trunk ischemia may contribute to neuropathy.^[82] Biopsy of the sural nerve reveals segmental demyelination, axonal degeneration, loss of large myelinated fibers, and an increase of collagen fibers, without evidence of vasculitis.^[83]

Differential Diagnosis. Chronic graft-versus-host disease following bone marrow transplant can mimic the picture of PSS, though esophageal and renal involvement are usually not seen. Sclerodermatous skin changes can be seen in response to certain chemotherapeutic agents.

Evaluation. The diagnosis of PSS is generally made clinically. Evidence of disturbed gastrointestinal motility and vasculopathy on nailfold capillary microscopy are confirmatory. Generalized or focal CNS abnormalities can be investigated using MRI. Nerve conduction velocities (NCV) and EMG are useful in the elucidation of neuropathy syndromes, and NCV can be used to detect subclinical neuropathy.

Management. Symptomatic treatments include nonsteroidal anti-inflammatory drugs for arthritis and vasoactive drugs for Raynaud's phenomenon. Neuropathic pain, especially that associated with trigeminal neuropathy, can be treated with carbamazepine or tricyclic antidepressants. Penicillamine, colchicine, prednisone, and immunosuppressants have been used for more severe disease manifestations, but their relative effectiveness has not been determined.^[84]

Prognosis and Future Perspectives. The 10-year survival rate in PSS approximates 50 percent.^[84] In some cases the disease is rapidly progressive, and death occurs within 1 year. The most common causes of death are renal failure and cardiac complications. Individual survival is largely dependent on the extent of involvement. Digital sclerodactyly alone carries a very benign prognosis. Prognosis is worse with diffuse disease, older onset age, and early involvement of internal organs.^[85]

Mixed Connective Tissue Disease

Pathogenesis and Pathophysiology. In 1971, Sharp described patients in whom a new type of antibody to ribonuclease-sensitive extractable nuclear antigen was accompanied by clinical features of more than one connective tissue disease. He called the syndrome mixed connective tissue disease (MCTD), and described several serologic characteristics: (1) high titers of hemagglutinating antibody to saline-extractable nuclear antigen; (2) marked sensitivity of this antibody to ribonuclease with moderate sensitivity to trypsin and resistance to deoxyribonuclease; (3) high

titers of speckled pattern on fluorescent antinuclear antibody testing; and (4) absence of Smith antibody. Saline-extractable nuclear antigen appears to represent two moieties: ribonucleoprotein (RNP) and the Smith (Sm) antigen, a glycoprotein. While high titers of anti-RNP antibodies appear to be associated with MCTD, the presence of anti-Sm correlates highly with the diagnosis of SLE. The etiopathogenesis of MCTD is poorly understood, but is felt to relate to formation of autoreactive T-cells in response to exposure to microbial antigens, which are similar to an autoantigen.^[86] Patients with MCTD may have antinuclear antibody in a speckled pattern, RF, and cold-reactive lymphocytotoxic and anticardiolipin antibodies.^[87]

Epidemiology and Risk Factors. The prevalence of MCTD is unknown. It is intermediate in frequency between SLE and systemic sclerosis.^[88] Women are more frequently affected than men by a factor of 4 to 79:1.^[89] Although most frequently seen in the second and third decades of life, it has been reported in children and the elderly as well.^[90] There is an association between the 68-kd-U1 snRNP and the DR4 haplotype in both SLE and MCTD.^[91] The existence of MCTD as a discrete syndrome is not universally accepted, because the serologic markers are not specific for the diagnosis^[88] and the disorder frequently evolves over a number of years into SLE or PSS.^[88],^[91] Nevertheless, the term is still considered helpful to describe a number of patients with a mixed clinical picture.

Clinical Features and Associated Disorders. Patients with MCTD have clinical features of at least two connective tissue disorders, among them SLE, PSS, and polymyositis. Nearly all have arthralgia, nondeforming arthritis, inflammatory myositis, Raynaud's phenomenon, sclerodactyly, and a tapered or sausage-like appearance of the digits, sometimes with digital ischemia and ulceration. Pitting edema of the forehead and erythematous malar or violaceous eyelid rash may be present. Disorders of esophageal motility affect more than 75 percent of patients. Lymphadenopathy is common and sometimes marked, suggesting lymphoma. Fever, hepatosplenomegaly, pleuritis, pericarditis, and cardiac and hair changes are seen in 20 to 40 percent of cases. Pulmonary disease is very common, and although it may be asymptomatic, pulmonary hypertension is the most common cause of death.^[92],^[93] Frequent laboratory abnormalities include leukopenia, anemia, and hypergammaglobulinemia.^[93] Renal disease is evident in some patients with MCTD. Proteinuria, sometimes with nephrotic syndrome, hematuria, glomerulonephritis, or proliferative vascular lesions, may be seen.

Neurological sequelae of MCTD occur in 10 to 55 percent of cases.^[94]^[95]^[96] The CNS complications of MCTD resemble those seen in SLE, whereas the PNS complications resemble those seen in PSS. CNS effects occur in the context of active systemic disease and are largely steroid-responsive, whereas PSS effects occur irrespective of systemic disease activity and are largely steroid-resistant. The most common disorders are vascular-type headache, aseptic meningitis, psychosis, and convulsions.^[96],^[97] Ischemic and hemorrhagic cerebrovascular disorders, optic neuritis, cerebellar ataxia, chorea, and transverse myelitis occur less commonly.^[95],^[96],^[98]^[99]^[100]

The peripheral nervous system is a more frequent target of MCTD than the central nervous system. In published series, unilateral or bilateral trigeminal neuropathy occurs in about 10 percent of MCTD patients.^[94],^[96],^[101] The maxillary and mandibular branches are usually involved.^[102] Some patients may have involvement of the motor root with masseter atrophy.^[96],^[102] Although dysfunction of regional cranial nerves is rare, associations with facial neuropathy have been reported.^[102],^[103] Vasculitic polyneuropathy has been reported in up to 10 percent of patients with MCTD.^[96] There have been rare reports of carpal tunnel syndrome^[104] and neuromuscular junction dysfunction.^[105] The importance of myositis in MCTD is underscored by its inclusion as a diagnostic criterion in virtually all series of patients.^[87] Concurrent changes of overlying skin mimic dermatomyositis in some patients.^[95]

Differential Diagnosis. The most important distinction is between MCTD and other connective tissue disorders such as PSS, SLE, and polymyositis. This distinction is blurred over time as the disease generally comes to resemble one of these connective tissue diseases.

Evaluation. The diagnosis of MCTD is made in patients with symptoms and signs of more than one connective tissue disease and the characteristic serologic markers. CNS manifestations are evaluated with MRI, which may demonstrate signs of vascular disease. In patients with seizures, EEG shows focal or generalized slowing and often epileptiform activity.^[96] CSF in patients with headaches or aseptic meningitis may be normal or show a lymphocytic pleocytosis or increased protein. Elevations of serum creatine phosphokinase occur in about half of those with myopathic symptoms. Electromyographic changes may confirm the presence of myopathy, and biopsy may show inflammatory myositis.^[96]

Management. The treatment of nervous system involvement in MCTD is based on anecdotal data rather than controlled clinical trials. CNS disorders such as headache, aseptic meningitis, psychosis, convulsion, optic neuritis, and transverse myelitis have been reported by various authors to be responsive to corticosteroids,^[95],^[96] plasmapheresis, or immunosuppressive drugs.^[99] Disorders of the PNS, including trigeminal and peripheral neuropathy, are relatively steroid-resistant.^[96],^[102],^[104] Myositis is believed to mirror the systemic signs of MCTD and be quite sensitive to corticosteroid therapy.

Prognosis and Future Perspectives. The majority of patients with MCTD evolve clinical features typical of another connective tissue disease within 5 years of diagnosis.^[86] Long-term follow-up of 194 patients in several series revealed that 13 percent to 28.2 percent had died by 13 years' follow-up.^[88],^[105] More benign prognosis appears to be associated with the presence of Raynaud's phenomenon, less widespread and severe organ system involvement, and HLA-DR2 or DR4.^[105],^[106]

The most compelling research questions are whether MCTD is a discrete diagnostic entity and what factors predict its evolution into other connective tissue diseases. Better elucidation of environmental triggering antigens and the autoantigen immune target may lead to more effective therapies, particularly for steroid-resistant symptoms.

Sjogren's Syndrome

Pathogenesis and Pathophysiology. Sjogren's syndrome (SS) is a chronic inflammatory disease of unknown

cause characterized by inflammation of the salivary and lacrimal glands and synovial tissues. Involved tissues have infiltrates of lymphocytes and plasma cells. Autoantibodies include RF, antinuclear antibodies (SS-A and SS-B type), and antibodies directed against salivary duct antigens.

Epidemiology and Risk Factors. SS is seen in 0.5 to 2.0 percent of the population; among the collagen vascular diseases, it is second in prevalence only to rheumatoid arthritis.^[107] Ninety percent of patients are women. Onset usually occurs during middle age.^[107] Genetic susceptibility is suggested by an association with HLA-B8, HLA-DR3, HLA-DR2, and HLA-DRw52. SS occurs in isolation in 50 percent of cases and in the context of rheumatoid arthritis, systemic lupus erythematosus, scleroderma, or another connective tissue disease in the remaining patients.^[107]

Clinical Features and Associated Disorders. Primary SS predominantly affects exocrine glands, with lymphocytic infiltration and fibrosis of lacrimal and salivary glands. Ocular, oral, and dental complications occur as a result of decreased tear and saliva production.^[107] Extraglandular manifestations occur in at least 25 percent of patients. Lymphadenopathy and hepatosplenomegaly are common. Cutaneous vasculitis may present with a picture of nonthrombocytopenic purpura or urticaria. Symmetrical, nondeforming arthritis of the small joints occurs in more than 80 percent of patients. Renal disease, usually interstitial nephritis, is seen in up to 40 percent of cases. Less commonly, the lungs may be involved, with interstitial pneumonitis and restrictive or obstructive abnormalities of pulmonary function. Vasculitis, usually localized to the skin, peripheral nervous system, and muscle, occurs in up to 20 percent. Lymphoproliferative disorders occur, and there is an increased risk of lymphoma in these patients.

Although neurological disorders have been thought to be rare manifestations of SS, as many as 25 to 80 percent of patients have nervous system dysfunction, sometimes in advance of other symptoms.^[108]^[109]^[110] CNS complications include mild aseptic meningitis; cognitive, affective, or personality disorders; focal cerebral deficits; and seizure.^[108]^[109] Optic neuropathy, nystagmus, ataxia, internuclear ophthalmoplegia, and parkinsonism or other movement disorders have occasionally been reported.^[111] Spinal cord involvement may take one of three forms: progressive myelopathy, acute transverse myelitis, or intraspinal hemorrhage.^[108]

PNS signs and symptoms occur in 10 to 32 percent of cases.^[112] Most commonly, there is a sensory or mixed motor- sensory polyneuropathy or entrapment neuropathy. The polyneuropathy may be abrupt or insidious in onset, is often asymmetrical, affects proprioceptive and kinesthetic senses, and causes mild distal motor weakness in the legs.^[113] Mononeuritis multiplex occurs somewhat less commonly, and cranial nerve involvement, specifically trigeminal, oculomotor, and abducens nerves, can occur.^[113]

Differential Diagnosis. The diagnosis of primary SS is made in the presence of two of the typical manifestations of xerostomia, xerophthalmia, and arthritis. Illnesses that should be considered in the differential diagnosis are all causes of parotitis, including malignancy, nutritional and endocrine disorders, sarcoidosis, infections, and amyloidosis.

Evaluation. Xerophthalmia can be demonstrated by Schirmer's test, staining of the corneal and conjunctival epithelium by Rose Bengal dye, or demonstration of epithelial strands by slit-lamp examination. Xerostomia can be assessed by nuclear scanning of the salivary glands, radiologic sialography, or calculation of salivary flow rate. Biopsy of minor salivary glands, found on the inner aspect of the lower lip, is well tolerated and diagnostic when lymphocytic aggregation is demonstrated. Anemia, leukopenia, and elevated ESR are common. Hypergammaglobulinemia and positive RF are common, but not specific for the diagnosis. SS-B antibodies are relatively specific for primary SS. SS- A antibodies are seen in primary SS and SS associated with SLE. Half of SS patients have antibodies against salivary duct antigens.

The EEG is abnormal in nearly 50 percent of patients with CNS dysfunction, but the findings are nonspecific. CT and MRI scans usually show focal regions of abnormality in patients with clinical evidence of focal pathology.^[108] Electrophysiologic studies are consistent with demyelination, denervation, or both. CSF may be normal or may show pleocytosis and elevated protein. CSF is characterized by protein elevation and evidence of intrathecal immunoglobulin synthesis, with increased IgG and oligoclonal bands.^[108] Pathologic studies are limited, but perivascular inflammation and diffuse vasculitis involving the cerebral blood vessels, as well as acute necrotizing arteritis of the spinal cord, have been described.^[112] Peripheral nerve tissue shows demyelination and acute or chronic vasculitis or perivasculitis.^[113] Dorsal root ganglionitis, with lymphocytic infiltration and degeneration of ganglion cells, has also been reported to accompany subacute sensory neuronopathy, which is a rare complication of SS.^[114]

Management. Ocular and oral symptoms are managed conservatively, with artificial tears and saliva and good oral hygiene. Corticosteroids may be needed to control arthritis and symptoms related to vasculitis.

Prognosis and Future Perspectives. Primary SS is generally compatible with prolonged survival. A small number of patients develop more serious disease manifestations, including primary biliary cirrhosis, renal disease, chronic active hepatitis, pancreatitis, visceral lymphocytic infiltration, lymphoma, immunoblastic sarcoma, or Waldenstroaum's macroglobulinemia. Future research should focus on the etiopathogenesis of the disorder in order to increase understanding of the cause and potential treatments.

OTHER AUTOIMMUNE CONDITIONS

Myasthenia Gravis

Pathogenesis and Pathophysiology. Myasthenia gravis (MG), although described for many years, was first associated with decreased numbers of muscle acetylcholine receptors about 25 years ago.^[115] Since then, the identification of antiacetylcholine receptor antibodies (AChR-ab), the development of an animal model of the disease, and an overall improved knowledge of immune mechanisms have led to a very precise understanding of the pathophysiology of MG.^[115]

The immune effector cells in MG are both T and B cells. Although the key to acetylcholine receptor damage is

through the AChR-ab, sensitized T cells and complement play a role in the continued stimulation of B cells and in cell-mediated postsynaptic destruction at the neuromuscular junction.^[116] The histologic hallmarks of MG include decreased numbers of acetylcholine receptors, simplification of the postsynaptic clefts, and widening of the synaptic space with a normal presynaptic nerve terminal.^[115]

The thymus is unequivocally involved in the pathogenesis of the disease, and its surgical removal often is associated with improvement in disease severity.^[116] Thymic abnormalities are either hyperplastic or neoplastic. Hyperplasia is associated with areas of germinal centers that may enlarge the gland beyond the normal size for age. Neoplasms occur in about 12 percent of patients and are usually locally invasive epithelial cell tumors (thymomas or rarely carcinomas).^{[115], [116]}

In addition to immune activation against acetylcholine receptors, there is functional blockade of postsynaptic receptors, which can in part explain the response to acetylcholinesterase inhibitors and the relatively quick response to therapies that reduce the number of AChR-ab.^[115]

Epidemiology and Risk Factors. MG can occur throughout life, with a bimodal peak of incidence in younger women (second and third decades) and older men (fifth and sixth decades).^[116] Overall, MG has a prevalence of 1 in 25,000 in the United States.^[115] There are cases of overlap of MG with other autoimmune diseases and case reports of families with various autoimmune conditions including MG. This suggests a partial genetic predisposition.^[115]

Clinical Features and Associated Disorders. The typical features of MG are fatigability and weakness of skeletal muscles without reflex, sensory, or coordination abnormalities. Many cases begin with involvement of ocular muscles such as diplopia and ptosis. Weakness may remain confined to ocular muscles for long periods or involve bulbar muscles, which control chewing, swallowing, or articulation. The disorder remains confined to ocular muscles in up to 15 percent of patients, but becomes generalized in the majority.^[115] Examination of neck extensors and flexors is often more sensitive in demonstrating generalized disease than the motor exam of other muscle groups.^[115] Under periods of physical stress, such as infection or surgery, a precipitous worsening may occur, and failure of respiratory muscles can be life threatening. Classification of disease severity is usually assessed according to a scale devised by Osserman where grade I is ocular disease only, grade II is generalized weakness of mild (IIa) or moderate (IIb) intensity, grade III is severe generalized disease, and grade IV is myasthenic "crisis" with respiratory failure.^[115]

Transient neonatal MG can occur from passive transfer of maternal AChR-ab causing a myasthenic syndrome that may require ventilatory assistance.^[115] These symptoms typically resolve in under two weeks, with routine clearance of antibodies from the neonate's circulation.

Differential Diagnosis. A number of disorders may mimic MG, and include other disorders of neuromuscular transmission, metabolic or toxic syndromes, and neurogenic weakness.^[115] Botulism and Lambert-Eaton myasthenic syndrome (LEMS) can cause ophthalmoplegia and fatigue. Botulism affects cranial nerves early, affects the pupillary light response, and shows an incremental response on repetitive nerve stimulation. Botulinum toxin may be detectable in the stools. LEMS is often associated with an oat-cell carcinoma of the lung, dry mouth and eyes, and more distal weakness, which improves with exercise. The presence of voltage-gated calcium channel antibodies in the serum and an incremental response on postexercise repetitive nerve stimulation are confirmatory objective signs.^[115] The congenital myasthenic syndromes appear as MG but are not autoimmune in nature.^[116]

Certain drugs, including penicillamine, curare, aminoglycosides, quinine, procainamide, and calcium channel blockers may cause a myasthenia-like syndrome or exacerbate weakness in MG patients. Hyperthyroidism or Graves' disease may cause generalized fatigue or worsen MG, and is detectable by abnormal thyroid function tests.^[115] Cranial nerve abnormalities may cause symptoms that mimic MG.^[115]

Evaluation. Timed endurance tasks such as prolonged upgaze, holding outstretched arms in abduction, or vital capacities at every visit are often helpful in providing objective information about fatigability.^[115] Laboratory tests useful in excluding other diagnoses include thyroid function tests, antithyroid antibody, ANA, and voltage gated calcium channel antibodies and chest radiograph.

Improvement of weakness after edrophonium chloride (Tensilon) injection is a useful sign, although false-negative and false-positive tests do occur.^[117] The test is performed by first fatiguing the patient with a task that includes signs that can be easily clinically assessed (ptosis, vital capacity, slurred speech). The diagnostic test is then performed by injection of 1 mg as a test dose, then injecting 9 mg intravenously with attention to the fatigued muscles. A rapid improvement or recovery of the fatigued muscles (resolved ptosis, normalized vital capacity, clear and strong voice) over the subsequent 2 minutes is a positive test. In recent years, the detection of AChR-ab in the serum, using a commercially available immunoprecipitation test, has significantly changed the evaluation of MG patients.^[117] The sensitivity of AChR-ab in ocular myasthenia is 70 percent and in generalized disease is 80 percent.^[117]

Repetitive nerve stimulation may demonstrate a reduction of the compound muscle action potential (CMAP) consistent with a postsynaptic transmission defect. For patient comfort, the test should first be performed on a distal muscle; negative studies on distal muscles should prompt more extensive study of proximal muscles. Clinically weak muscles are more likely to demonstrate the decremental response.^[117] The sensitivity of repetitive nerve stimulation is about 75 percent. It may be normal in ocular MG, but is virtually always abnormal in generalized MG.^[117]

The demonstration of increased "jitter" by single fiber electromyography is the most sensitive test for MG. The sensitivity ranges from 80 percent in ocular MG to virtually 100 percent in moderate generalized MG. In 9 percent of MG cases, this is the only abnormal test.^[117] Using AChR-ab, repetitive stimulation and single fiber EMG identifies all MG cases.^{[117], [118]}

CT scanning or MRI of the chest should be done in all patients to screen for the presence of thymoma or thymic hyperplasia. Thymic enlargement or detectable thymic tissue in a patient over age 40 raises the suspicion of thymoma.^[115] Chest imaging is also indicated in patients who

have had thymectomy, but are experiencing unexplained worsening of MG symptoms. Residual thymic tissue may be found in some of these patients.

Management. Acetylcholinesterase inhibitors (mainly pyridostigmine) inhibit the enzymatic elimination of acetylcholine, increasing its concentration at the postsynaptic membrane. They play a supporting role in the management of symptoms throughout the disease course, but do not affect the primary immune mechanism of the disease.^[116] Cholinergic toxicity causing transient weakness can result from overuse of pyridostigmine and can be difficult to distinguish from the weakness of MG. MG is rarely controlled by symptomatic treatment alone and immunomodulating therapy is often required.

There is broad consensus that thymectomy is helpful in the treatment of MG, and it is recommended for patients aged from puberty to approximately 60 years.^[115] The beneficial effects of thymectomy usually occur in the first year but may be seen as late as 5 years from the time of surgery.^[116] No prospective, controlled trials have been done to determine the exact effects of thymectomy but retrospective analyses suggest 85 percent of patients will show improvement or remission.^[115] Thymectomy is never an urgent procedure, but can be done on optimally stabilized patients and in centers with experience in managing the perioperative course of MG patients. The transsternal approach is preferred because it allows for direct visualization and complete removal of the thymus and adipose tissue of the anterior mediastinum. In contrast, the transcervical approach by indirect mediastinoscopy is associated with a higher occurrence of residual thymus tissue although this method is cosmetically more appealing.^{[115], [116]}

Corticosteroids have been the mainstay of immunotherapy for MG. Seventy to 80 percent of patients have complete remission of their disease within weeks to months

of adequate doses of prednisone.^[116] The starting dose is dependent upon the severity of symptoms, but most patients require 40 to 60 mg/d. Alternate-day dosing is encouraged to lessen adverse side effects, and should be tapered to the lowest effective dose.^[115]

Cytotoxic therapies are useful in MG, and should be considered in patients who are not able to achieve sufficiently low doses of prednisone or who are having significant steroid side effects. Azathioprine 2 to 3 mg/kg/d is effective in a number of patients as an adjunct to prednisone, and its use allows lowering of the total dose of the prednisone to more tolerable levels. Some patients respond well enough to discontinue the prednisone.^[116] Cyclosporine is a more effective and more toxic immunosuppressive agent.^[115] The typical dose is 5 mg/kg/d. Improvement occurs in the first several months of therapy.^[115] Nephrotoxicity, hypertension, neutropenia, and remote risk of leukemia are potential complications of therapy, and blood levels need to be monitored to reduce the incidence of these toxic side effects.^[116]

Plasma exchange and intravenous pooled immune globulin are effective short-term treatments for MG. For the treatment of MG crisis or prior to thymectomy, five courses of plasma exchange, given on alternate days, cause rapid improvement, which lasts for several weeks. Venous access, a mild increased risk of infection, hypotension during exchanges, deep venous thrombosis, and cost are drawbacks to this treatment.^[115] There is preliminary evidence to support the use of pooled intravenous immunoglobulin in the treatment of MG. Like plasma exchange, the treatment is given over a few days (0.4 g/kg/d times 5 days) and the effect is relatively short-lived, lasting a few weeks.^[116]

Prognosis and Future Perspectives. Before 1958, approximately one third of MG patients died, one third failed to improve, and one third improved spontaneously.^[115] Currently the mortality rate is essentially zero, and most patients lead normal lives. Lifelong immunomodulating therapy is often required.^[115]

Novel approaches for potential treatment of MG are increasing with advancing knowledge of the immune system. Targeting specific T cells and B cells, which are "programmed" to mediate antiacetylcholine receptor activity, is the focus of recent experimental work.^[115] Such therapy would tightly target the effector arm of the immune system. This strategy is limited by evidence that T cells have a number of targets, and lack of knowledge of which T cells are relevant to the pathogenesis of MG. Animal models suggest that the nonselective removal of the T helper cells may also be beneficial.^[115] Lastly, there is renewed interest in inducing tolerance to self-antigens by ingesting them. Oral ingestion of antiacetylcholine receptor antibodies has been found to prevent the disease in rat models of MG.^[115] New insights generated by this work will lead to safer and more effective therapies.

Dermatomyositis and Polymyositis

Pathogenesis and Pathophysiology. Dermatomyositis (DM) and polymyositis (PM) have been thought to have an autoimmune origin for many years. This concept is based on indirect associations with other autoimmune disorders, mononuclear inflammatory cells in affected muscles, and responsiveness to immunosuppressive agents. Genetic factors play a role, as evidenced by reports of identical twins with DM, families with other connective tissue diseases and DM or PM, and increased associations with HLA-DR3. Without convincing evidence of support, it has been hypothesized that these inflammatory myositides are the result of a viral infection.

In DM, several observations suggest that circulating immune complexes or antibodies induce vascular injury. Intramuscular blood vessels show endothelial hyperplasia with tubuloreticular profiles, fibrin thrombi, and obliteration of capillaries. Even in cases where light microscopy is normal, electron microscopy reveals microtubular inclusions and vacuoles in the lining of endomesial capillaries, suggesting that the capillary lining may be the target of the immune response. Perifascicular atrophy results from ischemic changes secondary to the endomesial vasculopathy. Similar changes occur in skin vasculature leading to the rash, which is often part of the DM syndrome.

In PM, there is strong histochemical evidence for cell-mediated immune mechanisms in the pathogenesis. The inflammatory exudate is predominantly CD8⁺ T cells within the endomysium. These exudates are seen in muscle cells undergoing necrosis and phagocytosis. Further evidence suggests that these T cells (and monocytes) are a

few distinct clones (i.e., oligoclonal) and are not simply nonspecific inflammatory effectors.

Epidemiology and Risk Factors. Both of these syndromes affect women slightly more than men. PM typically occurs after the age of 20 years and rarely in childhood, whereas DM affects both children and adults. The incidence of the inflammatory myopathies is less than 1 in 100,000 population. Although the adult cases of PM and DM present in the fifth and sixth decades of life, the majority of cases of DM are childhood onset with typical age of 5 to 14 years.

The risk of cancer in association with adult PM or DM ranges from 6 to 45 percent in DM and zero to 28 percent in PM. A population-based retrospective study in 788 DM patients and 396 PM patients over 20 years reported the rate of cancer occurrence to be 9 percent in the PM group and 15 percent in the DM group. The majority of these cancers were within 5 years of the diagnosis of the myopathy. In PM, the relative risk of malignancy was 1.7 for women and 1.8 for men, with the most common site of malignancy in men being the lung (relative risk 5.6). In DM, the relative risk for malignancy was 2.4 in men and 3.4 in women, with the ovary most often affected (relative risk 16.7).^[115] Patients with associated malignancy have a higher than average age of DM or PM onset.

Clinical Features and Associated Disorders. Childhood DM is a relatively uniform disorder usually characterized by erythematous rash and skin lesions, and coincidental muscle weakness. This photosensitive rash usually begins as periorbital heliotrope (blue-purple) discoloration with subsequent erythematous involvement of extensor surfaces of the limbs and joints. The anterior neck and chest rash may form a "V" sign or rash over the shoulders in a "shawl" sign. The proximal muscles of the limbs are more affected than distal ones, the abductors of the leg affected more than the adductors, and the extensors more than the flexors. Ectopic calcifications are present in subcutaneous tissues and muscle in about half of the cases. Associated complications include hemorrhagic gastrointestinal vasculitis and pulmonary fibrosis.

Adult DM shares the same skin features with childhood DM and often helps secure a clinical diagnosis. On occasion the skin manifestations are subtle or absent and the diagnosis of DM over PM relies on the muscle biopsy appearance.

The clinical features of muscle involvement are similar in DM and PM. Muscle pain and tenderness are common and usually more prominent in the arms. Onset of symptoms is subacute or insidious. As the disease progresses, dysphagia and neck flexor weakness begin. Respiratory muscles are impaired in severe cases and result in a restrictive pulmonary defect. In addition, pulmonary interstitial fibrosis may appear as a complication of the disease and may even precede the muscle weakness. There is an increased frequency of electrocardiographic abnormalities (dysrhythmias, heart block, etc.), and occasionally patients may have pericarditis as part of their syndrome.

A number of other related conditions may have myositis as a feature and are considered to be "overlap" syndromes when the diagnostic criteria for both conditions are fulfilled. These are other autoimmune diseases such as PSS, SS, SLE, RA, and MCTD.

Differential Diagnosis. The main clinical differentiation to be made is between DM/PM and other acquired myopathies or inflammatory diseases. The rash of DM limits the potential diagnoses to the overlap syndromes. The diagnosis of PM is one of exclusion. Inclusion body myositis may appear similar to PM, and the serum creatinine phosphokinase (CK) is elevated although typically not to the same extent. Endocrinopathies such as hyperthyroidism and Cushing's syndrome can behave similarly. Toxic exposures and drugs that induce myopathy should be sought as potential etiologies. Additionally, inherited neuromuscular or metabolic disease may have a similar appearance. Serologic testing and muscle biopsy should resolve the differences in most cases.

Evaluation. In a patient with a possible inflammatory myopathy, the diagnosis is strengthened or confirmed by serum CK, electromyography, and most important, muscle biopsy to help exclude overlap syndromes. ESR is neither a sensitive nor a specific indicator of PM or DM but does correlate in general with inflammatory diseases. Testing for autoantibodies such as antinuclear antibodies and anti-Sm (SLE), SS-A and SS-B (Sjogren's), PM-Scl and anti-Ku (scleroderma), anticentromere (CREST syndrome), and anti-U1snRNP (MCTD and SLE) may be useful in considering the overlap syndromes.

Serum CK is the most sensitive muscle enzyme for the detection of destruction of muscle cells. Typically, 10-fold elevations can be seen; however, it is possible to have normal levels even during active disease. There are elevations of both muscle and brain isoenzyme forms of CK reflecting both necrosis and new fiber regeneration. The CK is often used for a marker of disease activity.

Certain autoantibodies are associated with the inflammatory myopathies. Of these autoantibodies (such as anti- nRNP, PM-Scl, and antisynthetases), the anti-Jo-1 is the most useful because 75 percent of the patients with anti- Jo-1 have interstitial lung disease.

Electrodiagnostic studies are helpful to evaluate clinically weak muscles for evidence of a myopathic pattern of activity and to exclude a neurogenic component. Muscle biopsy is the gold standard in the diagnosis of inflammatory myopathies and to exclude other neuromuscular diseases. Histopathologic evaluation is the mainstay of diagnosis of these conditions. Treatment of the condition, however, should not be delayed while awaiting the histopathology results.

Management. Immunosuppressive therapy is the mainstay of treatment. Prednisone is the agent of choice for DM and PM, and treatment should begin with 80 to 100 mg/d (or 1 mg/kg/d) given in a single morning dose. This dose should be maintained for 3 to 4 weeks. If a clinical response has occurred, then tapering of the dose on every other day (by 5 to 10 mg every 3 to 4 weeks) should take place with an eventual goal of 80 to 100 mg every other day. This dose can then be tapered slowly over a period of months. The inability to taper the prednisone without disease reactivation or a lack of clinical response suggests the need for another agent. Corticosteroids may cause a clinical worsening secondary to steroid myopathy. Worsening in the absence of CK elevation and absence of neck flexor weakness may point to steroid myopathy in treated patients with inflammatory myopathy.

Azathioprine is most helpful in combination with corticosteroids and has a steroid-sparing effect. The recommended dose is approximately 2 mg/kg/d, and side effects may include gastrointestinal upset, a flu-like syndrome, hepatotoxicity, and bone marrow suppression. A several- month delay in effectiveness is common and should be expected. Azathioprine can be used alone but is probably not as effective.

Methotrexate, cyclophosphamide, and cyclosporine A are agents that also may be useful in the treatment of DM or PM. These agents have associated potential toxicities to bone marrow, liver, and during pregnancy. The effectiveness of these agents is not well studied, but they may be promising, particularly in patients who are not responding to prednisone, azathioprine, or both. ^[120]

IVIg is an expensive, relatively safe, and promising treatment for DM and PM. The dose is 2 g/kg, divided over 2 to 5 days initially, then 0.4 g/kg given at intervals based upon the clinical response. The exact mechanism of action is not clear but is felt to affect circulating autoantibodies, the autoimmune target, or complement activation. Side effects include increased serum viscosity with potentiation of thromboembolic events, aseptic meningitis, rash, anaphylaxis in IgA-deficient individuals, and a low risk of transmissible diseases such as hepatitis C. Many patients who have failed other treatments may respond to IVIg. Plasmapheresis has been shown ineffective in a controlled clinical trial.

Prognosis and Future Perspectives. Childhood DM has a variable prognosis. Some cases may have complete reversal of signs and symptoms after months, but 7 percent of cases have a fatal condition. The disease may recur, even after prolonged remission. Overall, the prognosis for DM and PM is relatively favorable with 10-year survival rates as high as 90 percent. Patients with interstitial lung disease have a mortality that approaches 40 percent at 3 years. Other factors that adversely affect prognosis include advanced age at onset, acute onset, involvement of respiratory muscles, dysphagia, fever, and inadequate therapy.

Potential avenues for treatment include more specific immunotherapies. Proteins that could bind the antigenic targets and interfere with recognition by auto-directed T cells or products that mimic the antigenic target are possible new avenues of treatment.

Eosinophilic Myositis and Related Syndromes

Pathogenesis and Pathophysiology. True eosinophilic myositis occurs in the setting of a subacute or chronic unexplained peripheral blood eosinophilia. Patients with hypereosinophilia may be asymptomatic, or may have end- organ damage including myositis. The skeletal muscle in such patients resembles polymyositis with an eosinophil- predominant infiltrate. ^[121]

Eosinophilic fasciitis is likely a separate condition with eosinophilia, elevated ESR, and hypergammaglobulinemia. Clinically, these patients present with taut skin and flexion contractures secondary to intense diffuse fasciitis. Pathologically eosinophilic inflammation of the fascia extends into adjacent muscle, but there is no primary muscle involvement. ^[121]

Eosinophilia-myalgia syndrome (EMS) is a more recently described condition. A number of patients developed peripheral eosinophilia, fatigue, and myalgia associated with the chronic ingestion of L-tryptophan. Biopsies demonstrate inflammatory infiltrates of small and medium-sized vessels and connective tissues consisting of various cell types (histiocytes, CD4⁺ and CD8⁺ lymphocytes, and mast cells) but few if any eosinophils. ^[121] An autoimmune disorder or idiosyncratic response is suspected. ^[121] Since the withdrawal of L-tryptophan from the market, the number of cases reported has dramatically dropped. ^[122] It is likely that the vehicle, not L-tryptophan, was the responsible agent. The toxic oil syndrome, which was the result of a toxic contaminant in the production of rapeseed oil in Spain, is nearly an identical syndrome with identical pathology as EMS. ^[121]

Epidemiology and Risk Factors. The number of cases of eosinophilic myositis is small. The syndrome is associated with the systemic hypereosinophilic syndromes almost as a rule. With eosinophilic fasciitis, men 30 to 60 years of age are more often affected, and about half have a history of intense exertion prior to the onset.

In a study of 205 patients with EMS associated with L- tryptophan ingestion, 79 percent were women and almost all were Caucasian. ^[123] The EMS from L-tryptophan ingestion was associated with contamination by 1,1-ethylidenebis tryptophan and 3-phenylamino alanine. The doses taken in the EMS patients were generally higher than the at-risk patients who did not develop the syndrome. One of the toxic contaminants in rapeseed oil was 3-phenylamino-1,2- propanediol, an alanine derivative similar to the 3-phenylamino alanine in the EMS outbreak. ^[121]

Clinical Features and Associated Disorders. The systemic syndrome associated with eosinophilic myositis involves other organs such as lungs, heart, and skin. There may be heart block, arrhythmias, and pulmonary infiltrates, resulting in death. Esophageal motility can be affected in some patients. Proximal muscle weakness and elevated CK, suggestive of myositis, may be accompanied by signs of neuropathy. ^[121]

Diffuse fasciitis presents acutely, usually after a short prodromal period with low-grade fever, myalgias, and fatigue. Thickening of the subcutaneous tissues ensues, sparing the face, with pitting edema of involved areas. Over the next weeks there may be limitations of movement of the small joints and to a lesser degree of large joints. Proximal and distal muscle weakness has been described in a few patients. Spontaneous remissions are common, and a rapid response to treatment is a rule. ^[121]

EMS begins insidiously, with severe fatigue and myalgias. Low-grade fever, transient maculopapular rash, muscle pains, and cramps and weakness of the extremities with or without paresthesias may all be part of the syndrome. The features of the syndrome in a given patient will vary depending on whether fasciitis, myositis, peripheral neuropathy, or mixed features predominate. ^[121] There are some vague reports of an acute encephalopathy at presentation. ^[122] Cognitive changes have been described 1 to 23 months after the acute syndrome. Objective neurocognitive changes were present in almost two thirds of those with

subjective complaints of mental difficulties. Affected were verbal and visual memory, conceptual reasoning, and motor speed. No risk factors for the development of cognitive changes have been identified, and the pathogenesis of these changes remains unknown. ^[122] Proposed mechanisms include a direct toxic effect, eosinophil-derived neurotoxin or major basic protein, and effects of cytokines. ^[122]

Differential Diagnosis. Other conditions usually considered with this group of diseases are other autoimmune or inflammatory states such as polyarteritis nodosa, rheumatoid arthritis, allergic granulomatosis, hypersensitivity vasculitis, scleroderma, or parasitic infections. History, organ involvement, serologic studies, and tissue biopsy may be necessary to distinguish among these conditions.

Evaluation. In eosinophilic myositis, the severity of peripheral blood eosinophilia is helpful in terms of diagnosis and reflects the severity of tissue eosinophilic inflammation. RF may be present, a feature that does not occur with eosinophilic fasciitis or EMS. ESR is often moderately elevated in all of these states. Serum CK, EMG, and muscle biopsy aid in the diagnosis of eosinophilic myositis. The serum CK is often elevated with true myositis, but may be normal in eosinophilic fasciitis. In EMS and in toxic oil syndrome the CK is normal or only slightly elevated.^[121]

The EMG reveals a myopathic pattern with eosinophilic myositis. There have been reports of myopathic changes in EMS and eosinophilic fasciitis, but this is less common. When peripheral neuropathy is associated with eosinophilic myositis, EMG may demonstrate axonal or demyelinating lesions.^[121]

In EMS, one should be aware of potential signs of cognitive dysfunction and differentiate them from fatigue or depression. If there is a question of an encephalopathy, neuropsychological testing is recommended with follow-up assessments. The cognitive changes in EMS may begin or progress while other symptoms and signs of the syndrome are improving.^[122]

Management. Treatment of eosinophilic myositis is initiated with high-dose prednisone at 1 mg/kg/d. With control of the symptoms and peripheral blood eosinophilia, gradual reduction of dose on an alternate-day regimen can be initiated. Cytotoxic agents may be of benefit if steroid doses remain high or if it is mandatory to reduce the steroid dose because of side effects. Improvement of survival has resulted.^[121]

Eosinophilic fasciitis often will improve spontaneously, but resolution is faster with corticosteroid treatment. Relapses are infrequent. Although the treatment and resolution are in most cases good, the acute phase of the illness can be complicated by aplastic anemia, and either amegakaryocytic or idiopathic thrombocytopenia. Delayed lymphoproliferative disorders have also occurred.^[121]

There are no specific recommendations on the treatment of EMS other than cessation of the inducing agent. Corticosteroids may induce clinical improvement and remission of eosinophilia. The drugs should be tapered after clinical benefit is maintained.^[123] Beneficial responses to other medications have been reported, but the number of patients is too small to draw significant conclusions.^[123]

Prognosis and Future Perspectives. In a 1982 study of 57 patients with hypereosinophilic syndromes, the average survival was 9 months, with 12 percent of patients surviving 3 years.^[121] Eosinophilic fasciitis has a good prognosis with spontaneous recovery or response to corticosteroids in most patients. Occasional patients develop recurrence of fasciitis or secondary myeloproliferative disorder.^[121] In a follow-up of over 200 patients with EMS, at 18 to 24 months, almost all of the symptoms and signs of the syndrome had improved or resolved completely.^[123] Neurocognitive deficits and peripheral neuropathy are less likely to respond to therapy.^[123]

With the exception of EMS, the pathogenesis of these syndromes is unclear, and directing more specific therapies is difficult. The hypereosinophilic syndromes in particular are associated with a high morbidity and mortality despite treatment with nonspecific immunosuppressives. The identification of the driving force behind these inflammatory states will likely lead to novel approaches to influence the effects of these diseases, probably at the level of the cytokines and their regulatory effects.

Inclusion Body Myositis

Pathogenesis and Pathophysiology. The specific hallmarks of inclusion body myositis (IBM) are inflammation, vacuolated muscle fibers, intracellular amyloid deposits, and 15 to 18 nm tubulofilamentous inclusions. Although there are familial forms of this disease, either autosomal dominant or recessive, inflammation is only rarely seen in those cases,^[124] and, therefore, the familial forms are best referred to as inclusion body myopathies.

The inflammatory cells that are present in affected muscle are mostly CD8⁺ lymphocytes or macrophages expressing MHC II surface markers. These findings suggest a directed response against specific antigens and a role of immune-mediated cytotoxicity. In addition, there are changes in the mitochondria and the nuclei of the myofibers, amyloid protein, and abnormally present filaments that suggest a possible "neurodegenerative" pathogenic mechanism. It is also suggested that the expression of an abnormal gene product may lead to a cytodestructive process and help explain the inflammatory and neurodegenerative evidence.^[124]

Epidemiology and Risk Factors. IBM is the most common inflammatory muscle disease occurring over the age of 50.^[125] Patients are greater than 30 years of age and usually greater than 50 at the time of onset of symptoms. Men are more often affected than women in contrast with other autoimmune and inflammatory diseases.^[126] There are no known risk factors other than genetic risk in those families with a history of IBM.

Clinical Features and Associated Disorders. The clinical weakness of IBM may resemble that of PM or DM, but more typically evolves over years and resembles a limb-girdle dystrophy. Distal weakness is common and dysphagia occurs in as many as 60 percent of patients. The weakness and atrophy may be asymmetrical and involve solitary muscles such as the quadriceps, iliopsoas, biceps, or triceps. Over years, there is more symmetry and weakness of the involved muscles. IBM is suspected when a patient with the diagnosis of PM does not respond to corticosteroid therapy, has early involvement of distal muscles such as

long-finger flexors of the hand and wrist, and extensors of the foot, or has dysphagia.^[125] Unlike other inflammatory myopathies, patients with IBM do not have an increased risk of malignancy.

Differential Diagnosis. As alluded to above, the other diagnoses to consider in these patients are PM, DM, or a myositis as the result of another systemic illness. With an earlier and gradually progressive onset, there may be features in common with limb-girdle muscular dystrophy. If there is focal atrophy or weakness, the possibility of a mononeuropathy or plexopathy should be considered. These can be differentiated with electrodiagnostic testing. The lack of respiratory involvement, EMG features, and slow course differentiate IBM from motor neuron disease.

Evaluation. As in DM and PM, the diagnosis of IBM relies on the assessment of CK, electromyography, and most important, muscle biopsy. Suggested diagnostic criteria are listed in [Table 50-7](#).^[124] CK levels are often mildly elevated but should be less than 12 times normal.^[124] Electromyography may show fibrillation potentials, positive sharp waves, complex repetitive discharges, and a mixture of myopathic, normal, and neurogenic motor units. These findings are not specific to the diagnosis of IBM, though short- and long-duration polyphasic potentials may be more prominent in IBM than other myopathies.

TABLE 50-7 -- CHARACTERISTIC FEATURES AND DIAGNOSTIC CRITERIA FOR INCLUSION BODY MYOSITIS

CHARACTERISTIC FEATURES

Clinical

Duration of illness >6 months

Age of onset >30 years old

Weakness of proximal and distal arm and leg muscles and must include at least one of the following features: Finger flexor weakness Wrist flexor > wrist extensor weakness Quadriceps muscle weakness (= or < grade 4 MRC)

Laboratory

Serum creatine kinase <12 times normal

Muscle biopsy:

Inflammatory myopathy characterized by mononuclear cell invasion of non-necrotic muscle fibers

Vacuolated muscle fibers

Intracellular amyloid deposits or 15-18 nm tubulofilaments by electron microscopy

Electromyography consistent with inflammatory myopathy

DIAGNOSTIC CRITERIA

Definite inclusion body myositis

Patients must exhibit all of the muscle biopsy features including invasion of non-necrotic fibers by mononuclear cells, vacuolated muscle fibers, and intracellular (within muscle fibers) amyloid deposits or 15-18 nm tubulofilaments

None of the other clinical or laboratory features are mandatory if the muscle biopsy features are diagnostic

Possible inclusion body myositis

If the muscle shows only inflammation (invasion of non-necrotic muscle fibers by mononuclear cells) *without* other pathologic features of inclusion body myositis, *then* a diagnosis of possible inclusion body myositis can be given if the patient exhibits the characteristic clinical and laboratory features

Modified from Griggs RC, Askanas V, DiMauro S, et al: Inclusion body myositis with IVIg: a double-blind, placebo-controlled study [see comments]. *Neurology* 1997; 48:712-716.

Muscle biopsy alone can make the diagnosis of IBM but may not always show the typical pathologic features of the disease, even in patients with clinically typical presentations. Additional sections, additional stains (i.e., Congo red to assess for amyloid deposits), or another biopsy may increase this yield. ^[124]

Management. IBM is generally resistant to all therapies, but a trial of corticosteroids and one aggressive immunosuppressive agent is probably reasonable. Although initial reports suggested IVIg was useful in IBM, subsequent studies, including one with placebo control, have shown response in only about one third of patients. ^[124], ^[125] IVIg is given in a dose of 2 g/kg divided over 2 to 5 days followed by monthly maintenance therapy. Adverse events such as fever, rash, and pruritus can be relieved by slowing the infusion rate or prevented by pretreatment with acetaminophen and diphenhydramine. Anaphylactic reactions to the small amount of IgA contained in IVIg have been reported in patients with congenital IgA deficiency. There is no way to predict a positive response to therapy, and whether the potential benefits warrant the high cost of IVIg remains unclear. ^[125], ^[126]

Prognosis and Future Perspectives. Despite treatment, IBM is typically a slowly progressive disease. Further studies with currently available agents may require larger numbers of patients and a longer duration of treatment to demonstrate a clear pattern of benefit or predict which subset of patients may respond. A better understanding of the etiologic mechanisms of the unusual constellation of pathologic findings will likely tailor new approaches to treatment.

Behcet's Disease

Pathogenesis and Pathophysiology. In 1937, Hulusi Behcet (1889-1948), a Turkish dermatologist, described the syndrome that bears his name. Behcet's disease (BD) is a relapsing inflammatory disorder without a defined cause. It may be a viral or autoimmune disorder, although familial cases and an association with HLA-B5 and HLA-B1 support a genetic role. ^[127], ^[128] Although it was previously thought to be a hypercoagulable state, elevation of procoagulant factors such as aPL is now known to be a secondary feature of the syndrome. ^[128] Pathologically, there is infiltration of smaller venules with lymphocytes and plasma cells, disrupted architecture of vessels, and occlusion with fibrin to fibrotic replacement, depending on the age of the lesion. There may be involvement of larger arteries or veins resulting in thrombosis, aneurysm formation, or hemorrhage. ^[128]

Epidemiology and Risk Factors. The syndrome occurs with a prevalence of about 1 in every 16,000 to 20,000, although more aggressive ocular disease tends to occur in Japan and Mediterranean countries. ^[128] Although children may be affected, mean age of onset is in the third decade. Neurological signs may occur at presentation, but more typically occur several years later. ^[129] It is unclear if there are risk factors independent of genetic predisposition.

Clinical Features and Associated Disorders. The cardinal features of BD are uveitis or retinitis, oral aphthous

ulcers, genital ulcers, and recurrent skin lesions. Three of the four cardinal features are necessary to make the diagnosis. ^[129] Ocular signs include uveitis and vitritis, which are often present bilaterally, hypopyon, and vasculitis of the retinal vessels, sometimes with permanent visual loss. ^[128] Skin lesions include small, oval to round buccal and genital aphthous ulcerations, erythema nodosum, and pustules. Patients may have pathergy, the delayed development of a pustular or nodular skin reaction at the site of needle puncture. ^[128] A polyarteritis may occur, and larger arteries or veins may be affected, producing superior or inferior vena cava syndrome, intermittent claudication, edema, pulmonary infarct or fistula, or myocardial infarction. ^[128] Although nervous system involvement occurs in up to 33 percent of patients with BD, it is not a defining criterion for the disease. ^[130] Meningoencephalitis or aseptic meningitis may present subacutely with chronic headache and lymphocytic pleocytosis. ^[129] Vasculitis of venules or veins may cause significant thrombosis. In a prospective study of 31 patients with BD and neurologic involvement, 10 patients had intracranial venous thrombosis. All had intracranial hypertension, but only two had focal neurologic deficits. ^[130] Angiography may confirm a suspected thrombosis that is not visualized by MRI, or be performed in the appropriate setting if MRI is not available. Focal brain lesions account for over one third of the neuro-Behcet's cases. Headache, hemiparesis, ataxia, pseudobulbar palsy, and dementia can be seen. In most cases, the clinical abnormality will correlate with lesions seen on neuroimaging studies. Focal lesions in BD are usually multiple and may involve gray or white matter, deep gray nuclei, brain stem, cerebellum, or spinal cord. ^[130] CSF studies typically show lymphocytic pleocytosis and elevated protein, with normal glucose but may be normal despite grossly abnormal MRI studies. ^[130] Serial CSF studies may be intermittently abnormal regardless of CNS disease activity. ^[129] Normal CSF can occur in the presence of significant neuroimaging abnormalities.

Differential Diagnosis. Other diagnostic considerations include inflammatory conditions or systemic infections such as systemic lupus erythematosus, polyarteritis nodosa, and bacterial endocarditis. The presence of arthritis may lead to the diagnosis of rheumatoid arthritis or postviral polyarthritis. Prominent neurologic signs suggest other conditions including meningitis, encephalitis, stroke, and multiple sclerosis. Meningitis can be caused by bacterial or viral infection, drugs (i.e., ibuprofen, trimethoprim), or can be recurrent Mollaret's meningitis. Focal brain lesions may resemble those of multiple sclerosis or be radiologically identical to other vasculitic syndromes. ^[130]

Evaluation. Since there is no definite test to confirm the diagnosis of BD, the constellation of symptoms and signs over time allows the diagnosis to be made. A thorough history, physical examination, and review of previous symptoms are required. ESR is likely to be elevated if there is large-vessel vasculitis but may be normal if the only evidence of disease is uveitis. Fibrin split products and platelet count may be elevated. aPL are present in 15 to 35 percent of patients. ^[128] These changes are felt to be secondary effects of the inflammatory process.

Skin manifestations may lead to a diagnostic skin biopsy in patients with accessible lesions. Only occasionally is vasculitis proven, however. There is often infiltration of the dermis with lymphocytes and plasma cells, and deposits of IgM and C3 sometimes occur in cutaneous vessels. ^[128] A test for pathergy can be done by making a few sterile puncture sites in the forearm. Formation of nodule or pustule supports the diagnosis of BD; however, the absence of pathergy does not exclude BD as a potential diagnosis. ^[128] Visual complaints should be evaluated by an ophthalmologist to prevent morbidity owing to visual loss. Neurologic evaluation is guided by the clinical presentation of the patient. MRI is superior to CT in detection of BD-related lesions. ^[130] T2-weighted MRI images may show multiple high-intensity lesions. Lesions occur in the cerebral white matter (70 percent), brain stem (60 percent), and deep gray matter (40 percent). They may be confluent and more extensive than suspected clinically. They do not have a predilection for the periventricular white matter. A lumbar puncture with assessment of opening pressure will identify those cases of intracranial hypertension secondary to venous thrombosis and confirm the presence of meningitis or meningoencephalitis. ^[130] CSF pleocytosis may range from zero to 850 cells/ml (mean, 82), with the percentage of lymphocytes ranging from 25 to 100 (mean, 63), protein ranging from 16 to 101 mg/dl (mean, 43), and glucose ranging from 40 to 89 mg/dl (mean, 59). ^[129] Blood-brain barrier function may be abnormal as measured by the albumin ratio of CSF to serum; oligoclonal bands may be demonstrated. ^[131]

Management. Corticosteroids palliate inflammation at any disease stage by reducing the current vascular inflammation. ^[128] Therefore, their use is justified during disease activation. However, corticosteroids are not effective in the prevention of blindness or the morbidity and mortality that can be associated with neurologic sequelae. ^[128] Other agents (e.g., alkylating agents) are needed in the long-term management of the disease to prevent or reduce significant morbidity.

Chlorambucil is helpful in controlling uveitis or meningoencephalitis. The dose is 0.1 mg/kg/d with gradual reduction in the dose if the disease remains controlled. Prolonged treatment at doses of 2 to 4 mg/d may be required to keep control. Routine blood counts should be followed, and the risk of sterility is a factor if treatment continues longer than 1 year. ^[128] Cyclosporine at 6 mg/kg/d is tried if chlorambucil is ineffective or not tolerated. Monitoring of routine blood counts, blood urea nitrogen, creatinine, and cyclosporine levels is necessary owing to the renal disease that can result from cyclosporine. ^[128] Azathioprine, methotrexate, and colchicine

(which is widely used in Japan) may also be effective. The treatment of major vessel occlusion is not clearly agreed upon. Treatment with prednisone and an alkylating agent should be initiated. Anticoagulation has been shown useful in patients with intracranial venous infarction,^[130] although this treatment should be avoided in patients with pulmonary vasculitis.^[128] Low-dose aspirin may reduce secondary thrombosis without significantly increasing the bleeding risk.^[128]

Prognosis and Future Perspectives. Mucocutaneous lesions can exist for years without substantial morbidity or mortality. Ocular and neurologic involvement, however, can lead to significant disability or mortality. Appropriate evaluation

102

and prompt treatment reduce this morbidity.^[128] After several years, most patients enter a period of relative disease inactivity and are less prone to complications as a result.^[128]

Disorders due to head, spine, and peripheral nerve injuries are among the most commonly seen by neurologists. The impact of these injuries can be devastating for individuals and society, because injuries occurring in a fraction of time can result in death or lifelong impairments associated with chronic pain syndromes. Motor vehicle accidents continue to be a leading cause of neurological trauma despite efforts at primary prevention. Although some neurological injuries such as those due to gunshot and stab wounds reflect a violent society, others, like a lightning strike, are random and capricious. Basic and clinical neuroscience research is directed toward prevention and better treatment of traumatic neurological injury.

ACUTE HEAD INJURY

Pathogenesis and Pathophysiology. Head injury (HI) accounts for a disproportionate share of morbidity and mortality in traumatized patients. The past two decades have witnessed a significant decline, however, in overall HI mortality from the mid-30 percent range in the 1970s to less than 20 percent in the 1990s. This improvement has paralleled an understanding of the secondary injury process and an appreciation that all neurological damage does not occur at the moment of insult but evolves over the ensuing hours and days from various biochemical and molecular derangements. This understanding has led to the development of aggressive treatment strategies to prevent intracranial pressure (ICP) elevations and ischemia. This understanding has led also to extensive clinical therapeutic trials to identify pharmacological neuroprotective agents. The structural injury to the brain at the time of impact is rarely the sole determinant of outcome. Hypoxia, hypotension, mass lesions, increased ICP, ischemia, free radical production, excitotoxicity, and loss of calcium homeostasis are also important.

The frequent occurrence and deleterious effects of the secondary insults of hypoxia and hypotension have long been known.^[1]^[2] Mortality is doubled when these insults are superimposed on severe HI ([Fig. 51-1](#)), and, similarly, concomitant elevated ICP increases morbidity.^[3] Considerable research has focused on the biochemical and molecular mechanisms of secondary injury. Although these events are multifactorial and interrelated, their timing sequence justifies consideration of each component ([Fig. 51-2](#)).

The contribution of oxygen free radicals to secondary injury following HI is a subject of active research.^[4]^[5] Free radicals generated by HI, including superoxide, hydroxyl, hydrogen peroxide, singlet oxygen, nitrous oxide, have the potential to damage proteins and the phospholipid components of cells and organelle membranes. Additionally, extensive membrane depolarization, induced by trauma, allows for a nonselective opening of the voltage-sensitive calcium channels and an abnormal accumulation of calcium within neurons and glia. Such calcium shifts are associated with activation of lipolytic and proteolytic enzymes, protein kinases, protein phosphatases, dissolution of microtubules, and altered gene expression.^[6] Another method of abnormal calcium influx is via activation of excitatory amino acid receptors such as glutamate and aspartate. Excitotoxicity occurs in a widespread fashion after trauma, resulting in cell swelling, vacuolization, and death.^[7]

Head injury can result in various types of primary injury occurring at the moment of impact including lacerations of the scalp, skull fractures, cortical contusions and lacerations, diffuse axonal injury, and intracranial hemorrhage. A coup contusion occurs at the site of impact in the absence of a fracture. A contrecoup contusion occurs in the brain diametrically opposite the point of impact. Acceleration/ deceleration forces may cause tearing of nerve fibers at the moment of impact, which is called *shearing injury* or *diffuse axonal injury*. Types of intracranial hematomas include extradural, subarachnoid, subdural, and intracerebral hematomas.

Epidemiology and Risk Factors. Closed HI leads to

Figure 51-1 Influence of hypoxia and hypotension on mortality after head injury.

500,000 hospitalizations per year resulting in over 175,000 deaths and significant disability. Although the statistics are somewhat variable, it is estimated that the incidence of HI currently approaches 222 in 100,000 population per year.^[8] The peak incidence occurs in men 15 to 24 years of age. Whereas motor vehicle accidents still account for the majority of injuries, the increasing mandate for seatbelt use and availability of airbags appear to be reducing injuries. The incidence of penetrating HI from gunshot wounds is ever increasing, and in some urban communities it is now the most common type of injury seen.

A number of classification schemes have been developed for assessment of neurological damage after HI. The most reliable scheme, from a clinical and prognostic standpoint, is based on the Glasgow Coma Scale (GCS):

GCS 3-7 Severe

GCS 8-12 Moderate

GCS 13-15 Mild

Mild HI is termed a *concussion*. Concussions are infrequently associated with structural brain injury and rarely lead to significant long-term sequelae. The postconcussion syndrome is distinct. Attention to neuropsychological testing has shown the possibility of significant cognitive disability following a concussion.^[9] Moderate HI may be associated with significant structural injury such as hemorrhage or contusion, but death is uncommon. Severe HI generally results in some form of cognitive and/or physical disability or in death, especially with very low GCS scores.

Figure 51-2 Biochemical/molecular substrates of the secondary injury cascade.(From Salaman M: *Current Techniques in Neurosurgery*, 2nd ed. Philadelphia, Current Medicine, 1993.)

The accurate classification of HI is critical in both triage and management. Severe HI should be treated at facilities with appropriate neurotrauma resources, whereas moderate HI requires close clinical observation for possible neurological deterioration. In the setting of mild HI, the most important management issues are related to the need for computerized tomographic (CT) scanning, possible inpatient observation, and appropriate follow-up.

Clinical Features and Associated Disorders. HI is frequently associated with skull fracture, and the significance of the fracture depends on the type of head injury. When associated with severe HI, linear fractures have little practical significance, whereas with mild HI, the presence of a skull fracture increases the risk of an intracranial abnormality by as much as four-fold.^[10] Basilar skull fractures may be complicated by cerebrospinal fluid (CSF) leak, infection and/or cranial nerve palsies. Patients with basilar skull fractures generally deserve closer clinical monitoring than those with linear skull fracture. In infants and young children, however, linear fractures may be complicated by leptomeningeal cysts or "growing" skull fractures. When such lesions occur, a mass may develop over the fracture site as CSF collects from a disruption of arachnoid integrity underlying the injury. Cysts always require surgical correction; it is important to follow young children for several months for this possible occurrence.

Infrequently, blunt trauma to the head can tear the middle meningeal artery, diploic veins, or the dural sinuses, resulting in a collection of blood in the epidural space, which is an epidural hematoma. Epidural hematomas are associated with a skull fracture in 85 percent of cases. They most commonly occur in the temporal region, although they can also occur in other locations such as the frontal or parietal regions or within the posterior fossa. The classically described lucid interval associated with this entity is rarely seen because most patients are unconscious from the time of injury. Examination of the head may reveal a laceration and skull fracture over the region of the hematoma. If uncal herniation (that is, herniation of the mesial temporal lobe) occurs from mass effect, findings may include an ipsilateral third nerve palsy and contralateral hemiparesis. An ipsilateral hemiparesis can occur as a result of compression of the contralateral cerebral peduncle against the edge of the tentorium. Most epidural hematomas require immediate

surgical intervention; however, there are exceptions, particularly in alert pediatric patients.^[11]

Acute subdural hematomas occur in approximately 20 percent of patients with severe HI. Impact injury to the brain can rupture the parasagittal bridging veins (which drain blood from the surface of the hemisphere into the dural venous sinuses) leading to hematoma formation within the subdural space. Subdural hematomas can also occur without head injury in patients with a coagulopathy or on anticoagulants. Subdural hematomas can also be due to rupture of cerebral aneurysms. Subdural hematomas are usually located over the hemispheres, although other locations such as between the occipital lobe and tentorium cerebelli or between the temporal lobe and base of the skull can occur. About 50 percent of patients with acute subdural hematomas are unconscious from the time of injury. Focal findings can occur because of herniation, as described for epidural hematomas. Surgery within the first 4 hours from injury is generally associated with improved outcome; however, this

basic tenet of HI management has been challenged.^{[12], [13]}

A subdural hematoma becomes subacute between 2 and 14 days after the injury when there is a mixture of clotted and fluid blood. A subdural hematoma becomes chronic when the hematoma is filled with fluid more than 14 days after the injury. Most patients with chronic subdural hematomas are late middle age or elderly. Up to 50 percent of those with chronic subdural hematomas, however, have no history of head injury. Patients with chronic subdural hematomas may have multiple types of presentations such as the following: headache and nausea without focal findings; a slow progression of focal signs; altered mental status, apathy, and unsteady gait; an acute focal neurological deficit; fluctuating neurological deficits that may clear; and seizures. Thus, it is easy to see how the various presentations of chronic subdural hematoma can lead to misdiagnoses such as stroke, transient ischemic attack, brain tumor, depression, and dementia. Although occasionally chronic subdural hematomas can be treated with diuretics and corticosteroids, symptomatic patients generally require surgery.

Cerebral contusions are frequently associated with intracranial mass lesions, although they may occur as a result of the coup-contrecoup phenomenon, especially in the temporal and inferior frontal regions. The clinical presentation depends upon the location and severity of the contusion and whether other lesions are present. Patients with small focal contusions can present with speech or motor deficits, whereas larger contusions can act as a mass lesion. Contusions themselves rarely require surgical intervention; however, they necessitate careful clinical and CT follow-up because they may evolve into delayed post-traumatic intracerebral hematomas.^[14]

Diffuse axonal injury (DAI) is a frequent CT and pathological correlate of severe head injury, accounting for about 50 percent of primary brain injuries. DAI is usually associated with a poor outcome.^[15] DAI is readily identifiable on CT as multiple punctate hemorrhages, typically in the deep white matter and corpus callosum and occasionally in the brain stem. DAI may also occur as a result of mild head injury and may culminate in subtle types of cognitive deficits.

Approximately 10 to 15 percent of patients with clinically severe HI have a normal CT scan. In such situations, the possibility of extracranial or intracranial vascular disruptions must be considered, and angiography should be considered. Occasionally, magnetic resonance imaging (MRI) may demonstrate lesions not appreciated on CT in this setting.

Approximately 5 to 10 percent of patients with severe HI have an associated spine and/or spinal cord injury. Initial HI evaluation and management thus require simultaneous evaluation and management for potential spinal injuries. The majority of patients with severe HI have multisystem injury. Possibility of other significant and potentially life-threatening injuries should be evaluated and the proper treatment priorities accordingly established.

Multiple medical complications can also occur after HI.^[16] Cardiovascular effects of head injury include neurogenic hypertension and cardiac dysrhythmias. Respiratory complications such as neurogenic pulmonary edema, aspiration pneumonia, and pulmonary emboli usually caused by deep venous thrombosis are rather common. Other complications include disseminated intravascular coagulation, hyponatremia due to the syndrome of inappropriate antidiuretic hormone secretion, diabetes insipidus, and stress gastritis.

Differential Diagnosis. Many nontraumatic disorders may mimic HI including drug or alcohol intoxication, metabolic disturbances, and subarachnoid or other types of intracranial hemorrhages. When an intoxicated person falls or becomes involved in a fight and sustains a head injury, the emergency evaluation can be further complicated. Often, a patient presents after an apparent traumatic event that itself was precipitated by primary underlying intracranial pathology. Examples include the following: a stroke that causes loss of control while driving; a generalized seizure resulting in a head injury; a gait disturbance (due to Parkinson's disease, diabetes with a sensory ataxia, cervical spondylitic myelopathy, and others) causing a fall and an HI; and delirium or dementia as a cause of the fall. The physician should not only treat the injury but also should try to find out if there is an underlying cause.

Evaluation. The primary evaluation of a patient with HI necessitates a careful neurological evaluation. Because a significant number of these patients have multiple types of trauma, however, systemic evaluation and stabilization take precedence. The ABCs of trauma resuscitation must be followed. As noted previously, correction of hypoxia and hypotension has a significant impact on outcome from HI.

The neurological evaluation of these patients is often complicated by many physical and iatrogenic factors. In comatose patients, a cervical spine series should be performed to exclude fractures before checking the oculocephalic reflex. Severe ocular trauma may obviate examination of pupillary reflexes. Alcohol intoxication and the use of sedatives or muscle relaxants to facilitate patient transport adversely affect the trauma-related neurological findings. Extremity fractures limit the extent of the neurological examination.

The GCS score has been the most reliable indicator of the severity of injury and deterioration or improvement. The initial GCS score often influences early treatment decisions. Thus, an intimate familiarity with the examination essentials to establish the GCS score is important: eye

opening, verbal response, and motor response ([Table 51-1](#)).^[17]

Once the GCS score has been established, a more detailed head and neurological examination can be pursued. A careful examination of the head is essential for findings such as scalp lacerations, skull fractures, blood in the external auditory canal, a hemotympanum, or Battle's sign (ecchymosis of the scalp overlying the mastoid bone). Any laterality to the neurological findings (i.e., a dilated pupil, hemiparesis) suggests a focal mass lesion. The higher the GCS score, the more important a detailed mental status examination becomes in determining management. For penetrating HI and especially gunshot wounds, there must also be a full and

Careful documentation of entry and exit wounds, powder burns, and foreign bodies.

In pediatric patients, the possibility of child abuse must be borne in mind, especially when the primary structural brain injury is subdural hematoma. The *shaken baby syndrome* refers to violent shaking of an infant or small child resulting in retinal hemorrhages and subarachnoid or subdural hemorrhage, but with minimal or no external evidence of severe trauma.^[18] When such concerns arise, there must be a careful systemic survey for evidence of other injuries--retinal hemorrhages, skin bruising, new and old long bone fractures.

The more severe the HI, the greater the urgency for CT scanning as an integral part of initial evaluation to exclude lesions that require neurosurgical intervention. The only exception is when other life-threatening injuries take precedence. With minor HI, CT is not routinely indicated. Similarly, if CT is to be obtained, plain skull radiographs are unnecessary. Additional diagnostic evaluations such as MRI, cerebral angiography, and transcranial Doppler examination may be appropriate depending on clinical and/ or CT findings.

Management. The management of minor HI is primarily directed toward a determination of which patients require CT scanning and/or in-hospital observation. Considerable effort has been expended to determine the risk of deterioration in this group of patients so that appropriate triage protocols may be established. A meta-analysis of a large number of series indicates that approximately 2.5 percent of patients presenting to an emergency room with minor HI require neurosurgical intervention.^[19] This observation has led to current recommendations that only patients with GCS scores of 15 be discharged without prior CT scanning. Risk factors that must be taken into consideration when making this determination include palpable depressed skull fracture, seizures, extremes of age, persistent headache or vomiting, therapeutic anticoagulation, and suspected abuse. Unless there are significant associated extracranial injuries, it is rare for a minor HI to necessitate more than 24 hours of hospital observation.

Moderate HI is generally associated with significant symptoms and/or findings and necessitates CT scanning and hospitalization for serial neurological monitoring. Repeat CT scanning is indicated if there is any deterioration in neurological functioning. Delayed hematomas are occasionally seen after moderate HI. These usually represent bleeding into areas of contusion not well visualized initially, and patients typically present 24 to 48 hours after injury.^[20]

The management of severe HI requires intensive support and monitoring. Because all patients are comatose, intubation and artificial ventilation are mandatory. Blood pressure monitoring and support are crucial to prevent hypotension. Monitoring via Swan-Ganz catheterization may be helpful to maximize perfusion. The first priority is complete and rapid physiological resuscitation. Hypotension (systolic blood pressures less than 90 mm Hg) and hypoxia (PaO₂ less than 60 mm Hg) should be avoided if possible and corrected if present.

The institution of intracranial pressure monitoring remains somewhat controversial; however, ICP monitors are appropriate in this setting and provide the most reliable guide to treatment of the underlying brain injury. Because elevation of ICP more than 20 mm Hg is a significant predictor of a poor outcome, an appropriate threshold to begin aggressive ICP treatment appears to be 20 to 25 mm Hg.^{[3], [21]}

Considerable interest has been focused on cerebral perfusion pressure (CPP) in treating severe HI.^[22] CPP is determined by subtracting the ICP value from mean arterial blood pressure and represents the pressure driving cerebral blood flow. Thus, CPP and cerebral blood flow can be positively affected by either lowering ICP or elevating systemic blood pressure. It is generally believed that active attempts to maintain CPP above 70 mm Hg improves outcome.

The primary treatments for elevated ICP have traditionally included hyperventilation, diuretics, and, in extreme circumstances, barbiturates. If an ICP monitor is in place, the drainage of CSF may have significant therapeutic benefits. Care must be taken if hyperventilation is implemented, because the cerebral vasoconstriction induced may produce ischemia. Thus, PaCO₂ levels lower than 25 mm Hg are rarely indicated. Mannitol is the primary diuretic used to control ICP. Effective doses range from 0.25 to 1.0 g/kg, which are typically given as intermittent boluses. Care must be taken to prevent hypernatremia and hyperosmolarity when giving frequent boluses.

High-dose barbiturate therapy is generally reserved for those situations in which ICP becomes refractory to other available therapies.^[23] Many potential complications, including cardiovascular instability, are associated with barbiturate

TABLE 51-2 -- WHEN TO RETURN TO PLAY AFTER REMOVAL FROM CONTEST

Grade of Concussion	Time Until Return to Play*
Multiple Grade 1 concussion	1 week

use, however, and extremely careful monitoring is necessary. Although steroids have been often used to treat severe HI, there are no data to support their use to either control ICP or to affect of long-term outcome.^[24] Their current use in this setting is thus usually discouraged.

Research has focused on attempting to identify neuroprotective agents to ameliorate secondary injury and thus improve outcome from severe HI. Two large-scale prospective randomized trials of the free radical scavengers, tirilazad mesylate and polyethylene glycol-superoxide dismutase (PEG-SOD), have been reported to show no significant reduction in mortality or outcome.^[25] There are ongoing trials with *N*-methyl-D-aspartate (NMDA)-receptor antagonists in an attempt to limit excitotoxicity. A recent randomized controlled trial reported by Marion and colleagues^{23a} demonstrated that moderate hypothermia for 24 hours in patients with severe traumatic brain injury and coma scores of 5 to 7 on admission hastened neurological recovery and may have improved the outcome.

Prognosis and Future Perspectives. Minor HI is rarely associated with significant long-term sequelae. It is well established, however, that a significant minority of patients suffer chronic disability attributable to neurobehavioral sequelae.^[26] The exception to this is sports-related minor HI in which death from the second impact syndrome or cognitive disability from cumulative concussions may occur.

Second impact syndrome refers to malignant cerebral edema resulting from relatively mild head trauma occurring after a recent concussion. The syndrome is believed to be due to impaired cerebral autoregulation. It has been

TABLE 51-3 -- CURRENT PROGNOSIS FROM SEVERE HEAD INJURY

Data from Young B, Runge JW, Waxman KJ, et al: Effects of pegorgotein on neurologic outcome of patients with severe head injury. JAMA 1996;276:539-543.

well documented that fatal brain swelling may occur in the setting of one minor HI followed in short order by a second minor HI in athletes who are still symptomatic from the first injury.^[27] The cumulative effects of multiple minor HIs is recognized in boxing as the *punch drunk syndrome* (see later); however, the occurrence of this syndrome in association with other sports is controversial.

For sports-related minor HI, the American Academy of Neurology has defined three grades of concussion and recommended guidelines for return to play.^[28] For Grades 1 and 2, there is transient confusion and no loss of consciousness. Resolution of concussion symptoms or mental status abnormalities occurs in less than 15 minutes in Grade 1 and more than 15 minutes in Grade 2. Grade 3 concussion is any loss of consciousness. Players with Grade 1 concussion may return to play the same day if they have a normal sideline neurological assessment including a detailed mental status examination. Players with Grade 2 and 3 concussions should not return to play the same day. Guidelines for return to play after removal from the contest ([Table 51-2](#)) are necessary because of concern over the cumulative effects of even mild head injury and the rare occurrence of second impact syndrome.^[29]

Dementia, long recognized as a sequela of multiple head injuries in boxing, was termed *punch drunk* by Martland in 1928 and *dementia pugilistica* by Millspaugh in 1937. Neuropathological study of brains of boxers with dementia pugilistica demonstrate beta-amyloid protein-containing diffuse plaques and neurofibrillary tangles, which are pathological features of Alzheimer's disease. Increased expression of beta-amyloid precursor protein is part of an acute-phase response to neuronal injury, which can lead to deposition of beta-amyloid protein.^[30]

Patients with moderate HI usually experience both cognitive and physical disabilities and typically require rehabilitation services after acute hospitalization. Nevertheless, the incidence of severe long-term disability is small.

In contrast, few patients with severe HI recover completely to their preinjury state. The most common system to rate recovery is the Glasgow Outcome Scale: Good Recovery (GR), Moderate Disability (MD), Severe Disability (SD), Vegetative (V), and Death (D).^[31] The tirilazad mesylate and PEG-SOD trials provide excellent information on current severe HI outcomes ([Table 51-3](#)).

POSTCONCUSSION SYNDROME

Sequelae of mild head injury have been recognized for the last few hundred years.^[32] In 1866, Erichsen initiated the

1540

controversy with his description of patients with persistent complaints after mild head and neck injury due to "molecular disarrangement" of the spinal cord. This condition was known as *railway spine* because many cases were the result of railway accidents. Rigler introduced the concept of compensation neurosis in 1879, because he believed that many persons with persistent symptoms were trying to obtain financial compensation for the injuries. Charcot believed that the impairment was actually the result of hysteria and neurasthenia. Similar debates about the organicity of persistent complaints after mild head injury are still common today, especially in medicolegal cases. The use of the term *postconcussion syndrome* dates back to 1934.

Pathogenesis and Pathophysiology. Mild head injury may result in cortical contusions due to coup and contrecoup injuries and diffuse axonal injury resulting from shear and tensile strain damage. Subdural and epidural hematomas can also occasionally result. Release of excitatory neurotransmitters including acetylcholine, glutamate, and aspartate may be a neurochemical substrate for mild head injury.

Epidemiology and Risk Factors. Mild head injury accounts for 75 percent or more of all brain injuries. The annual incidence of mild head injury in the United States is about 140 in 100,000 population, with the relative causes as follows: motor vehicle accidents, 45 percent; falls, 30 percent; occupational accidents, 10 percent; recreational accidents, 10 percent; and assaults, 5 percent. Falls are the more likely cause in the elderly, whereas motor vehicle accidents are more common in the young. Men are more commonly injured, with a 2:1 ratio, and about one half of all patients are between the ages of 15 and 34 years. Perhaps 50 percent of patients with mild head injury develop the postconcussion syndrome.^[33]

Clinical Features and Associated Disorders. The postconcussion syndrome, which is usually the result of mild head trauma, comprises one or more of a large array of symptoms and signs ([Table 51-4](#)).^[33] The most common complaints are headaches, dizziness, fatigue, irritability, anxiety, insomnia, loss of concentration and memory, and noise sensitivity. Loss of consciousness does not have to occur for the postconcussion syndrome to develop. Headaches have been estimated to occur in 30 to 90 percent of patients who are symptomatic after mild injury. Headaches may occur more often and with longer duration in patients with mild rather than severe head injury. Tension-type headaches account for about 85 percent of all post-traumatic headaches. Neck injuries, which often occur at the time of the head injury, may cause referred headaches due to myofascial, intervertebral disc, and facet joint injury. Greater occipital neuralgia may occur from a direct blow to the nerve or may be associated with muscle spasm of the superior trapezius and semispinalis capitis muscles in the suboccipital region. Similar headaches may arise from the C2-C3 facet joint, which are known as *third occipital headaches*. Temporomandibular joint injury may also cause tension-type headaches.

Migraine headaches with and without aura can develop in the hours to weeks after a mild head injury. Immediately after mild head injury in sports such as soccer, football, rugby, and boxing, children, adolescents, and young adults may have a first-time migraine with aura. This syndrome

TABLE 51-4 -- SEQUELAE OF MILD HEAD INJURY

Headache types and causes
Muscle contraction or tension type
Cranial myofascial injury
Secondary to neck injury (cervicogenic)
Myofascial injury
Intervertebral discs
Cervical spondylosis
C2-C3 facet joint (third occipital headache)
Secondary to temporomandibular joint injury
Migraine
Without and with aura
Footballer's migraine
Greater and lesser occipital neuralgia
Mixed
Cluster
Supraorbital and infraorbital neuralgia
Due to scalp lacerations or local trauma
Dysautonomic cephalgia
Orgasmic cephalgia
Carotid or vertebral artery dissection
Subdural or epidural hematomas
Hemorrhagic cortical contusions
Cranial nerve symptoms and signs
Dizziness
Vertigo
Tinnitus
Hearing loss
Blurred vision
Diplopia
Convergence insufficiency
Light and noise sensitivity
Diminished taste and smell
Psychological and somatic complaints
Irritability
Anxiety
Depression
Personality change
Fatigue
Sleep disturbance
Decreased libido

Decreased appetite
Cognitive impairment
Memory dysfunction
Impaired concentration and attention
Slowing of reaction time
Slowing of information processing speed
Rare sequelae
Subdural and epidural hematomas
Seizures
Transient global amnesia
Tremor
Dystonia

Modified from Evans RW: Post-concussion syndrome. In Evans RW, Baskin DS, Yatsu FM (eds): Prognosis of Neurological Disorders. New York, Oxford University Press, 1992.

may be triggered multiple times after additional mild head injury and has been termed *footballer's migraine*. Cluster headaches can rarely develop after mild head injury. Various other less common causes of post-traumatic headaches are found, including supraorbital and infraorbital neuralgia, dysesthesias over scalp lacerations, carotid or vertebral artery dissections, and subdural and epidural hematomas (see [Table 51-1](#) . Subdural hematomas can result in headaches that are nonspecific and that can be mild to severe, paroxysmal or constant, and bilateral or unilateral.

Cranial nerve symptoms and signs also occur. About one

half of patients after mild head injuries report dizziness, which can be caused by various types of central and peripheral pathology including labyrinthine concussion, benign positional vertigo, and brain stem injury. Blurred vision, reported by 14 percent of patients, is usually caused by convergence insufficiency. Blurred vision is occasionally the result of III, IV, and VI cranial nerve palsies. Decreased smell and taste are reported by 5 percent of patients after mild head injury; the symptoms can be due to damage to the olfactory filaments. Approximately 10 percent of patients describe light and noise sensitivity after mild head injury.

Nonspecific psychological symptoms such as personality change, irritability, anxiety, and depression are reported by over one half of patients within 3 months of mild head injury. Fatigue and disruption of sleep patterns are also often reported. Post-traumatic stress disorder, which has many symptoms similar to those of the postconcussion syndrome, may occur after mild head injury.

Four weeks after a mild head injury, 20 percent of patients complain of impaired memory and concentration. Neuropsychological testing has documented cognitive impairments including a reduction in information processing speed, attention, reaction time, and memory for new information.

Differential Diagnosis. The incidence of complications that require neurosurgical consultation after mild head injury has been estimated to be between 1 and 3 percent. For adults with mild head injury and an initial GCS score of 13 to 15, the incidence of subdural hematomas is approximately 1 percent and epidural hematomas about 0.5 percent.

Evaluation. Single-photon emission computed tomography (SPECT) and positron emission tomography (PET) scans, brain stem auditory evoked potential studies, and brain mapping currently lack adequate sensitivity and specificity to justify use in the evaluation of the postconcussion syndrome. Electroencephalogram (EEG) studies are usually not indicated except for evaluating post-traumatic seizure disorders. Neuropsychological testing can be quite useful for the evaluation of patients with persistent cognitive complaints.

Management. Treatment should be individualized after the patient's particular problems are diagnosed. Tension- and migraine-type headaches can be treated with the usual prophylactic and symptomatic medications. Greater occipital neuralgia may improve with local anesthetic nerve blocks, which can be combined with an injectable corticosteroid. Physical therapy and transcutaneous electrical nerve stimulators (TENS units) may also help tension-type headaches. For patients with cognitive difficulties, the efficacy of cognitive retraining has not yet been established by prospective studies. Patients with prominent psychological symptoms may benefit from supportive psychotherapy and use of antidepressant and antianxiety-type medications. Simple reassurance is often the major treatment because most patients improve after 3 months. One of the most important roles for the physician is education of the patient and family members, other physicians, and, when appropriate, employers, attorneys, and representatives of insurance companies.

Prognosis and Future Perspectives. The probability of having persistent symptoms and neuropsychological deficits is the same whether a patient is only dazed or loses consciousness for less than 1 hour. Persistent symptoms occur more often in women than men, in patients over the age of 40 years, and in those with a prior history of head trauma. Two years after the injury, about 20 percent of patients still complain of headaches. Cognitive deficits usually resolve within 3 months after the injury, although a small minority of patients report persistent problems for months or years. When patients have unusual or persistent complaints, the possible contributions of personality disorders, psychosocial problems, or secondary gain should be considered.

A compensation case or lawsuit is often filed in circumstances in which another party may be responsible for the head injury, such as a motor vehicle accident or on-the-job injury. In this circumstance, when patients have persistent complaints, many physicians are appropriately concerned about compensation neurosis or malingering being the cause. Patients with claims, however, have similar symptoms that improve with time and similar cognitive test results as those without claims. For many claimants, the end of litigation does not mean the end of symptoms or return to work. They are not cured by a verdict.

CRANIAL NEUROPATHIES

Blunt trauma can result in a stretching injury of cranial nerves, which, when severe, can result in nerves being torn loose from the brain stem. Stretching injuries often occur at points of attachment or at points of angulation. Skull fractures and penetrating trauma such as gunshot wounds can cause nerve lacerations.

Blunt trauma most often damages cranial nerves I, VII, and VIII; less often II, III, IV, and VI; and least often V, IX, X, XI, and XII. The incidence of cranial neuropathies increases with more severe head injury. For example, the overall incidence of anosmia is about 7 percent but increases to 30 percent in patients with anterior fossa fractures or severe head injury. Even trivial head injury can result in anosmia. Injury to the optic nerves and chiasm has been reported in up to 5 percent of patients with head injuries. Ocular motility disorders occur in up to one third of patients sustaining closed head injury; the abducens nerve is the most commonly injured. Trigeminal nerve and branch injuries often occur as a result of facial trauma. Facial nerve injuries frequently occur with temporal bone fractures.

The site of likely trauma, clinical features, evaluation, management, and prognosis are summarized in [Table 51-5](#).

[PreviousNext](#)

POST-TRAUMATIC EPILEPSY

Pathogenesis and Pathophysiology. Post-traumatic seizures may be associated with the typical pathological changes that may be seen in brain injuries including reactive gliosis, axon retraction balls, wallerian degeneration, microglial scar formation, and cystic white matter lesions. [34]

TABLE 51-5 -- A SUMMARY OF TRAUMATIC CRANIAL NEUROPATHIES

Cranial Nerve	Site of Likely Trauma	Clinical Features	Evaluation	Management	Prognosis
I	Any part of head. More common with occipital than frontal trauma	Decreased or absent sense of smell	Check for possible ethmoid fractures, CSF rhinorrhea, and injury to orbital surface of frontal lobes	Educate patient	Resolves in up to 50% of cases, usually during first 3 months but up to 5 years after injury
II	Intracanalicular often Associated with a skull base fracture	Decreased or loss of vision. Scotomas, sector, and altitudinal defects can occur	Check visual acuity, fields, and for afferent pupillary defect. CT scan and ultrasound A and B are useful to assess for possible compressive lesions	Controversial for indirect optic neuropathy: include observation, high-dose steroids, and surgery. Surgical decompression often recommended in cases of delayed onset of visual loss	Extremely variable. Varies from 0-100% depending upon the study
III	Where the nerve enters the dura at the posterior end of the cavernous sinus. Uncal herniation much less common	Dilated pupil and turned out eye present in complete palsy. Anisocoria and diplopia in partial lesions.	CT and/or MRI scans to look for a compressive lesion	Symptomatic such as eyepatch, semitransparent tape to glasses and prisms for diplopia. Muscle shortening procedures may be helpful for permanent diplopia	Recovery begins within 2-3 months when nerve in continuity. Aberrant regeneration often occurs with findings such as lid elevation or pupillary attempted adduction or depression
IV	Stretching or contusion of the nerve as it exits the dorsal midbrain near the anterior medullary velum	Trauma is the most common cause of trochlear palsies. Bilateral palsies are rather common	Same as above	Same as above	Only about 50% recover because of frequent avulsion of the trochlear nerve
VI	As the nerve ascends the clivus, in fractures of the petrous bone along with VII and VIII, in the superior orbital fissure along with III and IV, and in its subarachnoid course due to raised intracranial pressure	Bilateral palsies are rather common	Same as above	Same as above	Recovery often occurs after 4 months
V	Trigeminal nerves and branches are commonly injured with facial trauma, especially supraorbital and supratrochlear nerves. The infraorbital nerve is often injured in orbital floor blowout fractures	Injury to the gasserian ganglion and trigeminal trunk is rare after closed head trauma	Imaging studies to exclude underlying fractures	Decompression of the infraorbital nerve in orbital floor fractures. Symptomatic for hyperpathia due to supra- and infraorbital neuropathies with medications such as carbamazepine, tricyclics, and baclofen	Hyperpathia in the distribution of the nerve may be permanent
VII	Most commonly within the petrous bone but can be injured anywhere along its course	Injured in 50% with a transverse temporal bone fracture. Facial palsy in 25% with a longitudinal fracture, often with a delayed onset	CT scan to evaluate temporal bone trauma. A nerve conduction study 5 or more days after the injury is helpful to assess the degree of nerve injury	Facial nerve decompression is usually indicated for transverse fractures. Artificial tears and eye patch at night to prevent exposure keratitis	Spontaneous recovery usual after longitudinal fractures. When due to transverse fractures, 50% recovery after decompression
VIII	Labyrinthine concussion without a skull fracture is the most common site. Conductive hearing loss follows longitudinal temporal bone fractures in over 50% of cases. Transverse fractures result in vestibular and cochlear nerve laceration in over 80%	Findings associated with a fracture of the petrous portion of the temporal bone include hemotympanum or tympanic membrane perforation with blood in the external canal, hearing loss, vestibular dysfunction, peripheral facial nerve palsy, CSF otorrhea, and ecchymosis of the scalp over the mastoid bone (Battle's sign). Benign positional vertigo occurs in about 25% of patients following head trauma	Examine the external canals and tympanic membranes. An audiogram including pure-tone and speech audiometry, acoustic reflexes, and middle ear function is used to assess hearing loss. An electronystagmogram (ENG) is used to assess vestibular function. CT scan to evaluate temporal bone trauma	A hearing aid may help those with sensorineural hearing loss. Surgical correction is indicated for conductive hearing loss due to ossicular chain disruption. Positioning maneuvers, such as Epley's or Semont's, which move the debris out of the semicircular canal and into the utricle, can be curative for benign positional vertigo	Following temporal bone fractures, patients with low- or high-frequency hearing loss may have some recovery but those with low- and high-frequency loss usually do not recover. Vertigo due to a labyrinth concussion usually resolves within a year
IX, X, XI, XII	Gunshot or stab wounds occasionally cause injury. A fracture of the occipital condyle, Collet-Sicard syndrome, can injure all 4 nerves The peripheral portion of XI can be injured in surgical procedures such as posterior cervical lymph node biopsies. The hypoglossal and recurrent laryngeal nerves can be traumatized in anterior neck operations such as carotid endarterectomy	Lower cranial nerve findings associated with signs of brain stem compression are consistent with an intracranial lesion, whereas the presence of a Horner's syndrome is consistent with an extracranial lesion	A careful clinical examination is mandatory. CT and MRI imaging are both useful, depending upon the case	Treatment of Collet-Sicard syndrome is supportive with elevation of the head for drainage of excess saliva and IV or nasogastric nutrition until normal swallowing returns. Accessory nerve injuries in the neck may require exploration with neurolysis or resection and repair or grafting, depending upon the degree of injury	Collet-Sicard syndrome may show slow partial recovery. Patients with vagal, spinal accessory, and hypoglossal nerve injuries associated with carotid endarterectomy often recover

When a contusion or cortical laceration is present, the breakdown of hemoglobin releases iron. Based on animal and cell culture studies, iron may increase intracellular calcium oscillation and may increase free radical formation through activation of the arachidonic acid cascade producing increased intracellular calcium resulting in excitotoxic damage, neuronal death, and glial scarring, which lead to epileptiform activity.^[35] These findings suggest a possible role for neuroprotective treatment in the future.

Epidemiology and Risk Factors. Head injury is the cause of about 4 percent of all cases of epilepsy. In teenagers and young adults, head injury is the most common cause of symptomatic epilepsy. Post-traumatic seizures can be divided into different types based on the time of onset after the injury. Immediate seizures occur within minutes of the injury. Early seizures occur within 1 week, whereas late seizures occur after 1 week.

The incidence of early post-traumatic seizures is about 4 percent. Early seizure rates are higher in patients with more severe head injuries, intracranial and subdural hematomas, depressed skull fractures, focal neurological signs, loss of consciousness, or post-traumatic amnesia present for more than 24 hours, and in children under the age of 5 years.

Late seizures have an incidence of about 2 percent.^[35] Risk factors for late seizures include penetrating missile wounds; an early seizure; intracerebral, epidural, and subdural hematomas; GCS score of 10 or less; depressed and linear skull fractures; and cortical contusions.

Clinical Features and Associated Disorders. About one third of early seizures occur during each of the following times: within the first hour, between 1 and 24 hours, and between 1 and 7 days. Over 60 percent of early seizures are partial, whereas the others are generalized tonic-clonic. About 10 percent of patients develop status epilepticus.

About 50 percent of patients with late seizures have their first seizure within 1 year of the injury and about 80 percent within 2 years. Over 60 percent of the seizures are generalized tonic-clonic with or without focal onset, whereas the others are simple or complex partial seizures.

Differential Diagnosis. In some cases, post-traumatic seizures must be distinguished from disorders that can result in psychogenic nonepileptic events including conversion, factitious behavior, malingering, reinforced behavior pattern, somatization, post-traumatic stress disorder, hypochondriasis, panic disorder, depersonalization, dissociative disorder, and hyperventilation syndrome. Because mild head injuries uncommonly result in seizures, nonepileptic events should be considered when these patients have "funny spells," or episodes that are atypical for epilepsy.^[36]

Evaluation. A detailed history from the patient and witnesses, if any, of the event, review of pertinent medical records, and general and neurological examination are often the bases for diagnosing post-traumatic seizures. Although an EEG study is certainly important, epileptiform activity is seen in only 50 percent of patients. Video or ambulatory EEG may be worthwhile in occasional cases when the diagnosis is unclear. A CT or MRI scan of the brain may also be indicated.

Management. In patients with risk factors for early seizures, prophylactic treatment with phenytoin reduces the incidence of early seizures. Within the first few weeks, however, phenytoin can be gradually withdrawn because the incidence of late seizures is not reduced by continuing treatment.^[37] Instituting long-term anticonvulsant treatment is beneficial for patients after an initial late seizure.

Prognosis and Future Perspectives. The remission rate for post-traumatic epilepsy is about 50 percent. An EEG is of no specific value in predicting either the development or remission of post-traumatic epilepsy. A greater number of seizures and abnormal findings on neurological examination decrease the chance of remission.

POST-TRAUMATIC MOVEMENT DISORDERS

An association between injuries and involuntary movements has been suggested since the nineteenth century speculation of Parkinson, Charcot, and Gowers. When a movement disorder begins shortly after a brain injury, a cause-and-effect relationship is apparent. An association is less obvious with longer latencies after the injury and after peripheral trauma, however. In some cases, the patient

may not have noticed or reported a mild movement disorder that was present before the injury.^[38], ^[39]

Pathogenesis and Pathophysiology. Direct trauma to subcortical and substantia nigral neurons can result in movement disorders occurring shortly after an injury. Movement disorders occurring months following the injury have been hypothesized to be related to sprouting, remyelination, ephaptic transmission, inflammatory changes, oxidative reactions, and central synaptic reorganization. Peripheral trauma that precedes the development of a movement disorder may alter sensory input, leading to central cortical and subcortical reorganization.^[40]

Epidemiology and Risk Factors. Movement disorders due to trauma are rare, and specific epidemiological and risk factor studies have not been performed.

Clinical Features and Associated Findings. Although head injury does not result in Parkinson's disease with pathological findings of Lewy bodies, head injury may result in a temporary exacerbation of motor function in patients with pre-existing Parkinson's disease.^[38] Parkinsonism is a rare complication of single closed head injuries and may also occur after penetrating bullet and knife injuries of the brain stem. Repeated head injury as in the case of boxers with dementia pugilistica may result in parkinsonism in association with many other neurological signs. Parkinsonian tremor may rarely be associated with peripheral body trauma, although a direct causal relationship cannot be established.^[41]

Postural and kinetic tremor can be due to direct traumatic lesions of the dentatothalamic circuit. Benedikt's syndrome (unilateral third nerve palsy and contralateral ataxic hemiparesis) can be associated with rest and postural and kinetic tremor. Postural-kinetic tremors of the arms, legs, or head may occur within weeks of mild head injury even without loss of consciousness. Peripheral trauma can induce tremor, which can occur along with reflex sympathetic dystrophy, dystonia, and myoclonus.^[41] Myoclonus, dystonia, and athetosis may be present in patients with post-traumatic tremors.

Contralateral dystonia can be due to a lesion in the striatum, particularly the putamen. Causes include perinatal trauma, closed head injury (severe much more often than mild), and thalamotomy. The onset of dystonia may have a latency period from 1 month to 9 years. Spastic dystonia due to pyramidal and extrapyramidal injury and paroxysmal nocturnal dystonia are variants of post-traumatic dystonia. Often patients develop post-traumatic dystonia as a delayed sequela of severe head injury, initially characterized by coma and quadriplegia. After the patient awakens and the plegia improves, severe action dystonia develops. Minor or moderate local peripheral trauma can be associated with focal dystonia, sometimes in patients with reflex sympathetic dystrophy. Examples of peripherally induced dystonia include the following: blepharospasm after surgery on the eyelids; oromandibular dystonia after dental procedures; spasmodic dysphonia after facial injuries; cervical dystonia after neck injuries such as whiplash; and foot dystonia after stubbing a toe.

A recent report by Kraus and colleagues studied survivors of severe HI, admitted to the hospital with GCS of 8 or less. Of the 264 survivors, follow-up was obtained on 221, and 22 percent reported or showed evidence of movement disorders, half transient and half persistent. Tremor, usually kinetic, and dystonia were the most common disorders, and usually developed with a post-trauma latency of 2 to 24 months.

Chorea, choreoathetosis, and ballismus can follow blunt head trauma with injury to the striatum, subthalamic nucleus, and anterior thalamus. The onset is usually days to months following the trauma.

Action myoclonus, palatal myoclonus, and segmental myoclonus may result from head injury not associated with anoxia or epilepsy. Segmental myoclonus may also occur after spinal cord injury.

A deep, burning pain followed by persistent, involuntary, and irregular movements of the toes and feet, termed *painful legs and moving toes*, can be associated with minor foot and ankle injuries. Hemifacial spasm has been rarely associated with trauma. Additionally, after amputation, the remaining stump can involuntarily jerk.

Differential Diagnosis. Because the relationship between many injuries and the movement disorder may be circumstantial and retrospective, an idiopathic movement disorder is always a diagnostic consideration. The possibility of psychogenic movement disorders, which may be more common in women, should also be considered. Because movement disorders often develop several weeks or months after trauma and because patients often receive neuroleptic medications after acute injuries, drug-induced movement disorders are another possible cause.

Evaluation. Neuroimaging such as MRI and occasionally PET can demonstrate responsible brain lesions. Depending upon the case, testing to exclude other potential causes of the movement disorder such as Wilson's disease may also be appropriate.

Management and Prognosis. Post-traumatic parkinsonism may respond to dopaminergic and cholinergic medications. Post-traumatic action tremors only occasionally respond to standard medical treatment. Selected cases may benefit from botulinum toxin injections into involved muscles and ventrolateral thalamotomy. Medications are usually not helpful for dystonia associated with central and peripheral trauma, although botulinum toxin injections can produce temporary relief.^[40] Post-traumatic chorea and choreoathetosis may respond to valproic acid and haloperidol, whereas trauma-induced cortical myoclonus can be treated with clonazepam.

SPINAL CORD INJURY

Over the past decade there have been significant advances in transport, emergency management, pharmacological resuscitation, comprehensive acute care, and rehabilitation. Nevertheless, spinal cord injury (SCI) remains a physically and emotionally devastating problem. The neurologist may thus be confronted with the need for recognition of a potential spinal injury or SCI and institute appropriate stabilization procedures.

Pathogenesis and Pathophysiology. The pathophysiology of SCI may be divided into two distinct phases--primary and secondary injury. Primary injury refers to the structural damage occurring instantly after the

traumatic event. Further primary injury may occur, however, if an injured spine is not adequately immobilized. Secondary injury refers to a pathophysiological cascade initiated shortly after injury, including such insults as ischemia, hypoxia, edema, and various harmful biochemical events. Because it is extremely rare for the primary injury to cause transection of the spinal cord, and it has been shown that less than 10 percent of the cross-sectional area of the spinal cord supports locomotion, it is very important to focus clinical attention of the secondary injury process. ^[42]

Ischemia is a very prominent feature of post-SCI events. Within 2 hours of injury there is a significant reduction in spinal cord blood flow. This ischemia may be confounded by loss of the normal autoregulatory response of the spinal cord vasculature. When autoregulation is lost, blood flow becomes dependent on systemic pressures. Thus, in the multitraumatized patient or the patient with vasogenic spinal shock complicating the SCI, severe systemic hypotension may exacerbate the spinal cord ischemia.

Edema formation is another feature of the secondary injury process. Edema develops first at the injury site and subsequently spreads into adjacent and sometimes distant segments of the cord. The relationship between this edema and worsening of neurological function is not well understood.

Many biochemical mechanisms have been implicated in the evolution of the pathological changes and physiological derangements occurring after SCI. Electrolyte disturbances have been well documented including increased intracellular calcium level, increased extracellular potassium level, and increased sodium permeability. Other events such as excitatory neurotransmitter accumulation, arachidonic acid release, endogenous opiate activation, and prostaglandin production have all been implicated as damaging elements of the post-injury cascade. Other events, free radical production and lipid peroxidation, are believed to play a central role in this process. Ultimately, however, all of these events cumulatively result in ischemia, edema formation, membrane destruction, cell death, and eventually permanent neurological deficits.

Epidemiology and Risk Factors. Spinal cord injury occurs at a rate of 30 to 40 per million population per year, resulting in approximately 10,000 new cases each year. The prevalence of SCI is over 200,000. ^[43] SCI occurs primarily in young males 18 to 25 years of age. The primary precipitant of injury is motor vehicle accidents, although in some areas of the country, swimming and diving-related accidents may take precedence. Sports-related injuries account for less than 5 percent of the total. In some urban areas the incidence of gunshot-related SCI is increasing (Fig. 51-3). SCI rarely occurs in isolation, and over 75 percent of these patients has some other systemic injury. In 10 to 15 percent, there is an associated head injury. This concern has led to the widely quoted clinical maxim that all multitraumatized patients or any patient with a severe head injury should be presumed to have a spine injury or SCI until proven otherwise.

Clinical Features and Associated Disorders. Although general physical assessment of the patient may raise concerns over a possible SCI, a detailed neurological assessment is the only reliable means to rule out this diagnosis. A standardized means of performing and recording

Figure 51-3 Epidemiology of spinal cord injury. MCA, motor cycle accident; MVA, motor vehicle accident.

the neurological examination has been advocated by the American Spinal Injury Association (ASIA) and has been accepted internationally by both clinicians and researchers (Fig. 51-4). With a complete transverse myelopathy, all motor and sensory function below the level of injury is absent. The neurological level of injury is the most caudal or lowest spinal cord segment with normal sensation and a muscle strength of 3/5 or better. An incomplete injury is present when there is preservation of any motor or sensory function below the zone of injury, including sacral sparing.

Acute SCI can result in spinal shock with a total flaccid paralysis below the level of the lesion. Basic knowledge of myotomes, dermatomes, and deep tendon reflexes is essential for localization. Injury to the upper cervical cord can also damage brain stem structures either because of direct trauma or because of vascular injury of the vertebral arteries. This cervicomedullary syndrome is characterized by respiratory dysfunction, hypotension, variable tetraparesis, hyperesthesia from C1 to C4, and sensory loss of the face with an onion-skin pattern.

Partial or incomplete lesions of the spinal cord can result in four patterns of deficit. In the central cervical cord syndrome, the paresis involves the upper extremities, especially the hands, more than the lower extremities. The mechanism of injury is acute cord compression between bony bars or spurs anteriorly and thickened ligamentum flavum posteriorly, resulting in relatively more injury to the medial segments of the corticospinal tracts, which control arm function. The anterior cord syndrome, complete paralysis and hyperesthesia at the level of the lesion but intact light touch and vibration sense, is due to a large disc herniation compressing the anterior cord but without compression of the dorsal columns. The posterior cord syndrome is posterior column damage with impaired light touch and proprioception resulting from hyperextension injuries with fractures of the vertebral arch. The Brown-Sequard syndrome, caused by a lesion of half of the spinal cord, is defined by ipsilateral motor and proprioceptive loss and contralateral pain and temperature loss with the upper level one or two segments below the level of the lesion. This syndrome can occur after various injuries including penetrating trauma, hyperextension and flexion injuries, locked facets, and compression fractures.

Figure 51-4 The ASIA system for examination and classification of spinal cord injury.(From American Spinal Injury Association: Standards for Neurological and Functional Classification of Spinal Cord Injury, Revised 1992, p 278.)

The conus medullaris syndrome is due to a compression injury at T12 that can occur from a disc herniation or a burst fracture of the body of T12. Because almost all the lumbar cord segments are opposite the T12 vertebral body, a severe compression can produce dysfunction in any or all of the lumbar as well as the sacral segments. Flaccid paralysis of the legs and anal sphincter with variable sensory deficits can be present. Because the spinal cord usually terminates at the L1-L2 disc space, trauma below this level injures the nerve roots. The cauda equina syndrome, which is compression of nerve roots below the L1 level, can be caused by fractures and dislocations of the spine or large posterocentral intervertebral disc herniations. Lower motor neuron deficits result with variable sensorimotor, reflex, bladder, bowel, and sexual dysfunction.

In the unconscious patient, neurological evaluation for SCI is very difficult. The only clues to the presence of a significant SCI may be a lack of facial grimacing to peripherally applied painful stimuli, indicating a sensory loss over the trunk, or a lack of withdrawal behavior in the arms or legs in response to painful stimulation applied to the head or face.

The biomechanics of the pediatric spine are fundamentally different from that of the adult. These differences-- ligamentous laxity, wedge-shaped vertebrae, horizontally-oriented facets--account for distinct clinical presentations. The clinical differences between adult and pediatric SCI include the following: disproportionate involvement of the upper cervical spine in pediatric patients; high frequency of spinal cord injury without radiographic abnormality; high susceptibility to the delayed onset of neurological deficits in children; and a higher proportion of complete neurological injuries in children (Table 51-6). ^[44], ^[45]

A unique SCI syndrome--the burning hands syndrome--was first described in sports injury. ^[46] This syndrome appears to be a variation of central cord syndrome associated with severe burning paresthesias and dysesthesias in the hands and/or the feet. Other signs of neurological dysfunction are minimal or absent. Over 50 percent of the time there is an underlying spine fracture-dislocation. It is important to differentiate this syndrome from the much more common and usually innocuous

"burner" or "stinger" of brachial plexus origin.

The syndrome of neurapraxia is also of special concern after athletic injury. Affected individuals experience dramatic, although transient, neurological deficits including quadriplegia. Frequently this syndrome is associated structurally with degenerative or congenital spinal canal stenosis. Many attempts have been made to quantitate the level of risk to these individuals from continued athletic participation; however, considerable controversy still exists. [47], [48]

The majority of spinal cord injured patients have at least one other system injury. Occasionally these injuries take precedence in evaluation and treatment. If one level of bony injury has been identified it is necessary to survey the entire spine because there is a 10 to 15 percent incidence of spine injury at other levels.

Various problems may occur with chronic SCIs. Within a few weeks of the injury, hyperactive reflexes develop, which are associated with hypertonicity of the extremities.

TABLE 51-6 -- SPINE AND SPINAL CORD INJURIES

Characteristics	Adult	Pediatric
MECHANISM OF INJURY	Motor vehicle accidents	Pedestrian/falls
LEVEL OF INJURY		
C1-C3	1-2%	60%
C3-C7	85%	30%-40%
Thoracolumbar	10-15%	5%
TYPE OF INJURY		
Fracture-dislocation	>70%	25%
Subluxation alone	<20%	>50%
SCIWORA	Rare	Up to 50%
DELAYED NEUROLOGICAL DEFICITS	Rare	Up to 50%

SCIWORA, Spinal cord injury without radiological abnormalities.

Although moderate spasticity is not a problem for the patient, severe spasticity may lead to flexor spasms and contractures. Central deafferentation pain, dysesthesias described as burning, stinging, or freezing, may be present. Autonomic dysfunction can occur as early as 2 to 3 weeks after complete or incomplete lesions of the cervical or thoracic cord. Orthostatic hypotension is frequent when the patient is first allowed to sit. Autonomic hyperreflexia or "mass reflex" may be triggered by noxious stimuli such as fecal impaction, urinary tract infections, distention of the bladder, uterine contraction, and decubiti. Manifestations include nausea, throbbing headache, skin blanching and diaphoresis below the level of the cord lesion, and paroxysmal hypertension.

When patients develop progressive neurological deficits any time from several months to many years after SCI, post-traumatic syringomyelia may be responsible. Present in up to 3 percent of patients, four kinds of trauma may be responsible: repeated microtrauma, arachnoiditis, severe single trauma, and minor single trauma. [49] One mechanism of syrinx formation is an initial hematomyelia with subsequent resorption and formation of a cyst cavity.

Differential Diagnosis. Very few disorders mimic acute SCI. Occasionally a patient with hysterical paralysis presents a diagnostic and therapeutic dilemma. It should be borne in mind that true SCI is almost always associated with obvious physiological disturbances such as bradycardia, hypotension, and respiratory compromise.

Evaluation. The injured spine may become a radiological diagnostic dilemma, and one must constantly bear in mind the normal radiological appearance of the spine. The initial evaluation should always include plain radiographs of the cervical or thoracolumbar spine, depending on the neurological findings. [50], [51], [52] If an abnormality is identified, complete spine films must be obtained because there is a 10 to 15 percent incidence of multiple fractures following trauma.

Additional useful information can often be obtained by performing flexion-extension views. Extreme caution must be taken if instability is suspected, however. To better interpret plain films or to better define a definite abnormality, CT is extremely helpful. MRI is sometimes necessary for the complete evaluation of SCI. MRI is the only diagnostic modality that allows direct visualization of the injured cord. [53]

The first principle in evaluating the cervical spine is a clear visualization of all seven cervical vertebrae. At times, a swimmer's view is necessary to visualize this region. If the C7-T1 junction cannot be imaged on plain films, a CT should be performed.

All films should be reviewed for alignment of the vertebral bodies and the facet joints, vertebral body height, and interpedicular distance and normal soft tissue configuration. When evaluating the C1-C2 region, careful attention must be given to the distance separating the anterior arch of C1 and the odontoid process. In an adult, this distance is normally less than 2 mm; in children up to 5 mm distance is acceptable. If any questions arise over possible pathological separation, flexion-extension films may be helpful. Alternatively, MRI may be employed to evaluate the competency of the transverse axial ligament. [54]

Another important consideration when evaluating cervical spine films is the entity of pseudosubluxation. Pseudosubluxation of up to 3 to 4 mm of C2 on C3 may appear in up to 40 percent of normal radiographs in children younger than 8 years old. A similar abnormality can occur at C3-C4 in up to 20 percent. If there is any question about this entity, flexion-extension views should be helpful. A true subluxation cannot be reduced, as contrasted with a pseudosubluxation.

The usual mechanism for atlas fractures involves axial compression of the head with downward displacement of the occipital condyles into the lateral masses of C1. The most important radiographical view is the open-mouth odontoid. With a C1 fracture, the lateral masses of C1 are offset laterally with respect to C2. CT scanning clearly demonstrates the associated C1 ring fractures (Fig. 51-5).

Dens fractures occur as a consequence of either forced hyperextension or hyperflexion of the head. With hyperflexion injuries and associated transverse axial ligament damage, the dens is displaced anteriorly with forward subluxation of C1 on C2. With hyperextension injuries the dens is displaced posteriorly with associated posterior subluxation of C1 on C2. Three type of dens fractures may be seen--type 1, fracture line across tip of dens; type 2, at the base of the dens; and type 3, with a fracture extending into the body of C2. CT scanning may not demonstrate a dens injury if the fracture line is axially oriented.

Another type of axis fracture is the hangman's fracture, usually resulting from hyperextension. Typically there are

Figure 51-5 A C1 burst or Jefferson's fracture.

fractures through both pedicles of C2 with associated forward subluxation of C2 on C3 (Fig. 51-6).

Except in infants and young children, over 85 percent of cervical fractures occur below C3. Locked facets, either unilateral or bilateral, and compression fractures are the most common lesions. These types of injuries are characteristically produced by flexion complicated by axial loading.

Compression fractures are characterized radiographically by loss of vertebral height, retropulsion of bone into the spinal canal, and kyphotic angulation. The hallmark

of facet dislocation is subluxation ([Fig. 51-7](#)).

Figure 51-6 Plain radiograph of a typical C2-hangman's fracture.

Figure 51-7 Plain lateral radiograph demonstrating C5-C6 subluxation secondary to bilateral facet dislocation (From Wilberger JE: *Spinal Cord Injuries in Children*. Mount Kisco, NY, Futura Publishing, 1986, p 29.)

The most common fracture of the thoracolumbar spine is the compression or burst fracture brought about by flexion and axial loading. The T12-L1 level is the one most frequently affected. Typical radiographical features are loss of vertebral height, retropulsion of bone fragments, and kyphotic angulation. The degree of bony disruption and spinal canal compromise is well demonstrated on CT ([Fig. 51-8](#)).

A small but definite subtype of SCI occurs without

Figure 51-8 CT scan slice of an L1 compression-burst fracture with significant spinal canal compromise.

Figure 51-9 Sagittal MRI image showing a large dorsal epidural hematoma after posterior element fracture.

any demonstrable radiographical abnormality, including the appearance on MRI. This type is more likely to occur in children rather than adults; it is often associated with a delayed onset of symptoms after injury, and there is a very poor prognosis for neurological recovery. ^[55]

MRI is becoming increasingly useful in the evaluation of SCI. MRI is adequate for demonstrating most bony injury and is superior to all other modalities for exposing the soft tissue and ligaments. Additionally, MRI is the only modality that allows direct visualization of the injured cord ([Fig. 51-9](#)).

Several patterns of cord injury have been identified on MRI--transection, contusion, hemorrhage, edema--and preliminary studies suggest a correlation between initial and follow-up MRI findings and neurological prognosis. ^[56] When MRI is not available, not feasible, or contraindicated, intrathecally enhanced CT scan is the best alternative. Myelography can also be performed initially when movement of the patient is feasible.

Management. Resuscitation and stabilization of the patient's condition must be accomplished simultaneously with immobilization and stabilization of the spine in the patient with SCI. Because of the frequent occurrence of multisystem injury, the principles of advanced trauma life support (ATLS) must be methodically applied. If significant chest or abdominal injuries coexist, immediate treatment should be directed to those injuries considered most life-threatening.

In the initial management, establishment and maintenance of the airway takes precedence. With known or suspected SCI, neck manipulation should be minimized. Appropriate large-bore intravenous lines should be placed and fluid resuscitation provided. If possible, both a Foley catheter and a nasogastric tube should be placed. When SCI is related to sports injury, the sensational nature of these cases often generates considerable interest. When these injuries do occur it is important to immobilize the athlete on the field and to leave intact any protective headgear, unless airway maintenance is threatened.

During the process of general stabilization, the clinician must remain constantly aware of the principles of spine stabilization. As noted earlier, intubation when necessary should be accomplished with the neck in as neutral position as possible. Adequate stabilization of the cervical spine requires both a hard cervical collar to prevent flexion or extension and side supports to prevent rotation. This immobilization can be accomplished by using sandbags or bolsters on the sides of the head or by taping the head to a rigid backboard. Thoracolumbar injuries are stabilized on a backboard. It is important to remember, however, that insensate patients with SCI left on hard backboards rapidly develop decubiti.

Once the patient's condition is stabilized and appropriate diagnostic studies have been accomplished, more definitive spine stabilization can be undertaken. For cervical injuries, this involves immobilization and reduction of any dislocations, usually by skeletal traction. Many devices are currently available for this purpose; the most commonly used are Gardner-Wells (GW) tongs and halo rings. Once a traction device has been placed, weights can be added to aid in spinal realignment. It has been generally recommended that no more than 5 pounds of weight be applied for each cervical level involved (i.e., for a C5 level dislocation no more than 30 pounds should be applied). In routine clinical practice, however, especially for injuries such as bilateral facet dislocations, weights in excess of 50 pounds may be necessary to achieve reduction. Some controversy exists over how rapidly reduction should be undertaken; however, most agree that with incomplete SCI, rapid intervention is most appropriate.

When traction is applied, the patient must be continually monitored both radiographically and clinically. Overtension of the spine may cause cranial nerve deficits or neurological worsening. Muscle relaxants such as diazepam are often helpful adjuncts in reducing spasm, which may inhibit efforts at reduction. Fluoroscopy may be useful for frequent radiographical monitoring during active attempts at reduction through traction. If closed reduction through traction fails, a decision must be made about open reduction and surgical stabilization. Although there are no good scientific data to indicate any definite advantages with respect to neurological improvement from rapid aggressive surgical intervention in these cases, there is a growing tendency to advocate such an approach. ^[57] ^[58] ^[59] ^[60]

Generally, realignment of the thoracolumbar spine cannot be accomplished with external traction. Affected patients are immobilized on rotating beds until a decision is made regarding surgical intervention.

The best current initial medical and pharmacological therapy of SCI is based on the potentially reversible pathophysiological changes that occur in relation to spinal cord blood flow and the beneficial effects that have been demonstrated with high-dose methylprednisolone treatment.

Because of the known tendency for spinal cord perfusion to fall abruptly after SCI, systemic blood pressure should be vigorously supported and on occasion mild hypertension induced to ensure adequate perfusion for at least the first 24 hours after injury. ^[61] Fluid resuscitation should consist of an appropriate combination of crystalloid and colloid or blood replacement, if necessary. In most instances, lactated Ringer's solution or normal saline is the best initial fluid. If, despite adequate fluid replacement, the blood pressure cannot be normalized, pressors such as dopamine or phenylephrine hydrochloride (NeoSynephrine) may be instituted. An additional temporary measure to improve peripheral vascular resistance may be a pneumatic antishock garment.

Because spinal cord blood flow is dependent not only on perfusion pressure but also on blood rheology, it is important to consider measures to reduce blood viscosity, thereby increasing perfusion. Optimal viscosity for this purpose is achieved with a blood hematocrit in the range of 33 to 37 percent.

A wide variety of hemodynamic derangements is seen in association with SCI, and there is some indication that their correction improves the chances for neurological recovery. Thus placement of a Swan-Ganz catheter is appropriate after SCI to better detect and treat these problems.

If treatment can be initiated within 8 hours of injury, methylprednisolone should be given as an intravenous bolus of 30 mg/kg followed by continuous infusion of 5.4 mg/ kg/hr. If treatment is initiated within 3 hours of injury, the continuous infusion should be continued for 24 hours. Patients initiating treatment 3 to 8 hours after injury should have the continuous infusion for 48 hours. The odds of a methylprednisolone-treated patient improving motor function is greater than 2:1 when compared

with other pharmacological therapies, whereas the odds of improving sensory function is 3:1.^[62],^[63] Methylprednisolone should not be given if more than 8 hours have elapsed since the SCI, because patients treated in this manner have a slightly worse outcome.

Once the immediate problems attendant on the SCI have been stabilized, attention must be directed to preventing the many complications--pulmonary, cardiovascular, urinary tract, gastrointestinal, skin--that typically threaten in the first week to 10 days after SCI ([Fig. 51-10](#)).

Pulmonary problems are the single most common cause

Figure 51-10 Frequency of acute complications after spinal cord injury. MI, myocardial infarction; PE, pulmonary embolism. (From American Spinal Injury Association: Standards for Neurological and Functional Classification of Spinal Cord Injury, Revised 1992, p 278.)

of morbidity and mortality following SCI. The higher the anatomical level of injury, the greater the risk of neurological problems. Impaired deep breathing and coughing, on the basis of either pain or neurological compromise, increase the risks of atelectasis and pneumonia. Additionally, the need for maintaining recumbency to allow for immobilization of the spinal injury further compromises respiratory status.^[64] Careful serial observation must be maintained to guard against the insidious development of respiratory insufficiency. Measurements of arterial blood gases or pulse oximetry should be supplemented by measurements of vital capacity at regular intervals. Pulmonary toilet is enhanced by regular nasotracheal suctioning, frequent chest physiotherapy, and the use of rotating beds or frames.^[65]

Several cardiovascular problems may complicate acute management--vasogenic spinal shock, paroxysmal hypertension, arrhythmias, and thermoregulatory dysfunction. Vasogenic spinal shock results from peripheral pooling of blood from loss of sympathetic vasomotor control; it generally requires treatment with vasopressors. The most common arrhythmia is bradycardia, which may be so pronounced as to produce hypotension. On occasion, temporary pacing may be required. Thus, all patients with SCI should be monitored hemodynamically for the first several days after injury.

The gastrointestinal (GI) tract must be monitored for the development of paralytic ileus, which almost universally occurs. Associated abdominal distention may adversely affect respiratory function. Judicious use of nasogastric suctioning should prevent these problems. Once the ileus has resolved, it is important to initiate and maintain regimens of bowel regulation and retraining to prevent constipation and impaction and their undesirable effects.

The primary source of infection after SCI is the genitourinary tract. The bladder can also account for significant long-term disabilities consequent to associated renal damage if appropriate care is not taken early on. Because reflex micturition almost always begins within several days of injury, long-term Foley catheterization is discouraged in favor of intermittent catheterization. Prophylactic antibiotics are not indicated, and bladder re-education should begin promptly.

Attention to skin care is vitally important. Immobility and lack of sensation predispose to skin breakdown. Prolonged pressure over bony prominence must be avoided. Pressure reduction can only be accomplished by frequent turning.^[66]

Considerable disagreement exists regarding the place of surgery after SCI and, should surgical treatment be decided upon, what should be done and when.

General agreement exists as to the necessity for immediate immobilization and early stabilization of fractures and dislocations of the spine. Immobilization and early stabilization can be accomplished without surgical intervention (i.e., with external orthoses such as the halo) in over 60 percent of SCI cases. The timing and method of internal surgical stabilization are points of controversy. The single widely accepted indication for acute surgical intervention is documented neurological deterioration in association with ongoing spinal cord compression from bone and disc fragments, hematoma, or unreduced subluxation. Nevertheless, the presence of an incomplete SCI with persistent spinal cord

181

deformity and presence of complete SCI when the perceived possibility exists for recovering some neurological function have been advocated as rationales for early aggressive surgical intervention.^[11]^[12]^[13]

Oral and injectable diazepam, baclofen, dantrolene, and clonidine are helpful for the treatment of spasticity. When these medications are inadequate, other treatments include motor point blocks with phenol, botulinum toxin injections, and intrathecal perfusion with baclofen or morphine. Central deafferentation pain may respond to treatment with tricyclic antidepressants, valproic acid, carbamazepine, mexiletine, and intrathecal morphine. Occasional patients may be helped by surgical approaches such as dorsal root entry zone lesions and implantation of a dorsal column stimulator.

Prognosis and Future Perspectives. It is important to attempt to quantify the natural history of the degree and extent and time course of neurological recovery after SCI to prognosticate function, determine the effectiveness of various interventions, and develop a comprehensive rehabilitation plan.

Waters and coworkers^[67] reported a study of 148 patients with complete SCI followed for 5 years with annual examinations using the ASIA scoring system. Very little, if any, significant recovery was documented after 1 year of follow-up. In these patients, however, 18 percent had at least one level improvement at 1 year in their neurological level of injury and 7 percent had two levels of improvement. Ditunno and coworkers^[68] undertook a study to determine the recovery of key muscles of the upper extremities in motor-complete quadriplegics. One hundred fifty patients were followed for 24 months. Recovery persisted in muscles with no initial motor power from the ninth to twenty-fourth month, with ultimately 64 percent achieving some increased function. The recent National Acute Spinal Cord Injury Study found a plateauing of recovery between 6 and 12 months after injury.^[65],^[66] If an athlete suffers a SCI, return to any level of competition is medically precluded. Risks to the individual from other less severe spinal injuries are debated, however. In general, any injury that necessitates internal surgical spinal stabilization probably obviates return to contact sports. More minor injuries that heal correctly with bracing may not limit athletic involvement.^[69]

WHIPLASH INJURIES

The term *whiplash* refers to the mechanism of the neck injury, which can result from hyperextension followed by flexion that occurs when an occupant of a motor vehicle is hit from behind by another vehicle. Some clinicians use the term to also describe other types of collisions wherein the neck is subjected to different sequences and combinations of flexion, extension, and lateral motion. The term was first used in 1928. Other terms used include cervical sprain, cervical myofascial pain syndrome, acceleration-deceleration injury, and hyperextension injury. ^[70]

Pathogenesis and Pathophysiology. Animal and human studies have demonstrated structural damage including muscle tears, rupture of ligaments, avulsions and herniations of intervertebral discs, retropharyngeal hematoma, nerve root damage, cervical sympathetic chain injury, and hemarthrosis of facet joints.

Epidemiology and Risk Factors. In 1994, there were 11,200,000 motor vehicle accidents including 2,600,000 rear-end collisions in the United States. Although neck injuries can commonly occur after side or front impact collisions, rear-end collisions are responsible for about 85 percent of all whiplash injuries. Although only rough estimates exist, perhaps 1 million people sustain whiplash-type injuries per year in the United States. Women have persistent neck pain more often than men, especially those women in the 20- to 40-year age group, by a ratio of 7:3. The greater susceptibility of women to whiplash injuries may be due to a narrower neck with less muscle mass supporting a head of roughly the same volume compared with men.

Clinical Features and Associated Disorders. Following a motor vehicle accident with a whiplash-type mechanism of injury, 62 percent of patients presenting to the emergency room complain of pain. The onset of pain is within 24 hours in 93 percent of the injured. The most common cause of the neck pain is myofascial injury. Cervical disc herniations, cervical spine fractures, and dislocations are uncommon. Cervical facet joint injury can also be a source of pain. ^[71]

Eighty percent of patients with whiplash-type injuries complain of headaches during the first 4 weeks after the accident. The headaches are usually of the muscle contraction type and are often associated with greater occipital neuralgia. Whiplash trauma can also injure the temporomandibular joint and can cause jaw pain often associated with headache. Headache may be referred from the C2-C3 facet joint that is innervated by the third occipital nerve, which is third occipital headache. Occasionally, whiplash injuries can precipitate recurring common, classic, and basilar migraines de novo.

Dizziness is a common complaint and can be due to dysfunction of the vestibular apparatus, cervical proprioceptive system, brain stem, and cervical sympathetic nerves.

Paresthesias of the upper extremities can be referred from trigger points, brachial plexopathy, facet joint disease, entrapment neuropathies, cervical radiculopathy, and spinal cord compression. Thoracic outlet syndrome, which occurs four times more often in women than men, is a common cause of paresthesias, which often radiate down the ulnar arm and forearm into the fourth and fifth fingers. Eightyfive percent of these cases are of the non-neurogenic type with subjective complaints but no objective findings.

Cognitive impairment due to a whiplash injury without direct head trauma is a controversial topic. One well done prospective study using matched controls reports attention deficits present in 18 percent of patients 2 years after the injury. ^[72]

Interscapular pain and low back pain are frequent complaints after whiplash injuries and are reported in 20 percent and 35 percent of patients, respectively, after the injury. Visual symptoms, especially blurred vision, are often reported by patients and are usually due to convergence insufficiency, although oculomotor palsies can occasionally occur. Rare sequelae include cervical dystonia or torticollis, transient global amnesia, esophageal perforation and descending

182

mediastinitis, hypoglossal nerve palsy, and cervical epidural hematoma.

Differential Diagnosis. Whenever patients have pain complaints without objective findings, nonorganic explanations should be considered. Other possible causes of pain complaints after whiplash injuries include psychological problems, secondary gain and malingering in cases in which litigation is pending, and social and peer copying. ^[73]

Evaluation. A cervical spine MRI study is helpful to evaluate patients with persistent complaints of neck pain and paresthesias or those with abnormal results on examination. When radiographical abnormalities are present, the possibility that they are pre-existent should be considered. Cervical spondylosis, degenerative disc disease, and cervical disc protrusions occur with increasing frequency with older age and are often asymptomatic.

Management. Neck pain is often treated initially with ice then heat, nonsteroidal anti-inflammatory drugs, muscle relaxants, and pain medications. Use of soft cervical collars should be kept to a minimum during the first 2 to 3 weeks and then avoided. Range-of-motion exercises, physical therapy, trigger point injections, and TENS units may be helpful for patients with persistent complaints. Prospective controlled studies on treatment of those patients with chronic pain have not been done. ^[74]

Prognosis and Future Perspectives. Neck pain and headaches can persist for months and sometimes years in a minority of patients. According to various studies, neck pain and headache, respectively, have been reported as persisting for the following intervals after the accident: ^[75], ^[76] 1 month, 64 percent and 82 percent; 3 months, 38 percent and 35 percent; 1 year, 19 percent and 21 percent ^[75], ^[76]; and 2 years, 16 percent and 15 percent. Psychosocial factors, negative affectivity, and personality traits are not predictive of the duration of symptoms. Risk factors for more severe symptoms include an unprepared occupant, a rear-end collision, and a rotated or inclined head position at the moment of impact. Despite the common belief that pending litigation is responsible for persistent symptoms, litigants and nonlitigants have similar psychological profiles and similar recovery rates. Most patients who are still symptomatic at the time when litigation is settled are not cured by a verdict.

BRACHIAL AND LUMBOSACRAL PLEXOPATHIES

Pathogenesis and Pathophysiology. Trauma can result in variable injury to the myelin, axon, and connective tissue covering of plexus elements. Mild injuries may result in focal demyelination with conduction slowing. More severe injuries may cause demyelinating conduction block (neurapraxia), which can occur alone or in association with axon degeneration. Axonotmesis, which is loss of the relative continuity of the axon and myelin but preservation of the connective tissue framework, leads to Wallerian degeneration. *Neurotmesis* refers to an injury in which the axons and investing connective tissues lose their continuity. A combination of different grades of injury can occur. An axonal nerve injury in continuity may heal as a neuroma that consists of axons growing in all directions surrounded by connective tissue. Root avulsion is the traumatic separation of a nerve root from the spinal cord. ^[77]

Epidemiology and Risk Factors. Closed lesions usually resulting from traction are the most common causes of traumatic brachial plexopathy. Stretch injuries are responsible for about 70 percent of serious brachial plexus injuries. High-velocity closed injuries, which usually involve the supraclavicular plexus, are primarily due to motor vehicle accidents, occupational injuries, and falls. Falls, which result in scapular and proximal humeral fractures and humeral head dislocations, are the most common causes of infraclavicular injuries. Brachial plexus injury, usually involving the lower trunk or medial cord, occurs in 5 percent of patients undergoing coronary artery bypass surgery. Brachial plexus injury is probably due to traction associated with sternal retraction. Most brachial plexus avulsion injuries are due to motor vehicle accidents, especially motorcycle accidents, industrial accidents, or to obstetrical injury, falls, objects falling on the shoulder, and sports injuries (most commonly football, bicycling, skiing, and equestrian activities). Root avulsions more commonly involve the C7, C8, and T1 roots, whereas extraforaminal ruptures more commonly affect the C5 and C6 roots.

The less common open lesions, which most often affect the infraclavicular plexus, are often associated with injuries to major limb vessels and the lung. Gunshot wounds, which account for 25 percent of the cases of surgical repair of the brachial plexus in the United States, usually involve the infraclavicular or retroclavicular plexus and less often the supraclavicular plexus. Laceration injuries of the brachial plexus are usually the result of broken glass and knives.

Injury to the lumbosacral plexus is uncommon because it is protected by the pelvic bony ring. Pelvic fractures, which are usually due to motor vehicle accidents, crush injuries, and falls from a height, result in lumbosacral plexus injury in about 7 percent of cases.

Clinical Features and Associated Disorders. Plexus injuries can result in sensory loss, paresthesias, motor loss, and pain, which can be particularly severe after root avulsions. A detailed knowledge of the anatomy of the brachial and lumbosacral plexus is essential to localizing lesions (see [Chapters 15](#), [19](#), and [20](#)).

Burners and *stingers* are synonymous terms that refer to the radicular and plexus symptoms following sudden depression of the shoulder in contact sports, usually football. The player experiences burning dysesthesias going down the ipsilateral upper extremity, often into the thumb, and sometimes weakness of the biceps and shoulder girdle muscles. The symptoms usually resolve within a few minutes, although occasional cases last for weeks.

Other causes of acute compression of the brachial plexus include the following: prolonged compression in someone inebriated or comatose; compression of the plexus against the first rib due to heavy backpacks carried by students or soldiers; prolonged firing of shotguns or rifles; and shoulder restraints in motor vehicles. In addition to coronary artery bypass surgery, other intraoperative causes of plexus injury include malpositioning of the arm often affecting the upper plexus; damage during other procedures such as radical mastectomies, transaxillary arterial bypasses, and biopsies;

orthopedic procedures on the humerus or shoulder; and, ironically, first rib resections and scalenotomies performed to treat thoracic outlet syndrome. False aneurysms of the axillary artery due to trauma and hematomas from transaxillary percutaneous angiograms can also injure elements of the plexus. Stretch injuries of the plexus in neonates, often resulting from shoulder dystocia, most commonly involve the upper trunk (Erb's palsy) and only occasionally the lower trunk (Klumpke's palsy).

Repetitive activity such as working at a keyboard or playing a musical instrument and single injuries such as a fall or whiplash-type injury commonly result in the non-neurogenic type of thoracic outlet syndrome. Patients may complain of aching of the shoulder and arm with paresthesias going down the arm into the fourth and fifth fingers. The symptoms may be worse at night, with repetitive activity, and/or with use of the arm overhead. Although they are nonspecific causes, medial supraclavicular palpation and the exaggerated military posture may reproduce the symptoms. Most of the patients are women; long necks, droopy shoulders, and pendulous breasts may be contributing factors. No objective findings appear on examination or electrodiagnostic studies. ^[77]

In addition to pelvic fractures and gunshot wounds, there are other important causes of lumbosacral plexus injury. During labor and delivery, pressure on the lumbosacral trunk by the fetal head or forceps may result in a postpartum footdrop. Ischemic injury of the plexus can result from inadvertent injection of drugs into the gluteal arteries, leading to a propagating thrombus to the iliac arteries. Blunt trauma to the abdomen can rarely result in a retroperitoneal hemorrhage into the psoas muscle, which compresses the lumbar plexus causing pain and extremity weakness. Neuromas may form after partial or complete injuries to peripheral nerves. The only neuromas that are symptomatic are those that contain sensory nerve fibers. Sensory nerves of the hands and feet are especially likely to form painful neuromas. Symptomatic neuromas produce a burning or aching pain that may radiate proximally or distally. A Tinel's sign may be present. The diagnosis can be confirmed by temporary relief of symptoms after injection of local anesthetic. Injection of a corticosteroid may significantly improve or cure symptoms in some cases. Various surgical approaches such as nerve grafting, decompression and translocation, excisional neurectomy, and transposition may be appropriate, depending upon the case. ^[78]

Differential Diagnosis and Evaluation. Cervical and lumbosacral disc herniations and peripheral nerve injuries should be considered. The clinical examination can often localize the lesion as pre- or postganglionic or to various elements of the plexus. For example, the presence of a Horner's syndrome indicates lesions of the roots of C8 and T1 proximal to the site where the white rami communicantes exit to enter the sympathetic chain. Depending upon the specific injury, various imaging techniques include plain radiographs, CT and MRI scans, arteriography, venography, and myelography may be indicated. Pseudomeningoceles, which are formed when a nerve root is avulsed and the meninges are pulled through the neural foramina, may be detected on myelography, followed by CT scan as well as MRI imaging. Electromyogram (EMG) and nerve conduction studies can be very helpful in localizing and determining the extent of the lesion.

Management. Management depends upon the location of the lesions, the grade of nerve injury, and the presence of root avulsions. Patients with acute transections of the brachial plexus due to lacerations with a knife or glass should undergo relatively rapid primary repair. For closed stretch injuries with severe axonal degeneration present on electrophysiological studies 3 to 5 months after the injury, surgical exploration and repair are indicated. ^[79] Because missile wounds usually leave the nerve in continuity, initial management is often conservative. Although avulsion of nerve roots has been regarded as an untreatable injury, animal and human studies suggest that implantation of ventral roots into the spinal cord may lead to recovery of motor function. ^[80]

Up to 80 percent of patients with obstetrical palsy have no paresis or mild paresis by the age of 1 year. Surgery for infants with obstetrical palsy not improving is controversial with recommendations for the time of surgery ranging from 3 to 9 months of age. Non-neurogenic thoracic outlet syndrome may respond to Peet's exercises, which strengthen the muscles of the pectoral girdle and improve posture. In very occasional cases, scalenotomy or first rib resection may be indicated. Physical and surgical rehabilitation may help to improve function after brachial plexus injuries.

Pain following brachial plexus injuries may be difficult to manage with various treatments depending upon the type and severity of the pain. Treatments range from pain pills, anticonvulsants, and transcutaneous nerve stimulators to stellate ganglion blocks and sympathectomy, dorsal column stimulators, and dorsal root entry zone lesions. Similar considerations apply to lumbosacral plexus injuries. When indicated, surgery may be helpful in some cases of pelvic fractures, gunshot wounds, stab wounds or lacerations, and iatrogenic injuries.

Prognosis and Future Perspectives. In cases of neurapraxia, spontaneous recovery may occur within 3 to 4 months of the injury. Because of the long regeneration distances and lack of collateral sprouting, the intrinsic hand muscles with lower trunk lesions and the muscles below the knee with sacral plexopathies reinnervate poorly after severe axon loss lesions. For severe brachial plexus lesions, satisfactory results may occur postoperatively in up to 70 percent of patients after primary repair and up to 48 percent after a nerve graft. Fifty to 85 percent of patients with non-neurogenic thoracic outlet syndrome may improve with exercises. ^[81]

REFLEX SYMPATHETIC DYSTROPHY AND CAUSALGIA

In 1864, the Philadelphia neurologist S. Wier Mitchell and colleagues reported the cases of Union soldiers who sustained gunshot wounds at the battle of Gettysburg resulting in partial nerve lesions of the brachial plexus and peripheral nerves followed by a severe burning pain of the hand or foot associated with trophic changes. Mitchell coined the term *causalgia*, which is from the Greek for "burning pain," to describe this syndrome.

Pathogenesis and Pathophysiology. The pathophysiology of reflex sympathetic dystrophy (RSD) and causalgia is poorly understood. Various mechanisms proposed include the following: sympathetic hyperactivity; ephaptic transmission between sympathetic and primary afferents; a reverberating circuit in the spinal internuncial pool; sensitization of wide dynamic range neurons in the dorsal horn; and neurogenic inflammation. Despite common perception and nomenclature, some researchers strongly argue that the sympathetic nervous system is not involved.

Epidemiology and Risk Factors. Causalgia may occur in up to 5 percent of patients after partial peripheral nerve injury, but it does not occur when a nerve is completely severed. The incidence of RSD is 1 to 2 percent after various fractures but is particularly common following Colles' fracture, occurring in about 30 percent. RSD may occur after various other injuries including minor soft tissue trauma, operations such as carpal tunnel release and arthroscopic knee surgery, myocardial and cerebral infarction, and frostbite and burns. In up to 25 percent of RSD cases, a precipitant cause is not identified. RSD occurs in all ages with a median of 40 years. Females account for about 70 percent of cases.

Clinical Features and Associated Disorders. RSD is a syndrome with variable major components of burning pain, autonomic dysfunction, edema, dystrophy and atrophy, and sometimes a movement disorder. When this pain syndrome follows peripheral nerve injury, the term *causalgia* is used. Various other terms for reflex sympathetic dystrophy are used including Sudeck's atrophy, algodystrophy, post-traumatic dystrophy, reflex neurovascular dystrophy, shoulder-hand syndrome, sympathetic maintained pain syndrome, and complex regional pain syndrome.

The symptoms of RSD and causalgia may develop within days to months after injury. The pain, which begins in the area of the injury or event, may then spread throughout the extremity and, in perhaps 5 percent of cases, involves the contralateral extremity (rarely, three and four extremities may become involved). The burning, aching, or constant pain is associated with hyperalgesia (lower pain threshold with enhanced pain perception), allodynia (pain induced by innocuous mechanical and thermal stimuli, especially cold), and hyperpathia (an exaggerated response to a stimulus, which may be delayed and may persist after cessation of the stimulus). Spontaneous paroxysmal shooting, sharp, or electrical sensations may be described. Decreased sensation may be present in affected areas. Proprioception may be limited. As in other pain disorders, RSD patients are often depressed and anxious.

Edema over the site of injury and distally may be present. At first, the involved extremity is usually warm, red, and dry but occasionally may be cold. Over time, the extremity usually becomes cool, pale, cyanotic, and hyperhydrotic. Early on, the nails may become thickened and the hair darker. Later, the hair may be lost in the affected areas, the skin may become shiny, and the nails may break. Dystrophy and atrophy of subcutaneous tissue, muscles, and bone may be present. Nodular fasciitis of the palmar or plantar skin may be present. RSD affecting the hand may be associated with a frozen shoulder. Motor manifestations variably present include weakness, an enhanced physiological tremor, spasm and increased reflexes, focal dystonia, and an inability to initiate movement. Exercise or use may aggravate RSD complaints.

Differential Diagnosis. Other disorders that may have some features of RSD include chronic arterial insufficiency, thrombophlebitis, infection, collagen vascular disorders, postherpetic neuralgia, entrapment neuropathies (which can coexist with RSD), painful neuromas, plexopathies and radiculopathies, phantom limb pain, and central pain syndromes. When pain complaints are the major problem, psychological causes such as depression, factitious disorders, conversion, and malingering should be considered.

After amputation of an extremity, up to 85 percent of patients describe phantom limb pain, which may still be present in about 30 percent 1 year later. The patients describe pain, which may be a continuous numbing or an intermittent sharp, stabbing, shooting, cramping, or burning sensation, as being present either in the stump or in the absent limb. Both peripheral and central mechanisms for the pain have been suggested, with one study showing evidence of plastic changes in the primary somatosensory cortex. Despite various medical and surgical treatments, the pain is often intractable.

Evaluation and Management. The diagnosis of RSD and causalgia is based on the symptoms and signs. Laboratory testing sometimes used includes thermography and a triple-phase bone scan (which may reveal abnormal uptake and increased periarticular uptake in 30 percent of patients); abnormal findings are not specific. Pain relief following sympathetic blockade or an intravenous phentolamine test is supportive of the diagnosis. The possibility of a placebo response should be considered.

The inciting disorder should be appropriately diagnosed and treated. Although many treatments have been proposed, there is a lack of prospective and controlled studies. Medications reported as useful include the following: narcotic and nonsteroidal anti-inflammatory drugs; adrenergic blockers such as clonidine and prazosin; tricyclic antidepressants; anticonvulsants; corticosteroids; and intranasal calcitonin. Physical therapy modalities, rehabilitation, transcutaneous nerve stimulators, and psychological treatment are often worthwhile. A series of five sympathetic anesthetic blocks of the stellate ganglion for upper extremity or lumbar chain for lower extremity cases can be beneficial. If the blocks improve the pain but only temporarily, many clinicians recommend sympathectomy. Dorsal column stimulators and morphine intrathecal pumps are sometimes recommended for refractory cases.

Prognosis and Future Perspectives. Prognostic information is quite limited. Many clinicians believe that recovery occurs more frequently when treatment is begun early in the course. Pain may still be present in 25 percent of cases with RSD after 1 year and in 60 percent of patients with causalgia after 3 years. Reported response rates for surgical sympathectomy range from 12 to 97 percent. RSD may resolve early in the clinical course only to return weeks or months later.

MOUNTAIN SICKNESS

Pathogenesis and Pathophysiology. As the partial pressure of oxygen decreases with increasing altitude, ventilation rises, leading to respiratory alkalosis. Although hypocapnia alone results in cerebral vasoconstriction, hypoxia

produces a net decline of cerebral vascular resistance and increased cerebral blood flow. Hypoxia can result in cerebral edema, which may be due to cerebral vasodilatation and elevated cerebral capillary hydrostatic pressure. An increase in sympathetic activity follows, causing an elevated heart rate, pulmonary vasoconstriction, and an initial increase and later decrease of cerebral blood flow. ^[87]

Epidemiology and Risk Factors. Acute mountain sickness (AMS) develops in about 25 percent of visitors to moderate altitudes (6300 to 9700 feet). Symptoms usually occur within the first 12 hours of arrival but may be delayed 24 hours or more. Risk factors for AMS include those who are younger than 60 years, less physically fit, live at sea level, have a history of AMS, or have underlying lung problems. ^[88]

AMS leads to high-altitude cerebral edema (HACE) in perhaps 1.5 percent of cases. Alcohol use inhibits acute ventilatory adaptation to mild hypoxia at moderate altitude.

Clinical Features and Associated Disorders. AMS, which usually occurs above 8200 feet, is defined by the presence of a headache and at least one of the following symptoms: GI (anorexia, nausea, or vomiting), fatigue or weakness, dizziness or lightheadedness, and difficulty sleeping. ^[89] The headache is usually bilateral but may be unilateral. HACE, which is uncommon below 12,000 feet, is defined by the presence of a change in mental status and/or ataxia in a person with AMS or the presence of both mental status change and ataxia in a person without acute mountain sickness. HACE, which can lead to coma and death, may be associated with urinary incontinence, papilledema, cranial nerve palsies, tremor, and abnormalities in limb tone.

High-altitude pulmonary edema (HAPE), which can occur along with HACE, usually occurs above 9840 feet. High-altitude retinal hemorrhage is common in people who go above 15,000 feet.

Evaluation and Management. The diagnosis is usually a clinical one that is made in the setting of a recent gain in altitude. Altitude sickness may be prevented in those planning higher ascents by starting below 8000 feet, resting the first day, and then ascending about 1000 feet per day. Sleeping at a lower altitude at night may be helpful because hypoxia is worse with sleep. It is also important for climbers to keep well hydrated and avoid alcohol. Acetazolamide, at a dose of 250 to 1000 mg/day starting 8 to 12 hours before ascent and continuing for 3 to 4 days, may prevent AMS and improve sleep. Dexamethasone may also reduce the incidence and symptoms of AMS.

AMS may be treated symptomatically with rest, mild analgesics, alcohol avoidance, and adequate hydration. Depending upon the severity of symptoms, avoiding going any higher, or slowing the rate of ascent or descent may be necessary. Acetazolamide may also help acute symptoms. In addition to descent, HACE may be treated with acetazolamide, dexamethasone, supplemental oxygen, and use of a portable hyperbaric bag. Nifedipine and perhaps inhalation of nitric oxide may be beneficial for HAPE. ^[90]

Prognosis and Future Perspectives. AMS usually resolves after 16 to 72 hours at altitude. When descent is impossible and treatment is unavailable, HACE and HAPE have a mortality up to 50 percent.

DECOMPRESSION SICKNESS

Pathogenesis and Pathophysiology. With descent, the partial pressure of the gases breathed by the diver increases proportionately, according to Dalton's law. Although oxygen is metabolized, tissues soak up inert nitrogen and become saturated. With ascent, the nitrogen moves from the tissues to the blood and is exhaled by the lungs, which is a process termed *decompression*. When ascent is too rapid and the tissues are supersaturated, dissolved gas changes to free gas, which creates bubbles. When the filtering capacity of the pulmonary capillaries is exceeded, the bubbles enter the arterial circulation. Symptoms depend on those tissues in which the bubbles accumulate. Bubbles in the paravertebral veins, Batson's plexus, can result in stasis and venous infarction in the spinal cord. Cerebral injury can develop from bubbles occluding vessels or directly disrupting tissue. Symptoms may also result from secondary effects such as activation of complement, platelet aggregation, and release of vasoactive mediators.

Epidemiology and Risk Factors. Decompression sickness (DCS), also referred to as *the bends* or *caisson disease*, usually affects divers and caisson workers but can also occur in pilots during rapid ascent in a nonpressurized cabin. About 900 cases of DCS are reported yearly in the United States among recreational scuba divers. Most accidents occur in inexperienced divers. The incidence of DCS for recreational divers is one per 5000 to 10,000 dives, and for commercial divers, one incident per 500 to 1000 dives. Up to 50 percent of cases of DCS occur in divers who claimed to have been diving within the limits set by a standard table or decompression computer. Divers with a patent foramen ovale are five times more likely to sustain serious decompression problems because bubbles can go directly from the right to left atrium without being filtered by the lungs. ^[91]

Clinical Features and Associated Disorders. DCS, which can occur after diving to a depth of more than 25 feet, usually appears within a few minutes to a few hours after the end of a dive. Mild DCS (type I) is defined by pain usually in the joints (bends) and/or itching of the skin. Serious DCS (type II) is characterized by neurological problems. Involvement of the thoracic spinal cord, the most commonly affected area, leads to low back or pelvic pain and dysesthesias, which may be accompanied by sensory loss, weakness, and incontinence. Less often, the brain may be involved, resulting in various symptoms and signs such as headache, confusion, lethargy, vertigo, speech disturbance, hemiparesis, visual impairment, and seizures, depending upon the site of the insult. ^[92]

Rupture of alveoli, which may occur when a diver ascends without venting air from the lungs or from blockage of part of the bronchial tree, can result in additional arterial gas embolism. During ascent or shortly after surfacing, divers may develop various problems ranging from acute respiratory distress and headache to cardiorespiratory arrest and seizures. Depending upon the site of embolism to the brain, cortical blindness, dysphasia, and hemiplegia may occur. Arterial gas embolism and DCS may coexist.

Evaluation and Management. DCS is typically diagnosed based upon the findings on history and physical examination. The results of MRI studies of the brain and

106

spinal cord may often be normal or may show only nonspecific abnormalities in cases of DCS. ^[92] Initially, high concentrations of oxygen should be administered by face mask. As soon as possible, the patient should undergo recompression in a hyperbaric chamber while breathing oxygen.

Prognosis and Future Perspectives. Prompt treatment usually results in a complete recovery. Neurological deficits may persist in cases where recompression is delayed or not done. ^[93]

LIGHTNING AND ELECTRICAL INJURIES

Pathogenesis and Pathophysiology. Although incompletely understood, the two major causes of tissue damage are thermal injury and electroporation, which is the production and expansion of transient aqueous pores in the lipid bilayer component of the cell membrane. ^[94]

Epidemiology and Risk Factors. About 100 lightning and 1500 technical electricity-related deaths per year occur in the United States. The following routes can produce lightning injury. A direct strike is the most damaging, which is more common if the person is carrying a metal conductor such as an umbrella or golf club above shoulder level. A side flash or splash injury occurs when lightning first strikes a tall object such as a tree and then arcs to the person standing next to the object or when lightning first strikes a person or animal and then the second victim. A ground or stride current occurs when lightning strikes the ground first and then travels along the surface before reaching the person. Occasionally, people can sustain injury indoors while on the telephone from current conducted through the lines or in the bath or shower from ground current traveling along the water pipes.

Technical electrical injuries can occur from exposure to high-voltage electricity (1000 volts or more) and low-voltage electricity. High-voltage electricity injuries, which are almost always work-related, account for about 70 percent of electrical injuries and deaths. Low-voltage injuries typically happen in the home with the following common circumstances: the use of electrical appliances while standing on a wet floor or while in the bathtub; children playing with outlets or wires; or use of faulty electrical equipment. When the energized conductor is held in the hand, alternating current exposure in the range of 8 to 22 mA at 60 Hz may result in long exposure due to a state of tetanic contraction of flexor muscles of the forearm and hand, which is paradoxically termed *let go current*.^[95]

Clinical Features and Associated Disorders. Lightning and electrical injuries may result in sudden death or cerebral hypoxia from inducing ventricular fibrillation. Transient loss of consciousness, confusion, and amnesia may also occur.^[96] Lightning injury may result in keraunoparalysis, which is a transient paralysis usually of the lower extremities associated with sensory loss and pale skin. Lightning and electrical injuries may also cause acute spinal cord, focal brain, and peripheral nerve damage and rhabdomyolysis. Deep burns are more common with electrical than with lightning injuries. Delayed neurological disorders associated with lightning and electrical injuries include cognitive deficits, motor neuron disease, parkinsonism, choreoathetosis, dystonia, myoclonus, basilar artery thrombosis, seizures, myelopathy, generalized polyneuropathy, and reflex sympathetic dystrophy.^[97], ^[98] An additional type of injury is secondary trauma, such as from falls.

Management, Prognosis and Future Perspectives. Evaluation and management depend upon the sites, types, and extent of injury. About one third of lightning strikes are fatal. The symptoms and signs of keraunoparalysis typically resolve within a few hours. Victims of lightning and electrical injuries who are comatose due to a hypoxic encephalopathy as a result of cardiac arrest usually have a poor prognosis. Most patients with spinal cord injuries due to lightning and electrical injuries have permanent disability.

HISTORY AND DEFINITIONS

Epilepsy, from the Greek *epilepsia* (a taking hold of or seizing) is a chronic disorder characterized by a spontaneous tendency for recurrent seizures. Seizures are the clinical manifestation of abnormally hyperexcitable cortical neurons. Whereas all patients with epilepsy have seizures, many more patients have a single seizure during life and are not considered to have epilepsy.

The earliest descriptions of epilepsy appear in Mesopotamian writings from the fifth millennium BC. Persons with epileptic seizures were believed to be possessed by demons or evil spirits, and as a result, the disorder became known as the *sacred disease*. In the book *On the Sacred Disease*, a collection of Hippocratic writings from around 400 BC, the notion that epilepsy was caused by the gods and should be treated by the invocation of supernatural powers was challenged. In these writings, epilepsy was described as a hereditary disease caused by an overflow of phlegm in the brain. Treatment interventions, including proper diet and hygiene, were suggested in lieu of superstitious remedies. Nevertheless, during the middle ages, the drinking of human blood, trephination, skull cauterization, and sterilization were routinely practiced to cleanse the body of evil spirits and reduce the likelihood of transmission. ^[1]

By the eighteenth century, epilepsy became recognized as a chronic disorder of cerebral function. In the latter half of the nineteenth century, the British neurologist John Hughlings Jackson hypothesized that epilepsy was due to hyperexcitable cerebral gray matter. By correlating focal motor seizure semiology with postmortem pathological examinations, Jackson was the first to localize epileptogenic lesions. In 1886, the first surgery for epilepsy was performed by Sir Victor Horsley, who resected a traumatic cortical scar in a patient with focal motor seizures, rendering him seizure-free.

The invention of the electroencephalogram in 1929 had a profound impact on the diagnosis and classification of the epilepsies. During the 1930s and 1940s, Wilbur Penfield and colleagues mapped the primary sensory and motor cortices in human subjects, advancing the concept of functional localization. In the last several decades, a universally accepted classification of epileptic seizures and syndromes emerged through advancements in electrophysiology, neuroimaging, and molecular biology.

Epilepsy affects six to seven per 1000 population in the United States, and 40 to 50 new cases per 100,000 develop annually. ^[2] The risk of epilepsy increases from approximately 1 percent at birth through early adulthood to 3 percent by age 75 years. In two thirds of cases, the etiology is not identified.

BASIC MECHANISMS OF EPILEPTOGENESIS

To understand the mechanisms related to the development of epilepsy, some basic principles of normal neurophysiology must be reviewed. Electrical signals in neurons take two forms: the action potential, which propagates down the axon of the neuron from the soma to the axon terminal translocating information within a neuron; and transmission of information between neurons, which is accomplished primarily by chemical synapses.

A complex series of events underlie these electrical signals. Central to the understanding of these events is that the neuronal membrane is semipermeable to different ions carrying electrical current. The neuronal membrane's permeability

exhibits rapid changes that can dramatically alter the voltage across it. At the resting membrane potential, sodium ions (Na^+), which are concentrated in the extracellular space, flow into the cell, and intracellular potassium ions (K^+) flow out. A $\text{Na}^+ - \text{K}^+$ pump, utilizing adenosine triphosphate (ATP), replaces the displaced ions. Influx of positively charged ions (Na^+ and calcium ions [Ca^{2+}]) raises the membrane potential in the direction of depolarization, whereas chloride ion (Cl^-) influx and K^+ efflux hyperpolarizes the membrane. When a cell membrane is depolarized to threshold, Na^+ channels open, allowing the ions to flow intracellularly, which produces an action potential. Potassium efflux from the cell leads to repolarization of the membrane. The propagation of action potentials along axons transmits information throughout the nervous system. When the presynaptic axon terminal is stimulated by an action potential, there is an influx of Ca^{2+} triggering the release of neurotransmitters that bind to postsynaptic membrane receptors. This process produces excitatory and inhibitory postsynaptic potentials (EPSPs and IPSPs) whose summation and synchronization comprise the electrical activity recorded from the surface electroencephalogram (EEG). Glutamate and aspartate are the primary excitatory neurotransmitters in the central nervous system (CNS). Gamma aminobutyric acid (GABA) is the major inhibitory neurotransmitter in the brain.

A number of cortical cytoarchitectural and anatomical factors influence the propagation of electrical activity. The cerebral cortex is subdivided into neocortex, paleocortex, and archicortex. The archicortex includes the hippocampus and dentate gyrus, and the paleocortex consists of the piriform and olfactory cortices. The neocortex constitutes the remaining cortical regions characterized by the infolding of gyri and sulci. Epilepsy is a disorder that affects neocortical and archicortical neurons and their interconnections with brain stem and diencephalic structures.

The gray matter of the neocortex contains six types of neurons: pyramidal, stellate, horizontal, fusiform, basket, and Martinotti's cells ([Fig. 52-1](#)). The vertically aligned pyramidal cells are the main output neurons; they have extensive dendritic arborizations and excitatory synaptic endings that facilitate propagation of electrical activity. The granule, or stellate, cells are the major interneuronal pool. They are the second most numerous cells in the neocortex and are responsible for the propagation of both excitatory and inhibitory information. Axons of the horizontal and granule cells and collaterals of pyramidal and fusiform cells traverse parallel to the surface of the cortex. Pyramidal, fusiform, stellate, and Martinotti's cell axons form radial networks that travel vertically as projection or association fibers.

Projection fibers are afferent and efferent fibers conveying impulses to and from the cortex. Efferent fibers arise from the cortex and descend through the corona radiata and internal capsule. Afferent fibers arise primarily from the thalamus and project via the internal capsule to all regions of the cortex. Fibers interconnecting various cortical regions within the same hemisphere are known as *association fibers*. These include three main bundles: the uncinate fasciculus, connecting the orbital frontal gyri with anterior portions of the temporal lobe; the arcuate fasciculus, connecting the superior and middle frontal gyri with parts of the temporal lobe; and, the cingulum, connecting medial regions of the frontal and parietal lobes with parahippocampal and adjacent temporal cortical regions. Commissural fibers interconnect corresponding cortical regions of the two hemispheres and are represented by the corpus callosum and the anterior commissure. These pathways are important in the relay of information between hemispheres.

The pathophysiology of epilepsy involves alterations of normal physiological processes. An epileptic seizure is produced by synchronous and sustained firing of a population of neurons in the brain. The behavioral manifestations of a seizure reflect the function of the cortical neurons involved in the generation and spread of abnormal electrical activity. Epileptogenicity refers to the excitability and synchronization of neuronal networks that produce epileptiform activity in the brain. Both excitatory and inhibitory influences may be altered, creating a predisposition to excessive synchrony within neuronal populations.

Differences exist between patients who experience a single seizure and those with a tendency for recurrent seizures. Single seizures have various causes including electrolyte disturbances, drugs, and toxins. Increased extracellular K^+ leading to regenerative hyperexcitability underscores seizures that accompany metabolic aberrations. In hyponatremia, the extracellular space shrinks, leading to an increased concentration of extracellular K^+ and increased nonsynaptic or ephaptic coupling. This rise in K^+ facilitates neuronal firing. Similarly, because membrane excitability varies inversely with the extracellular concentration of Ca^{2+} , hypocalcemia can contribute to the synchronization and spread of abnormal electrical activity. Other metabolic disturbances such as hypomagnesemia, hyperglycemia, hypoxia, and ischemia can also produce seizures.

Alterations of neurotransmission, the ionic milieu, neuronal morphology, and neuronal networks are instrumental in the production of recurrent unprovoked seizures. Animal models using maximal electroshock and chemoconvulsants such as pentylenetetrazol have been used for decades to investigate the pathophysiology of generalized and focal seizures.

Experimentally induced focal epilepsies have been produced by the application of topical metals, such as cobalt, aluminum, and iron to the sensorimotor cortex. Pathological examination of these lesions reveals gliosis and neuronal loss. Neurons in the surrounding area may demonstrate abnormal dendritic morphology including denuded spines and reduced branching. Iron salts applied or injected into the cortex of experimental animals have been used in the investigation of post-traumatic epilepsy. Although the precise mechanisms of iron-induced epilepsy are unclear, iron is known to bind strongly with ATP and inhibit $\text{Na}^+ - \text{K}^+ - \text{ATPase}$ activity, leading to neuronal hyperexcitability. Additionally, iron reacts with the neuronal cell lipid membrane, producing free radicals and resulting in lipid peroxidation.

The kindling model is currently used in the study of partial epilepsy, particularly that involving the mesial temporal structures. *Kindling* refers to the processes that mediate long-lasting changes in brain function in response to repeated, gradually augmented stimulation of the brain. In the kindled animal, there is a permanent state of enhanced

Figure 52-1 Types and orientation of neurons within the six-layer neocortex (From Pansky B, Allen DJ: *Review of Neuroscience*. New York, MacMillan, 1980, p 287.)

seizure susceptibility. These models are important not only in the understanding of the pathophysiological basis of epilepsy but also in the screening of new compounds that may have anticonvulsant activity.

The structures most susceptible to the development of recurrent seizures include the motor cortex and the hippocampal formation and amygdaloid complex of the limbic system. The motor cortex is comprised of three areas: primary motor cortex, premotor cortex, and supplementary motor area. The motor cortex exerts its control by way of descending corticospinal and corticobulbar tracts and pathways originating in the brain stem. The motor cortex receives input from the thalamus, parietal lobe, and prefrontal cortex. These afferents allow seizures arising in restricted areas to propagate diffusely.

The amygdaloid complex (see [Chapter 3](#)) is an aggregate of subcortical nuclei within the rostral pole of the mesial temporal lobe having reciprocal interconnections with the septal area, hypothalamus, and brain stem nuclei. The hippocampal formation extends along the floor of the temporal horn of the lateral ventricle and is comprised of the dentate gyrus, hippocampus proper (CA fields), and the subicular complex (see [Chapter 4](#)). Hippocampal or mesial temporal sclerosis is characterized by variable degrees of pyramidal cell loss and gliosis in the hippocampal subfields and dentate gyrus. This condition represents the most common pathological substrate of partial epilepsy in adolescents and adults.

The notion that epilepsy is an inherited disorder was suggested more than 2000 years ago. The prevalence of epilepsy in relatives of affected individuals ranges from 0.5 to 15 percent. Rates are higher in idiopathic than symptomatic epilepsies. Studies of twins have demonstrated concordance rates as high as 70 percent in monozygotic and 10 percent in dizygotic pairs, implying that factors other than genetics play a role in the occurrence of seizures in these groups. Thus far, three syndromes have been mapped to a single gene locus: juvenile myoclonic epilepsy to chromosome 6q, benign familial neonatal convulsions to 20p, and progressive

myoclonic epilepsy of the Unverricht-Lundborg type to 21q. Several other epilepsies, including childhood/juvenile absence epilepsy, benign childhood epilepsy with centrotemporal spikes, childhood epilepsy with occipital paroxysms, and epilepsy with grand mal seizures on awakening appear to exhibit mendelian inheritance patterns and are likely to be mapped in the future. Additionally, as the result of various metabolic abnormalities, tumor formation, or impairment of normal brain growth or differentiation, seizures may occur in a large group of inherited neurological disorders. The investigation of these disorders may further elucidate the processes involved in epileptogenesis.

[PreviousNext](#)

EPILEPTIC SEIZURES

Efforts to classify epileptic seizures date back to the earliest of medical literature. In 1964, the Commission on Classification and Terminology of the International League Against Epilepsy (ILAE) proposed the first official classification of epileptic seizures, which was revised in 1981. ^[4], ^[5] Based on this classification, seizures are divided into *focal*, those in which the first clinical and/or electrographical

manifestations indicate initial activation of a limited population of neurons in part of one hemisphere, and *generalized*, those in which the initial manifestations suggest initial activation of neurons throughout both hemispheres. Focal seizures are further subdivided into *simple* and *complex*, based on level of consciousness. Seizures in which consciousness is preserved are referred to as *simple partial seizures*. Those in which consciousness is impaired are classified as *complex partial seizures*. Secondly generalized seizures are generalized seizures preceded by focal clinical and/or electrographical manifestations that occur in patients with focal epilepsy. The revised classification uses seizure semiology and EEG features to establish whether seizures are focal or generalized. For example, a seizure characterized by staring and loss of awareness is classified as *absence* when generalized spike-wave complexes are noted on the EEG, and as *complex partial* when associated with focal epileptiform discharges. Although this classification has gained worldwide acceptance, debate regarding terminology and the classification of seizures in infants and neonates continues.

The following discussion describes the clinical semiology of the various types of seizures. A later section describes epilepsy syndromes, which are characterized by combinations of seizure types and clinical, historical, and electrographical manifestations.

Generalized Seizures

TONIC-CLONIC SEIZURES

Tonic-clonic seizures (TCS) are the most common type of seizure encountered in childhood, adolescence, and adulthood. The manifestations of generalized TCS can be divided into several phases beginning with vague prodromal symptoms that may occur hours to days before the actual convulsion. Common premonitory symptoms include headache, mood change, anxiety, irritability, lethargy, changes in appetite, dizziness, and lightheadedness. The tonic phase may be preceded by a series of brief, bilateral muscle contractions lasting a few seconds. The tonic phase begins with brief flexion of the trunk, accompanied by upward deviation of the eyes, mydriasis, and a characteristic vocalization as contraction of abdominal muscles produces forced expiration across a spasmodic glottis. This process is followed by a period of generalized extension lasting 10 to 15 seconds. With evolution of the clonic phase, tonic contractions alternate with periods of muscle atonia of gradually increasing duration until contractions cease. The seizure terminates with a final generalized tonic spasm. Loss of consciousness and autonomic alterations occur during the tonic and clonic phases. Secondly, generalized seizures may be preceded by focal or lateralized clinical behaviors such as involuntary jerking of an extremity or head version before the onset of bilateral motor manifestations. Similarly, focal weakness of an extremity during the postictal state (Todd's paralysis) indicates seizure origin from the contralateral hemisphere. Tonic-clonic seizures commonly produce hypocarbia, owing to a combined respiratory alkalosis and lactic acidosis, transient hyperglycemia, mild CSF pleocytosis, and elevated serum prolactin. The immediate postictal state is characterized by coma that is gradually replaced by a confusional state. Once consciousness is regained, lethargy, myalgia, and headache are often reported. Most TCS are less than 1 minute in duration. Potential complications include oral and head trauma, vertebral body stress fractures, aspiration pneumonia, pulmonary edema, and sudden death.

Generalized TCS occurring in patients with idiopathic generalized epilepsies are associated with normal background activity and bilaterally synchronous and symmetrical spikes, polyspikes, or spike-wave complexes in the interictal EEG. Secondly generalized TCS are usually associated with background abnormalities and focal or lateralized slowing and epileptiform activity. During the tonic phase of a TCS, generalized low-amplitude 20- to 40-Hz activity evolves into a bilaterally synchronous and symmetric 10-Hz rhythm, which is referred to as the *epileptic recruiting rhythm*. Generalized polyspikes interrupted by slow waves characterize the clonic phase. The postictal period is characterized by generalized suppression or low-amplitude slow activity.

Experimental animal models using systemic chemoconvulsants and maximal electroshock provide some insight into the neuronal structures involved in the production of TCS. Lesions involving the pontine reticular formation produce the tonic phase in several animal models. Involvement of forebrain structures is required for the production of clonus, suggesting that an interaction of brain stem and neocortical structures takes place. These findings, however, have not been confirmed in humans.

TCS are observed in patients with idiopathic and symptomatic epilepsies and in association with systemic disease. ^[6] Hyponatremia, hypoglycemia, alcohol withdrawal, and drugs are common causes of isolated seizures particularly in hospitalized patients. Drugs that may precipitate TCS include tricyclic antidepressants, antipsychotics, anticholinergics, antihistamines, methylxanthines, antibiotics, and withdrawal from barbiturates and benzodiazepines. The prognosis for patients with idiopathic generalized TCS is better than that for those with focal or secondary generalized seizures, which tend to persist if untreated. The remission rate is greatest in patients who develop TCS in childhood in the absence of other seizure types.

TONIC, ATONIC, AND CLONIC SEIZURES

Tonic and atonic seizures are clinically distinct, although they are often present in the same patient. Tonic seizures are characterized by sustained, nonvibratory contractions of axial musculature usually involving flexion of the upper extremities and flexion or extension of the lower extremities. Impairment of consciousness and autonomic alterations occur, but to a lesser extent than in TCS. Seizures last typically less than 10 seconds, but they may be as long as 1 minute in duration. Tonic seizures are typically abrupt in onset and are followed by a rapid return to baseline. Seizures commonly occur in clusters during drowsiness and nonrapid eye movement (nonREM) sleep, frequently occurring dozens of times per day. Tonic seizures during wakefulness commonly produce injuries owing to sudden, unexpected falls. The interictal EEG typically shows a poorly organized background with generalized spike-wave

discharges of less than 3.0 Hz (slow spike-wave complexes) or focal or multifocal spikes and sharp waves. Ictal patterns include generalized attenuation, known as an *electrodecremental response*, low-voltage fast activity (15 to 25 Hz), high-amplitude 10-Hz rhythms, and generalized theta or delta activity.

The pathophysiology of tonic seizures is poorly understood. Lesions of brain stem nuclei produce the tonic phase of TCS and are implicated in the generation of tonic seizures as well. Other animal studies have suggested that discharges in the reticular gray matter caudal to the thalamus may produce EEG desynchronization, autonomic phenomena, and tonic seizures. Tonic seizures are typically observed in children with symptomatic generalized epilepsy, such as Lennox-Gastaut's syndrome. Prolonged tonic seizures may be mistaken for generalized TCS, decerebration, paroxysmal dystonia, convulsive syncope, and the tonic spasms seen in patients with neurodegenerative disorders such as multiple sclerosis. Tonic seizures arising from the supplementary motor area are characterized by bilateral electrographical manifestations on surface EEG, although motor activity is asymmetrical and consciousness is usually preserved.

Atonic seizures, or drop attacks, are characterized by abrupt loss of postural tone lasting 1 to 2 seconds. Consciousness is usually impaired, although recovery is rapid. Seizures may be limited to head and neck musculature producing a head drop, or they may involve all postural musculature resulting in sudden unexpected falls and injuries. The loss of tone may be preceded by a series of myoclonic jerks. The terms *atonic* and *astatic* are not synonymous. The latter refers to loss of erect posture resulting in a fall, which may occur with atonic, tonic, and myoclonic seizures. Like tonic seizures, atonic seizures are observed in neurologically abnormal children with symptomatic generalized epilepsy syndromes. Atonic seizures may be mistaken for breath-holding spells, syncope, and cataplexy. The ictal EEG demonstrates polyspike-wave or spike-wave discharges. More prolonged seizures may be accompanied by generalized spike-wave discharges followed by diffuse generalized slowing that is maximal at the vertex and central regions. This slow wave activity can be accompanied by severe, generalized hypotonia. Postictal changes are not prominent. With no experimental animal models available, the pathophysiology of atonic seizures is poorly understood. Because corpus callosotomy is effective in some patients with atonic seizures, interhemispheric mechanisms are suspected.

Generalized clonic seizures are rare and are usually seen in children with febrile illnesses. These seizures are characterized by an abrupt loss of consciousness with hypotonia or a generalized tonic spasm, followed by a series of myoclonic jerks. Motor involvement may be asymmetric, migratory, or focal. Significant autonomic changes and postictal confusion do not occur. Clonic seizures may be mistaken for TCS, when the onset is not observed, and myoclonic seizures when the phenomenology of the movement is more arrhythmical and random. In addition, nonepileptic clonic jerks may be seen in syncope and breath-holding spells and during the recovery phase of cataplexy. The interictal EEG in patients with clonic seizures reveals generalized spike- or polyspike-wave discharges. Seizures are

accompanied by a generalized 10-Hz rhythm intermixed with slow waves of variable frequency. As in TCS, neocortical structures are implicated in the generation of clonic seizures.

ABSENCE SEIZURES

Absence seizures (AS) are subdivided into typical and atypical forms. Typical AS are characterized by sudden behavioral arrest and unresponsiveness that may be accompanied by eyelid or facial clonus; automatisms; and autonomic, tonic, or atonic features. The duration rarely exceeds 10 seconds, and no aura or postictal state is observed. Atypical AS generally exceed 10 seconds in duration, begin and end more gradually, and produce less marked alteration of consciousness. Tonic, atonic, and myoclonic features are commonly observed.

Brief AS without automatisms or motor features may be mistaken for daydreaming or inattention. Absences with automatisms must be differentiated from temporal lobe complex partial seizures because treatment and natural history differ. Temporal lobe complex partial seizures usually exceed 30 seconds in duration and are characterized by prominent oral and hand automatisms, auras, and postictal confusion. Frontal lobe complex partial seizures may be more difficult to differentiate owing to their brevity, tendency to cluster, and higher incidence of bilateral EEG changes.

The interictal EEG in patients with typical AS reveals generalized 3.0-Hz spike-wave complexes superimposed on normal background activity. Bursts of generalized 3.0- to 4.0-Hz spike-wave complexes slowing to 2.5- to 3.0-Hz are observed during seizures (Fig. 52-2). Typical AS are commonly precipitated by hyperventilation and infrequently by photic stimulation. Behavioral changes are usually observed during bursts exceeding 3 seconds. Atypical AS are associated with 0.5- to 2.5-Hz slow spike-wave complexes superimposed on abnormal background activity. Unlike typical AS, atypical absences are rarely provoked by hyperventilation or photic stimulation.

Animal models of generalized absence seizures and in vitro electrophysiological techniques have shed light on the pathogenesis of AS. ¹² The corticoreticular theory postulates that typical AS involve the generation of abnormal oscillations within thalamocortical circuitry. Thalamic neurons have the ability to shift between oscillatory and tonic firing modes. During normal wakefulness, EEG desynchronization and tonic thalamocortical neuronal firing take place. With oscillatory rhythmic firing, thalamic excitatory postsynaptic potential (EPSP) threshold is raised, which produces dampening of signal transmission to the cortex, resulting in impairment of consciousness. Oscillatory behavior relies on the nucleus reticularis thalami, which is composed of GABAergic neurons that project to thalamic relay nuclei and to one another. The nucleus reticularis thalami receive excitatory glutaminergic inputs as well. Biochemically, a phase-locked GABA_a/GABA_b-mediated inhibition followed by glutamate-mediated excitation appears to be operative within the thalamocortical circuitry. The GABA_a/GABA_b-mediated inhibition triggers the key event, a low-threshold Ca²⁺ current in the nucleus reticularis thalami neurons, leading to recurrent depolarization and

1984

Figure 52-2 3.0-Hz spike-wave complexes during a seizure in a child with absence epilepsy.

repetition of the cycle. Neurons of the reticular nucleus of the thalamus and voltage-dependent Ca²⁺ channels (T-channels) of thalamic relay neurons are required to sustain the series of oscillatory burst firings between thalamic relay neurons and neocortical pyramidal cells. Generalized AS represent a potentiation of the rhythmicity so that the rhythmic firing mode predominates. The anti-absence agents ethosuximide and valproic acid suppress T-channel currents, whereas other anticonvulsant agents do not.

The high concordance for seizures and the 3.0-Hz spike-wave trait in monozygotic twins supports a genetic basis for AS. Typical AS occur in neurologically normal children with idiopathic generalized epilepsy. Atypical absences are observed in patients with diffuse or multifocal cerebral dysfunction resulting from acquired or inherited neurological disorders such as Lennox-Gastaut's syndrome (see later).

MYOCLONIC SEIZURES

Myoclonic seizures are single or repetitive, bilaterally synchronous and symmetric, rapid muscular contractions. Jerks are often restricted to facial and shoulder girdle muscles, although involvement of the trunk and limbs may occur. Consciousness is usually preserved. The EEG reveals generalized polyspikes or spike-wave complexes, which may or may not be time-locked to the muscular contraction. Interictal findings vary from normal background rhythms with generalized epileptiform discharges to severe background abnormalities with multifocal spike discharges, depending on the etiology.

Myoclonic seizures are commonly observed in neonates and children with idiopathic or symptomatic epilepsy. These seizures should be differentiated from nonepileptic events including movement disorders, hypnic jerks, nocturnal myoclonus, and segmental myoclonus of spinal cord or brain stem origin. Nonepileptic reticular and cortical reflex forms of myoclonus may occur in the setting of anoxia, trauma, stroke, degenerative or neoplastic disorders.

The pathophysiology of myoclonic seizures is poorly understood, partly because of the diversity of syndromes in which they appear and the difficulty in differentiating nonepileptic from epileptic myoclonus. Three subgroups of epileptic myoclonus have been described based on etiology, distribution, and the back-averaged EEG. ¹³ In idiopathic generalized epileptic myoclonus, generalized myoclonic jerks preceded by spike discharges are thought to be produced by abnormal subcortical influences on a diffusely hyperexcitable neocortex. Reticular reflex myoclonus consists of generalized, synchronous muscle contractions that precede the electrographic correlate and originate in brain stem structures. Cortical reflex myoclonus is characterized by unilateral or asynchronous jerks restricted to a few contiguous muscles preceded by spike discharges in the contralateral sensorimotor cortex. This form of myoclonus is thought to represent a form of focal epilepsy.

Partial (Focal) Seizures

SIMPLE PARTIAL SEIZURES

Simple partial seizures are epileptic seizures characterized by motor, sensory, autonomic, or psychic symptomatology during which consciousness is preserved. The term *aura* is reserved for subjective symptoms of epileptic origin reported by the patient in the absence of objective signs. Simple partial seizures can occur in isolation or preceding

1985

complex partial or tonic-clonic seizures. Multiple symptoms or signs may occur during a single seizure. Simple partial seizures with motor features include focal tonic and clonic activity, vocalizations, speech arrest, and version, defined as sustained, forced, involuntary turning of the eyes or head. The epileptic focus is usually in the hemisphere contralateral to the motor manifestations. The classic "Jacksonian march" in which focal clonus in distal muscles gradually spreads proximally along the motor homunculus occurs only rarely. Simple partial seizures with sensory symptoms include somatosensory, visual, auditory, vertiginous, gustatory, and olfactory disturbances. Autonomic phenomena include epigastric sensation, pallor, sweating, flushing, piloerection, and pupillary dilatation. Seizures with psychic symptoms include affective and cognitive disturbances and illusions or hallucinations of memory (*deja vu*, *jamais vu*), visions, sounds, self-image, and time.

Simple partial seizures should be differentiated from the prodromal symptoms that precede complex partial and TCS. Movement disorders including paroxysmal dyskinesias and tonic spasms, transient ischemic attacks, migraine, and psychiatric disease should be considered in patients with transient symptoms without impairment of consciousness.

Less than one third of simple partial seizures are associated with changes on surface EEG recordings. EEG changes are more common when the epileptic focus is close to the recording electrodes, such as in seizures arising from the perirolandic area. Neurons within an epileptogenic focus produce a synchronized burst of action potentials known as the *paroxysmal depolarization shift*, which is responsible for the generation of partial seizures. This paroxysmal depolarization shift is believed to produce focal interictal epileptic discharges.

The signs and symptoms of simple partial seizures reflect the function of the cortex involved in the generation and propagation of the abnormal electrical activity. A

strong association exists between semiology and site of seizure origin.^[9] Seizures with motor manifestations usually arise from the frontal lobes, although tonic activity and version may be seen in parietal and occipital lobe epilepsy. Autonomic, affective, and psychic phenomena are produced by activation of temporal lobe, and, less commonly, frontal lobe structures. Activation of epileptogenic foci in the insula and parietal operculum produces gustatory symptoms. Olfactory disturbances occur with orbitofrontal and mesial temporal lobe seizures. Elementary visual or auditory phenomena indicate activation of primary visual and auditory cortices in the occipital and superior temporal lobes, respectively. Complex illusions and hallucinations occur with activation of association areas. Whereas the first sign or symptom of a focal seizure aids in the localization of the epileptogenic focus, postictal focal motor, sensory, or visual field deficits can reliably identify the hemisphere of seizure origin. Consequently, whenever possible, a careful neurological examination should be performed immediately following a seizure.

Common pathological substrates of partial seizures include mesial temporal sclerosis, congenital malformation, neoplasm, CNS infection, head trauma, and cerebrovascular disease. With modern neuroimaging techniques, the ability to detect neuronal migration disorders, mesial temporal sclerosis, and low-grade gliomas has improved dramatically. The most common etiologies for partial seizures in children are congenital malformations and low-grade gliomas. Mesial temporal sclerosis predominates in young adults, and cerebrovascular disease is the most common cause of new-onset partial epilepsy in older adults.

COMPLEX PARTIAL SEIZURES

Complex partial seizures are partial seizures that are associated with an alteration of consciousness. The term *psychomotor* describes a particular semiology characterized by automatisms and impairment of consciousness, usually of temporal lobe origin. Complex partial seizures are also observed in frontal, parietal, and occipital lobe epilepsies. As in simple partial seizures, the clinical manifestations reflect the origin and propagation pattern of the epileptic focus. Seizures often begin with a motionless stare or arrest of activity followed by oroalimentary, hand, or gestural automatisms; eye movements; speech disturbances; and automatic behavior.

Complex partial seizures must be differentiated from typical and atypical absences. Psychogenic seizures, fugue states, panic attacks, inattention, sleep disorders, syncope, transient global amnesia, metabolic derangements, drug and alcohol ingestion, migraine, transient ischemic attacks, and fluctuations in mental status in patients with dementia should also be considered in the evaluation of patients with transient alterations in consciousness.

The interictal EEG in patients with complex partial seizures demonstrates focal or lateralized sharp waves, spikes, and slow waves. Several ictal patterns are observed. Rhythmical sinusoidal activity or repetitive spike discharges maximal over one region or hemisphere is most common. Nearly one third of complex partial seizures are not accompanied by EEG changes. A lack of EEG correlate is more likely to occur with brief seizures arising from deep regions such as orbitofrontal cortex or mesial temporal structures. The neuronal substrates of complex partial seizures are the same as in simple partial seizures except that alteration of consciousness implicates more extensive spread usually involving both cerebral hemispheres.

GENERAL APPROACH TO THE INITIAL SEIZURE

Approximately 6 percent of the population experiences an afebrile seizure at least once in their lifetime. ^[10] The decision to initiate antiepileptic drug (AED) therapy after a single seizure is based on the risk of recurrence versus that of treatment. Nearly 30 percent of treated patients experience unacceptable side effects requiring discontinuation of anticonvulsant medication. ^[11] In addition, although the initiation of AED therapy significantly reduces the risk of recurrence, it does not guarantee remission. Recurrence rates after single unprovoked seizures range from 27 to 71 percent. ^[12] The most reliable predictors of recurrence are (1) evidence of a neurological abnormality based on known etiology, neurological examination, or neuroimaging studies; (2) epileptiform abnormalities on EEG; and (3) partial

106

versus generalized seizures. The risk of recurrence increases with the number of abnormalities identified.

Patients who experience their first seizure should be evaluated with an EEG and a magnetic resonance imaging (MRI) study. The need for laboratory studies, toxicological screens, and cerebrospinal fluid analysis should be determined on an individual basis. Seizures due to drugs, alcohol, and metabolic disturbances require treatment of the underlying cause instead of AED therapy. Patients with evidence of neurological abnormalities that are likely to persist should be treated with anticonvulsants after discussing the potential risks and benefits. Treatment is generally continued for a period of 1 to 2 years, after which medication is gradually withdrawn if seizures have not recurred. Approximately 80 percent of recurrences appear within 2 years, and the majority do so within 6 months. ^[13] As a result, most states have laws requiring that driving be restricted for periods ranging from 3 to 12 months after a single unprovoked seizure. Individual state laws vary, as do the requirements for the reporting of patients to state authorities by physicians.

EPILEPSIES AND EPILEPSY SYNDROMES

Certain epileptic disorders are characterized by specific clusters of signs and symptoms that are considered epileptic syndromes. Because most of these syndromes have numerous etiologies, few have been defined as specific diseases. Proposed in 1989, the current classification of the epilepsies subdivides epilepsies and epileptic syndromes into three categories based on clinical history, electroencephalographic manifestations, and etiology. ^[12] *Localization-related epilepsies and syndromes* are typified by seizures that originate from a localized cortical region. The *generalized epilepsies and epilepsy syndromes* are characterized by seizures with initial activation of neurons within both cerebral hemispheres.

The syndromes are further divided into idiopathic and symptomatic types. *Idiopathic* refers to syndromes that arise spontaneously without a known cause, presumably having a genetic basis. Most affected patients are of normal intelligence and have normal results on neurological examinations. *Symptomatic* denotes epilepsies with an identified cause such as mesial temporal sclerosis. The term *cryptogenic* describes syndromes that are presumed to be symptomatic but have no known etiology and that occur in patients with or without abnormalities on neurological examination. Epilepsies that are characterized by both partial and generalized seizures and focal and generalized epileptiform discharges, but without a clear predominance of one over the other, are classified as *undetermined*. The term *lesional epilepsy* refers to focal epilepsy in which a lesion is identified on neuroimaging studies that is the probable cause of seizures. Lesions include mesial temporal sclerosis, congenital malformations, neoplasms, vascular malformations, and ischemic insults. The distinction between lesional and nonlesional focal epilepsy is particularly important in patients being considered for epilepsy surgery. In this population, surgical outcome is dependent upon the completeness of resection of epileptogenic lesion, which is accomplished more readily when a well-defined structural abnormality is present.

Localization-related (Focal) Epilepsies and Syndromes

BENIGN FOCAL EPILEPSIES OF CHILDHOOD

Benign focal epilepsies of childhood are idiopathic localization-related epilepsies characterized by partial seizures, focal EEG abnormalities, and absence of a known etiology. These are age-related syndromes occurring in neurologically normal children that have a tendency for spontaneous remission. BCECT is the most common, comprising 15 to 20 percent of all childhood epilepsies. ^[13] In comparison, benign epilepsy of childhood with occipital paroxysms (BCEOP), benign frontal epilepsy of childhood, and benign epilepsy with affective symptoms are rare.

Age of onset of BCECT ranges from 2 to 13 years, with peak incidence of 9 years. Simple partial seizures with sensorimotor symptoms of the face and oropharynx, hemi-convulsions, and TCS followed by Todd's paralysis occur typically during nonREM sleep. Nearly 80 percent of patients experience isolated or infrequent seizures. A family history of epilepsy is reported in 15 to 30 percent of patients. Centrotemporal sharp waves are observed in the EEGs of 15 to 30 percent of first-degree relatives. An autosomal dominant mode of inheritance with age-dependent penetrance is suspected. In BCEOP, seizures consist of visual symptoms with frequent evolution to hemiclonic, complex partial, and TCS. Tonic eye deviation and vomiting with alteration of consciousness are also observed. Headache, nausea, and vomiting occur postictally in 20 to 30 percent of patients.

Benign childhood epilepsy with centrotemporal spikes (BCECT) can be distinguished from the symptomatic epilepsies by seizure semiology, EEG manifestations, response to AEDs, and absence of abnormalities on neurological examination and neuroimaging studies. Similar seizure patterns and electrographical features may be seen in patients with lesions of the operculum and perirolandic cortex, however. Migraine, lesional occipital lobe epilepsy, MELAS (mitochondrial myopathy, lactic acidosis, and stroke-like episodes), and bilateral occipital cortico-subcortical calcifications with focal motor seizures should be considered in patients presenting with symptoms of BCEOP.

The interictal EEG in BCECT shows stereotypic unilateral or bilateral high-voltage diphasic centrotemporal sharp waves superimposed on normal background activity. Epileptiform activity tends to be markedly enhanced during nonREM sleep. The results of neuroimaging studies are normal. In BCEOP, high-amplitude, rhythmical, unilateral or bilateral occipital or posterior temporal spikes or sharp waves appear with eye closure and attenuate with eye opening.

Children with benign focal epilepsy who experience isolated or rare nocturnal seizures do not necessarily require treatment with AEDs. Treatment should be considered in patients with frequent TCS or seizures during wakefulness, however. Phenytoin, carbamazepine, phenobarbital, and

valproic acid are equally effective; however, carbamazepine is often preferred for its lower incidence of adverse reactions. The use of gabapentin in patients with BCECT is under investigation. Medication withdrawal should be considered after 1 to 2 years of seizure control or by age 16 years, when spontaneous remission usually occurs. Spontaneous remission by 16 to 18 years occurs in all patients with BCECT, although 1 to 2 percent experience rare TCS in adulthood. Satisfactory seizure control is achieved in only 60 percent of patients with BCEOP, 5 percent of whom develop new seizure types in adulthood.

TEMPORAL LOBE EPILEPSY

Temporal lobe epilepsy (TLE) constitutes nearly two thirds of localization-related epilepsies that appear during adolescence and adulthood. ^[14] Mesial temporal lobe epilepsy (MTLE), in which seizures arise from the hippocampus or amygdala, is most common, although neocortical onset occurs. The natural history is variable, and as many as 30 to 40 percent of patients continue to have seizures despite appropriate medical management. ^[14] Seizure onset ranges from the latter half of the first decade of life to early adulthood. In many cases, seizures begin several years after febrile seizures, head trauma, or CNS infection. Complicated febrile seizures are reported in 40 percent of patients with refractory TLE.

Visceral sensations, fear, anxiety, olfactory disturbances, and psychic phenomena are commonly reported by patients with seizures arising from the mesial temporal lobe. Auditory hallucinations or complex visual phenomena usually indicate neocortical temporal origin. Complex partial seizures are characterized by behavioral arrest, staring, automatisms, and occasionally, dystonic posturing of an extremity contralateral to the seizure focus. Seizure duration typically ranges from 30 to 120 seconds. Postictal confusion usually occurs, and language disturbances may follow seizures arising from the dominant hemisphere. Approximately 50 percent of patients also experience secondarily generalized TCS. Stress, sleep deprivation, and menstruation are common provoking factors. Status epilepticus is rare, and the results of the neurological examination are usually normal.

Mesial temporal sclerosis is the most common pathological substrate of TLE. Marked neuronal loss in the CA1, CA3, CA4, and the dentate granule cells is observed. The pyramidal cells in CA2, subiculum, entorhinal cortex, and temporal neocortex are relatively spared. Loss of granule cell innervation leads to reactive synaptogenesis, which results in an excitatory process capable of initiating and propagating seizures. The coexistence of mesial temporal sclerosis and extralimbic lesions is observed in 30 percent of surgical specimens. Seizure semiology may be indistinguishable in epilepsy arising from the orbitofrontal cortex, cingulate gyrus, and temporal lobe. Temporal lobe seizures should be differentiated from fugue states, syncope, psychogenic seizures, transient global amnesia, and absences.

The interictal EEG reveals slowing and spikes or sharp waves in the temporal region that are accentuated during nonREM sleep. The yield of EEG abnormalities is increased with sphenoidal or additional inferior temporal electrodes. Bitemporal independent discharges are observed in 30 percent of cases. The ictal EEG commonly begins with a regionalized or generalized attenuation followed by a gradual buildup of rhythmical theta or alpha frequencies intermixed with epileptic discharges ([Fig. 52-3](#)). Electroencephalographic manifestations are typically maximal in the anterior or mesial temporal region in patients

Figure 52-3 Rhythmic theta activity maximal at the left sphenoidal electrode during a seizure in a patient with mesial temporal lobe epilepsy.

with MTLE and lateral or posterior temporal area in neocortical TLE.

High-resolution MRI demonstrates hippocampal atrophy and abnormal signal intensities that are highly correlated with mesial temporal sclerosis in many patients with

MTLE. Fluorodeoxyglucose DG (¹⁸F) FDG positron emission tomography (PET) demonstrates temporal lobe hypometabolism in over 80 percent of cases. Both ictal and interictal single-photon emission computed tomography (SPECT) show unilateral abnormalities, although the spatial resolution is inferior to that of PET, and technical factors, such as time of injection in relation to seizure onset, dramatically influence results.

Carbamazepine and phenytoin are the recommended drugs of choice for the treatment of complex partial seizures with or without secondarily generalized TCS. ^[15] Outcome is poorer and the incidence of adverse effects is higher with phenobarbital or primidone monotherapy. ^[15] A comparison study of carbamazepine and valproic acid revealed similar efficacy against TCS, although carbamazepine was superior for the control of complex partial seizures and produced fewer adverse effects. ^[16] The newer anticonvulsant medications gabapentin, lamotrigine, and topiramate may also be effective. Sixty to 70 percent of patients achieve good control or remission with appropriate medical management. Factors predictive of less favorable outcome include onset before 2 years of age, frequent complex partial and tonic-clonic seizures, known etiology, status epilepticus, and history of febrile convulsions. Those who fail to respond to medical management after 1 to 2 years and those with structural lesions in the temporal lobe should be referred to an epilepsy center for surgical evaluation.

EXTRATEMPORAL NEOCORTICAL EPILEPSY

The incidence of neocortical epilepsy is derived from surgical series of medically refractory patients. Consequently, the incidence and natural history of extratemporal epilepsy are unknown. Frontal lobe epilepsy is most common after TLE, followed by parietal and occipital lobe epilepsies. ^[17]

Various seizure patterns are observed in frontal lobe epilepsy. Frontal lobe complex partial seizures are differentiated from those of temporal lobe origin by their abrupt onset, shorter duration, absence of prolonged postictal state, and tendency for status epilepticus and seizure clusters. Generalized motor activity, sexual automatisms, vocalizations, version, and focal clonic and tonic activity are observed. Seizures arising from the orbitofrontal cortex and cingulate gyrus produce staring, automatisms, and autonomic and affective manifestations. Brief, recurrent, nocturnal seizures characterized by asymmetrical tonic posturing and vocalizations with preserved consciousness are observed in supplementary motor area epilepsy. Opercular area seizures are associated with salivation, mastication, speech arrest, laryngeal symptoms, autonomic signs, and gustatory or epigastric disturbances. Seizures originating in the dorsolateral frontal convexity are characterized by focal tonic and clonic activity, version, and speech arrest. Koshewnikow's syndrome, characterized by repetitive focal motor seizures, myoclonus, and focal motor status epilepticus is observed in seizures originating in the perirolandic region.

In parietal lobe epilepsy, auras consist of lateralized somatosensory symptoms, vertigo, and epigastric or cephalic sensations. Automatisms and asymmetrical tonic posturing are observed with ictal propagation to the temporal or frontal lobes, respectively. Occipital lobe seizures are characterized by elementary visual hallucinations that may be limited to the contralateral hemifield, sensations of eye movement, eye blinking, and ictal blindness.

With the exception of head trauma, which commonly produces contusions of the frontal and temporal polar regions and orbitofrontal cortex, the location of the epileptic focus does not predict etiology. The various etiologies of neocortical epilepsies include neoplasm, head injury, CNS infection, vascular malformation, and neuronal migration disorder. ^[18] No cause is identified in 25 percent of cases.

Neocortical epilepsy should be differentiated from MTLE, which has a more favorable response to surgical intervention. Movement disorders, parasomnias, and psychogenic seizures may mimic frontal lobe seizures. Parietal and occipital lobe seizures may be mistaken for transient ischemic events. The differentiation of migraine and occipital lobe epilepsy may be difficult because both commonly produce transient visual phenomena followed by nausea, vomiting, and headache.

The yield of EEG abnormalities is dependent on the size of the epileptogenic focus and its distance from the recording electrodes. The EEG recording may be normal when seizures arise from deep, midline, or basal locations unless special recording techniques or montages are employed. Abnormalities consist of nonspecific slowing, focal or bilateral epileptiform discharges, and low-voltage fast activity. Secondary bilateral synchrony, in which a unilateral deep or midline focus produces bilaterally synchronous and symmetrical epileptiform activity, may be mistaken for generalized epileptic discharges found in idiopathic generalized epilepsy. In comparison with MTLE, a higher incidence of nonlocalized and nonlateralized ictal EEG patterns is observed. Consequently, intracranial monitoring is usually required in medically refractory cases when MRI fails to reveal focal pathology.

The management of neocortical epilepsy is similar to that for patients with TLE. No studies comparing the response to AEDs and remission rate in neocortical epilepsy and TLE are available. Patients with structural abnormalities on MRI and those who prove to be medically resistant after 1 to 2 years of treatment should be referred to an epilepsy center for surgical consideration. The outcome of surgical treatment depends on the extent of resection of the epileptogenic zone, which may be limited by involvement of cortical regions subserving motor or language functions. Following complete resection of an epileptogenic lesion, 40 to 70 percent of patients become seizure-free. ^[17], ^[18] The prognosis is less favorable when imaging studies fail to reveal a focal abnormality.

Generalized Epilepsies and Epileptic Syndromes

IDIOPATHIC, AGE-RELATED

Benign Neonatal Familial and Nonfamilial Convulsions. Benign idiopathic neonatal convulsions (BINNC)

and benign familial neonatal convulsions (BFNNC) are rare neonatal syndromes, characterized by seizures beginning in the first week of life. Most infants are neurologically normal, and spontaneous remission usually occurs. Benign idiopathic neonatal convulsions account for 2 to 7 percent of neonatal convulsions. ^[19] BFNNC is less common, with only 150 cases having been reported in the literature. ^[19]

Seizures in BINNC have been referred to as *fifth-day fits* because of their presentation between the fourth and sixth days of life. Recurrent focal or generalized clonic seizures, apneic events, and status epilepticus are observed. A family history of epilepsy may be present. In BFNNC, seizures begin on the second or third day of life and tend to recur for several months. Although most infants have no other abnormalities on examination, minor neurological findings have been reported. The etiology and pathophysiology of BINNC are unknown; BFNNC is an inherited disorder characterized by autosomal dominant transmission with a genetic defect located on chromosome 20q.

A diagnosis of BFNNC can be made only when other causes of convulsions are excluded and a family history of neonatal seizures with spontaneous remission is present. The diagnosis of both syndromes is usually made retrospectively after neurological deterioration and other seizure disorders fail to emerge. Laboratory and neuroimaging study results are unrevealing, although the EEG commonly shows "theta pointu alternant," which is a discontinuous, unreactive theta rhythm associated with neonatal seizures of various etiologies. In other cases, the EEG recording is normal or shows focal or multifocal abnormalities.

Anticonvulsant therapy has not had a consistent effect on the duration of seizures. Neonates with infrequent seizures and those in whom a family history of BFNNC is present do not require AED therapy. Prognostically, both syndromes are considered benign, although follow-up beyond early childhood has not been reported. Febrile and afebrile seizures during childhood have been described in 11 percent of patients with BFNNC and in 0.5 percent of patients with BINNC. ^[19]

Myoclonic Epilepsies of Infancy and Childhood. Myoclonus and myoclonic seizures are observed in various disorders affecting infants and children. Myoclonic seizures may be overshadowed by more striking seizure patterns and neurological abnormalities. As a result, the classification of these disorders is imprecise. Several syndromes demonstrating consistent etiological, clinical, and electrophysiological features have been described, however. ^[20]

Early myoclonic encephalopathy is a disorder affecting severely neurologically impaired infants shortly after birth. Erratic fragmentary myoclonus and generalized myoclonic, tonic, and focal motor seizures are observed. The EEG shows a suppression-burst pattern that evolves to hypsar-rhythmia or multifocal spike discharges within months. Antiepileptic medications are ineffective, and 50 percent of patients do not survive beyond the first year of life. Inborn errors of metabolism and congenital malformations are present in some cases.

Early infantile epileptic encephalopathy, or Ohtahara's syndrome, is characterized by tonic spasms beginning in the first few months of life, a suppression-burst pattern on EEG, and rapid progression from normal to severe neurological disability. Only 50 percent of infants survive beyond the first year of life. Hypsarhythmia, slow spike-wave complexes, or multifocal spikes are observed beyond the neonatal period. Ohtahara's syndrome represents the first in the spectrum of age-related epileptic encephalopathies, frequently evolving to West's syndrome, followed by Lennox-Gastaut's syndrome. Congenital malformations are commonly found.

Anticonvulsant treatment is usually ineffective, and the prognosis is poor.

Benign myoclonic epilepsy of infancy is characterized by myoclonic seizures in neurologically normal children in the first or second years of life. TCS may develop in adolescence. A history of febrile seizures is common, and a family history of seizures is reported in 30 percent of cases. The interictal EEG is usually normal, and seizures are readily controlled with valproic acid.

Severe myoclonic epilepsy in infancy appears in the first year of life as prolonged, recurrent febrile seizures. Other seizure patterns including atypical absences, myoclonic seizures, and myoclonic status epilepticus appear in early childhood. Affected children are initially normal but develop psychomotor retardation by the second year of life, which is often accompanied by ataxia, pyramidal signs, and myoclonus. The EEG reveals generalized epileptiform discharges. Medical treatment is generally ineffective, and prognosis is poor.

Epilepsy with myoclonic absences is characterized by rhythmical myoclonic seizures with impairment of consciousness beginning in childhood. Seizures are provoked by hyperventilation, and the EEG reveals 3.0-Hz spike-wave complexes. Nearly 50 percent of patients are cognitively impaired before seizure onset. Valproic acid and ethosuximide may be effective, but seizures are often medically refractory.

Absence Epilepsy. Previously referred to as "petit mal," absence epilepsy (AE) accounts for 3 to 4 percent of all seizure disorders.^[21] Childhood AE, which appears in children between the ages of 4 and 8 years, comprises 80 percent of cases. Juvenile AE constitutes the remainder, in which seizures begin around the age of 12 years. Typical AS occur several to hundreds of times per day. TCS occur in approximately 30 percent of childhood-onset and 80 percent of juvenile-onset patients. Absence status, consisting of prolonged periods of mental clouding associated with repetitive spike-wave complexes, occurs in 10 to 20 percent of childhood-onset AE (CAE) and 40 percent of juvenile-onset AE (JAE) cases. Myoclonic seizures, which are not routinely seen in CAE, occur in 15 percent of JAE. Neurological examination results and intelligence are normal. AE is presumed to be an inherited disorder, although the gene responsible for its expression has not been identified. A family history of epilepsy is present in approximately 30 percent of patients. In one study, the concordance rate for seizures and the spike-wave trait in monozygotic twins was found to be 64 percent and 82 percent, respectively, suggesting that a combination of genetic and nongenetic factors is operative.^[22]

AE should be distinguished from daydreaming, inattention, and temporal or frontal lobe seizures. In general, the diagnosis is readily confirmed by EEG, which demonstrates 3.0-Hz spike-wave complexes in CAE. Irregular 3.5- to 6.0-Hz polyspike-wave complexes are more commonly observed in juvenile-onset cases. Background activity is otherwise

normal. Hyperventilation accentuates spike-wave complexes in nearly 80 percent of cases. Additionally, nearly 30 percent of patients are photosensitive. Neuro-imaging, including MRI and CT scans, is usually unrevealing and is not required unless atypical features are present.

Ethosuximide or valproic acid controls absence seizures in 80 percent of cases. Because ethosuximide is not effective against TCS, valproic acid is the drug of choice in patients with both seizure types. The disease in 5 to 20 percent of patients is not satisfactorily controlled with monotherapy, and patients may benefit from a combination of ethosuximide and valproic acid, benzodiazepines, or acetazolamide. Lamotrigine may also be effective.

AS typically go into remission by early adulthood, although TCS are more likely to persist. Rhythmical occipital delta activity on EEG is associated with a more favorable course and lower incidence of TCS. Subnormal intellect, resistance to antiepileptic medication, and presence of myoclonic seizures portend a worse prognosis. A meta-analysis showed remission rates ranging from 21 to 89 percent with differences relating to inclusion criteria, follow-up lengths, and outcome definitions.^[23] Seventy-eight percent of patients with AS alone were seizure-free compared with 35 percent when TCS were also present.^[23]

Juvenile Myoclonic Epilepsy. Juvenile myoclonic epilepsy (JME) accounts for 4 to 10 percent of all epileptic syndromes.^[24] JME appears in neurologically normal adolescents between the ages of 12 and 18 years. Myoclonic seizures consist of bilaterally synchronous and symmetrical jerks of the neck, shoulders, and arms that may be single or repetitive. Consciousness is usually preserved. TCS preceded by a series of myoclonic jerks occur in over 90 percent of patients. One third have absences as well. Myoclonic and tonic-clonic seizures occur predominantly in the early morning hours shortly after awakening and are provoked by sleep deprivation, alcohol ingestion, fatigue, and menstruation.

Juvenile myoclonic epilepsy is a genetically determined syndrome with a gene locus on the short arm of chromosome 6 (6p). Nearly 50 percent of JME patients have relatives with seizures and 30 percent have asymptomatic family members with generalized epileptiform abnormalities on EEG. JME should be differentiated from the progressive myoclonic epilepsies (PMEs) and other idiopathic epilepsies in which absence, myoclonic, and tonic-clonic seizures are observed. The PME's are characterized by progressive neurological deterioration, myoclonus, and seizures, and may be mistaken for JME early on before severe neurological disabilities develop (see later).

The interictal EEG reveals bilaterally synchronous 4.0- to 6.0-Hz polyspike-wave complexes superimposed on normal background activity ([Fig. 52-4](#)). A photoparoxysmal response is elicited in 30 percent of patients. Myoclonic seizures are accompanied by bursts of generalized, synchronous, and symmetrical 10- to 24-Hz polyspikes followed by irregular slowing. AS are associated with 3.0-Hz spike-wave or 4.0- to 6.0-Hz polyspike-wave complexes. MRI and CT studies generally yield normal results and need not be routinely performed unless atypical features are present.

Patients should be advised to avoid precipitating factors. Photosensitive patients should also limit their exposure to flashing lights. Valproic acid is the drug of choice and is effective in 85 to 90 percent of patients. Lamotrigine may also be effective. Ethosuximide may be used for refractory absences. Uncontrolled myoclonic seizures may respond to benzodiazepines. Phenytoin, carbamazepine, primidone, phenobarbital, and acetazolamide may be effective against refractory TCS. Women of childbearing age should be counseled of the teratogenic potential of the AEDs, in particular, the association of valproic acid with neural tube defects. The prognosis of JME is excellent, and seizures are well controlled in most patients if precipitating factors are avoided. Because over 90 percent of patients relapse after medication withdrawal, AED therapy should be maintained even in patients with long seizure-free intervals.

Epilepsy with Generalized Tonic-clonic Seizures. Generalized TCS are observed in six idiopathic generalized epilepsy syndromes, which include CAE, JAE, JME, epilepsy with GTCS on awakening, epilepsies precipitated by specific modes of activation, and generalized idiopathic epilepsies not included in the other syndromes. A significant degree of overlap exists between these syndromes. Rarely, more than one has been present in the same patient at different periods in life.

By definition, idiopathic generalized TCS are not preceded by auras, although vague prodromal symptoms such as headache and malaise have been described hours or days before seizures. Seizures are usually infrequent; they tend to occur at the same time in the sleep-wake cycle of a given patient. Sleep deprivation, photic stimulation, alcohol consumption, menstruation, and stress are potent activators. The age of onset ranges from 6 to 20 years, usually peaking in puberty. Neurological examination results and intelligence are normal.

The family history of epilepsy exceeds that of the general population, suggesting a genetic etiology. Linkage to the gene locus of JME was demonstrated in a group of adolescents with generalized TCS on awakening, but such a phenomenon was not seen in patients with randomly occurring generalized TCS.^[25] A higher incidence of microdysgenesis exists in patients with idiopathic generalized epilepsy compared with controls, but the significance of this finding is unknown. The differential diagnosis includes generalized TCS due to drugs, alcohol intoxication and withdrawal, and medical disorders including metabolic derangements and electrolyte imbalance.

The EEG reveals diffuse, bilaterally synchronous 3.0-Hz or 4.0- to 6.0-Hz spike-wave or polyspike-wave complexes, similar to that seen in the other idiopathic generalized epilepsies. Background activity and neuroimaging study results are normal. Phenytoin, carbamazepine, valproic acid, and phenobarbital are equally effective, and newer antiepileptic medications such as lamotrigine may be beneficial. Patients should be instructed to avoid sleep deprivation and other precipitating factors. Eighty to 95 percent of patients experience prolonged seizure-free periods. Relapses after medication withdrawal are variable, tending to be lower in children than adults.

CRYPTOGENIC OR SYMPTOMATIC, AGE-RELATED

West's Syndrome. West's syndrome is an age-dependent epilepsy consisting of the triad of infantile spasms, psychomotor

Figure 52-4 Generalized polyspike-wave complexes in a patient with juvenile myoclonic epilepsy.

retardation, and a characteristic EEG pattern known as *hypsarhythmia*. The syndrome is named for WJ West, the nineteenth century neurologist who described the features he observed in his own son. Infantile spasms occur in 24 to 42 of 100,000 births.^[26] Spasms and psychomotor retardation appear in the first year of life in 85 percent of cases, the majority between 3 and 7 months. Infantile spasms are sudden, brief, usually bilaterally symmetrical flexor contractions of the neck, trunk, or limbs. Eye movements, autonomic signs, and brief lapses of consciousness may be observed. Less commonly, extension of the head, trunk, and limbs may be seen. Spasms are commonly repetitive, occurring in clusters on awakening, or during drowsiness, handling, feeding, or fever. Initially, the movements can be so slight that they may go unnoticed. Neurodevelopmental abnormalities may precede the onset of spasms. Moderate to severe cognitive disability occurs in 76 to 95 percent of patients. Associated abnormalities include generalized hypotonicity, microcephaly, paralysis, ataxia, blindness, and deafness. Because one third of patients lack the characteristic EEG features and 5 percent do not develop psychomotor retardation, the distinction between West's syndrome and the myoclonic epilepsies of infancy may be difficult. In addition, infantile spasms may be mistaken for nonepileptic phenomena that occur in infants with diffuse cerebral dysfunction, such as head-banging, colic, and decerebration.

West's syndrome is classified as symptomatic or cryptogenic based on the presence or absence of a known etiology. The proportion of symptomatic cases has increased in the years paralleling advances in neuroimaging. Tuberous sclerosis is one of the most common etiologies, comprising nearly 25 percent of symptomatic cases. Congenital malformations including midline defects, neurocutaneous disorders, and neuronal migration disorders comprise 30 percent of cases in neuropathological series.^[27] Another 30 percent occur in the setting of perinatal complications such as trauma or hypoxic ischemic injury. Tumors, CNS infections, metabolic disorders, and inherited diseases such as Aicardi's syndrome are less common. A family history of epilepsy or febrile seizures is present in 10 to 15 percent of cases.

Although the underlying pathophysiology of infantile spasms is unknown, the age-dependency and diffuse EEG abnormalities imply widespread cortical dysfunction. Increased synthesis and activity of corticotrophin-releasing hormone (CRH) has been postulated as a mechanism that might predispose to the development of spasms. Increased CRH may follow an abnormal stress during early life or an errant response to common stressors, resulting in growth or hyperfunction of certain CRH-containing neuronal pathways. Supporting this theory are various animal studies demonstrating the excitatory effects of CRH on neurons, including those in the hippocampus and the beneficial effects of adrenocorticotropin (ACTH) and glucocorticoids in the treatment of spasms. Although ACTH and glucocorticoids may have intrinsic anticonvulsant activity, they may also suppress CRH production via the hypothalamic-pituitary-adrenal axis and thereby alleviate the excitatory effects of CRH on certain neuronal networks.

The typical EEG reveals *hypsarhythmia*, a chaotic pattern of high-amplitude slow waves with multifocal epileptiform discharges and poor interhemispheric synchrony ([Fig.52-5](#)). Sleep is markedly disrupted and REM sleep is reduced. An electrodecremental response consisting of generalized low-voltage fast activity accompanies spasms. By 3 years of age, *hypsarhythmia* typically evolves to slow spike-wave complexes or multifocal spikes and sharp waves. Abnormalities on neuroimaging studies are found in over 60 percent of infants. These abnormalities include generalized

Figure 52-5 Hypsarhythmia in an infant with West's syndrome.

atrophy, white matter hyperintensities, and focal or multifocal lesions. Regional hypometabolism on PET studies has been demonstrated in some patients with focal cortical lesions.

The dose and duration of steroid therapy has not been standardized. The most common treatment is ACTH 40 IU per day administered intramuscularly. Approximately 75 percent of patients achieve initial seizure control using this regimen. The response rate tends to increase with duration of therapy. Within 2 months of remission, however, approximately 30 to 50 percent of patients suffer relapse after the first course of steroids. The relapse rate may be somewhat lower in cryptogenic than symptomatic cases. No differences in long-term response rates are observed with low-and high-dose therapy. Although there have been few reports using oral steroids, a noncontrolled study comparing hydrocortisone with ACTH found no difference in the rate of response.^[28] Others have achieved better results early on with high-dose ACTH as compared with prednisone or prednisolone therapy.^[29] Side effects are common and include electrolyte disturbances and cardiac, infectious, and neuropsychiatric complications. Valproic acid, pyridoxine, vigabatrin,, and immune globulin have shown some efficacy, as has nitrazepam, which is not currently commercially available in the United States. Favorable results have been reported following lesionectomy or hemispherectomy in patients with focal abnormalities on MRI or PET scans.^[27]

Infantile spasm and the *hypsarhythmia* tend to diminish with increasing age. Complete resolution is achieved in 50 percent of patients by 2 years and 72 to 99 percent by 5 years of age.^[27] Over 50 percent of patients develop Lennox-Gastaut's syndrome, multifocal or secondarily generalized epilepsy, or other forms of epilepsy during childhood. Only 5 percent of patients experience spontaneous remission without neurological sequelae. Mental retardation is observed in 50 to 60 percent of cases. The condition ultimately leads to death in 5 to 20 percent of patients. Factors associated with a poor prognosis include delay in treatment, unilateral spasms, neurological deficits, abnormal neuro-imaging study results, atypical EEG manifestations, and known etiology.

Lennox-Gastaut's Syndrome. Lennox-Gastaut's syndrome is responsible for 2 to 3 percent of childhood epilepsies.^[29] The syndrome is characterized by multiple seizure types, slow spike-wave complexes, and diffuse cognitive dysfunction. Seizure onset ranges from 1 to 8 years of age, with a peak incidence between 3 and 5 years of age. Tonic seizures during sleep or on awakening occur in virtually all cases. Atonic, atypical absence, and myoclonic seizures are commonly observed. Status epilepticus, consisting of repetitive tonic seizures or clouding of consciousness lasting hours to weeks, is seen in nearly two thirds of patients. Severe mental retardation is found in 50 percent of cases, preceding the onset of seizures in 20 to 60 percent. In addition, disturbances of behavior and personality are common.

Approximately 70 percent of cases occur in children with acquired or genetic disorders affecting the nervous system. Congenital malformations, hypoxic-ischemic encephalopathy, CNS infections, and neurocutaneous disorders, particularly tuberous sclerosis, are frequent causes. Thirty percent of patients have a history of West's syndrome. A family history of epilepsy may be found in cryptogenic cases; however, familial Lennox-Gastaut's syndrome has not been reported. Lennox-Gastaut's syndrome should be differentiated from epilepsy with myoclonic atstatic seizures In this

syndrome, multiple seizure types occur in previously normal children, 50 percent of whom develop mental retardation. A genetic etiology is suspected.

The EEG reveals 2.0- to 2.5-Hz slow spike-wave complexes and multifocal spikes superimposed on abnormal background activity. Runs of generalized paroxysmal fast activity and rhythmical 10-Hz spikes are observed during sleep. Atypical AS are associated with runs of slow spike-wave complexes. Tonic seizures are accompanied by an electrodecremental response or generalized 10- to 25-Hz spikes. Neuroimaging studies commonly demonstrate generalized cerebral atrophy and focal or multifocal abnormalities.

In general, seizures respond poorly to anticonvulsant treatment, and polytherapy is usually required. Benzodiazepines and valproic acid are the most effective agents, although the former may precipitate tonic status. Sedation should be minimized because of the tendency for seizures to increase in sleep. Phenytoin and rectal diazepam are effective for serial tonic seizures and status epilepticus. Lamotrigine may be effective against atypical absence, myoclonic, and atonic seizures. Refractory cases may benefit from the ketogenic diet or corpus callosotomy, which reduces tonic and atonic seizures in some cases.

The prognosis for seizure control and mental development is poor. Daily seizures occur in most patients. Factors that portend a poor prognosis include known etiology, onset before 3 years of age, prior West's syndrome, refractory tonic seizures, and severe mental retardation. Seizures usually persist into adulthood, and

fatal injuries related to seizures occur in 5 percent of cases.

SPECIAL EPILEPSY SYNDROMES

Progressive Myoclonic Epilepsies (PMEs). The PMEs represent a group of disorders of various etiology that collectively account for 1 percent of all epilepsy syndromes.^[30] The natural history varies with the specific disorder from mild neurological impairment to severe disability progressing to death in early childhood. Onset is typically during childhood or adolescence, although some of the disorders may appear at any age. Clinically, the PMEs are characterized by progressive myoclonus, seizures, variable degrees of cognitive impairment, and other neurological deficits. Myoclonus is commonly precipitated by action, sustained posture, or sensory stimulation including touch, cold, or light. Fragmentary and asynchronous myoclonic jerks primarily involving the limbs occur without associated alteration of consciousness. Myoclonus varies from mild to debilitating, depending on the specific disorder. Dementia is a characteristic sign of many of the PMEs but is not a universal feature. The severity of intellectual deterioration is related to the degree of cortical loss and varies between individuals affected with the same disorder. Other neurological findings include ataxia, spasticity, visual impairment, hearing loss, peripheral neuropathy, and extrapyramidal signs such as choreoathetosis. TCS represent the most common seizure type, although atypical absence and focal seizures are observed in some disorders.

The disorders comprising the PMEs may be classified into the following categories: (1) those with well-defined biochemical defects; (2) those with a known pathological or biochemical marker yet poorly defined mechanism; and (3) the "degenerative" PMEs, in which there are no known pathological or biochemical markers ([Table 52-1](#)). The PMEs with known biochemical defects include the sial-idoses, sphingolipidoses, and myoclonic epilepsy with ragged red fibers (MERRF).

Of the PMEs with a known pathological or biochemical marker but imprecisely defined mechanism, Lafora's disease and neuronal ceroid lipofuscinosis (see [Chapter 30](#)) are most common. *Lafora's disease* is a rapidly progressive autosomal recessive disorder affecting individuals in late childhood or adolescence, although adult onset rarely occurs. Generalized TCS or partial seizures of occipital lobe origin are usually the initial manifestation. Progressive cognitive decline is a universal feature. Severe resting and action myoclonus develops early in the course of illness. Ataxia, decreased vision, and spasticity are variably present. Death occurs within 2 to 10 years of symptom onset. Skin, liver, and muscle biopsies demonstrate periodic acid-Schiff stain polyglucosan inclusions, or Lafora's bodies, which are a hallmark of the disease.

Other rare PMEs having known biological or pathological markers but poorly defined mechanisms include the *childhood form of Huntington's chorea*, *juvenile neuroaxonal dystrophy*, and *action myoclonus-renal insufficiency syndrome*.

Unverricht-Lundborg's disease, or Baltic myoclonus, and *dentatorubropallidoluysian atrophy* (see [Chapters 34](#) and [35](#)) represent the degenerative PMEs in which no pathological or biochemical markers are known to exist. Baltic myoclonus has long been shrouded in controversy, and its existence as a separate entity has only recently been confirmed. This disorder occurs predominantly in Finland, Estonia, and Sweden. The disease is autosomal recessive, and the responsible gene has been linked to the long arm of chromosome 21. The syndrome is characterized by myoclonus and TCS beginning between the ages of 8 and 13 years in individuals with no prior neurological abnormalities. The myoclonus is severe and can be precipitated by movement, stress, light, noise, or tactile stimulation. Repetitive myoclonic jerks in the morning may culminate in generalized TCS later in the day. Ataxia, intention tremor, and dysarthria usually develop in the later stages of illness. Gradual intellectual decline is observed; however, severe dementia does not occur. Depression is a common feature. Death typically occurs within 14 years of onset.

Dyssynergia cerebellaris myoclonica, or the Ramsay Hunt syndrome, describes a nonspecific disorder characterized by a gradually progressive cerebellar syndrome followed by myoclonus and infrequent TCS beginning in childhood or adolescence. The disorder does not represent a specific disease. Seizures and epileptiform electrographical findings are rare. Consequently, Ramsay Hunt syndrome is generally not considered a PME, but rather it is considered to be a progressive ataxia.

In general, treatment of the PMEs is difficult. Myoclonus responds best to valproic acid and benzodiazepines, particularly clonazepam. L-tryptophan, 5-hydroxytryptophan with carbidopa, and piracetam may also be useful. Mechanical techniques may be useful in lessening the incapacitating effects of action myoclonus. Valproate, clonazepam, and phenobarbital alone or in combination may be

TABLE 52-1 -- PROGRESSIVE MYOCLONIC ENCEPHALOPATHIES

Disorders	Age at Onset	Clinical Features	Prognosis	Laboratory	Inheritance/Deficiency
WITH WELL-DEFINED BIOCHEMICAL DEFECTS					
Sialidoses					
Type I	8-15	Myoclonus, visual deficit, TCS, ataxia, spasticity, burning sensation in extremities	Poor	Urinary sialyloligosaccharides Demonstration of enzymatic deficiency	AR, chromosome 20q alpha-N-acetyl-neuramidase
Type II	Adolescence or adulthood	Myoclonus, visual deficit, TCS, ataxia, coarse facies, dysostosis multiplex, hearing, corneal opacities, dementia	Poor	Urinary sialyloligosaccharides Demonstration of enzymatic deficiency	AR, chromosome 20q beta-galactosidase alpha-N-acetyl-neuramidase
Sphingolipidoses					
Gauchers type III	Childhood to adulthood	Myoclonus, SNGP, impaired saccades, dementia, seizures, ataxia	Poor	beta-glucocerebroside storage in lymphocytes Demonstration of enzymatic deficiency	AR beta-glucocerebroside
GM2 gangliosidosis	Childhood to adolescence	Myoclonus, ataxia, spasticity, dystonia, tremor, seizures, optic atrophy, dementia	Poor	Demonstration of enzymatic deficiency	AR beta-N-acetylhexosaminidase
MERRF	Any age	Myoclonus, TCS, dementia, ataxia, lipomas, myopathy, neuropathy, deafness,	Variable	Ragged-red fibers in skeletal muscle; lactate; respiratory chain defect	Substitution at pair 8344 mitochondrial DNA, sporadic

WITH BIOLOGICAL OR PATHOLOGICAL MARKERS					
Ceroid lipofuscinosis		optic atrophy			
Late infantile	1-4	Myoclonus, visual failure, optic atrophy, ataxia, speech alterations, dementia, TCS	Death by 10 years	Urinary dolichol phosphates; lipopigment inclusions (skin, rectal, brain) on EM	AR
Juvenile	4-10	Myoclonus, vision, optic atrophy, dementia, ataxia, EPS, seizures, dysarthria, psychosis	Death by 20 years		AR, chromosome 16
Adult	>10	Myoclonus, ataxia, seizures, dementia, vision not impaired	Death 10 years after onset		AR
Lafora's disease	6-18	Myoclonus, TCS, ataxia, dementia, vision, depression	Death 2-10 years after onset	Polyglycan inclusions in sweat glands	AR
DEGENERATIVE Unverricht-Lundborg	6-15	Myoclonus, TCS, ataxia, dysarthria, depression, dementia absent	Variable, usually mild impairment	None	AR, chromosome 21q

AR, Autosomal recessive; DNA, deoxyribonucleic acid; EM, electron microscopy; EPS, extrapyramidal signs; SNPG, supranuclear gaze palsy; TCS, tonic-clonic seizures. used to control seizures. Phenytoin typically exacerbates ataxia and myoclonus and should be avoided.

Neonatal Seizures. Seizures are a common manifestation of cerebral dysfunction in the first 4 weeks of life. The incidence of neonatal seizures is unknown owing to the lack of consensus on which behaviors constitute epileptic seizures in this population. [31], [32] Neonatal seizures are paroxysmal events associated with alteration in neurological function that may or may not have an electrographical correlate. Brief, recurrent, focal or multifocal clonic, focal or generalized tonic, and myoclonic seizures are observed. Although these seizure types have already been discussed, brief mention as to their clinical appearance in neonates is appropriate.

Focal clonic seizures consist of rhythmical twitching of a limb or one side of the face that may be sustained for long periods without apparent spread. Multifocal clonic seizures are characterized by random, migratory clonic movements

involving limb and facial muscles bilaterally. Tonic seizures may be focal or generalized. Generalized tonic seizures are characterized by bilaterally symmetrical extension of the trunk and limbs often associated with apnea and upward deviation of the eyes. Focal tonic seizures include asymmetrical flexion of the trunk and eye deviation. Myoclonic seizures consisting of focal or generalized brief muscle jerks occur rarely. The term *subtle seizures* includes behaviors that are not clearly epileptic, including oral-buccal-lingual movements, eye movements, pedaling, swimming, and autonomic phenomena. These signs are commonly observed in premature infants. Because of incomplete CNS myelination, which prevents synchronous and symmetrical propagation patterns, generalized TCS are not observed in the neonatal period.

Neonatal seizures are caused by a wide variety of disorders affecting the brains of neonates. Clinically, the etiologies of neonatal seizures may be classified based on age of seizure onset (Table 52-2). [33] Hypoxic-ischemic encephalopathy (HIE) is the most common etiology of neonatal seizures overall and the most common etiology encountered within the first 24 hours of life. Other causes of seizures within the first day of life include bacterial meningitis, sepsis, subarachnoid hemorrhage, intrauterine infection, laceration of the tentorium or falx, drug effects, and pyridoxine dependency. From 24 to 72 hours of life, additional etiologies include cerebral contusion with subdural hemorrhage, drug withdrawal, congenital malformations, and metabolic disorders. When seizures appear beyond the third day of life, inborn errors of metabolism, herpes simplex infection, kernicterus, and neonatal adrenoleukodystrophy should be considered. Neonatal seizures should be differentiated from tremor, clonus, decerebration, and jitteriness, which commonly occur in neonates with diffuse cerebral dysfunction. Unlike epileptic events, these nonepileptic phenomena can often be elicited by limb repositioning

TABLE 52-2 -- ETIOLOGIES OF NEONATAL SEIZURES BY PEAK TIME OF ONSET

Disorder	24 Hours	24-72 Hours	3-7 Days	7-28 Days
Cerebrovascular	Hypoxic-ischemic encephalopathy Subarachnoid hemorrhage Intraventricular hemorrhage	Intraventricular hemorrhage Cerebral infarction Intracerebral hemorrhage Subdural hemorrhage Subarachnoid hemorrhage	Cerebral infarction Intracerebral hemorrhage	
Traumatic	Laceration of tentorium or falx	Cerebral contusion		
Infectious	Bacterial meningitis Sepsis	Bacterial meningitis Sepsis		Herpes simplex encephalitis

Iatrogenic	Intrauterine infection	Drug withdrawal		
Nutritional	Anesthetic toxicity	Pyridoxime dependency	Hypocalcemia	
	Pyridoxine dependency	Hypoglycemia		
Developmental	Hypoglycemia	Congenital malformations	Congenital malformations	Congenital malformations
		Neurocutaneous disorders	Neurocutaneous disorders	
Metabolic		Hypoparathyroidism	Hypoparathyroidism	Adrenoleukodystrophy
		Hypocalcemia	Kernicterus	Fructose dysmetabolism
		Glycine encephalopathy	Ketotic hyperglycinemia	Gaucher's disease type II
		Glycogen synthase deficiency	Urea cycle disorders	GMI gangliosidosis
		Urea cycle disorders		Ketotic hyperglycinemia
		Nonketotic hyperglycinemia		Maple syrup urine disease

or tactile stimulation and suppressed by physical restraint.

The EEG is important in determining adequacy of therapy and in predicting neurological outcome. Prolonged or serial recordings should be performed in pharmacologically paralyzed infants at risk for developing seizures. The severity of background abnormalities is correlated with the extent of neurological impairment. Infants with suppressed, undifferentiated, or suppression-burst patterns have a high incidence of neurological and developmental sequelae. In contrast, isolated sharp waves are commonly seen in neurologically normal neonates without seizures and are not predictive of seizures or the future development of epilepsy. Ictal patterns are more variable in neonates than in older patients; typically, they consist of runs of focal paroxysmal activity of varying frequency and polarity. Clonic, focal tonic, and generalized myoclonic seizures are consistently accompanied by EEG changes, whereas generalized tonic, focal or multifocal myoclonic, and subtle seizures are not.

Cranial ultrasound or CT studies should be performed to rule out structural lesions. Cerebrospinal fluid analysis and metabolic screens are indicated when infection or inborn errors of metabolism are suspected.

Severely impaired neonates with clinical seizures unaccompanied by EEG changes should not be treated with anticonvulsant medication. In this setting, AEDs are not likely to reduce the clinical manifestations, and affected patients have a high incidence of adverse reactions. Antiepileptic drug therapy is recommended when recurrent clinical events are accompanied by EEG seizure patterns. Phenobarbital is the most widely used agent, although phenytoin and benzodiazepines are also effective. Because protein binding is altered in sick infants, monitoring of total and free drug levels is advised. Pyridoxine, 50 to 100 mg, should be administered intravenously with simultaneous

1076

EEG recording when seizures are refractory to conventional agents. In the absence of CNS pathology and significant EEG abnormalities, neurologically normal infants do not require prolonged therapy and should be withdrawn from medication before hospital discharge. Neonates with abnormal findings on neurological examinations and focal cerebral pathology have a high risk of recurrence and should be treated for longer periods.

The mortality rate for neonates with seizures is 40 percent for full-term and 50 percent for premature infants. Subsequent epilepsy develops in nearly 25 percent of patients. Aside from etiology and findings on neurological examination, the presence and severity of background abnormalities on EEG are the most reliable predictors of outcome. Most infants with normal background features on EEG have normal development, whereas severe background abnormalities, independent of electrographical seizures, portend a poor prognosis.

Febrile Convulsions. Febrile seizures occur in 2 to 5 percent of children, representing the most common seizure disorder in this age group. ^[34] Approximately 30 percent of patients experience a single recurrence, and of this group, half will experience multiple seizures. ^[35] The age of onset ranges from 3 months to 5 years with a peak incidence from 18 to 24 months. Seizures occur during a sudden rise in temperature early in the course of an illness in the absence of intracranial infection or a defined etiology. Simple febrile seizures, which are single, generalized convulsions less than 15 minutes in duration, comprise 80 to 90 percent of cases. Seizures that exceed 15 minutes in duration, occur more than once in a 24-hour period, or show focal motor manifestations are classified as complex or complicated febrile seizures. Patients with complex febrile seizures have a higher rate of subsequent epilepsy.

The risk of seizures in family members of patients with febrile seizures is two to three times that of the general population. Generalized epileptiform activity and photosensitivity have been reported in asymptomatic relatives of affected patients. These findings support a genetic etiology, although the mode of inheritance is unknown. Similarly, the relationship between febrile seizures and mesial temporal lobe epilepsy is poorly understood. Prolonged febrile convulsions are associated with various physiological alterations capable of producing ischemic changes in hippocampal neurons. Whether these changes are operative in the development of epilepsy or whether they simply represent the effect of recurrent seizures remains a matter of debate.

Febrile seizures should be distinguished from seizures due to intracranial infection, electrolyte disturbance, inborn errors of metabolism, and nonepileptic events such as breath-holding spells. The extent of laboratory and radiological evaluation depends on results of the clinical history and examination. Because the condition of most children with simple febrile seizures has returned to baseline by the time of evaluation, laboratory testing, EEG, and neuro-imaging studies are generally unrevealing. Patients with complex febrile seizures, especially those with focal motor manifestations, should undergo a neuroimaging study to rule out structural lesions. Cerebrospinal fluid analysis is indicated in cases of suspected CNS infection. Patients presenting with their first febrile seizure before 6 months and after 5 years of age should be thoroughly evaluated because secondary causes are more likely.

Single seizures do not necessarily require treatment with AEDs. Repetitive seizures and status epilepticus should be terminated with intravenous benzodiazepines or phenobarbital. Prophylactic anticonvulsants are usually not recommended because of the high incidence of behavioral and cognitive adverse reactions and their failure to reduce the risk of subsequent epilepsy. Parents should be assured of the benign nature of the disorder and instructed in the administration of antipyretics, tepid sponge bathing, and emergency first aid. Rectal diazepam should be considered in children with frequent febrile illnesses. The risk of recurrent febrile seizures is highest in children younger than 1 year of age and those with complicated seizures. Two to 9 percent of affected children develop afebrile seizures. Patients with abnormal findings on neurological examinations or abnormal development, family history of afebrile seizures, and complicated seizures have a higher risk of subsequent epilepsy.

Acquired Epileptic Aphasia. Approximately 200 cases of acquired epileptic aphasia, or Landau-Kleffner's syndrome, are reported in the literature. ^[36] This syndrome is characterized by an acquired aphasia with epileptiform activity over the temporal or temporo-parieto-occipital regions and psychomotor and behavioral difficulties.

An auditory verbal agnosia and reduction of spontaneous speech typically begin before 6 years of age, after the initial acquisition of verbal language. Consequently, many patients are misdiagnosed as deaf or autistic. Infrequent tonic-clonic, focal motor, and atonic seizures are observed in 75 percent of cases. Psychomotor disturbances or personality disorders occur in 70 percent of patients. Seizures persisting into adolescence tend to be infrequent and nocturnal. Males are affected twice as often as females. Interruption of subcortical fibers resulting in the deafferentation of language cortex has been hypothesized as the underlying pathogenesis; however, no etiological factors have been identified. In cases in which brain biopsies were performed, no specific abnormalities have been identified. [36]

The waking EEG in Landau-Kleffner's syndrome is characterized by multifocal spikes in the temporal and parieto-occipital regions superimposed on normal background activity and markedly enhanced sleep. Audiography, auditory evoked potentials, and neuroimaging study results are normal. Landau-Kleffner's syndrome bears striking resemblance to epilepsy with continuous spike waves during slow-wave sleep (CSWS). In both disorders, EEG abnormalities are markedly accentuated, and at times continuous, during sleep. Seizures are more frequent and global neurological deterioration emerges rather than aphasia in CSWS, however.

Administration of intravenous diazepam may produce dramatic but transient improvements in language and EEG abnormalities. The benefit of long-term anticonvulsant therapy has not been demonstrated, however. In most cases, seizures and EEG abnormalities undergo remission spontaneously by 15 years of age, and speech typically recovers by adulthood. Onset after 6 years of age and early speech therapy are associated with a more favorable prognosis.

Epilepsy and Pregnancy. Epilepsy is the most common

neurological disorder encountered by obstetricians. Approximately 0.3 to 0.5 percent of all pregnancies and over 1 million women of childbearing age are affected. [37] Seizure frequency during pregnancy typically parallels preconception seizure control, and 50 to 75 percent of women experience no significant change. Breakthrough seizures are usually due to noncompliance, stress, or sleep deprivation. The incidence of status epilepticus is similar to nonpregnant epileptic controls. The risk of spontaneous abortion, bleeding diatheses, premature labor, pre-eclampsia, eclampsia, and placental defects in women with epilepsy is two to four times higher than in nonepileptic women. In most cases, labor and delivery progress without complications. Elective cesarean section should be performed when there is poor seizure control during the third trimester, in cases of severe stress-induced seizures, and in patients with neurological deficits interfering with labor. Emergency cesarean section is indicated in women with recurrent seizures during labor and delivery and when seizures result in fetal distress.

Most seizures during pregnancy occur in association with subtherapeutic anticonvulsant levels. The serum concentration of AEDs gradually declines during pregnancy, reaching a nadir near term and returning to preconception levels by 8 to 12 weeks post partum. During pregnancy, a reduction in protein binding leads to a higher percentage of unbound, free drug that is more rapidly excreted by the kidneys. The dilutional effects of water retention and increased hepatic microsomal activity, which enhances drug metabolism, are additional factors that contribute to subtherapeutic drug concentrations and breakthrough seizures.

Seizures may be the initial manifestation of a host of diseases that present during pregnancy. Ischemic stroke, paradoxical embolus, vasculitis, and metastatic choriocarcinoma may appear at any time during pregnancy with seizures and focal neurological deficits. Vascular anomalies should be considered when seizures develop in pregnancy because the risk of bleeding due to arteriovenous malformations and aneurysms tends to increase as pregnancy progresses. Eclampsia, oxytocin-induced water intoxication, toxicity of local anesthetics, amniotic fluid embolus, thrombotic thrombocytopenic purpura, cerebral venous thrombosis, pheochromocytoma, and subarachnoid hemorrhage may produce seizures in the peripartum period. These disorders should be considered in the differential diagnosis of patients with new onset of seizures during pregnancy.

The evaluation and treatment of pregnant women with epilepsy are summarized in [Table 52-3](#). [38] Patients should be treated with monotherapy when possible, because the incidence of fetal malformations increases with the number of AEDs administered. Total and free antiepileptic drug levels should be monitored at least once per trimester. Serum drug concentrations should be maintained in the therapeutic range near term to prevent seizures during labor. Dosage adjustments should be made when seizures occur that pose a significant risk to the mother and fetus.

Several anticonvulsants may lead to folate deficiency, which is associated with an increased incidence of neural tube defects in offspring of epileptic women. Women with epilepsy of childbearing age should take multivitamins containing folate 1 mg per day. Folate therapy should be instituted in those not already taking the preparation as

TABLE 52-3 -- GUIDELINES FOR THE MANAGEMENT OF EPILEPSY DURING PREGNANCY

Baseline antiepileptic drug (AED) levels (total/free) and f)late (serum/RBC)
Folate supplementation level 10 mg/day
Maternal alpha-fetoprotein level at week 15-16
AED levels and fetal ultrasound at 18-19 weeks
Repeat fetal ultrasound at 22-24 weeks
AED levels at 34-36 weeks. Make adjustments to ensure therapeutiv drug levels at term.
Vitamin K 20 mg/day during eighth month or 10 mg IV 4 hours before bOErth and 1 mg IM to newborn at birth
Monthly AED levels post partum for 12 weeks

soon as pregnancy is recognized. Fetal ultrasound and maternal alpha-fetoprotein testing should be performed during the second trimester to assess for fetal malformations. In women taking carbamazepine or valproic acid, the risk of fetal neural tube defects is 1 percent and 2 percent, respectively. These drugs should be avoided in women with a family history or prior pregnancy complicated by such defects.

Obstetrical and neonatal outcome is normal in over 90 percent of pregnant patients with epilepsy. Proper nutrition, regular prenatal care, folate supplementation, and optimal seizure control improve the chance of a favorable outcome. Women with new onset of seizures should be carefully evaluated for medical and neurological etiologies, drugs, and alcohol use. If nonepileptic events are suspected, ambulatory EEG or video EEG monitoring should be considered before empirical institution of anticonvulsant therapy.

Epileptic woman of childbearing age taking hepatic enzyme-inducing AEDs and oral contraceptive agents should be advised of the risk of contraceptive failure due to the accelerated metabolism of steroids. To prevent pregnancy, moderate- or high-dose estradiol preparations or barrier methods are recommended. In women planning pregnancy, anticonvulsant regimens should be reassessed before conception, and the agent most likely to control seizures should be maintained at the lowest effective serum concentration. Drug withdrawal may be considered in patients with prolonged seizure-free periods and seizures not impairing consciousness.

Status Epilepticus. Status epilepticus (SE) is a medical emergency that demands prompt diagnosis and treatment if severe neurological sequelae and death are to be minimized. An estimated 125,000 to 195,000 episodes of SE occur in the United States annually, resulting in 22,000 to 42,000 deaths. [39] Despite improvements in medical management, the incidence of significant morbidity and mortality remains high. Status epilepticus is defined as continuous clinical or electrical seizure activity or repetitive seizures with incomplete neurological recovery interictally for a period of at least 30 minutes. Patients having continuous seizure activity for 10 minutes or longer should be treated as if in status, because most seizures terminate spontaneously within 1 to 2 minutes. In addition, impending status epilepticus should be suspected in patients experiencing three or more TCS within a 24-hour period, particularly

when this represents an increase from the typical frequency.

Status epilepticus is classified as generalized or partial (focal), and convulsive or nonconvulsive. Generalized convulsive status includes tonic-clonic, tonic, clonic, or myoclonic SE, although the majority of cases consist of recurrent TCS. Nonconvulsive SE includes absence and complex partial status epilepticus, both of which are characterized by clouding of consciousness with or without minor motor manifestations. EEG is usually required to distinguish the two. Any type of simple partial seizure, including seizures with sensory, motor, language, autonomic, or psychic manifestations, can evolve into SE. Partial SE characterized by focal clonic activity is referred to as *epilepsia partialis continua* (EPC). This condition is seen in patients with lesions involving the periorlandic region such as in children with Rasmussen's encephalitis.

In adult patients, the most common type of SE is secondary generalized convulsive SE (GCSE). Generalized convulsive SE is characterized by intermittent or continuous overt convulsive activity accompanied by coma and epileptiform activity on EEG. The manifestations change over time such that discrete convulsions give way to increasingly subtle clinical manifestations, which is a condition known as *subtle SE*. Eventually, electrical status without clinical manifestations is all that remains. Occasionally, subtle SE occurs without prior convulsive activity in patients with severe diffuse cerebral dysfunction. Generalized convulsive activity produces various systemic effects including hypoxia, hyperpyrexia, blood pressure instability, and cerebral dysautoregulation. Metabolic derangements including respiratory and metabolic acidosis; hyperazotemia; hypokalemia; hyponatremia; hyperglycemia followed by hypoglycemia; and marked elevations of plasma prolactin, glucagon, growth hormone, and corticotropin may be observed. Rhabdomyolysis may produce myoglobinuria and renal failure.

Acute CNS insults including anoxia, head injury, stroke, neoplasm, and infection account for 50 percent cases. In children, the most common precipitants are fever and infection, whereas cerebrovascular disease predominates in older adults. Approximately 20 percent of all SE cases occur in epileptic patients during medication adjustment or as a result of noncompliance. In one third of patients, the cause for SE is undetermined. Status epilepticus should be suspected in patients with unexplained coma with or without motor manifestations. Nonepileptic phenomena including tremor, myoclonus, eye movements, and oral-buccal movements that frequently occur following anoxia, brain stem or bilateral cerebral ischemia, drug overdose, and severe metabolic and electrolyte disturbances may be difficult to differentiate clinically from nonconvulsive SE. Occasionally, prolonged psychogenic seizures are misinterpreted and treated as SE.

A protocol for the treatment of GCSE is provided in [Table 52-4](#). Treatment should begin with assessment of cardiorespiratory function. An oral airway should be secured and oxygen administered when needed. Blood should be drawn for antiepileptic drug, glucose, blood urea nitrogen, and electrolyte levels as well as drug screens. An intravenous infusion with isotonic saline solution should be placed and glucose 25 g and thiamine 100 mg administered.

TABLE 52-4 -- MANAGEMENT OF STATUS EPILEPTICUS

STEP 1

Assess Airway, Breathing, Circulation

1. Administer O₂. monitor cardiac rhythm, O₂ saturation, and vital signs
2. Bedside glucose test
3. Draw blood for AEDs, hematology, and chemistries studies, and toxicological screens
4. Establish intravenous line with normal saline
5. Thiamine 100 mg and dextrose 50% 50 ml intravenous (D25 2 ml/kg in children)
6. Obtain history and perform examination

STEP 2

Administer intravenous diazepam 0.25 mg/kg in adults, 0.1 to 1.0 mg/kg in children (up to 5 mg/min) or lorazepam 0.1 mg/kg in adults, 0.05 to 0.5 mg/kg in children (up to 2 mg/min) Repeat once if seizures persist

Simultaneously administer phenytoin 20 mg/kg load (up to 50 mg/min in adults and 1 mg/kg/min in patients >50 kg) or fosphenytoin 15-20 mg/kg (up to 150 mg/min)

If seizures persist, give phenytoin 5 mg/kg, up to 30 mg/kg total or a level of 30 mg/ml

STEP 3

Intubate, place arterial line, draw arterial blood gases

Phenobarbital 20 mg/kg load (100 mg/min or 3 mg/kg min in children)

STEP 4

If seizures persist, consider pharmacological coma with pentobarbital 5-8 mg/kg load, followed by maintenance 2-4 mg/kg/hr titrated to burst-suppression for 6 to 48 hrs

A history and neurological examination should be performed once the patient's condition is stabilized. When an acute CNS insult or infection is suspected, further investigations including neuroimaging (cranial CT) and lumbar puncture should be performed once treatment is initiated. EEG is useful when the diagnosis of GCSE is in doubt, during pharmacological coma, or when assessing the adequacy of treatment.

Generalized convulsive seizures and electrical seizures in patients with subtle SE should be terminated as rapidly as possible, because the duration of SE is a major determinant of morbidity and mortality. Absence, complex partial, and focal motor SE may be treated less aggressively, because the risk of neurological sequelae is significantly lower. Generalized convulsive SE should be treated with medications administered intravenously until seizures are aborted. The most common cause of treatment failure is when the appropriate medication is administered in inadequate dosages via an inappropriate route.

Once an intravenous line has been secured, diazepam 0.25 mg/kg (given no faster than 5 mg/min) or lorazepam (0.1 mg/kg (no faster than 2 mg/min) should be administered. Because of its high lipid solubility and rapid CNS entry, diazepam frequently abolishes seizure activity within minutes, only for seizures to recur within 30 minutes as the drug redistributes to other fatty tissues. Consequently, lorazepam is preferred for its longer duration of action.

In most circumstances, following treatment with a benzodiazepine, phenytoin 20 mg/kg (no faster than 50 mg/min) or fosphenytoin should be administered. Alternatively, one may choose to begin treatment with phenytoin if seizure activity is not apparent at the time of arrival to the emergency room. Fosphenytoin, a phosphate ester of phenytoin

was released by the Food and Drug Administration (FDA) in 1996 for use in the treatment of escalating seizures requiring parenteral treatment and SE. Its advantages over phenytoin include a more rapid rate of infusion (150 mg/min) and lower incidence of hypotension and cardiac arrhythmias. If seizure activity continues after phenytoin/fosphenytoin loading, additional 5 mg/kg boluses should be given to achieve a serum concentration of 25 to 30 g/ml. This regimen is effective in terminating over 90 percent of cases. Anticonvulsant medications should be administered in a setting equipped to provide advanced cardiac life support. Patients should be continuously monitored during parenteral administration of AEDs for signs of respiratory depression, hypotension, and cardiac arrhythmias.

If seizures persist, elective intubation should be performed before phenobarbital loading (20 mg/kg no faster than 100 mg/min), particularly if other CNS depressants have been previously administered. Only 6 percent of cases prove refractory to this approach and require anesthetic doses of barbiturates titrated to achieve burst-suppression. Pentobarbital is the most commonly used agent for refractory SE. A loading dose of 5 mg/kg followed by a maintenance infusion of 1 to 3 mg/kg/hour titrated to burst-suppression is recommended. Treatment is continued for 6 to 48 hours, after which the drug is withdrawn and the EEG observed for recurrence of seizure activity. Midazolam, lidocaine, and propofol have been used for refractory SE; however, no controlled studies using these agents are available, and experience with them is limited. For the treatment of absence status epilepticus, intravenous benzodiazepines followed by ethosuximide or valproic acid are usually effective. Depending on the situation, simple and complex partial status epilepticus may be treated with oral anticonvulsants, fosphenytoin (IM or IV), or

intravenous benzodiazepines. The use of phenobarbital or pharmacologic coma is rarely indicated.

Morbidity and mortality in SE are largely dependent on the speed of intervention, age of the patient, and etiology. Although mortality in adults ranges from 1 to 32 percent, subtle SE and GCSE exceeding 1 hour in duration carry a poor prognosis. A favorable outcome is observed in children, patients with pre-existing epilepsy, and individuals with drug-induced SE.

Nonepileptic Seizures. Nonepileptic seizures, also referred to as *psychogenic* or *pseudc* seizures, constitute 15 to 20 percent of admissions to epilepsy units.^[40] Affected women outnumber men by a factor of 3.5:1. Psychogenic seizures are infrequent before 12 years of age but have been observed in children as young as 5 years old. Peak incidence is in the third to fourth decades, although onset may occur later in life. The incidence of epilepsy in patients with psychogenic seizures ranges from 10 to 60 percent.^[40]

Psychogenic seizures are episodes involving affective, autonomic, or sensorimotor manifestations that are precipitated by emotional distress. Palpitations, choking sensations, dizziness, malaise, acral paresthesias, sensory disturbances, crying, and alterations in consciousness with or without motor manifestations are observed. Unlike epileptic seizures, motor activity generally consists of side-to-side head movements, opisthotonus, pelvis thrusting, trembling, and random asynchronous movements. Micturition, injuries, amnesia, and postictal somnolence may occur. Psychogenic seizures tend to be less stereotyped, more gradual in evolution, and longer in duration than epileptic seizures.

Psychogenic seizures are believed to represent subconsciously mediated behavior resulting from emotional distress. Unlike malingers, affected individuals do not feign illness for obvious secondary gain. Psychogenic seizures occur in patients with conversion disorders, anxiety and panic disorder, depression, post-traumatic stress disorder, schizophrenia, and personality disorders. Additionally, over two thirds of patients have a history of sexual or physical abuse in childhood.

Patients with psychogenic seizures frequently present to neurologists or epilepsy monitoring units having been diagnosed with epilepsy and treated with anticonvulsants. Seizures may be difficult to differentiate from frontal lobe seizures characterized by violent motor activity and sexual automatisms. Malingering and physiological nonepileptic events such as cerebral hypoperfusion, hypoxia, hypoglycemia, electrolyte disturbances, alcohol and drugs effects, migraine, gastroesophageal reflux, parasomnias, and movement disorders including paroxysmal dyskinesias may produce similar symptoms.

The EEG is the most valuable diagnostic tool. The persistence of normal background activity in a comatose patient essentially rules out epilepsy as a cause of that spell. Because 30 percent of complex partial seizures and 70 percent of simple partial seizures are not accompanied by EEG changes, however, events characterized by subtle behavior without complete loss of consciousness should be interpreted with caution. Induction procedures are commonly employed to provoke seizures in the EEG laboratory. Serum prolactin is elevated following 60 percent of complex partial seizures and 90 percent of TCS, provided that the serum sample is obtained within 10 minutes of the seizure. Normal values do not reliably predict a nonepileptic event, however.

The patient should be informed of the diagnosis of psychogenic seizures, and consideration should be made for AED withdrawal. A psychiatric evaluation should be obtained and underlying psychological disorders addressed. Psychotherapy and pharmacological treatment of psychiatric disease is indicated in most cases. Typically, a team approach involving neurologist, psychiatrist, and therapist is most effective.

NEUROPHARMACOLOGY OF THE ANTIPILEPTIC DRUGS

Pharmacological Principles

Pharmacokinetics refers to drug concentrations and their variability over time based on absorption, distribution, and elimination ([Table 52-5](#)). Absorption is defined as the passage of a drug from the site of administration to the vascular space. Absorption is measured in terms of rate and bioavailability, which is the amount of drug that reaches the systemic circulation. Both vary with route of administration and drug formulation. Bioavailability is 100 percent following intravenous administration, the route against which

TABLE 52-5 -- PHARMACOKINETIC PARAMETERS OF ANTIPILEPTIC DRUGS

Drug	Vd l/kg	Protein Binding(%)	T _{1/2} Hr	Elimination Route 1%1		Maintenance Dose (mg/kg/d)	Dosing Interval	Loading Dose (mg/kg)	Range (ug/ml)
				Renal	Liver				
Carbamazepine	0.8	75	9-15	<5	>90	10-25	BID-TID	---	4-12

mg/ml

others are measured. With oral administration, absorption is influenced by gastric pH, bowel motility, splanchnic blood flow, and concomitant medications and food intake. Large variations in absorption occur with intramuscular administration, making this an undesirable route if high drug concentrations are required rapidly.

Following absorption, drugs are distributed into other compartments. The extent of distribution is expressed as the volume of distribution (Vd), a hypothetical volume of total body fluid within which a drug is evenly distributed. Distribution depends on extent of protein binding, solubility, and blood flow. Most AEDs are partially protein bound, and only the free, or unbound, fraction penetrates the blood-brain barrier to produce an effect. The Vd required to dissolve an amount of drug (D) to achieve a given concentration (deltaC=desired minus actual concentration) can be calculated by using the equation

$$Vd = D \div \text{deltaC}$$

By solving for

$$D = Vd \times \text{deltaC}$$

the dose of drug required to achieve a particular serum concentration can be determined.

Elimination of anticonvulsant medications occurs through hepatic metabolism and renal excretion. The major metabolic pathway in humans is the hepatocyte endoplasmic reticulum P-450 mixed oxidase system. Phenobarbital, primidone, phenytoin, and carbamazepine induce this enzyme system, thereby facilitating metabolism of other hepatically metabolized drugs including oral contraceptives, folic acid, warfarin, quinidine, and steroids. Conversely, valproic acid is an enzyme inhibitor which, when combined with other hepatically metabolized agents, impairs their metabolism, potentially leading to toxicity. Analgesics, cardiac drugs, antimicrobials, antiulcer agents, and psychotropics may also interfere with the metabolism of AEDs and produce toxic reactions. Carbamazepine, valproic acid, primidone, and diazepam are converted to active metabolites having additional anticonvulsant properties.

Half-life (T_{1/2}) is the time required for the serum concentration of a drug to decrease by 50 percent following complete absorption and distribution of a single dose. A drug's half-life determines the dosing frequency and, as a rule, the dosing interval should not exceed one half-life. Drugs with short half-lives should be administered multiple times per day to prevent large fluctuations in serum concentration that may produce adverse effects or breakthrough seizures. Those with longer half-lives may be administered once daily, which generally improves compliance.

A drug's half-life may be altered by hepatic enzyme induction or inhibition and impaired renal function. With the exception of phenytoin, metabolism of anticonvulsant medications follows linear, or first-order kinetics, in which the rate of metabolism is directly proportional to serum concentration. Phenytoin is metabolized through nonlinear, or zero-order kinetics. The enzymes responsible for the elimination of phenytoin become saturated at levels within the therapeutic range. Once enzyme systems are saturated, the rate of metabolism fails to increase proportionately with further dosage increments, and modest increases in dosage result in marked increases in serum concentration. To avoid toxicity, the daily dosage of phenytoin should be increased by no more than 50 mg when serum concentration exceeds 10 to 12 µg/ml.

Principles of Antiepileptic Drug Treatment

The selection of an AED is based on efficacy against specific seizure types and the potential for producing adverse effects ([Table 52-6](#)). First-line agents against TCS include phenytoin, carbamazepine, and valproic acid. Ethosuximide and valproic acid are effective against AS. Valproic acid is the only primary drug effective against tonic-clonic, absence, and myoclonic seizures, making it the drug of choice for JME. Myoclonic seizures are responsive to valproic acid and benzodiazepines. Carbamazepine and phenytoin, followed by valproic acid, are the drugs of choice in the treatment of partial seizures. Although primidone

TABLE 52-6 -- ANTIPILEPTIC AGENTS FOR SPECIFIC SEIZURE TYPES

Seizure Type	First-line Agents	Adjunctive Agents
Tonic-clonic	Phenytoin	Phenobarbital

Absence	Carbamazepine Valproic acid Ethosuximide Valproic acid	Primidone Lamotrigine Benzodiazepines Lamotrigine Acetazolamide
Myoclonic	Valproic acid Benzodiazepines	Lamotrigine
Tonic/atonic	Valproic acid Benzodiazepines	Lamotrigine
Focal (partial)	Carbamazepine Phenytoin Valproic acid	Gabapentin Lamotrigine Phenobarbital/primidone

and phenobarbital are effective against tonic-clonic and partial seizures, they are not considered first-line agents because of their sedative properties. In controlled trials, lamotrigine and gabapentin produced a 30 to 50 percent reduction in seizures in approximately one third of patients with partial epilepsy. [41], [42] Lamotrigine may also be effective against generalized seizures in patients with idiopathic generalized epilepsy and Lennox-Gastaut's syndrome. In unpublished series, topiramate proved to be effective as adjunctive therapy in adults with partial seizures, reducing seizure frequency by 50 percent in approximately 50 percent of patients. [43] Felbamate has a broad spectrum of action but is no longer indicated for routine use because of hematologic and hepatic toxicity. The potential for long-term complications has not been established for newer AEDs, and their cost is significantly greater than the older agents.

Dose-related adverse effects commonly occur in patients taking anticonvulsant medication and usually resolve spontaneously or with reduction in dosage or discontinuation of the drug. Gastrointestinal distress and dizziness are frequently reported with primidone, carbamazepine, valproic acid, and ethosuximide. Nystagmus, dysarthria, diplopia, and ataxia are associated with phenytoin, carbamazepine, primidone, and phenobarbital. The benzodiazepines, phenobarbital, primidone, and phenytoin may produce sedation and cognitive impairment. Dizziness, headache, diplopia, and ataxia are the most common adverse effects associated with lamotrigine. Somnolence, dizziness, ataxia, fatigue, and nystagmus may be observed with gabapentin. The institution of felbamate is usually associated with GI disturbances that occasionally require drug withdrawal.

Skin eruptions represent the most commonly encountered idiosyncratic reaction associated with AEDs. Generally appearing within the first 3 months of treatment, rashes are usual benign, and they resolve with dosage reduction or discontinuation. Severe reactions including Stevens-Johnson syndrome, exfoliative dermatitis, and toxic epidermal neurolysis occur rarely. Antiepileptic drugs can produce megaloblastic anemia, leukopenia, thrombocytopenia, aplastic anemia, asymptomatic elevations of hepatic transaminases, and life-threatening hepatotoxicity. Chronic idiosyncratic reactions include disorders of connective tissue and nervous system, endocrinopathies, and autoimmune disease.

Drug Interactions

The goal of treatment is to control seizures using a single agent maintained at serum concentrations that do not produce adverse effects. If seizures persist, the dosage should be gradually increased until seizure control is achieved or intolerable side effects appear. Trough blood levels should be obtained during steady-state conditions, generally no sooner than five half-lives after a dosage adjustment. A second agent is introduced only after an adequate trial of the first drug has failed. If polytherapy is required, drugs should be chosen with different mechanisms of action and side effect profiles to maximize anticonvulsant benefit and minimize toxicity. Interactions among the various AEDs must also be kept in mind in the selection of drug combinations ([Table 52-7](#)). Patients whose seizures continue despite adequate trials of several AEDs should be referred to an epilepsy center for further evaluation.

Clinical and laboratory monitoring is routinely performed in patients taking anticonvulsant medication. Blood levels help to achieve maximal medication effect and identify patients who are noncompliant. The older agents have an established therapeutic range within which most patients experience an improvement in seizure control and few or no adverse reactions. The therapeutic range should serve as a general guide only. Some patients become seizure-free with subtherapeutic serum concentrations, whereas others require levels in the "toxic" range to achieve satisfactory seizure control.

No standard recommendations exist for the timing of laboratory monitoring. Hematological parameters should be assessed periodically during carbamazepine, ethosuximide, and valproic acid therapy. Hepatic transaminases should be monitored in patients taking carbamazepine, valproic acid, phenytoin, primidone, and phenobarbital. Laboratory monitoring is particularly important in the setting of hepatic or renal dysfunction and during pregnancy. Free levels are useful when protein binding is altered such as in pregnancy, uremia, and hypoalbuminemia, and with highly protein-bound drugs like phenytoin and valproic acid.

Clinical Use and Adverse Effects of Specific Antiepileptic Drugs

Phenobarbital, first marketed in the United States in 1912, is the oldest of the currently available AEDs. It is effective against partial, tonic-clonic, tonic, and clonic seizures and is the most commonly prescribed agent for neonatal seizures. Phenobarbital enhances GABA transmission by interacting with the GABA_a receptor-chloride channel complex, and it acts at glutamate receptors to decrease excitatory synaptic transmission. Long-term use is associated with chronic connective tissue disorders. Safety, affordability, and a broad spectrum of action contribute to its continued use in the United States and worldwide. Common neurological side effects include sedation, nystagmus, ataxia, and irritability and hyperactivity in children. Phenobarbital is available in 15-, 30-, 60-, and 100-mg tablets, elixir (20 mg/5 ml), and injectable formulations.

193

Primidone has been available in the United States since 1954 for the treatment of partial and generalized seizures. Primidone is metabolized to phenobarbital and phenylethylmalonamide (PEMA), both of which possess anticonvulsant properties. The adverse effects are similar to phenobarbital, although initiation of primidone is associated with a higher incidence of GI distress, dizziness, ataxia, and diplopia. Primidone is available in 50- and 250-mg scored tablets and elixir (250 mg/5 ml).

Phenytoin became available in 1938 and remains a first-line agent in the treatment of tonic-clonic and partial seizures and status epilepticus. Its primary mechanism of action is inhibition of sustained high-frequency firing through blockade of voltage-gated Na^+ channels. Phenytoin precipitates in muscle and can cause tissue necrosis if administered intramuscularly. Long-term complications include gingival hyperplasia, hirsutism, coarsening of facial features, hyperpigmentation, acne, pseudolymphoma, cerebellar degeneration, movement disorders including chorea and dystonia, and disorders of vitamin D metabolism. Phenytoin is available in 30- and 100-mg capsules, 50 mg chewable Infatabs, elixir (125 mg/5 ml), and injectable forms. *Fosphenytoin sodium*, a phosphate ester prodrug of phenytoin, has gained FDA approval and has replaced the injectable formulation of Dilantin. Because of its higher water solubility, fosphenytoin can be safely administered intramuscularly and intravenously at a rate of 150 mg phenytoin equivalent per minute.

Ethosuximide has been marketed in the United States since 1960 for the treatment of AS. It is the drug of choice in AE without TCS, against which it is ineffective. Ethosuximide blocks T-type Ca^{2+} channels that trigger and sustain rhythmical burst discharges in thalamic neurons. Trimethadione, which is no longer available in the United States, is the only other agent with a similar mechanism of action. Ethosuximide does not induce hepatic microsomal enzymes and is not protein-bound. Idiosyncratic reactions include headache, hiccups, blood dyscrasias, lupus-like syndromes, behavioral disturbances, and parkinsonism. Ethosuximide is available in 250 mg capsules and syrup (250 mg/5 ml).

Carbamazepine, available in the United States since 1974, has a similar mechanism and spectrum of action as phenytoin. The carbamazepine-10, 11-epoxide metabolite also possesses anticonvulsant properties. Autoinduction occurs during the first several weeks of therapy, necessitating gradual titration. Concomitant use of propoxyphene, erythromycin, and cimetidine results in significant accumulation of carbamazepine. Despite its association with aplastic anemia, serious hematological complications are rare. A mild, dose-related leukopenia may occur, which does not require discontinuation of the drug unless the total white blood cell count falls below $2500/\text{mm}^3$ or the total granulocyte count is less than $750/\text{mm}^3$. Neurological side effects include drowsiness, vertigo, ataxia, and diplopia. Idiosyncratic reactions include hyponatremia due to inappropriate antidiuretic effect; disturbances of thyroid, adrenal, and sex hormones; cardiac conduction disturbances; impaired renal function; movement disorders; and a lupus-like syndrome. Carbamazepine is available in 200-mg tablets; 100-mg chewable tablets; 100-mg, 200-mg, and 400-mg extended-release capsules, and elixir (100 mg/5 ml).

Valproic acid is a branched-chain fatty acid that was approved for use in the United States in 1978. The enteric-coated preparation, divalproex sodium, became available in 1983. Multiple mechanisms likely contribute to its broad spectrum of action, including inhibition of sustained repetitive firing through blockade of voltage-gated Na⁺ channels. Valproic acid is effective against generalized and partial seizures including absence, myoclonic, and tonic-clonic seizures. High protein binding and hepatic enzyme inhibition contribute to the high incidence of drug interactions. Adverse reactions include tremor, weight gain, alopecia, hyperammonemia, carnitine deficiency, and thrombocytopenia. Fulminant hepatic failure and fatal pancreatitis have been reported. Valproate is available in 250-mg tablets and syrup (250 mg/5 ml), and divalproex sodium in 125-, 250-, and 500-mg tablets and 125-mg sprinkles for mixture with food. Rectal and parenteral formulations are being developed.

For the last 30 years, benzodiazepines have been used in the treatment of nearly every type of seizure disorder. As a class, benzodiazepines bind to their receptor on the GABA_A receptor-chloride ionophore complex, increasing the frequency of Cl⁻ channel opening and potentiating GABA transmission. Long-term usage is limited by their sedative properties and development of tolerance to the anticonvulsant effect. Only *clonazepam* and *clorazepate* are used for the long-term treatment of seizures. *Lorazepam* and *diazepam* have a major role in the treatment of status epilepticus. Clonazepam is available as 0.5-, 1-, and 2-mg tablets. Clorazepate is available as 3.75-, 7.5-, and 15-mg capsules and 3.75-, 7.5-, 11.25-, 15-, and 22.5-mg tablets.

Felbamate was approved in the United States in 1993 for the treatment of partial seizures in adults and as adjunctive therapy in children with the Lennox-Gastaut's syndrome. Just over 1 year later, the FDA recommended limiting its use due to its association with aplastic anemia. Currently, the FDA recommends that felbamate be used only in situations in which the risk of seizures exceeds the risks of the drug. As of December, 1995, there have been 31 cases of aplastic anemia reported, including 10 fatalities, and numerous cases of hepatitis. The mechanism of action of felbamate is unknown, although it likely has multiple actions including blockade of voltage-gated Na⁺ channels, potentiation of GABA transmission, and inhibition of excitatory neurotransmission through interaction with the NMDA receptor. Felbamate is effective against partial and generalized seizures, including absences. Common adverse effects include insomnia, weight loss, nausea, anorexia, dizziness, and lethargy. Although there is no evidence that laboratory monitoring will prevent serious complications, the manufacturer currently recommends monitoring liver function studies, complete blood count, and reticulocyte count monthly. Felbamate is available in 400-mg capsules, 600-mg tablets, and suspension (600 mg/5 ml). To avoid drug interactions, concomitant AEDs should be reduced by 20 to 30 percent when felbamate therapy is initiated.

Gabapentin was approved in the United States in 1993 for add-on therapy against partial seizures in patients over the age of 12 years. Despite being an amino acid derivative of GABA, gabapentin does not interact with GABA receptors or potentiate gabaminergic transmission. Absorption is dose-dependent, and doses exceeding 1200 mg produce

only modest increases in bioavailability. Lack of protein binding and hepatic metabolism contribute to the absence of significant drug interactions. Gabapentin is eliminated by the kidneys unchanged, which necessitates dosage adjustments in renally compromised patients. The most common adverse effects include somnolence, dizziness, ataxia, fatigue, and nystagmus. Gabapentin is available in 100-, 300-, and 400-mg capsules.

Lamotrigine received FDA approval in the United States in 1994 for the adjunctive treatment of partial seizures in patients older than 12 years of age. Its mechanism of action and spectrum of activity are similar to those of phenytoin and carbamazepine. In addition, lamotrigine may be effective in some patients with Lennox-Gastaut's syndrome and idiopathic generalized epilepsies. Lamotrigine does not induce hepatic microsomal enzymes and does not significantly affect the metabolism of other drugs. The half-life of lamotrigine, however, is significantly prolonged by the concomitant use of valproic acid and shortened by agents that induce hepatic microsomal enzymes. The most common adverse effects are dizziness, headache, diplopia, ataxia, somnolence, and vomiting. Hepatic or hematological abnormalities have not been reported, and routine laboratory monitoring is not required. Lamotrigine is available in 25-, 100-, 150-, and 200-mg tablets.

Topiramate received FDA approval in December 1996 for use as an adjunctive agent in adults with partial seizures with and without secondary generalized TCS. The drug may also be effective against generalized seizure types. Topiramate has several mechanisms of action including effects at voltage-gated Na⁺ channels, enhancement of GABA activity at GABA_A receptors, and antagonism of glutamate receptors. The drug does not affect the metabolism of concomitant AEDs. Dose-related adverse effects include cognitive dysfunction, visual disturbance, and nervousness. Topiramate is not associated with organ toxicity, although renal stones develop in 1.5 percent of patients. It is available in 25-, 100-, and 200-mg tablets.

Other anticonvulsant agents currently under investigation in the United States include vigabatrin, oxcarbazepine, and tiagabine. *Vigabatrin* is an irreversible inhibitor of GABA transaminase (GABA-T), the major enzyme responsible for the degradation of GABA. The drug is not protein-bound and does not induce hepatic enzymes. Vigabatrin produced intramyelinic vacuolation and prolonged somatosensory conduction in experimental animal models, which has not been replicated in humans as of yet. Oxcarbazepine is a 10-keto analogue of carbamazepine that has a spectrum of action similar to that of carbamazepine with fewer drug interactions and adverse effects. Tiagabine is a GABA uptake inhibitor under investigation as adjunctive therapy against partial seizures.

SURGICAL TREATMENT

General Principles

Candidates for epilepsy surgery are those patients with seizures refractory to appropriate medical management and a well-defined epileptogenic focus not involving eloquent cortex. Surgery is contraindicated in patients with generalized epilepsy, benign childhood epilepsy, progressive diseases, and significant noncompliance. Mental retardation, psychiatric disease, and the coexistence of epileptic and nonepileptic seizures are not absolute contraindications. Dominant hemisphere seizure origin, bilateral or multifocal epileptic discharges on EEG, and neurological deficits on examination should not preclude surgical consideration. Rarely, surgery is considered in patients with seizures arising from more than one epileptogenic focus. Surgery should be performed as early as possible, because intractable seizures portend a poor prognosis for seizure remission and psychosocial outcome. Once adequate trials of several first-line AEDs prove ineffective, the likelihood of improvement with adjunctive agents is low.

Surface and Intracranial Electroencephalography

The goal of the presurgical evaluation is to define the epileptogenic zone, which is the region of cortex capable of generating seizures. Complete removal of the epileptogenic zone is necessary to produce a seizure-free state.^[44] The clinical history and EEG are used to identify patients who may be candidates for surgery. The yield of surface EEG, however, is limited by the attenuating effects of the skull and intervening tissue, distance of the recording electrodes from the generator of ictal activity, and variable orientation of generator. Cerebral activity from mesial or basal cortical areas is particularly apt to escape detection. Modified electrode placements and semi-invasive techniques such as sphenoidal electrodes increase the yield of surface recordings. In general, the distribution of interictal abnormalities extends beyond the epileptogenic zone. Nevertheless, interictal epileptiform discharges generally provide more reliable localizing information than ictal recordings because of the tendency for seizures to spread rapidly to contiguous regions.

Intracranial EEG may be required when surface EEG and neuroimaging studies fail to adequately delineate the epileptogenic zone. Although more sensitive than surface EEG, intracranial EEG provides a limited view of cerebral activity, because recordings are obtained only from areas where electrodes are placed.

The successful use of intracranial EEG requires that noninvasive studies provide enough information to ensure appropriate electrode placement. Intracranial monitoring is performed with depth and subdural electrodes. Depth electrodes are multiple-contact wires placed stereotactically into the brain. Their primary indication is for the identification of the epileptogenic zone in patients with TLE and bitemporal abnormalities on surface EEG or MRI. Electrodes embedded in thin Silastic plates arranged in strips or grids can be placed through burr holes or craniotomy within the subdural space over cortical areas of interest. This technique allows for the recording of multiple regions over one or both hemispheres and mapping of eloquent cortex. Complications of depth and subdural electrodes include intraparenchymal hemorrhage, infection, and cerebral edema in 1 to 2 percent of patients.

Figure 52-6 MRI showing atrophy (T1-weighted image on left) and increased signal (fluid-attenuated inversion-recovery sequence on right) in the right hippocampus in a patient with right mesial temporal lobe epilepsy.

Neuroimaging

Advances in neuroimaging have revolutionized the approach to patients with partial epilepsy. MRI has replaced CT as the study of choice, although CT remains superior in the detection of calcified lesions. SPECT and PET scans measure functional changes produced by seizures. All patients with partial epilepsy should undergo an MRI during the course of their illness to rule out structural lesions. The use of special imaging sequences and thin cuts increases the detection of small neoplasms, developmental abnormalities, and mesial temporal sclerosis. In most cases, mesial temporal sclerosis is associated with unilateral hippocampal

Figure 52-7 ^[45] FDG PET demonstrating significant hypometabolism involving the left temporal lobe in a patient with left mesial temporal lobe epilepsy. The darkness scale is divided into 10 equal intervals each representing a 10-percent change in hypometabolism. The level of darkness at the top of the scale represents an increase in metabolism as compared to the normal state with glucose metabolism decreasing as one progresses down the darkness scheme. (See CD-ROM for color (Photo n.) courtesy of C. Oliver Wong, MD, PhD, FACP.)

atrophy on T1-weighted images and increased signal in the mesial temporal structures on T2-weighted sequences ([Fig. 52-6](#)). These findings are highly predictive of seizure remission and lack of material-specific memory deficits following mesial temporal resection. Magnetic resonance spectroscopy is a new tool that demonstrates regional metabolic alterations in epileptogenic tissue.

Cerebral glucose metabolism measured with ^[18] FDG PET is reduced in some patients with partial epilepsy. Temporal lobe hypometabolism is seen in 60 to 90 percent of patients with intractable TLE ([Fig. 52-7](#)).^[46] The extent of abnormality is usually larger than the epileptogenic zone, frequently extending into the ipsilateral basal ganglia, thalamus, and

fronto-parietal cortices. The yield of PET in nonlesional extratemporal epilepsy is significantly lower. The short half-life of the isotope precludes its use for ictal studies.

SPECT is more readily available than PET because it utilizes commercially available isotopes and does not require an on-site cyclotron. Technetium 99m-hexamethylene-propylene-amine-oxime SPECT reveals hypoperfusion in the epileptogenic temporal lobe during the interictal state in over 50 percent of patients with TLE.^[46] False lateralization has been reported in 15 to 20 percent of cases. The resolution of SPECT is inferior to that of PET, and quantitative analysis is not available. The long half-lives of the isotopes make ictal and immediate postictal SPECT a useful noninvasive localizing tool. The results of ictal SPECT depend on the time of injection of the isotope from seizure onset. Under optimal circumstances, 65 to 90 percent of studies demonstrate hyperperfusion ipsilateral to seizure origin ([Fig. 52-8](#)).^[46] Delayed injections produce widespread hyperperfusion and a higher incidence of false lateralization.

Specific Surgeries

TEMPORAL LOBECTOMY

Anterior temporal lobectomy is the most common surgical procedure for the treatment of intractable epilepsy in

Figure 52-8 Interictal and ictal Tc-99m SPECT in coronal and transverse planes in a patient with right mesial temporal lobe epilepsy. There is a reduction in blood flow in the right temporal lobe interictally and hyperperfusion in the same region during a typical partial seizure. (See CD-ROM for color version (Photo courtesy of C. Oliver Wong, MD, PhD, FACP.)

adolescents and adults. The resection typically includes the anterior 3.0 to 3.5 cm of the inferior and middle temporal gyri, uncus, part of the amygdala, and the anterior 2.0 to 3.0 cm of the hippocampus and adjacent parahippocampal gyrus. In patients with mesial temporal sclerosis, selective amygdalo-hippocampectomy may suffice. Lesionectomy with preservation of the mesial temporal structures may be indicated in patients with discrete temporal lobe lesions without evidence of mesial involvement. Language mapping is required when lesions are located near the language cortex. The use of tailored resections based on intraoperative electrocorticography remains controversial. A seizure-free state is achieved in 60 to 70 percent of patients, although auras may persist.^[47] A risk of verbal memory impairment exists in patients with normal preoperative memory scores undergoing dominant hemisphere anterior temporal lobectomy. Transient dysnomia after dominant anterior temporal lobectomy occurs in approximately 30 percent of patients.

EXTRATEMPORAL LESION RESECTION, HEMISPHERECTOMY, CORPUS CALLOSOTOMY

The procedure of choice for patients with extratemporal epilepsy due to a structural brain lesion is complete resection

1987

of the lesion and surrounding epileptogenic cortex. Lesionectomy is the most common type of epilepsy surgery performed in infants and children. Subtotal removal of a structural lesion is associated with a lower likelihood of seizure remission. Patients with nonlesional extratemporal epilepsy generally require intracranial monitoring to delineate the epileptogenic zone, and cortical mapping if the proposed resection is located in or around eloquent cortex. Surgical outcome in these cases depends on the certainty with which the epileptogenic zone is defined and the completeness of the resection. Only 25 to 35 percent of patients become seizure-free, and another 20 to 30 percent has a significant reduction in seizures. ^[48]

Hemispherectomy is indicated in patients with intractable partial and secondarily generalized seizures in whom an entire hemisphere is considered epileptogenic with little or no remaining functional cortex. The procedure is usually performed in patients with Rasmussen's encephalitis, Sturge-Weber syndrome, hemimegacephaly, or large hemispheric infarctions. Functional hemispherectomy consists of the removal of the frontal and temporal lobes and complete disconnection of the remaining cortex and corpus callosum. This procedure is an alternative to total hemispherectomy, which is associated with a high rate of cerebral hemosiderosis and hydrocephalus. Seizures are completely abolished in nearly 80 percent of patients. ^[49]

Corpus callosotomy should be considered in patients with frequent secondary generalized tonic-clonic, tonic, and atonic seizures that lead to falls and injuries. The goal of the procedure is to disrupt the major central pathways necessary for the propagation of generalized seizures. Complete callosal section may result in mutism, apraxia, or frontal lobe dysfunction. For this reason, the procedure is often performed in two stages beginning with sectioning of the anterior two thirds followed by section of the remainder of the corpus callosum, if necessary. Nearly two thirds of patients experience a significant reduction in seizures, although few are rendered seizure-free. ^[50]

HISTORY AND DEFINITIONS

Headache is a problem that has plagued humans since the beginning of recorded time. The earliest written reference to migraine is found in an epic poem written in Sumeria around 3000 BC^[1]: "*The sick-eyed says not I am sick-eyed. The sick-headed not I am sick-headed.*" From Mesopotamia comes a description of a headache sufferer with an associated visual disturbance, in which "the head is bent with pain gripping his temples . . . and his eyes are afflicted with dimness and cloudiness." Hippocrates described the visual aura that can precede the migraine headache and the relief that can be induced by vomiting.^[2] Aretaeus of Cappadocia is credited as the discoverer of migraine because of his classic description of the symptoms in the 2nd century AD.^[3] Migraine clearly was well known in the ancient world.

In 1778, Fothergill introduced the term fortification spectra to describe the visual aura of migraine. A hundred years later, Airy gave a vivid description of the same phenomenon, which he called teichopsia, quoting Tennyson^[4]: "*...as yonder walls rose slowly to a music slowly breathed, a cloud that gathered shape.*" In 1783, Tisso distinguished migraine from common headache and ascribed it to a supraorbital neuralgia "provoked by reflexes from the stomach, gallbladder, or uterus."^[5] Over the next century, DuBois, Reymond, Mollendorf, and later, Eulenburg proposed different vascular theories for migraine.

Living wrote the first monograph on migraine entitled *On Megrim, Sick-headache, and Some Allied Disorders: A Contribution to the Pathology of Nerve-Storms*^[6] and was the originator of the neural theory of migraine, ascribing the problem to "disturbances of the autonomic nervous system," which he called "nerve storms." In 1900, Dey^[7] suggested that migraine resulted from intermittent swelling of the hypophysis with compression of the trigeminal nerve. Later in the 20th century, Harold Wolff (1950) developed the experimental approach to the study of headache^[8] and elaborated the vascular theory of migraine, which has come under attack as the pendulum again swings to the neurogenic theory.^[9]

In 1962, an Ad Hoc Committee established descriptive definitions of migraine, tension-type headache (TTH), and other headache disorders. In 1988, the International Headache Society (IHS) published a formal classification system for the diagnosis of headache disorders.^[10] This system is being re-evaluated, modified, and improved. The IHS classification system ([Table 53-1](#)) divides headache into primary and secondary disorders. In a primary headache disorder, headache itself is the illness and no other etiology is diagnosed. In a secondary headache disorder, headache is the symptom of an identifiable structural or metabolic abnormality.

HEADACHE

Migraine Headache

Pathogenesis and Pathophysiology. Although the exact pathophysiology of migraine is unknown, several theories exist. Any migraine theory must explain the prodrome, the aura, the headache with its associated symptoms, and the postdrome. The traditional vascular theory proposed that the migraine aura was caused by intracerebral vasoconstriction and the headache by painful reactive vasodilation. This theory cannot explain the prodromal features of migraine or the reason some antimigraine drugs have no effect on the cerebral vasculature.^[1] Furthermore, this theory has not been substantiated by cerebral blood flow (CBF) studies.

The comprehensive neurovascular theory, which has replaced the vascular theory, is based on CBF studies, magnetic resonance spectroscopy, and magnetoencephalography research. It suggests that hypothalamic and limbic system disturbances may produce the prodromal symptoms of migraine, and that neuronal dysfunction with secondary vascular changes is responsible for the aura and headache

TABLE 53-1 -- INTERNATIONAL HEADACHE SOCIETY CRITERIA

Migraine
Migraine with aura
Migraine without aura
Tension-type headache
Episodic tension-type headache
Chronic tension-type headache
Cluster headache and chronic paroxysmal hemicrania
Cluster headache
Chronic paroxysmal hemicrania
Miscellaneous headaches unassociated with structural lesion
Idiopathic stabbing headache
Cold stimulus headache
Benign cough headache
Benign exertional headache
Headache associated with sexual activity
Headache associated with head trauma
Headache associated with vascular disorders
Headache associated with nonvascular intracranial disorders
Headache associated with substances or their withdrawal
Headache associated with noncephalic infections
Headache associated with metabolic disorders
Headache or facial pain associated with disorders of cranium, neck, eyes, ears, nose, sinuses, teeth, mouth, or other facial or cranial structures
Cranial neuralgias, nerve trunk pain, and deafferentation pain

of migraine. During the aura of classic migraine, a wave of decreased CBF spreads forward from the occipital cortex, preceding the aura symptoms and persisting into the headache phase. This change in CBF may be caused by cortical spreading depression (a short-lasting wave of neuronal activation, followed by inhibition), which may also produce the aura symptoms and activate trigeminal nerve endings. In the headache of migraine with aura (classic migraine), increased CBF occurs after the headache begins, and this change continues until the headache subsides. There is no change in CBF in migraine without aura (common migraine).^[2]

It is unclear how the brain stem nucleus for facial pain (the nucleus caudalis trigeminalis) is activated, but it may be due to cortical spreading depression or biochemical dysfunction, or both, that stimulates its peripheral nerve terminals. Activation of the central midbrain region during migraine has been demonstrated and has resulted in the speculation that this region may be the generator of migraine.^[3] An imbalance between facilitation and inhibition to the nucleus caudalis trigeminalis may render it more sensitive to nonpainful stimuli that are misinterpreted as painful. This theory may explain why migraine sufferers have an increased propensity to head pain (such as a so-called ice-pick headache) even during migraine-free periods.

Peripheral mechanisms may also play a role in migraine. Stimulation of the trigeminal nerve results in release of substance P, calcitonin gene-related peptide, and neurokinin A.^[4] These chemicals cause neurogenic inflammation and may further enhance neuronal sensitivity and altered blood flow in the microcirculation. Neurogenic inflammation-induced meningeal inflammation may produce some of the pain of migraine.

Serotonin (5-HT) also appears to play a role in migraine pathogenesis.^[5] Stimulation of the midbrain serotonergic cells results in increased CBF, and reserpine, a central nervous system (CNS) 5-HT-depleting agent, can precipitate migraine headaches. Similarly, sleep reduces CNS 5-HT neuronal firing and is a well-established method of aborting migraine attacks. Biochemical studies demonstrate that plasma 5-HT concentrations decrease during a migraine attack, and urinary excretion of 5-hydroxyindoleacetic acid, the main 5-HT metabolite, may increase. 5-HT receptor distribution and function, however, are not uniform in the brain. Some receptors modulate CBF, whereas others modulate pain, sleep, thermoregulation, motor activity, emotional behavior, and sensory responsiveness. Activation of inhibitory 5-HT_{1B/1D} receptors decreases the release of 5-HT, norepinephrine, acetylcholine, and substance P. When activated, the inhibitory 5-HT_{1B/1D} heteroreceptor, located on trigeminal nerve terminals, blocks neurogenic inflammation. Antimigraine drugs that are 5-HT agonists, such as dihydroergotamine (DHE) and sumatriptan, have high affinity for this receptor. Additionally, many drugs used to prevent migraine headaches are 5-HT₂ antagonists. 5-HT₃ receptor stimulation causes nausea, vomiting, and activation of autonomic reflexes.^[6] Other neurotransmitters and mediators, such as catecholamines, histamine, vasoactive peptides, endogenous opiates, prostaglandins, free fatty acids, and steroid hormones, are also implicated in the pathogenesis of migraine, but their specific effects are less clearly established.

Epidemiology and Risk Factors. Migraine occurs in 18 percent of women, 6 percent of men, and 4 percent of children in the United States.^[7] This disorder usually begins in the first three decades of life, with prevalence peaking in the fifth decade (Fig. 53-1 (Figure Not Available)). Most migraineurs have a family history of migraine. At least 60 percent of women with migraine experience clear improvement during later pregnancy, yet in some women, migraine worsens during the first trimester. Additionally, many women experience

Figure 53-1 (Figure Not Available) Migraine prevalence by age (From Silberstein SD, Lipton RB: Epidemiology of migraine. Neuroepidemiology 1993;12:179-194. Reproduced with permission of S. Karger AG, Basel.)

improvement of their migraine with natural, but not surgical, menopause.

Lance and Anthony found improvement in 58 percent of 120 women migraineurs who had borne children.^[8] Bousser found that migraine was improved or disappeared

in 69.4 percent of pregnancies, worsened in 6.8 percent, unchanged in 11 (7.9 percent), variable in 5.4 percent, and appeared for the first time in 10.9 percent. ^[12] Although disappearance or improvement did not differ significantly in migraine with or without aura, worsening was much more common in migraine with aura. Headache occurs frequently in the postpartum period, particularly in known migraineurs. Migraineurs do not have an increased risk of complications during pregnancy, and the children of migraineurs do not have an increased incidence of birth defects. ^[13]

Migraine is a risk factor (that is, co-morbid) for affective disorders. Compared with nonmigraineurs, migraineurs have a 4.5-fold increased risk of major depression, a six-fold risk of manic episodes, a three-fold increase in anxiety disorder, and a six-fold prevalence in panic disorder. Migraineurs without depression develop depression at follow-up at three times the rate of nonmigraineurs. Furthermore, depressed patients without migraine develop migraine at three times the rate of nondepressed patients. ^[14] The prospective data indicates that the cross-sectional or lifetime association between migraine and major depression could result from a bidirectional influence. These recent epidemiological studies support the association between migraine and major depression previously reported in clinic-based studies.

It has been proposed that major depression in migraineurs might represent a psychological reaction to repeated, disabling migraine attacks. Migraine has an earlier average age of onset than major depression in the population and in persons with co-morbid disease. Nonetheless, the bidirectional influence of each condition on the risk for the other is incompatible with the simple causal model. ^[14] Specifically, persons with depression but not migraine have an increased risk for migraine before painful attacks ever develop. ^[14] Furthermore, Breslau and Davis ^[15] reported that the risk for new episodes of major depression (or panic disorder) did not vary by the proximity of migraine attacks. Migraineurs may have affective spectrum disorders with associated irritable bowel syndrome, fibromyalgia, and chronic fatigue syndrome. Epilepsy, stroke, and mitral valve prolapse are also more common in migraineurs.

Contrary to the findings of clinic-based studies, population-based studies have shown migraine to be more prevalent in families of lower socioeconomic class. In addition, the economic impact of migraine and other headaches is enormous; the annual cost of headaches in terms of absenteeism, decreased productivity, and the cost of diagnostic tests and treatment ranges from five to 17 billion dollars. Despite ten million physician visits each year, migraine is still underdiagnosed and undertreated. ^[16]

Clinical Features and Associated Disorders. The migraine attack can be divided into four phases: (1) the prodrome, which occurs hours or days before the headache; (2) the aura, which immediately precedes the headache; (3) the headache itself; and, (4) the postdrome. ^[16] Although most migraineurs experience more than one

TABLE 53-2 -- DIAGNOSTIC CRITERIA FOR MIGRAINE

Migraine with Aura (Classic Migraine)	
<i>Diagnostic Criteria</i>	
At least two attacks fulfilling the following:	
At least three of the following four characteristics:	
1. One or more fully reversible aura symptoms	
2. At least one aura symptom over more than 4 minutes or 2 or more symptoms occurring in succession	
3. No single aura symptom lasts more than 60 minutes	
4. Headache follows aura with a free interval of less than 60 minutes (it may also begin before or simultaneously with the aura)	
Migraine Without Aura	
<i>Diagnostic Criteria</i>	
At least five attacks fulfilling the following:	
Headache lasting 4 to 72 hours (untreated or unsuccessfully treated)	
Headache has at least two of the following characteristics:	
1. Unilateral location	
2. Pulsating quality	
3. Moderate or severe intensity (inhibits or prohibits daily activities)	
4. Aggravation by walking stairs or similar routine physical activity	
During headache at least one of the following:	
1. Nausea and/or vomiting	
2. Photophobia and phonophobia	
For Both Disorders	
History, physical and neurological examinations, and appropriate investigations must adequately exclude secondary disorders. If a secondary condition co-exists, the migraine is considered primary only if the original migraine onset did not occur in close temporal relation with the other disorder.	

phase, no phase is obligatory for its diagnosis. Migraine with aura may occur with or without the headache, but migraine without aura requires the headache for its diagnosis (Table 53-2). Premonitory phenomena occur hours to days before the onset of headache in about 60 percent of migraineurs (Table 53-3). They include psychological, neurological, constitutional, and autonomic features. The migraine aura is a complex of focal neurological symptoms (positive or negative phenomena) that precedes or accompanies an attack. Most aura symptoms develop over 5 to 20 minutes and usually last less than 60 minutes. The aura can be characterized by visual, sensory, or motor phenomena and may also involve language or brain stem

TABLE 53-3 -- MIGRAINE PRODROME SYMPTOMS

Psychological	Constitutional and Autonomic
Depression	Stiff neck
Hyperactivity	Food cravings
Euphoria	Cold feelings
Talkativeness	Anorexia
Irritability	Sluggishness
Drowsiness	Diarrhea or constipation
Restlessness	Thirst
	Urination
	Fluid retention

Yawning	

disturbances. If the aura is prolonged, it may meet the criteria of what was formerly termed a complicated migraine. Headache, when present, usually occurs within 60 minutes of the end of the aura, and most patients do not feel well during the period from the end of the aura to the beginning of the headache. Many patients experience a variety of cognitive or emotional symptoms during this time.^[17]

The most frequently occurring aura is visual in nature. Elementary visual disturbances, including scotomata, photopsia, phosphenes (simple flashes), specks, geometrical forms, shimmering, or undulations are the most common and may occur singly or number in the hundreds. Interestingly, these elementary visual disturbances are more likely to occur during than before the headache. An occipital lobe origin is presumed based on their presence in both eyes and often in a hemifield distribution. More complicated hallucinations include teichopsia or fortification spectrum, which is the most characteristic visual aura and nearly diagnostic of migraine. An arc of scintillating lights, usually but not always beginning near the point of fixation, may form into a herringbone-like pattern that expands to encompass an increasing portion of a visual hemifield. It migrates across the visual field with a scintillating edge of often zigzag, flashing, or occasionally colored phenomena.^[17],^[18] Visual distortions and hallucinations, speculated to represent some of Lewis Carroll's descriptions in *Alice's Adventures in Wonderland*, occur more commonly in children. They are characterized by a complex disorder of visual perception that may include metamorphopsia, micropsia, macropsia, zoom vision (opening up or closing down in the size of objects), or mosaic vision (fracture of image into facets).^[18]

Paresthesias are the second most common aura and typically start in the hand, migrate up the arm, and then extend to involve the face, lips, and tongue. Paresthesias can become bilateral and may be followed by numbness and loss of positional sense.^[17],^[19] They typically progress over a period of more than 5 minutes and are often associated with a visual aura. More complex symptoms include difficulties in the perception and use of the body; speech and language disturbances; states of double or multiple consciousness associated with *dejà vu* or *jamais vu*; and elaborate dreamy, nightmarish, trancelike, or delirious states. Motor symptoms, when they occur, are usually associated with sensory symptoms, but true weakness is rare and usually unilateral.

The typical migraine headache is unilateral, throbbing, moderate to marked in severity, and aggravated by physical activity. Not all of these features are required. The pain may be bilateral at the onset or start on one side and become generalized.^[17],^[19] The onset is usually gradual. The pain peaks and then subsides, and usually lasts between 4 and 72 hours in adults and 2 and 48 hours in children. The frequency of attacks is extremely variable, from a few in a lifetime to several a week, and the average migraineur experiences from one to three headaches a month. The head pain varies greatly in intensity, although most migraineurs report pain ratings of five or greater on a 0 to 10 pain scale. Pain is throbbing in 85 percent of cases,^[17],^[19] although throbbing pain is not diagnostic of migraine because it is often described in other headache types.

The pain of migraine is invariably accompanied by other features. Anorexia is common, and nausea occurs in almost 90 percent of patients, while vomiting occurs in about one third of patients.^[20] Many patients experience sensory hyperexcitability manifested by photophobia, phonophobia, and osmophobia, and seek a dark, quiet room. Blurred vision, nasal stuffiness, diarrhea, polyuria, pallor, or sweating may be noted during the headache phase. There may be localized edema of the scalp or face, scalp tenderness, prominence of a vein or artery in the temple, or stiffness and tenderness of the neck. Impairment of concentration and mood are common. Lightheadedness, rather than true vertigo, and a feeling of faintness may occur. The extremities tend to be cold and moist. Following the headache, during the postdrome phase, the patient may feel tired, "washed out," irritable, and listless, and may have impaired concentration, scalp tenderness, or mood changes. Some people feel unusually refreshed or euphoric after an attack, whereas others note depression and malaise.

A variety of migraine clinical subtypes have been described. *Basilar migraine*, previously called "basilar artery migraine," was originally believed to be a disorder of adolescent girls, and although there is a clear female predominance, it is now known to affect all age groups. Severe headache is preceded by a visual aura, then brain stem signs of ataxia, vertigo, tinnitus, diplopia, nausea and vomiting, nystagmus, dysarthria, bilateral paresthesia, and a change in level of consciousness and cognition. Confusional migraine, which occurs more commonly in boys than in girls, is characterized by headache accompanied by inattention, distractibility, and difficulty maintaining speech and other motor activities. Spells of basilar and confusional migraine can present a confusing picture and should be considered in patients with paroxysmal brain stem disturbances.^[9],^[17]

Hemiplegic migraine occurs in two forms, sporadic and familial, both of which typically begin in childhood and cease with adulthood.^[21] The age of onset of hemiplegic migraine may be earlier than that of common migraine. The attacks are frequently precipitated by minor head injury. Accompanying changes in consciousness ranging from confusion to coma are a feature of hemiplegic migraine, especially in childhood, and occur in 23 percent of patients. The hemiplegia may be part of the aura and last less than 1 hour, or it may continue through the headache phase and last for days or weeks. Familial hemiplegic migraine has an autosomal dominant mode of inheritance with variable penetrance. It has been linked to chromosome 19 in many but not all families. Attacks of migraine lasting longer than 72 hours define status migrainosus. It is often associated with pernicious nausea, vomiting, dehydration, and despair.^[17]

Periodic focal neurological dysfunction, which may be part of the migraine aura, can occur in isolation without the headache.^[17],^[19] These phenomena can be part of migraine, but they are accepted as migraine only after a full investigation and prolonged follow-up. Occasional headaches occurring in association with the same symptoms as an aura help confirm the migraine diagnosis for the episodes without headache, because patients who have migraine with aura often experience aura without headache.

Late-life migrainous accompaniments are transient neurological

TABLE 53-4 -- MAIN CRITERIA FOR THE DIAGNOSIS OF LATE-LIFE MIGRAINOUS ACCOMPANIMENTS

Scintillations (or other visual display), paresthesias, aphasia, dysarthria, and paralysis
Build-up of scintillations
March of paresthesias
Progression from one accompaniment to another, often with a delay
Two or more similar attacks
Headache in 50 percent of attacks
Episodes last 15 to 25 minutes
Characteristic mid-life "flurry" of attacks
Generally benign course
Normal angiography
Rule out cerebral thrombosis, embolism and dissection, epilepsy, thrombocytopenia, polycythemia, and thrombotic thrombocytopenia

phenomena that frequently are not associated with headache.^[22] Attacks of episodic focal neurological dysfunction, which last from 1 minute to 72 hours, can occur with variable recurrence. Fisher considered scintillating scotoma to be diagnostic of migraine, even when it occurred in isolation, whereas other episodic neurological symptoms (paresthesias, aphasia, and sensory and motor symptoms) needed more careful evaluation (Table 53-4). Transient migrainous accompaniments may occur for the first time after the age of 45 and can easily be confused with transient ischemic attacks of cerebrovascular origin.

Ophthalmoplegic migraine^[9] is associated with acute attacks of third nerve palsy associated with a dilated pupil and migrainous unilateral eye pain. The fourth and sixth cranial nerves may be involved, but this situation is rare. The duration of ophthalmoplegia varies from hours to months. The differential diagnosis includes intracranial aneurysms and chronic sinusitis with a mucocele. However, many cases of ophthalmoplegic migraine fit the criteria for the Tolosa-Hunt syndrome of painful ophthalmoplegia^[23]: (1) steady, gnawing, boring, eye pain; (2) involvement of nerves of the cavernous sinus; (3) symptoms lasting days or weeks; (4) spontaneous remission, with recurrent attacks occurring after months or years; (5) computed tomography (CT) or magnetic resonance imaging (MRI) limiting disorder to the cavernous sinus; and (6) steroid responsiveness.

Various pain patterns have been described in migraine. Patients who have daily headaches that persist for months often have transformed migraine, with a past history of episodic migraine typically beginning in their teens or twenties.^[24] Most of these patients are women, 90 percent of whom have a history of migraine without aura. The headaches grow more frequent, and the associated symptoms of photophobia, phonophobia, and nausea become less severe and less frequent than during typical migraine. Patients often develop a pattern of daily, or nearly daily, headaches that phenomenologically resemble chronic TTH, with mild to moderate pain but with photophobia, phonophobia, or gastrointestinal features. Other features of migraine, including unilaterality and aggravation by menstruation and other trigger factors, may persist. Attacks of full-blown migraine superimposed on a background of less severe headaches often occur. In the past, this was called mixed tension-vascular headache. Most patients with transformed migraine overuse symptomatic medication. Stopping the overused medication frequently results in distinct headache improvement. Eighty percent of patients with transformed migraine have depression. The depression often lifts when the pattern of medication overuse and daily headache is interrupted.

Because of the limitations of patient recall, a past history of migraine and an escalation of symptoms over 3 months may be impossible to obtain. Three alternative diagnostic links to migraine have been proposed: (1) a prior history of IHS migraine; (2) a clear period of escalating headache frequency with decreasing severity of migrainous features; or (3) current superimposed attacks of headaches that meet all of the IHS criteria for migraine except duration.

There are a number of disorders that may present with migraine symptoms. Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL) is an inherited arterial disease of the brain that has been mapped to chromosome 19.^[25] The complete CADASIL syndrome consists of recurrent episodes of focal brain deficits (recurrent strokes) starting in midadult life, often leading to dementia, residual motor disability, and pseudobulbar palsy. Even before clinical symptoms or signs have developed, at-risk individuals may demonstrate an abnormal MRI, with extensive areas of increased T2 signals in the white matter. Many cases of familial hemiplegic migraine (all with associated cerebellar features) map to chromosome 19, close to the gene locus for CADASIL. The main clinical presentation of CADASIL is recurrent subcortical events, either transient or (more often) permanent. However, the vascular presentation is not constant, and other symptoms, such as dementia, migraine with aura, and depression, can occur.

Mitochondrial encephalopathy with lactic acidosis and stroke-like spells (MELAS) syndrome may present with otherwise typical migraine or migraine with hemiparesis. Ornithine transcarbamylase deficiency, a urea cycle enzyme abnormality, may resemble confusional migraine in children and young adults, with migraine-like headaches, cyclic vomiting, confusion, hallucinations, visual disturbances, and ataxia.

Differential Diagnosis. Migraine-like headaches with or without aura may occur as a result of a wide variety of structural abnormalities of the brain, including tumors, infections, and vascular malformations. Such headaches may be thought of as secondary migraine. Cerebrovascular disorders such as infarction, transient ischemic attack, venous thrombosis, vasculitis, and carotid or vertebral dissection should be included in the differentiation of migraine. Idiopathic intracranial hypertension (IIH), low pressure headache, and intracranial neoplasms may also mimic migraine, as may metabolic abnormalities, hypoxia, hypoglycemia, dialysis, pheochromocytoma, and various chemicals and medications. Raeder's syndrome, with carotid artery abnormalities along the base of the skull, may also resemble migraine. Sinusitis or glaucoma may occasionally resemble migraine, and sometimes epilepsy produces intermittent headaches. Although rare, the aura of migraine may lead directly to a partial or complex partial seizure, termed migralepsy.^[26] Other primary headache disorders such as TTH, cluster, and hypnic headache should be considered (see [Table 53-1](#)).^[17]

Evaluation. Patients who have normal neurological examinations

and benign recurrent headaches that fit the IHS criteria of migraine do not require brain imaging.^[27] Patients who have abnormal neurological examinations, atypical histories, or a sudden unexplained change in the frequency or major characteristics of their headaches should be imaged. All patients with chronic daily headaches should be imaged with CT or MRI, even if they fulfill the criteria for typical migraine. Unless a metabolic abnormality is suspected, blood tests for diagnostic purposes are rarely indicated. However, routine blood tests and an electrocardiogram should be obtained before initiating therapy for migraine. Despite ten million physician visits each year, migraine is still underdiagnosed and undertreated.^[10]

Management. Most migraineurs describe headache-provoking (trigger) factors ([Table 53-5](#)), with alcohol, stress, menstruation, and diet being the most common. Patients should attempt to avoid these triggers and keep regular exercise, meal, and sleep patterns.^[17] In the pharmacological treatment of migraine, there are two strategies: (1) abortive medications ([Table 53-6](#)), which are used to terminate attacks, and (2) prophylactic medications ([Table 53-7](#)), which are used to prevent future ones. Some rapid-acting drugs, such as metoclopramide, can prevent a headache attack when they are administered during the prodrome. Drugs used for abortive treatment include analgesics (aspirin, acetaminophen), nonsteroidal anti-inflammatory drugs (NSAIDs), serotonin agonists, ergot alkaloids, neuroleptics, steroids, and narcotics. The sooner treatment is begun, the more effective it will be. Caffeine, butalbital, isometheptene, and dichloralphenazone are adjunctive medications included in combination preparations to improve efficacy.^[17]

Analgesics and NSAIDs are first-line therapy in mild to moderate headache attacks. If patients are prone to stomach ulcers, acetaminophen should be used. If these drugs fail, combination analgesics can be used. More severe attacks should be treated with ergotamine, DHE, or sumatriptan. Ergotamine tartrate use should be limited to twice weekly, because of the risk of rebound headaches caused by more frequent dosing. Sumatriptan is effective but expensive, and up to 40 percent of patients have recurrent headaches with this drug. Some clinicians believe that patient-administered sumatriptan and DHE have the best efficacy-to-adverse-effect ratio of all the acute-treatment medications and are the most cost effective because their use results in fewer emergency visits. Because nausea and vomiting are symptoms that are commonly associated with

migraine headaches, oral medications may be unsuitable, and alternative formulations, as well as antiemetics, may be needed. Intravenous (IV) neuroleptics, corticosteroids, and DHE are highly effective. Patients with severe rebound headache, significant psychiatric or medical co-morbidity, or a severe intractable headache that has failed to respond to outpatient treatment may require inpatient treatment with IV medication. ¹¹⁷

Preventive (prophylactic) treatment (see Table 53-7) should be considered when: (1) acute symptomatic treatment is required more often than two times a week; (2) two or more attacks occur per month that produce disability for more than 3 days; (3) abortive drug treatment is ineffective, intolerable, or contraindicated; (4) headaches produce prolonged disability or are associated with neurological symptoms

or signs; or (5) attacks occur in a predictable pattern. Preventive drug treatment includes antidepressants, beta-blockers, calcium channel blockers, NSAIDs, serotonin antagonists (methysergide, cyproheptadine), and anticonvulsants (divalproex). Medication should be started at a low dose and increased slowly until

headache severity or frequency decreases, the maximum recommended dose is reached, or adverse effects develop. Dose titrations may take several months. When the headaches have been controlled for 6 months, attempts can be made to taper and discontinue therapy. Patients should be monitored for abortive medication overuse, which may result in chronic refractory headaches and withdrawal symptoms when the medication is discontinued. ^[17]

The pregnant headache patient should be treated conservatively, with nonpharmacological treatments first. If the patient does not respond to this form of therapy, acetaminophen (alone or with prochlorperazine or narcotics) can be used and NSAIDs may be used in the first two trimesters. Very severe attacks should be treated with IV fluids, prochlorperazine, or narcotics. Prednisone has occasionally been used, but aspirin, barbiturate, and benzodiazepine use should be limited. Ergotamine and sumatriptan should be avoided completely. In the breast-feeding migraineur, ergotamine and lithium should not be used, because these drugs readily transfer to the baby via breast milk and can cause significant toxicity. Benzodiazepines, antidepressants, and neuroleptics may be used cautiously. Acetaminophen is preferable to aspirin. ^[17]

Prognosis and Future Perspectives. The prognosis of migraine is generally good. It usually improves and may disappear in the sixth or seventh decade of life. The natural history of transformed migraine is less certain. With aggressive treatment, most patients improve, although many continue to have lower intensity chronic daily headache or frequent episodic migraine. Future research will involve the search for the migraine gene. To date, some varieties of familial hemiplegic migraine and CADASIL have been linked to chromosome 19, and perhaps gene-directed therapy may be a therapeutic option in the next decade.

Tension-Type Headache

Pathogenesis and Pathophysiology. Although many patients with TTHs have muscle tenderness, TTH is not the result of sustained contraction of the pericranial muscles with subsequent ischemic pain in response to emotion or stress. Muscle ischemia is not present during headache. Electromyography activity is increased in some muscles, independent of tenderness and pain. Reduced CNS 5-HT levels may be responsible for abnormal pain modulation, producing the decreased pain thresholds that are observed in patients with chronic TTH. A "myofascial-supraspinal-vascular" model has been proposed for TTH. ^[28] In the presence of pain facilitation, normal subthreshold stimuli may produce significant pain even if myofascial nociceptor hypersensitivity is not present. The cranial muscle ache of a TTH attack may, therefore, be due to increased neuronal sensitivity and pain facilitation due to chronic or intermittent dysfunction of the monoaminergic or serotonergic function in the hypothalamus, brain stem, and spinal cord. ^[29] Chronic TTH may be associated with a perceived increase in stressful life events. Depression is common in patients with chronic TTH, and neurotransmitter abnormalities in 5-HT, norepinephrine, dopamine, and enkephalins have been proposed as the etiology.

Epidemiology and Risk Factors. TTH is the most common headache type, with a lifetime prevalence of 69 percent in men and 88 percent in women. ^[19] TTHs can begin at any age, but onset during adolescence or young adulthood is most common. About 40 percent of patients evaluated in headache clinics suffer from daily headache, whereas only 3 percent of the population has daily headache. ^[30] Headache prevalence declines with increasing age, and severity decreases in the women who continue to report headaches but does not change in men. Only patients with more severe frequent headaches that are unresponsive to over-the-counter preparations seek medical attention.

Clinical Features and Associated Disorders. The IHS criteria for a TTH require that patients experience at least 10 previous headaches, each lasting 30 minutes to 7 days (median is 12 hours), with at least two of the following characteristics: a pressing/tightening (nonpulsating) quality, mild to moderate intensity, bilateral location, and no aggravation with physical activity. In addition, the patient should

not have nausea or vomiting or a combination of both photophobia and phonophobia. Episodic TTH occurs less than 15 days a month, whereas chronic TTH occurs 15 or more days a month. ^[29]

The onset of TTH is gradual, often occurring after or during stress and is typically worse late in the day. There is no prodrome. The pain is usually a nagging, tight, or viselike bilateral pressure that is located in the forehead, the temples, or the back of the head. It may radiate to the neck and shoulders. There are no associated autonomic or gastrointestinal symptoms except for occasional anorexia. The frequency of episodic TTH ranges from 2 to 12 days a month, with a median of 6 days a month. The headaches may be associated with menstruation. ^[29], ^[30]

Twenty-five percent of TTH patients also have migraine. Patients with episodic TTH are no different from controls in terms of stress, depression, anxiety, emotional conflicts, sleeping problems, and fatigue. Patients with chronic TTH are often depressed. ^[29]

Differential Diagnosis. Migraine is the primary headache disorder that may be confused with TTH. Both can be bilateral, nonthrobbing, and associated with anorexia. Migraine is more severe, often unilateral, and frequently associated with nausea. ITH, brain tumor headache, chronic sphenoid sinusitis, and cervical, ocular, and temporomandibular disorders need to be considered. ^[29], ^[30]

Evaluation. Most patients with a long history of unchanged episodic TTHs do not require extensive evaluation if they have normal neurological examinations and are otherwise healthy. Patients with chronic TTHs should be imaged with CT or MRI, even if their general and neurological examinations are normal. A metabolic screen, complete blood count, electrolytes, and kidney and thyroid function studies are also appropriate. ^[29]

Management. TTH patients usually self-medicate with over-the-counter analgesics (aspirin, acetaminophen, NSAIDs), with or without caffeine. If these medications are not effective, prescription NSAIDs or combination analgesic preparations can be used. Narcotics and combination analgesics that contain sedatives or caffeine should be limited, because overuse may cause dependence. Symptomatic medication overuse can cause episodic TTHs to convert to chronic TTHs. Patients with both migraine and TTHs benefit from specific migraine medication such as sumatriptan or DHE (see [Tables 53-6](#) and [53-7](#)). ^[29], ^[30]

Preventive therapy should be administered when a patient has frequent headaches that produce disability or may lead to symptomatic medication overuse. Medications used for TTHs prevention include antidepressants, beta blockers, and anticonvulsants. Antidepressants, the medication of first choice, should be started at a low dose and increased slowly every three to seven days. An adequate trial period of at least one to two months must be allowed. The addition of biofeedback therapy or beta-blocking agents may improve the therapeutic benefit derived from anti-depressants. ^[29], ^[30]

Prognosis and Future Perspectives. Episodic TTH is a benign recurrent condition that usually improves with time. Some patients may, however, progress to chronic TTH, especially when analgesic overuse is present. The prognosis of chronic TTH is controversial, because many studies include patients with more severe headaches and co-existing conditions such as migraine and psychiatric disorders.

Cluster Headache

Pathogenesis and Pathophysiology. The pathogenesis of cluster headaches has not been fully determined. Cluster events may be related to alterations in the circadian pacemaker, which may be due to hypothalamic dysfunction. Attacks increase following the beginning and end of daylight savings time, and there is a loss of circadian rhythm for blood pressure, temperature, and hormones, including prolactin, melatonin, cortisol, and beta endorphins. Neurogenic inflammation, carotid body chemoreceptor dysfunction, central parasympathetic and sympathetic tone imbalance, and increased responsiveness to histamine have been proposed as the cause of cluster pain. ^[31]

Epidemiology and Risk Factors. With an incidence of 0.01 to 1.5 percent in various populations, cluster headache prevalence is lower than that of migraine or TTH. Prevalence is higher in men than in women and in black patients compared with white patients. The male-to-female ratio is about 6:1. A family history of cluster headache is rare. The most common form of cluster headache is episodic cluster. The rarest form is chronic cluster headache without remissions, with only about 10 percent of patients suffering from this variety of cluster. Cluster headache can begin at any age, but it generally begins in the late twenties. Cluster headache rarely begins in childhood, and only about 10 percent of patients develop cluster when they are in their sixties. ^[31], ^[32]

Clinical Features and Associated Disorders. Patients with cluster headache have multiple episodes of short-lived but severe, unilateral, orbital, supraorbital, or temporal pain. At least one of the following associated symptoms must occur: conjunctival injection, lacrimation, nasal congestion, rhinorrhea, facial sweating, miosis, ptosis, or eyelid edema. Episodic cluster consists of headache periods of 1 week to 1 year, with remission periods lasting at least 14 days, whereas chronic cluster headache has either no remission periods or remissions that last less than 14 days. ^[31], ^[32]

The pain of a cluster attack rapidly increases (within 15 minutes) to excruciating levels. The attacks often occur at the same time each day and frequently awaken patients from sleep. If the condition is left untreated, the attacks usually last from 30 to 90 minutes, but may last up to 180 minutes. The pain is deep, constant, boring, piercing, or burning in nature, located in, behind, or around the eye. It may radiate to the forehead, temples, jaws, nostrils, ears, neck, or shoulder. During an attack, patients often feel agitated or restless and feel the need to isolate themselves and move around. Gastrointestinal symptoms are uncommon. The attack frequency varies from one every other day to eight a day, occurring in cluster periods that last a week to a year. Remission between cluster periods generally lasts 6 months to 2 years. Most patients have one or two cluster periods a year that last 2 to 3 months, with one to two attacks per day. [31]

Peptic ulcer disease is the only known associated medical

disorder. Secondary cluster-like headache may occur due to structural lesions near the cavernous sinuses. [31], [32]

Differential Diagnosis. The differential diagnosis of cluster headache includes chronic paroxysmal hemicrania, migraine, trigeminal neuralgia (TN), temporal arteritis, pheochromocytoma, Raeder's paratrigeminal syndrome, Tolosa-Hunt syndrome, sinusitis, and glaucoma. [31] Raeder's syndrome has characteristics similar to cluster headaches. It may be associated with severe pain, unilateral and supraorbital distribution, and an associated partial Horner's syndrome. It is distinct from cluster headache in that there are no distinct attacks and the pain is constant.

Evaluation. There are no studies that address the need for testing in cluster-like headache. In most cases, a careful history is all that is needed to make the diagnosis. MRI of the head is justified only in atypical cases or cases with an abnormal neurological examination (except when the abnormality is a Horner's syndrome).

Management. Patients with cluster headaches should avoid alcohol and nitroglycerin, yet other dietary and drug restrictions have little effect on cluster headaches. Pharmacological treatment for cluster headaches is divided into abortive and preventive therapy, and recommendations are mainly based on uncontrolled trials (Table 53-8). [31], [32] Oral preparations are absorbed slowly and are not recommended for the treatment of acute attacks. Effective abortive treatments that provide rapid onset of action include oxygen, sumatriptan, DHE, and (perhaps) topical local anaesthetics. Inhaled oxygen, 7 to 10 L/min for 10 minutes following headache onset, is 70 percent effective and is often the treatment of first choice. Parenteral injections of

TABLE 53-8 -- CLUSTER HEADACHE PROPHYLAXIS

Drug	Dosage	Adverse Effects
Episodic Cluster Headache*		
Divalproex	500-3000 mg/day	Nausea, lethargy, tremor, weight gain, hair loss; rarely abnormal liver function, pancreatitis
Ergotamine	Up to 4 mg/day	Nausea, paresthesia, intermittent claudication, ergotism
Lithium	300 mg bid or tid	Weakness, nausea, thirst, tremor, lethargy, slurred speech, blurred vision
Methysergide	2-14 mg/day	Muscle cramps, nausea, diarrhea, abdominal discomfort
Prednisone	40-100 mg/day,	Insomnia, restlessness, taper over 1-2 personality changes, weeks hyponatremia, edema, hyperglycemia, osteoporosis, myopathy, gastric ulcers, hip necrosis
Verapamil	120-720 mg/day	Constipation, edema, dizziness, nausea, hypotension, fatigue
Chronic Cluster Headache		
Divalproex	500-3000 mg/day	Same as episodic
Lithium	300 mg bid or tid (0.4-0.8 mmol/L)	Hypothyroidism and polyuria
Methysergide	2-14 mg/day	Fibrotic reactions
Verapamil	120-640 mg/day	Same as episodic

*Begin early in the cluster period and continue until the patient has been headache-free for at least two weeks.

Combinations are often required.

bid, twice daily; tid, three times daily.

sumatriptan or DHE mesylate provide significant relief for about 80 percent of patients. An intranasal local anesthetic may provide relief for some patients. [31], [32]

Most patients with cluster headache require preventive treatment because each attack is too short in duration and too severe in intensity to treat with only abortive medication. In addition, ergotamine, DHE, sumatriptan, and oxygen may just postpone rather than abort the attack. Preventive therapy for episodic cluster, in order of preference, includes ergotamine, calcium channel blockers, methysergide, lithium, corticosteroids, divalproex, and capsaicin. Occasionally, indomethacin is effective. If medical therapy fails completely, surgical intervention may be beneficial for the psychologically stable patient with strictly unilateral chronic cluster. The surgery consists of neuronal ablation procedures directed toward the sensory input of the trigeminal nerve and autonomic pathways, and is generally effective in 75 percent. [31] The prognosis of cluster headaches is guarded; it is a chronic headache that may last for the patient's life. Drug therapy may help convert some patients from chronic to episodic cluster. [31]

Chronic Paroxysmal Hemicrania

This headache resembles cluster headache in character but distinguishes itself by its dramatic responsiveness to indomethacin therapy. The pathophysiology of chronic paroxysmal hemicrania is unknown. Changes in intraocular pressure that occur during attacks suggest autonomic dysfunction, and the periodicity of this disorder suggests a central generator. [33] Chronic paroxysmal hemicrania is a rare disorder that affects women more than men (ratio approximately seven to one), in contrast to cluster headache. It appears to have approximately 2 percent the prevalence of cluster headache. [33]

Like cluster headache patients, chronic paroxysmal hemicrania patients have severe unilateral headache associated with unilateral nasal stuffiness, lacrimation, conjunctival eye tearing, ptosis, and eyelid edema. Headaches average 13 minutes in duration and occur an average of 11 times a day. Occasionally, there is a continuous dull ache between attacks. In 10 percent of patients, attacks may be triggered by flexing, rotating, or pressing the upper portion of the neck. [33] Typically, there are no remissions. Rarely, a patient may present with episodic paroxysmal hemicrania with remissions lasting weeks or months. Patients may evolve from the episodic to the chronic form of the illness. By definition chronic and episodic hemicrania are responsive to indomethacin. No other medical or psychiatric disorders have been associated with chronic paroxysmal hemicrania. [33]

The differential diagnosis of chronic paroxysmal hemicrania is similar to that of cluster headache. In addition, patients with "jabs and jolts syndrome" might occasionally resemble chronic paroxysmal hemicrania patients. A rare headache disorder called short unilateral neuralgiform headache with conjunctival injection and tearing should be considered, although the headaches are much shorter in duration (15 to 30 seconds) and occur much more frequently

(many times per hour) than those of chronic paroxysmal hemicrania.

In the evaluation of chronic paroxysmal hemicrania, a trial of indomethacin is necessary to establish the diagnosis. Brain imaging with MRI or CT should be

undertaken to exclude symptomatic causes of apparent chronic paroxysmal hemicrania. The treatment of choice is indomethacin (up to a dose of 200 mg per day). Aspirin may also be beneficial, but the relief afforded is usually not complete. Chronic paroxysmal hemicrania may last indefinitely, but over time, there is frequently a reduced indomethacin requirement. Temporary remissions and spontaneous cures have been described. Selective prostaglandin synthesis inhibitors, indomethacin-like drugs without the gastrointestinal side effects of the current NSAIDs, are in development and may be beneficial.

Idiopathic Intracranial Hypertension

Pathogenesis and Pathophysiology. The pathophysiology of IIH is unknown. Postulated mechanisms include increased CSF production, decreased CSF absorption, and increased venous sinus pressure. Some studies suggest that interstitial brain edema and a decreased rate of absorption at the arachnoid villi are the major contributors. The disturbances of CSF hydrodynamics in IIH persist for years.^[34] Increased CSF pressure in IIH may result from a rise in venous sagittal sinus pressure secondary to extracellular edema causing venous obstruction, or from low conductance for CSF reabsorption producing a compensatory increase in CSF pressure. Patients were evaluated with cerebral venography and manometry, and they demonstrated elevated venous pressure in the superior sagittal and proximal transverse sinuses. This elevated pressure dropped at the level of the lateral third of the transverse sinus resembling a mural thrombosis on venography. Two patients with intracranial hypertension due to minocycline did not have venous hypertension. The authors suggested that most patients with IIH may have partial venous outflow obstructions, blurring the distinction between idiopathic and symptomatic causes.^[35],^[36] In another study, the authors suggested that IIH was due to either venous obstruction or elevated central venous pressure, despite the absence of signs or symptoms of heart failure. The pathophysiology of IIH without papilledema is presumably similar to that with papilledema.

Epidemiology and Risk Factors. IIH with papilledema occurs with a frequency of about one case per 100,000 per year in the general population and 19.3 cases per 100,000 per year in obese women aged 20 to 44.^[35] The patient with IIH is commonly a young, obese woman with chronic daily headaches, normal laboratory studies, an empty sella, and a normal neurological examination (except for papilledema) ([Fig. 53-2](#)).^[35]

Clinical Features and Associated Disorders. The symptoms of IIH consist of generalized increased intracranial pressure, with headache occurring in most, but not all, patients. Bifrontotemporal headache is most common. Unilateral headache with increased CSF pressure due to IIH may be an exacerbation of migraine or a new local

Figure 53-2 An empty sella is shown.

phenomenon. Transient visual obscuration, an episode of visual clouding in one or both eyes usually lasting seconds, occurs with all forms of increased intracranial pressure with papilledema but is not a specific symptom. Transient visual obscurations can occur in patients without increased intracranial pressure who have elevated optic discs from other causes. Persons without papilledema do not have transient visual obscurations. Pulsatile tinnitus, diplopia, and visual loss can occur. Some patients report shoulder and arm pain (perhaps secondary to nerve root dilatation) and retro-orbital pain.^[35]

IIH without papilledema has been described in some patients. The headache and demographic characteristics are identical to those of patients with papilledema except for (1) possible association with prior head trauma or meningitis; (2) extended delay in diagnosis, which requires lumbar puncture in the absence of papilledema; and, (3) no evidence of the visual loss seen in patients with IIH with papilledema.^[35] There are no disorders associated with IIH other than obesity.

Differential Diagnosis. IIH may be either (1) truly *idiopathic*, with no clear identifiable cause, or (2) *symptomatic*, a result of venous sinus occlusion, radical neck dissection, hypoparathyroidism, vitamin A intoxication, systemic lupus erythematosus, renal disease, or drug side effects (nalidixic acid, danocrine, steroid withdrawal).

Evaluation. The diagnosis of IIH (with or without papilledema) is based on lumbar puncture following neuroimaging (paying attention to empty sella and sinus thrombosis). If CSF biochemical and cytological analyses are unremarkable and intracranial pressure is elevated to greater than 200 mm H₂O (in nonobese subjects), IIH is the likely diagnosis. Secondary causes should also be considered in the evaluation. Over 50 diseases, conditions, toxins, or pharmaceuticals have been associated with IIH. Patients, particularly obese women, with chronic daily headaches and symptoms of increased intracranial pressure, for example, pulsatile tinnitus, a history of head trauma or meningitis, an empty sella on neuroimaging

TABLE 53-9 -- POSSIBLE TREATMENTS OF IDIOPATHIC INTRACRANIAL HYPERTENSION

Eliminate symptomatic causes
Weight loss if obese
Standard headache treatment
Carbonic anhydrase inhibitors and loop diuretics
Short course of high dose corticosteroids
Serial lumbar punctures
Lumboperitoneal or ventriculoperitoneal shunt
Optic nerve sheath fenestration

studies, or a headache that is unrelieved by standard therapy, should have a diagnostic lumbar puncture.^[35]

Management. The treatment of IIH is multidimensional (see [Table 53-9](#)). Obese patients should be encouraged to lose weight. If patients are asymptomatic and do not have visual loss, treatment is not indicated. In these cases, careful ophthalmological follow-up is necessary. If there is headache with visual loss or papilledema, then aggressive treatment should be instituted.

Headache associated with IIH and papilledema frequently responds to the same treatments used for migraine and TTH. If rigorous headache therapy is unsuccessful, or if there is visual loss, then a 4- to 6-week trial of furosemide or a potent carbonic anhydrase inhibitor (acetazolamide) should be given. High-dose steroids may be effective, but headache commonly recurs when the drugs are withdrawn. Lumbar puncture typically relieves headache in patients with IIH and papilledema. Some intractable headache patients have a dissociation between the CSF pressure and the headache. In some patients, lumbar puncture reduces the pressure and relieves the headache; in others, there is no improvement. Surgical treatment of IIH has been directed toward preventing visual loss secondary to papilledema, and headache improvement occurs in many patients when optic nerve sheath fenestration is performed.^[35]

Prognosis and Future Perspectives. Most patients with IIH and papilledema can be managed successfully. The prognosis for headache control of idiopathic intracranial hypertension without papilledema is more guarded, although there appears to be no risk of visual deterioration. The development of drugs to control CSF production, perhaps acting via 5-HT_{2C} receptors, may revolutionize the treatment of IIH in the near future.

Low Pressure Headache

Pathogenesis and Pathophysiology. The most common cause of low pressure headache is a lumbar puncture. Head or back trauma, craniotomy, and spinal surgery can produce CSF hypotension as a result of a dural tear or a traumatic avulsion of a nerve root resulting in a CSF leak. In addition, craniotomy and trauma can produce intracranial hypotension not associated with a CSF leak. This may be a result of decreased CSF formation, decreased CBF, or both. Low pressure syndromes can occur secondary to CSF rhinorrhea, either spontaneous, post-traumatic, or due to a pituitary tumor. Spontaneous dural tears must be ruled out in all cases of spontaneous intracranial hypotension. Infusion of hypertonic solution or a systemic medical illness, including severe dehydration, hyperpnea, meningoencephalitis, uremia, and severe systemic infection, can cause CSF hypotension. Postural headache can also occur in patients who have had CSF shunts,

and this can be one of the complications of treating IIH (see Table 53-9).^[35] Intracranial hypotension may also respond to caffeine and an epidural blood patch even without correction of an underlying leak, suggesting that the CSF pressure indicator of some patients may be set too low.

Cases of spontaneous intracranial hypotension have been reported in which the radionuclide cisternogram showed rapid uptake in the bladder and kidneys and rapid transport of isotope with no evidence of a CSF leak. This finding is believed to be abnormal and consistent with CSF hyperabsorption. Many researchers believe that this abnormality is solely due to an occult CSF leak. Slowing of isotope flow, which is evidence for decreased CSF production, has also been reported. This could lead to brain sagging with compression of the pituitary-hypothalamic axis and further reduction in CSF production. Slitlike ventricles and tight basilar cisterns have been reported on CT scans in spontaneous intracranial hypotension, leading to speculation that this contributed to decreased CSF production. However, small ventricles (due to a compensatory increase in brain volume) is most likely a result, rather than a cause, of decreased CSF production.^[35]

Occult CSF leakage may also be a major cause of IIH according to some studies. A history of minor trauma is often elicited. In one report, approximately half the patients had a history of minor trauma or an inciting event. Traumatic rupture of spinal epidural cysts (formed during development), perineural cysts, or a nerve sheath tear could then produce a cryptic CSF leak. Cerebrospinal fluid can also leak into the petrous or ethmoidal regions or through the cribriform plate, and the patient may swallow the fluid and be unaware of the leak.

Epidemiology and Risk Factors. The incidence of spontaneous intracranial hypotension or secondary intracranial hypotension is unknown. Postlumbar puncture headache is more common in women, who are affected twice as often as men, and in younger patients. The incidence depends on the type of procedure: surgical lumbar puncture, 13 percent; obstetrical, 18 percent; and diagnostic, 32 percent.^[37]

Clinical Features and Associated Disorders. Low pressure headache is the most common complication of lumbar puncture, occurring in 15 to 30 percent of patients. Onset varies from 15 minutes to 4 days following lumbar puncture, but it can take as long as 12 days. If it is left untreated, the headache can last 2 to 14 days (most commonly 4 to 8 days) or even months.^[35] The headache of intracranial hypotension may be frontal, occipital, or diffuse. It is accentuated by the erect position and relieved with recumbency. The pain is severe, dull, or throbbing in nature, and usually not relieved with analgesics. It is aggravated by head-shaking, coughing, straining, or sneezing, and jugular compression. The more severe the headache, the more frequently it is associated with dizziness, nausea, vomiting, and tinnitus, and the longer the patient is upright, the longer it takes the headache to subside with recumbency. Physical examination is usually normal;

however, there may be mild neck stiffness and a slow pulse rate (so-called vagus pulse).^{[35], [37]} Spinal fluid pressure usually ranges from 0 to 65 mm. The CSF composition is usually normal, but there may be a slight protein elevation and a few red blood cells in the fluid. Reversible Arnold-Chiari type malformation has been reported in association with a low CSF pressure headache.^{[37], [38]}

Differential Diagnosis. The differential diagnosis of a spontaneous positional headache is limited, but other disorders, such as a colloid cyst of the third ventricle, need to be considered.

Evaluation. The diagnosis of low CSF pressure headache is easily made in the presence of orthostatic headache, particularly if there is an obvious etiology, such as head or back trauma, a recent lumbar puncture or craniotomy, or an associated medical illness. If no obvious cause is apparent or the diagnosis is uncertain, lumbar puncture (perhaps at the time of cisternography) is indicated, following a neuroimaging procedure (CT or MRI). Diffuse meningeal enhancement on enhanced gadolinium MRI has been reported.^[27] The opening pressure usually ranges from 0 to 70 mm H₂O. However, in the Mayo Clinic series of spontaneous intracranial hypotension, the opening pressure was, at times, in the normal range, especially if the measurement was made after a period of recumbency.^[37]

If the cause of the low pressure is known, one should proceed with the appropriate treatment modalities. If, however, treatment is unsuccessful, one should use radioisotope cisternography or ionic myelography to identify CSF leaks, which can be caused by a dural tear or nerve avulsion.^[35]

Management. The treatment of low CSF pressure headache begins with noninvasive therapeutic modalities. If these modalities fail, a brief trial of steroids with a quick taper is recommended. Intravenous or oral caffeine therapy may also be highly effective. If the patient continues to be symptomatic after noninvasive therapies, a blood patch should be used. If the headache of intracranial hypotension recurs, a repeat blood patch can be performed or a continuous intrathecal saline infusion can be attempted. In the latter procedure, an epidural catheter is placed at the L2-L3 level and a saline infusion begun at a rate of 20 ml/hour and continued for as long as 72 hours.^{[35], [39]}

Prognosis. Most patients with intracranial hypotension can be cured once a diagnosis is made. Occasionally, none of the treatments provides relief for a patient with a refractory CSF leak or refractory low pressure headache without apparent cause.^{[35], [37]} The development of atraumatic lumbar puncture needles has resulted in a decreased incidence of postlumbar puncture headache.^[37]

Other Headache Syndromes

HEADACHE OF INTRACRANIAL NEOPLASMS

Headache occurs at presentation in up to half of patients with brain tumors and develops in the course of the disease in 60 percent. Headache is partly dependent on the location of the tumor, and it is a rare initial symptom in patients with pituitary tumors, craniopharyngiomas, or cerebellopontine angle tumors.^[39] In a modern series, 111 consecutive patients with primary (34 percent) or metastatic (66 percent) brain tumor were diagnosed using neuroimaging. In this series, headache was present in 48 percent of patients with primary and metastatic tumor and was similar in quality to TTH in 77 percent and migraine in 9 percent of patients. Unlike primary TTH, brain tumor headaches were worsened by bending in 32 percent, and nausea or vomiting was present in 40 percent.^[40] Increased intracranial pressure was defined by the presence of papilledema, obstructive hydrocephalus, communicating hydrocephalus from leptomeningeal metastasis, or a lumbar puncture opening pressure greater than 250 mm of CSF.

Eighty-six percent of patients with increased intracranial pressure had headache that was typically constant, bilateral, and frontal in location with a pressure-like or aching character. Only 1 percent had unilateral headache. The pain was severe in intensity, associated with nausea and vomiting, and resistant to common analgesics. Ataxia occurred in 61 percent. In contrast, only 36 percent of patients with a supratentorial tumor without increased intracranial pressure had headache. These headaches were milder and more likely to be intermittent, yet they were constant in 20 percent of patients. Nausea, vomiting, and ataxia were much less common.^[40]

Patients with a history of prior headache were more likely to have a brain tumor headache. In many cases, this headache was similar in character to the prior headache, but it was more severe or frequent, or associated with neurological signs or symptoms.^[40] There is a significant overlap between brain tumor headache and migraine or TTH. Morning or nocturnal headache associated with vomiting and increased headache frequency can be seen with both migraine and brain tumors. Brain tumor headache is more common in patients with a history of prior headache, increased intracranial pressure, and large tumors with a midline shift.^[39] Headache of recent onset, or a headache that has changed in character, requires a thorough evaluation, particularly if the headache is severe or is accompanied by nausea or vomiting. Any neurological sign or symptom that is accompanied by a headache and cannot be easily explained by the aura of migraine must be carefully evaluated, as well.

HEADACHE DUE TO VASCULAR ANOMALIES

Thunderclap headache is defined as the sudden onset of a severe headache that reaches maximum intensity within 1 minute. It can be further defined by the absence of a subarachnoid hemorrhage. This can be due to acute onset migraine and is very difficult to differentiate from a subarachnoid hemorrhage.^{[41], [42]} An extensive neurological evaluation, including CT and lumbar puncture, is indicated in patients presenting with their first or worst headache, particularly one associated with focal neurological signs, stiff neck, or changes in cognition. CT can miss subarachnoid blood in as many as 25 percent of cases, particularly if it is not performed until days after the onset of headache.^[41] MRI is unreliable in detecting an acute subarachnoid hemorrhage. Only with a lumbar puncture can one unerringly diagnose subarachnoid hemorrhage. Day and Raskin^[42] have stated that all patients presenting with severe,

sudden-onset headache should be evaluated for an aneurysm, even if CT, MRI, and lumbar puncture do not show evidence of subarachnoid hemorrhage, based on reports of unruptured aneurysms presenting as thunderclap headaches.^[43]

Raps and associates^[44] looked at the clinical spectrum of unruptured intracranial aneurysms. Acute, severe thunderclap headache, comparable to subarachnoid hemorrhage but without nuchal rigidity, was seen in seven of 111 patients (6.3 percent) with unruptured aneurysms, most of which were located in the anterior circle of Willis. Because the true frequency of unruptured aneurysm among patients with thunderclap headache is unknown, all patients in whom unruptured aneurysm is a possibility should undergo at least an MRA. The routine use of cerebral angiography is proscribed by the risk of permanent (0.1 percent) and transient (1.2 percent) deficits in this low-yield population.^[44]

COUGH AND EXERCISE HEADACHE

Although coughing and exertion rarely provoke headache, these maneuvers can aggravate any type of headache. However, transient, severe head pain on coughing, sneezing, weight-lifting, bending, straining at stool, or stooping defines exertional headache.^[45] Exertional headache mainly affects middle-aged men, and it runs its course over a few years. It is uncommon, and only 93 diagnoses were made at the Mayo Clinic over a 14-year period by Rooke,^[46] who proposed the term benign exertional headache. In a population-based study,^[47] benign cough headache and benign exertional headache each occurred with a prevalence of about 1 percent.

The IHS distinguishes between benign cough headache and benign exertional headache, entities that do not have identical clinical features, diagnostic evaluations, and treatment responses.^[4] Benign cough headache is defined as a bilateral, throbbing headache of sudden onset lasting less than 1 minute and precipitated by coughing in the absence of any intracranial disorder. It lasts from 5 minutes to 24 hours and is produced by physical exercise without any associated systemic or intracranial disorder. In general, benign exertional headache starts at a much younger age than benign cough headache. Benign cough headache has been infrequently reported, and the mean age of onset is 55, with a range of 19 to 73 years. Benign cough headache is twice as common in patients older than 40 years of age and is four times more common in men than in women.^[48] The pain begins immediately^[48], ^[49] or within seconds after muscular effort, coughing, sneezing, lifting, straining at stool, blowing, crying, or singing. The pain is severe in intensity with a bursting, explosive, or splitting or stabbing quality that lasts a few seconds or minutes. The headache can be unilateral 35 percent of the time and may be maximal at the vertex or in the occipital, frontal, or temporal region. Bending the head or lying down may be impossible.^[48], ^[49] Benign cough headache is not generally associated with nausea or vomiting, and the neurological examination is usually normal. Vomiting, if present, suggests an organic basis for the headache.^[48], ^[49] Up to 25 percent of patients with benign cough headache have an antecedent respiratory infection.

Benign exertional headache and benign cough headache can be confused with other mechanically precipitated disorders such as effort migraine and coital headaches. In fact, 40 percent of patients with coital headache of the vascular type had benign exertional headache, suggesting a relationship between these entities. Most patients are free of pain between attacks of head pain, but in some cases, the paroxysms are followed by dull, aching pain that may persist for hours. Benign exertional headache lasts longer than benign cough headache and is bilateral and throbbing.^[48], ^[49] Five of the 21 patients reported by Symonds had such additional headaches.^[49] Because these patients often describe the problem as a continuous headache, they should be asked directly about the role of exertion as a trigger factor for their headaches. Autonomic symptoms are unusual in this disorder.

If a patient presents with cough or exertional headache, MRI must be performed to rule out posterior fossa abnormalities, which can cause this headache syndrome. These abnormalities include brain tumor, such as posterior fossa meningiomas, acoustic neurinoma, and other tumors; midbrain cysts; basilar impression; and Chiari malformations.^[48], ^[49]

Of the 219 cases of exertional and cough headache reviewed by Sands and colleagues,^[48] 48 had an identifiable organic etiology. Pascual and co-workers^[49] have suggested that symptomatic cough headache is more likely to be associated with a Chiari malformation and begin at an earlier age in life than benign cough headache. Symptomatic exertional headache began later in life and lasted longer than benign exertional headache. Most acute cases of exertional headaches were due to subarachnoid hemorrhage.

The long-term outlook for these patients is favorable. If the headaches are frequent or severe, prophylactic therapy is required, because the short duration of the headaches usually renders abortive therapy impractical. Patients with benign cough headache often respond dramatically to indomethacin in doses ranging from 25 mg to 150 mg daily.^[50] If there is gastrointestinal intolerance to indomethacin, concomitant treatment with misoprostol, sulcralfate, or antacids may be helpful. When indomethacin fails, Raskin^[50] reports that naproxen, ergonovine, and phenelzine are useful, but propranolol is not. Patients with benign exertional headache often respond to ergotamine or propranolol. Symonds^[49] performed four lumbar punctures or pneumoencephalograms on 21 patients with benign cough headache syndrome. One patient, a 38-year-old woman, developed a typical postlumbar puncture headache; her cough headache syndrome remitted for 3 weeks but then recurred. On the basis of this observation, some specialists recommend lumbar puncture to treat this disorder.^[50], ^[51]

COITAL HEADACHE

Headache associated with sexual activity may be precipitated by masturbation or coitus, in the absence of any intracranial disorder. Three types of sexual headaches are recognized in the IHS classification.^[5] The first, the dull type, is described as a dull ache in the head and neck that intensifies as sexual excitement increases. Type 2, also known as vascular or explosive, is a sudden, severe, explosive

headache occurring at orgasm. Type 3 is a postural headache, resembling that of low CSF pressure, developing after coitus.^[49], ^[52] Following the IHS criteria, Rasmussen and Olesen^[53] have shown that the lifetime prevalences of these headaches are 1 percent in each case (95 percent confidence interval [CI], 0 to 2 percent).

The coital type 2 headache, which usually begins at or shortly before orgasm, is of high intensity, frontal or occipital in location, explosive or throbbing in nature, and persists for a few minutes to 48 hours. Type 1, a less ominous type of headache, begins earlier in intercourse, is occipital or diffuse in location, is characterized as dull and aching, and is most severe at orgasm. For a new type 2 coital headache of sudden onset, a CT scan should be performed, and even if this is negative, a lumbar puncture should be obtained. Aneurysm without rupture has presented as coital headache. Again, magnetic resonance angiography (MRA) may be a reasonable alternative. Coital headache is often associated with benign exertional headache.^[49], ^[54]

SINUS HEADACHE

Sinus infections are much less common today than they were in the preantibiotic era. The diagnosis of sinusitis is usually based on symptoms indicating maxillary or frontal sinus involvement. This may occur secondary to, and is frequently a result of, ethmoid disease. The ultimate cause is usually obstruction of the sinus ostia. Acute sinusitis lasts from 1 day to 3 weeks. Subacute sinusitis lasts from 3 weeks to 3 months, whereas chronic sinusitis lasts for more than 3 months. The IHS criteria for acute sinus headache includes a purulent discharge, abnormal neuroimaging, and the simultaneous onset of headache and sinusitis. These criteria may not be valid for sphenoid sinusitis, because purulent discharge is often lacking and headache may precede sinus drainage. Once drainage begins, obstruction is relieved and the headache may begin to abate.

Maxillary sinusitis pain is typically located in the cheek, the gums, and the teeth of the upper jaw; ethmoid sinusitis pain is located between the eyes; and frontal sinusitis pain is located in the forehead. Ethmoid and maxillary sinusitis are usually associated with rhinitis. Sphenoid sinusitis is an uncommon infection that accounts for approximately 3 percent of all cases of acute sinusitis. It is usually accompanied by pansinusitis; less commonly, it occurs alone. Although sphenoid sinusitis is an uncommon cause of headache, it is potentially associated with significant morbidity and mortality, and requires early identification and aggressive management. The physical examination may not be helpful, because not all patients are febrile and sinus tenderness is not always present.

Standard radiography is inadequate for the evaluation of sinusitis, because it does not evaluate the anterior ethmoid air cells, the upper two thirds of the nasal cavity, or the infundibular, middle meatus, and frontal recess air passages. Neuroimaging (CT or MRI) is necessary to definitively diagnose sphenoid sinusitis, because plain x-ray studies are nondiagnostic in about 26 percent of cases. Diagnostic endoscopy with the flexible fiberoptic rhinoscope allows direct visualization of the nasal

passages and sinus drainage areas (osteomeatal complex), and is complementary to CT or MRI.

Management goals for the treatment of sinusitis include (1) treatment of bacterial infection, (2) reduction of ostial swelling, (3) sinus drainage, and (4) maintenance of sinus ostia patency. Uncomplicated sinusitis, other than sphenoid sinusitis, should be treated with a broad spectrum oral antibiotic for 10 to 14 days. Treatment failure and recurrent infections are indications for neuroimaging and endoscopy to search for a source of obstruction. Treatment of complications consists of high doses of intravenous antibiotics and surgical drainage, if appropriate, of any enclosed space. ^[55]

[PreviousNext](#)

NECK AND FACIAL PAIN

Trigeminal Neuralgia

Trigeminal neuralgia (TN) probably results from the focal demyelination of the trigeminal nerve or ganglia. ^[56], ^[57] Symptomatic causes include intrinsic and extrinsic tumors near the gasserian ganglia and multiple sclerosis (MS) plaques located around the root entry zone of the trigeminal nerve. In the past, dental disease or dental procedures were thought to occasionally cause TN. However, the delineation of the syndrome of pretrigeminal neuralgia, which mimics dental illness, casts doubt on whether dental procedures can ever cause TN. ^[58] Most cases of so-called idiopathic TN may be due to pulsations of an aberrant vascular loop on the trigeminal nerve. ^[56] These pulsations induce a series of neural events that result in changes in wide dynamic range neurons in the trigeminal nucleus caudalis.

The annual prevalence of TN is approximately 6 per 100,000 persons. Women are affected more than men. TN usually affects the elderly, with onset in the sixth or seventh decade in over 50 percent. Multiple sclerosis is the disease most clearly linked with TN, and 2 to 8 percent of patients with TN also have MS. ^[57] The second and third division of the trigeminal nerve are most frequently affected by the brief, repetitive, lightning-like pains of TN. In over 90 percent of cases, there is a trigger zone that, when stimulated, induces a train of painful sensations. Eating, talking, a light touch, or even a draft of air may induce an attack. During a severe attack, the face may contort; in some patients, it remains in that position until the pain eases--hence, the term tic. After a paroxysm, there is a relatively refractory phase during which it is difficult to trigger an attack. ^[57]

There are no known associated disorders except for the known or suspected causes of secondary TN. Psychological problems may occur secondary to chronic pain. Secondary causes of idiopathic TN other than MS include syringomyelia, postmedullary infarction, aneurysm, basilar impression, and tumors, which include acoustic neuromas, epidermoids, meningiomas, schwannomas, and cholesteatomas. In the evaluation of suspected TN, an MRI of the brain is indicated, even if there is no loss of sensation or other abnormality on neurological examination. The value of a dental evaluation is uncertain.

Medical therapy should be tried first. Carbamazepine, baclofen, and IV phenytoin are the most effective treatments. Oral phenytoin, valproic acid, clonazepam, and pimozide are alternatives. Distal nerve blocks or ablative

procedures generally are not recommended owing to a high incidence of early recurrence. More proximal procedures include retrogasserian glycerol injections and radiofrequency gangliolysis, which have acceptable recurrence rates and minor complications. The Jannetta procedure involves intracranial exploration of the trigeminal nerve root and removal of aberrant blood vessels. It is the most successful surgical procedure, but it also has the most complications. ^[57] Most patients with TN can be successfully treated with medical therapy; many will require lifelong medication, and some will require surgical intervention.

Cervicogenic Headache and Occipital Neuralgia

This is a controversial entity whose existence has been questioned. Pain from cervical structures is referred to the head through the C1 to C4 cervical roots. Accepted causes of head pain from the neck include developmental abnormalities, tumors, ankylosing spondylitis, rheumatoid arthritis, and osteomyelitis. Controversial causes include cervical disc herniations, degenerative disc disease, and whiplash injuries. ^[59] Occipital neuralgia is thought by some to occur as a result of an injury to the occipital nerve, which may be vulnerable to compression as it passes through the semispinalis capitis muscle. Referred pain of cervical origin has often been referred to as occipital neuralgia, modifying the definition of this disorder. The prevalence of cervicogenic headache and occipital neuralgia is unknown. Risk factors include whiplash injury.

Some patients who are said to have cervicogenic headache have a pattern of unilateral pain that originates in the neck and spreads to the oculofrontal area. The headache is of moderate severity. The upper cervical region is often tender; palpation often results in radiation of pain to the head. Relief may occur after anesthetizing the occipital nerve or C2 cervical root. Some authors believe that nausea, vomiting, photophobia or phonophobia, and eye changes may accompany this headache, thus confusing its diagnosis with migraine. The situation is further complicated by the ability of occipital nerve blocks to relieve migraine headaches. ^[60] Occipital neuralgia is an even more controversial entity. The pain, which is in the distribution of the occipital nerve, is aching or burning in quality.

Even if a structural abnormality of the neck is identified, migraine and TTH should be considered in the differential diagnosis of cervicogenic headache. Abnormal cervical x-ray studies and MRI are common and cannot be used by themselves to establish the diagnosis. A positive response to neuroblockade should *not* be considered diagnostic. Physical therapy, muscle relaxants, low doses of tricyclic antidepressants, and nerve blocks or trigger point injections are appropriate for most cases of so-called cervicogenic headache. Correction of anatomical abnormalities has been advocated, although surgery is often useless or harmful. Occipital neurectomy is usually unsuccessful and may cause anesthesia dolorosa. Most patients respond slowly to conservative management. There are no valid outcome studies. The results of ablative procedures are uncertain; with longer term follow-up, the initial benefit was lost.

Glossopharyngeal Neuralgia

The pathophysiology of glossopharyngeal neuralgia (GN) is similar to that of TN because the pain characteristics are so remarkably similar. Most cases are idiopathic, although vascular compression has been described. ^[61] Secondary GN may be due to oropharyngeal malignancies, peritonsillar infection, an osteophytic stylohyoid ligament, and carotid aneurysm. The incidence of GN is reported between 1/70 and 1/100 the incidence of TN. ^[61] The pain of GN is similar to that of TN, although a few patients experience a dull pain that persists for minutes or hours. The pain is located in the ear, tonsil, larynx, tongue, or combinations of these areas. Triggers include swallowing, chewing, or talking. Coughing may accompany the pain. Anesthetizing the throat may temporarily relieve the pain. Unlike TN, MS has not been associated with GN. The differential diagnosis of GN includes TN, geniculate neuralgia, and neck/tongue syndrome. MRI of the brain, x-ray studies to visualize the stylohyoid ligament and styloid process, and careful examination of the pharynx are indicated when evaluating the patient with a present diagnosis of GN. Medical management is identical to the treatment of GN. Surgical options include ablation of the glossopharyngeal nerve and microvascular decompression.

Carotidynia

The existence of carotidynia as a single pathological entity has been appropriately questioned. ^[62], ^[63] Acute monophasic carotidynia may have a viral etiology. Carotidynia often means nonspecific neck pain with carotid artery tenderness. Many cases of recurring carotidynia, however, are due to migraine. At present, the epidemiology and risk factors are not known. The clinical features of carotidynia generally include neck pain and carotid artery tenderness, particularly near the bifurcation. Occasionally, there is face pain rather than neck pain. A number of temporal patterns have been reported, with pain lasting seconds, minutes, hours, days, weeks, or months. Some cases of carotidynia may be associated with migraine. Symptomatic causes of carotidynia include carotid dissection, stenosis or occlusion with or without intraplaque hemorrhage, aneurysm, fibromuscular dysplasia, giant cell arteritis, and postcarotid endarterectomy. If the temporal profile suggests a monophasic illness rather than a recurrent condition, anatomical investigation, including ultrasound, MRI, MRA, or angiography, may be necessary. Indomethacin is often effective in treating the pain of carotidynia and migraine treatment may also be effective. ^[62], ^[63] Because carotidynia does not represent a single illness, the prognosis depends on the cause.

HISTORY

Sleep disorders are common age-old problems that can lead to distress and discomfort, impaired daytime functioning, and serious complications. In ancient Greece, Democritus believed that physical illness was the cause of daytime sleepiness and that poor nutrition was the main cause of insomnia. Effects of sleep on epilepsy and asthma were recognized in the Middle Ages, and Thomas Willis, a British physician of the 17th century, described nightmares and restless legs. For most of recorded history, however, sleep problems were considered a result of medical or psychiatric illnesses rather than primary disorders. Sleep was viewed as a passive process, akin to death, and the idea that disordered sleep physiology could lead to specific syndromes was unknown.

With the discovery of rapid eye movement (REM) sleep in 1953, the concept of sleep as a passive shutting down of cortical activity began to change to a view of sleep as an active process initiated by specific events of the nervous system and with two distinct states: REM and non-REM (NREM). The discovery of the association of narcolepsy with sleep-onset REM periods, as opposed to the usual onset of sleep in the NREM state, led to the idea that narcolepsy was a primary disorder of the sleep process and to the corollary that clinical syndromes could be caused by such disruption of sleep processes.

Forty years ago, the only sleep disorder of interest to most neurologists was narcolepsy; all other sleep problems generally were considered manifestations of psychiatric problems. The discoveries of sleep apnea and periodic leg movements, the use of sleep laboratories to study sleep patterns, the discovery of effective treatments for sleep apnea, and the recognition that untreated sleep apnea is associated with increased cardiovascular morbidity and mortality have dramatically changed the approach to sleep disorders. At present, most sleep medicine specialists have primary training in neurology or pulmonary medicine and the practicing neurologist is often expected by colleagues to be familiar with the major sleep disorders. ^[1]

INSOMNIA

Insomnia refers to the subjective sense that sleep is inadequate, insufficient, or interrupted. It is subjective because sleep requirements vary among individuals and because the restorative aspect of sleep is difficult to measure. Insomnia has many causes, and effective treatment requires an understanding of the basis for the symptoms.

Pathogenesis and Pathophysiology. Causes of insomnia include emotions and thoughts that interfere with sleep; medications and use of illicit drugs or alcohol; external stimuli, such as noise, excessive heat or cold, or bright light; alterations in the central nervous system (CNS) that initiate and maintain sleep; and bodily dysfunctions such as pain, decreased mobility, arousals, and disturbing sensations or movements. Mental activity during sleep may contribute to the impression that sleep is not restorative. In most patients, several elements contribute to insomnia and it is useful to identify the predisposing, precipitating, and perpetuating factors.

Personality and age affect the predisposition to insomnia. Tense, nervous, worried persons who internalize problems and have somatic responses to stress are at higher risk for insomnia than relaxed, phlegmatic types. Medical illnesses, deterioration of CNS functions responsible for sleep initiation and maintenance, and increased sensitivity to the sleep-disrupting effects of medications and other drugs contribute to the increase in insomnia with age.

Stress often precipitates insomnia. Medical or psychiatric illness and the medications used to treat them, death or illness of a loved one, divorce or separation, a move to a

new location, and a change in occupational status are common precipitants. A change in sleep-wake schedule or a change in the sleeping environment may also bring on insomnia.

Once insomnia begins, anxiety about sleep, conditioned negative associations, poor sleep habits, or secondary gain often perpetuate insomnia. Performance anxiety associated with the belief that good sleep is a requirement for effective functioning the next day makes falling asleep difficult. As sleep fails to occur, the patient becomes increasingly anxious. Soon the entire process of preparing for sleep becomes tied to anxiety and fear of insomnia. Some patients respond to insomnia by increasing the amount of time spent in bed with the hope that they will then obtain enough sleep. The usual result is increased time awake in bed rather than increased time asleep, which increases the negative conditioning associated with sleeplessness. The secondary gain associated with nighttime snacks and alcohol use, television use, time off from work, and the role of sickly child or dependent adult also may perpetuate insomnia.

Some insomniacs have the impression that they sleep very little, even when laboratory recordings reveal normal or near-normal sleep. The cause of this faulty impression, referred to as *sleep state misperception*, is unknown. Ruminative thoughts that recur with each awakening during the night may give the impression of uninterrupted consciousness and thereby contribute to the failure to perceive sleep. A subtle disturbance of sleep undetected by standard polysomnography could also be a factor.

Epidemiology and Risk Factors. About 10 percent of adults in the United States have chronic insomnia, and another 15 percent have short-term insomnia. The prevalence is higher in women and in older persons. Depression, anxiety disorders, and substance abuse disorders are substantially more common in insomniacs than in the general population.

Although insomnia is distressing to many individuals, less than one third of insomniacs complain about the problem to physicians, perhaps because they believe that physicians are not interested in the problem or are unable to treat it effectively.

Clinical Features and Associated Disorders. Patients with insomnia complain of difficulty falling asleep, difficulty staying asleep, early morning awakening, or a sense that sleep is nonrestorative. During nocturnal sleeplessness, some patients toss and turn in bed. Others watch television, read, eat, drink, or use the bathroom. Persons who do not like to waste time often do housework or homework. Common daytime symptoms include poor concentration, fatigue, irritability, mood changes, anxiety, and muscle aching. Fatigue is sometimes accompanied by sleepiness, but most insomniacs are unable to nap even if they lie down.

As insomnia continues, many patients become preoccupied with sleep. Evening rituals designed to promote relaxation may last for an hour or more. Many patients ruminate at night and during the day about the ill effects of poor sleep and its effects on daytime function. For some patients, insomnia is less severe on weekend nights and during vacations, when concerns about the effects on daytime function are less.

Although most insomniacs have significant sleep disruption, patients with sleep state misperception describe severe chronic insomnia even though they have relatively normal sleep. Such patients often report that they obtain as little as 2 hours of sleep per night and frequently have no sleep at all. Some describe long periods of resting in bed without sleeping.

Insomnia can occur with virtually any sleep disorder as well as with a host of medical and psychiatric disorders ([Table 54-1](#)). A psychiatric disturbance is present in about 40 percent of insomniacs. Overuse and abuse of alcohol and sedative medications is common.

Differential Diagnosis. The differential diagnosis of insomnia is extensive ([Table 54-2](#)), and a given patient may have several contributing factors, such as poor sleep hygiene, maladaptive conditioning, hypnotic dependence, and a predisposition to poor sleep. It is critical to determine whether the insomnia is secondary to a psychiatric or medical disorder because in such cases, the insomnia is best treated by optimal management of the underlying disorder.

It is sometimes difficult to determine whether insomnia is due to depression, especially a masked depression in which the patient denies sadness or hopelessness, because dysphoria is a common feature of all types of insomnia. A history of depressive episodes before insomnia began, a history of episodic insomnia at times of mood disturbance, and the occurrence of other depressive symptoms favor a primary diagnosis of an affective disorder. Although most insomniacs are anxious, the anxiety is usually focused on sleep and generalized anxiety disorder as a cause of insomnia should be suspected only if anxiety affects many aspects of life.

When insomnia is caused by learned sleep-preventing

TABLE 54-1 -- MEDICAL AND PSYCHIATRIC DISORDERS ASSOCIATED WITH SLEEP DISTURBANCES

Infectious diseases	Sleeping sickness, febrile illnesses
Cardiac diseases	Congestive heart failure, nocturnal angina
Pulmonary diseases	Chronic obstructive pulmonary disease, asthma
Gastrointestinal diseases	Gastroesophageal reflux, peptic ulcer disease, inflammatory bowel disease
Neurological disorders	Degenerative disorders of the CNS, neuromuscular disorders
Rheumatological disorders	Rheumatoid arthritis
Renal disorders	Chronic renal failure
Psychiatric disorders	Acute psychosis, depression, anxiety disorders, panic disorder, alcoholism
Endocrine disorders	Cushing's disease, hyperthyroidism, hypothyroidism, diabetes, menopause
Skeletal and soft tissue disorders	Achondroplasia, craniofacial malformations, Down syndrome, mucopolysaccharidoses
Miscellaneous	Cancer, pruritus, Prader-Willi syndrome

CNS, Central nervous system.

TABLE 54-2 -- CAUSES OF INSOMNIA IN ADULTS

Disorder	Key Diagnostic Feature
INTRINSIC DISORDERS:	Insomnia related to processes within the body
Psychophysiological insomnia	Conditioned negative associations
Sleep state misperception	Marked discrepancy between subjective and objective sleep
Idiopathic insomnia	Insomnia caused by constitutional factors
Restless legs syndrome	Leg discomfort relieved by movement
Periodic limb movement disorder	Kicking movements during sleep
Sleep apnea and related disorders	Snoring, witnessed apnea
EXTRINSIC DISORDERS:	Insomnia due to processes outside the body
Inadequate sleep hygiene	Poor sleep habits
Environmental sleep disorder	Unsuitable sleeping environment
Adjustment sleep disorder	Insomnia related to specific stresses
Hypnotic dependent sleep disorder	Inability to obtain restful sleep without hypnotics
Drug and medication related insomnia	Insomnia caused by medications
Altitude insomnia	Insomnia only at high altitude
CIRCADIAN RHYTHM SLEEP DISORDERS	Schedule-dependent insomnia
SLEEP DISORDERS DUE TO MEDICAL OR PSYCHIATRIC ILLNESS	Insomnia fluctuates with severity of the underlying illness

associations, the diagnosis is *psychophysiological insomnia*, the most common form of primary insomnia.¹ Patients with psychophysiological insomnia tend to prefer regular routines and view good sleep as a necessity. For such patients, an awakening that would ordinarily be just long enough for a change in body position is instead followed by anxiety that sleep will not return or will not be restful. The anxiety about the consequences of not sleeping induces full alertness, and a rapid return to sleep becomes impossible.

Poor sleep hygiene as the cause of insomnia should be suspected in patients who have never had good sleep habits, perhaps because they were not required to sleep at regular times as children or because their internal sleep systems were initially so robust that they were able to sleep well despite poor habits. With increasing age or because of other factors, they may become less able to tolerate the effects of these poor sleep habits. Sleep state misperception should be suspected in patients who do not toss and turn or get out of bed despite complaints of severe insomnia.

Loud snoring, witnessed apneas, or frequent kicking movements suggest that insomnia may be due to sleep apnea or periodic leg movements. If the main problem is difficulty falling asleep, an anxiety disorder or a delayed sleep phase syndrome (DSPS) may be responsible. Early morning awakening with excessive rumination suggests depression or obsessive-compulsive disorder.

Evaluation. The history is the most crucial part of the evaluation. Circumstances at the onset of insomnia should be assessed, and the course of the insomnia should be determined, along with any factors the patient has identified that make insomnia better or worse. Times of going to bed, falling asleep, nighttime awakenings, and getting out of bed for good nights and bad nights should be determined, along with associated behaviors, thoughts, and emotions. Information about the patient's weekday and weekend schedule of work, alcohol use, meals, and medication use is also essential.

Psychiatric evaluation is helpful if a psychiatric etiology is a consideration. Polysomnography is useful if there is a suspicion that apnea or periodic leg movements are the cause of the symptoms, if there is a failure to respond to treatment, or if sleep state misperception is suspected.

Management. Treatment of insomnia is based on the underlying causes. From a therapeutic perspective, the factors that perpetuate insomnia are often the most important because they may be most amenable to change. Improved sleep hygiene can lead to marked improvement ([Table 54-3](#)), but poor sleep hygiene is sometimes a result of other problems, particularly psychiatric problems.

Behavioral treatments are a major part of treatment for patients with psychophysiological insomnia.² With sleep restriction therapy, mild sleep deprivation produced by eliminating naps and temporarily restricting time in bed to 1 to 2 hours less than the nightly reported amount of sleep tends to make sleep more continuous. Once sleep is consolidated, the time in bed can be gradually increased. With stimulus control therapy, the principle is to associate the bed and sleep environment only with sleep and intimacy; no reading, eating, or watching TV in bed is permitted. Patients are encouraged to get out of bed and to do something relaxing if unable to sleep after 15 to 20 minutes.

Hypnotics are often helpful in patients with acute situational insomnia and in some patients with chronic insomnia. Some chronic insomniacs do well using hypnotics 1 to 2 nights per week when they feel they simply must have a good night's sleep. Others find it reassuring to have a hypnotic available in the medicine cabinet; the knowledge reduces anxiety, and actual use may be minimal. Others

TABLE 54-3 -- PRINCIPLES OF SLEEP HYGIENE

Go to bed and arise from bed at the same time each day
Avoid daytime naps or limit them to one midafternoon nap
Avoid evening alcohol use
Avoid caffeinated drinks late in the day
Reduce or eliminate tobacco use, especially at night or in the evening
Exercise in moderation; avoid evening exercise
Use the bed only for sleep and sexual activity
Keep the bedroom dark, quiet, and cool
Avoid stress and worrisome thoughts in the evening before sleep

TABLE 54-4 -- MEDICATIONS USED FOR INSOMNIA

Short-acting benzodiazepines	Triazolam 0.125 to 0.25 mg
------------------------------	----------------------------

Intermediate-acting benzodiazepines	Midazolam 7.5 to 15 mg Temazepam 15 to 30 mg Oxazepam 15 to 30 mg Lorazepam 1 to 2 mg
Long-acting benzodiazepines	Alprazolam 0.25 to 0.5 mg Flurazepam 15 to 30 mg Diazepam 2.5 to 10 mg Clorazepate 7.5 to 15 mg Clonazepam 0.5 to 2 mg Prazepam 10 mg Halazepam 20 mg Chlordiazepoxide 10 to 20 mg
Imidazopyridines	Zolpidem 10 to 20 mg
Cyclopyrrolones	Zopiclone 7.5 to 15 mg
Antihistamines	Diphenhydramine 25 to 50 mg
Sedating antidepressants	Amitriptyline 10 to 75 mg Doxepin 10 to 75 mg Trazodone 25 to 100 mg Imipramine 25 to 100 mg

use a hypnotic nightly for years with good response and no dose escalation. Still others obtain no benefit from hypnotics or become dependent, or both. Other problems with hypnotics include nocturnal confusion, next-day memory impairment, and sedation. Low doses of sedating tricyclic antidepressants are sometimes useful as alternatives to standard hypnotics ([Table 54-4](#)). As a sedative, melatonin is much less effective than conventional hypnotics.

Patients with sleep state misperception should be educated about the distinction between subjective insomnia and objective sleep disruption; they may be reassured to know that restorative sleep-related processes are occurring even though they do not sense it. Behavioral treatment and hypnotics are helpful for some, perhaps because the amnesic effects interrupt the subjective impression that consciousness has been maintained during sleep.

Prognosis and Future Perspectives. The course of insomnia is variable; many patients have a lifetime of sleep problems, whereas others have episodic bouts of poor sleep separated by years of tranquil nights. Insomniacs who continue with symptoms after 12 months have an increased risk for depression, anxiety disorders, and alcohol abuse.¹³ Other complications include benzodiazepine dependence, decreased job performance and self-esteem, and an increased risk of motor vehicle accidents.

PRIMARY DISORDERS OF DAYTIME SOMNOLENCE

Narcolepsy

Narcolepsy is a genetically based neurological disorder associated with abnormalities of REM sleep and of sleep-wake control. Although the disorder has been recognized for more than 100 years, the discoveries of sleep apnea, other syndromes of excessive sleepiness, and the association of narcolepsy with REM sleep abnormalities and specific human leukocyte antigen (HLA) markers helped delineate narcolepsy as a distinct syndrome. Clinically, the usual hallmarks are excessive sleepiness and cataplexy.

Pathogenesis and Pathophysiology. More than 90 percent of narcoleptics have a specific HLA haplotype that includes HLA-DQB1-0602, which is present in less than one third of the general population.^[9] The penetrance of the HLA-associated gene is low, and the risk for narcolepsy in first-degree relatives, although 40 times greater than in the general population, is only about 1 percent.^[9]

The low penetrance of the HLA-associated gene and discordance for narcolepsy in identical twins indicates that unknown environmental factors play an important role in the pathogenesis of narcolepsy. The primary brain disturbance in narcolepsy may involve dopaminergic, adrenergic, and cholinergic systems that modulate expression of REM sleep.^[9] Canine narcolepsy, which is clinically similar to the human disease, is associated with monoaminergic abnormalities. The gene for canine narcolepsy is tightly linked to a DNA region involved in immune regulation.^[9] Despite the association of human narcolepsy with an HLA-associated gene, there is no direct evidence to indicate that narcolepsy is an autoimmune disease.

Abnormalities of REM sleep control probably contribute to narcoleptic symptoms. The muscle atonia that occurs with sleep paralysis and cataplexy is similar to the muscle atonia of REM sleep, and hypnagogic hallucinations probably represent an intrusion of REM sleep imagery into consciousness during transitions between wakefulness and sleep. However, the REM sleep abnormalities appear to be part of a broader problem of impaired sleep-wake regulation that includes an inability to sustain sleep, along with the daytime inability to remain awake.^[9]

Epidemiology and Risk Factors. The prevalence of narcolepsy with cataplexy in a white population is about 1 in 4000.^[9] Estimates for other populations range from 1 in 600 to less than 1 in 10,000. Narcolepsy affects men and women equally.

Clinical Features and Associated Disorders. Most patients report symptoms beginning gradually in the second decade of life. The appearance of symptoms before the age of 5 is rare; occasional patients develop narcolepsy after age 50. The primary symptoms include sleepiness and sleep episodes, cataplexy, sleep paralysis, hypnagogic and hypnopompic hallucinations, and nocturnal sleep disruption. Sleepiness and cataplexy may develop simultaneously, or cataplexy can begin years or decades later. Excessive sleepiness is present most of the time, although the severity fluctuates during the day and is variable among individuals. Boring sedentary situations and warm afternoons following lunch are especially difficult settings. Work performance is most often affected in sedentary jobs requiring sustained vigilance. Physical activity usually provides relief, but sleepiness returns as soon as the patient sits down. Brief daytime sleep episodes, often called sleep attacks, are common.

Cataplexy is a brief episode of bilateral weakness, without altered consciousness, that is brought on by strong emotion. Laughter, anger, embarrassment, excitement, elation, surprise, shock, and humor without actual laughter can induce the attacks. These events last a few seconds and are associated with buckling of the knees, sagging of the jaw or face, drooping eyelids, and mild dysarthria. Twitching around the face or eyelids may accompany the

weakness. Severe attacks produce almost complete paralysis, and prolonged episodes may be associated with auditory, visual, or tactile hallucinations. Cataplexy can be dangerous if it occurs during driving. Unlike sleepiness, definite cataplexy--defined as brief bilateral loss of strength without altered consciousness that responds to tricyclic antidepressants--is virtually pathognomonic for narcolepsy.

Sleep paralysis refers to episodes of partial or total paralysis that last a few seconds or minutes and occur at the beginning or at the end of a sleep period. The paralysis, which occurs in about 60 percent of narcoleptics, may be accompanied by a struggle to move, to speak, or to wake up. Patients often feel awake or half-awake and are usually aware of being in bed. Frightening hallucinations and a sense of suffocation may accompany the paralysis. Despite the intense psychic experience, patients appear to be asleep with eyes closed and with occasional twitches, slight moans, or irregular respirations.

Hallucinations are referred to as hypnagogic when they occur at the onset of sleep, and they are termed hypnopompic when they occur at the end of sleep. The hallucinations, which almost always include visual imagery, differ from dreams in that a thematic story is lacking and some awareness of the surroundings is preserved. Sometimes the hallucinations are so vivid and realistic that the subject may have difficulty believing that they are not real and may take actions to escape from the images.

Daytime drowsiness may also lead to complaints of memory difficulties, blurred vision, and amnesic episodes of automatic behavior lasting seconds to an hour or more during which patients drift in and out of sleep while engaging in aimless or semipurposeful activity. Disrupted nighttime sleep with frequent awakenings may be a prominent complaint.

Differential Diagnosis. Sleepiness should be distinguished from tiredness, fatigue, apathy, and weakness. Sleepiness is more likely to occur in boring sedentary situations, is relieved to some extent by movement or stimulation, and is associated with a feeling of impending sleep or a need to fight against sleep onset. Descriptions of daytime sleep episodes as periods of loss of awareness may suggest a diagnosis of syncope, partial complex, or absence seizures. Premonitory drowsiness, sleeplike appearance with absence of pallor, ease of arousability, and the association with sedentary situations are useful differentiating features. There are several causes of excessive sleepiness ([Table 54-5](#)). Unplanned daytime sleep episodes, or so-called sleep attacks, are an indication of severity of sleepiness rather than a marker of a qualitatively different process. They can occur with any disorder that causes severe sleepiness and are not specific for narcolepsy.

The association with emotion, the duration of episodes, and the preservation of consciousness help differentiate cataplexy from atonic seizures, myasthenia gravis, periodic paralysis, or drop attacks associated with vertebrobasilar insufficiency. Because cataplexy is not invariably present in narcoleptics, its absence does not exclude the diagnosis.

Sleep paralysis and hypnagogic hallucinations are less useful for diagnosis because they can occur as isolated symptoms in otherwise normal persons, often precipitated

TABLE 54-5 -- CAUSES OF DAYTIME SLEEPINESS

Narcolepsy
Sleep apnea and other breathing disorders of sleep
Insufficient sleep syndrome
Medication effects
Periodic limb movement disorder
Idiopathic hypersomnia
Brain lesions that compromise pathways involved in sleep-wake regulation
Circadian rhythm sleep disorders
Nocturnal sleep disruption caused by medical, neurological, or psychiatric illness

by sleep deprivation or a change in sleep schedule, as well as in other sleep disorders.^[10]

Evaluation. Because a variety of conditions can cause excessive sleepiness, sleep studies are generally required for accurate diagnosis. Nocturnal polysomnography

can determine the presence and severity of sleep apnea, periodic limb movements, and nocturnal sleep disturbance. A Multiple Sleep Latency Test (MSLT), usually performed the following day, provides a measure of the severity of sleepiness and an indication of the presence or absence of early onset of REM sleep. ^[11]

Early onset of REM sleep occurs with about 50 percent of sleep episodes, and the presence of two or more sleep-onset REM periods during the four to five nap opportunities provided by the MSLT is the usual diagnostic criterion for narcolepsy. However, this finding is not specific. Other potential causes of early-onset REM sleep include circadian rhythm disturbances, REM sleep deprivation, severe sleep disturbance from sleep apnea or other disorders, and drug or alcohol withdrawal. ^[10], ^[12] Some patients with brain pathology in areas concerned with sleep-wake regulation also may have early onset of REM sleep.

HLA typing has limited value for diagnosis. As the HLA haplotype associated with narcolepsy is present in about 20 to 35 percent of the general population, more than 99 percent of persons with the haplotype do not have narcolepsy.

Management. Medications and behavioral measures should be designed to enhance alertness during critical times of the day such as at work, during school, and while driving. The importance of good sleep hygiene and the risks associated with sleepiness while driving must be emphasized. Naps during lunch or other breaks are often helpful.

Stimulants such as methylphenidate, dextroamphetamine, and pemoline improve alertness in most narcoleptics ([Table 54-6](#)).^[13] Stimulants should be initiated at low doses and increased gradually until symptoms are controlled or side effects appear. In general, the lowest effective dose should be used, but some patients may not recognize the severity of their sleepiness and reports from family members should also be obtained to assess the effectiveness of treatment.

Although chronic use of stimulants can lead to irritability, insomnia, habituation, addiction, and psychosis, the risk for amphetamine abuse is no higher among narcoleptics than in other population groups. With appropriate management, most narcoleptics are able to take stimulants regularly for

TABLE 54-6 -- STIMULANT DOSAGES FOR TREATMENT OF NARCOLEPSY AND IDIOPATHIC HYPERSOMNIA

Amphetamines	Dextroamphetamine 5 to 60 mg/day
	Methamphetamine 5 to 40 mg/day
Nonamphetamines	Methylphenidate 5 to 80 mg/day
	Pemoline 18.75 to 112.5 mg/day
	Mazindol 2 to 8 mg/day

decades without harmful side effects. When sleepiness fails to respond to medications after a period of good control, the possibility of sleep apnea or chronically insufficient sleep should be considered.

Nonsedating tricyclic antidepressants and serotonin-reuptake inhibitors are effective treatments for cataplexy and sleep paralysis, probably by blockade of norepinephrine and serotonin reuptake (see [Table 54-6](#)). Patients with severe cataplexy may develop tolerance to the effects of tricyclics, and abrupt withdrawal can lead to a temporary rebound increase in cataplexy.

Prognosis and Future Perspectives. Sleepiness is a lifelong problem for most narcoleptics whereas cataplexy, hypnagogic hallucinations, and sleep paralysis improve with age in about one third of patients. Important unanswered questions concerning narcolepsy include the precise identity and function of the HLA-associated gene, the nature of the environmental factors that contribute to the development of narcolepsy, and the brain abnormalities that are responsible for symptoms.

Idiopathic Hypersomnia

Idiopathic hypersomnia is clinically similar to narcolepsy in that daytime sleepiness occurs despite adequate amounts of apparently normal sleep at night, but cataplexy does not occur and there is no association with specific HLAs. The pathogenesis is unknown. Circulating somnogenic factors or focal lesions that affect systems involved in sleep-wake regulation may play a role in some cases. Idiopathic hypersomnia is less common than narcolepsy by a ratio of about 1:10. Recent viral illness may be a risk factor.

Symptoms often develop gradually during adolescence or young adulthood. There appear to be at least two types of idiopathic hypersomnia, but many patients have mixed features. With the classic type, patients complain of an increased need for sleep, difficulty awakening in the morning, and sleep drunkenness with disorientation and confusion in the morning.^[14] Daytime naps are long and unrefreshing, and patients may sleep as much as 14 to 18 hours during the day and night. With the second type, daytime sleepiness is sometimes irresistible, similar to narcolepsy, but short naps are usually refreshing.

Other diagnostic considerations in patients who complain of long periods of unrefreshing sleep include atypical depression and chronic fatigue syndrome. In both of these disorders, patients often spend many hours in bed, but actual sleep time is increased only mildly or not at all. Idiopathic hypersomnia is usually considered in a patient who complains of sleepiness and has no apparent cause for sleepiness based on the clinical history and a nocturnal polysomnogram. For such patients, the differential diagnosis includes narcolepsy, upper airway resistance syndrome, insufficient sleep syndrome, and obstructive sleep apnea that occurs during some nights but not others. The diagnosis of idiopathic hypersomnia is not easy because it requires ruling out all other causes to the extent possible.

Evaluation should include one or more nights of polysomnography, MSLT, psychiatric assessment, and a trial of increased sleep. The upper airway resistance syndrome may be difficult to detect on polysomnography unless airway resistance is assessed with monitoring of endoesophageal pressure during polysomnography.^[15] Patients with narcolepsy may not have REM sleep abnormalities on an initial MSLT. Atypical depression or other psychiatric conditions may be associated with complaints of sleepiness, although the MSLT is usually not abnormal. Sleepiness caused by chronically insufficient sleep should improve after a trial of 1 to 2 hours of additional sleep each night. After these diagnoses have been excluded, one is left with the diagnosis of idiopathic hypersomnia.

Management is similar to the approach used for narcolepsy. Patients with the narcoleptic type of sleepiness often respond to stimulants, whereas those with long sleep periods and difficult awakening may not. For most patients, the disorder is chronic. A minority of patients improve with time, and in some, the disorder resolves completely.

Obstructive Sleep Apnea

Obstructive sleep apnea syndrome (OSA) is characterized by airway narrowing during sleep that leads to nighttime sleep disruption and associated daytime symptoms. The recognition that OSA is a common and treatable disorder with serious complications has been the most important factor in the growth of sleep medicine over the past 20 years.

Pathogenesis and Pathophysiology. Narrowing and occlusion of the upper airway during sleep is the basis for obstructive sleep apnea. Obstruction usually occurs in the pharynx, which lacks supporting cartilage and bone, and is therefore more collapsible than other portions of the upper airway. Upper airway size is determined by the anatomy of the bones and soft tissues of the neck and face, by the pressures acting on the pharyngeal tissues, and by their compliance. During wakefulness, contraction of pharyngeal muscles occurs just before the onset of inspiration and increases the outward pressure on the pharyngeal wall by pulling the soft palate, tongue, mandible, and hyoid bone forward. This outward pressure balances the inward pressure produced by negative pressure developed within the thorax and helps maintain airway patency.^[16] Activity of upper airway dilator muscle activity is affected by arterial blood gas concentration; by proprioceptive input to respiratory neurons from the jaw, mouth, and thorax; and by receptors sensitive to changes in upper airway transmural pressure. For example, increased negative upper airway pressure leads to increased activity of the genioglossus, which pulls the tongue forward and tends to open the airway.

Pharyngeal muscles relax during sleep, which leads to narrowing of the pharyngeal airway and increased resistance to airflow. The relaxation alone may be sufficient to close the airway in some persons. In others, inspiratory muscle activity increases to compensate for the increased airway resistance, and the increased negative pressure generated by the extra effort leads to airway collapse. Ultimately, the airway opens only after an arousal or brief awakening leads to increased activity of pharyngeal dilators. The patient then takes a few deep breaths and returns to sleep, whereupon the cycle repeats itself. Pharyngeal narrowing without complete occlusion may cause decreased ventilation. These episodes, referred to as hypopneas, lead to arousals, sleep fragmentation, daytime sleepiness, and hypoxemia, and thus have the same functional effect as apneas.

Pharyngeal narrowing with high resistance to airflow is sometimes associated with compensatory increased respiratory effort that minimizes changes in tidal volume, ventilation, and oxygenation but still leads to arousals and sleep fragmentation. The functional effect is similar to OSAs but without the associated hypoxemia. When such episodes are the predominant type of respiratory event, the disorder is referred to as the *upper airway resistance syndrome*.^[15] The body weight of patients with this disorder is often normal or near-normal, and there appears to be a higher proportion of women and children with the syndrome than occurs with OSA, perhaps because their upper airways tend to be less compliant.

Airway narrowing may be due to a variety of causes (Table 54-7), including craniofacial malformations (high arched palate, a long low-placed soft palate, dental malocclusion, or retrognathia), neurological diseases with incoordination of preinspiratory activation of upper airway dilators, mouth breathing with posterior displacement of the mandible, or weakness from neuromuscular diseases. The site of airway occlusion may be at the level of the velopharynx, the oropharynx, the hypopharynx, the epiglottis, or the larynx. In some patients, the occlusion may be at more than one level or at different sites during different stages

TABLE 54-7 -- CAUSES OF UPPER AIRWAY NARROWING

Genetic and developmental factors that influence craniofacial development
Anatomical malformations that affect craniofacial structures such as Crouzon's syndrome, Treacher Collins syndrome, Pierre Robin syndrome, Arnold-Chiari malformation achondroplasia, rheumatoid arthritis, and Klippel-Feil syndrome
Enlarged tongue, soft palate, or uvula associated with obesity, Downs syndrome, hypothyroidism, and acromegaly
Pharyngeal dilator weakness associated with neuromuscular diseases and medullary lesions
Infiltration of pharyngeal tissue associated with obesity mucopolysaccharidoses, and mucosal edema and inflammation
Structural lesions such as enlarged tonsils and adenoids and pharyngeal tumors
Dyscoordinated breathing from abnormal respiratory control associated with Arnold-Chiari malformation, dysautonomias, and degenerative CNS disorders
Abnormally compliant airway associated with Marfan's syndrome
CNS, Central nervous system.

of sleep owing to differential activity of muscles involved in maintenance of airway patency.

The reason for the more frequent occurrence of OSA in men than in women is not known. Men tend to have longer narrower upper airways, which may predispose them to airway collapse. The airway may be more compliant in men and may close at lower pressures for a given airway diameter. Women also show a greater augmentation of genioglossus activity in response to inspiratory loading, which may indicate a less collapsible airway. Testosterone may lead to increased bulk of neck muscles and may lead to a preferential deposition of fat in upper airway structures.

In susceptible persons, obstructive sleep apnea may be precipitated or made worse by sleep deprivation, evening alcohol use, sedative medications, and the supine sleeping position. Even small doses of alcohol enhance upper airway muscle relaxation that occurs during sleep, thereby exacerbating OSA. Alcohol also blunts chemoreceptor responses to blood gases and raises the arousal threshold, which increases the duration of apneas.

Arterial oxyhemoglobin saturation (SaO_2) falls during apneas and hypopneas at a rate of 0.1 to 1.6 percent per second. The severity of hypoxemia is a function of baseline oxygenation, lung oxygen stores, the degree of airway narrowing, and apnea duration. Drops in SaO_2 to below 70 percent are common in severe obstructive sleep apnea. Apneas during REM sleep tend to produce greater decreases in SaO_2 owing to decreased lung oxygen reserves and increased duration of apneas.

Arteriolar constriction as a result of hypoxemia, acidosis, and increased sympathetic tone contribute to increases in blood pressure during apneas that may reach 190 mm Hg systolic and 110 mm Hg diastolic. Right-to-left shifts of the cardiac interventricular septum and decreased cardiac output may occur as a result of increased negative intrathoracic pressure associated with attempts to breathe. Increased vagal tone associated with fluctuations in intrathoracic pressure, stimulation of the carotid body by hypoxemia, and increased sympathetic tone that accompanies the arousals at the end of apneas contribute to bradycardia, periods of asystole, atrioventricular block, premature ventricular contractions, and ventricular tachyarrhythmias.

The repeated arousals to resume breathing, along with reduced amounts of REM sleep and slow-wave sleep, appear to be the major causes of daytime sleepiness in patients with OSA.

Epidemiology and Risk Factors. Habitual snoring, which is more common in males than in females, occurs in 6 to 12 percent of children and 5 to 20 percent of adults. OSA has a prevalence of about 1 percent in children, 2 percent in adult women, and 4 percent in adult men.^{[17], [18]}

Clinical Features and Associated Disorders. The usual presenting symptoms are snoring, excessive sleepiness, daytime sleep episodes, and a sense that sleep is not restful. Morning headaches, frequent nocturnal urination, and nocturnal restlessness are also common. Some patients have no complaints and present only because the bed partner has noted periods of apnea. Others are referred because of a suspicion that OSA contributes to headaches, pulmonary or systemic hypertension, cardiac arrhythmias, or impotence.

Loud snoring, sometimes exceeding 90 dB, occurs in

more than 80 percent of patients and usually begins years before the onset of sleep apnea. Some patients report that they cannot go on camping trips and must have separate hotel rooms on business trips because of their obnoxious snoring. Increasing volume of snoring, snoring that has changed in character, and loud rhythmical snoring punctuated by snorts and choking noises are suggestive of obstructive sleep apnea. Snoring is produced by vibration of the soft tissues of the upper airway. The intensity and quality vary depending on the stage of sleep, the position of the body, the rate of airflow, the anatomical structure of the individual's nose and throat, and the amount of floppy airway tissue with potential to vibrate. Although snoring is common in patients with OSA, it is not universal. Snoring will not occur even with a very narrow pharynx if floppy tissue is absent.

Restless sleep is caused by the arousals at the end of apneas, which may be accompanied by jerks, twitches, and gross body movements. Changes in body position may occur several times per hour as patients attempt to find a sleeping position compatible with airway patency. With severe apnea, patients may sleep in a chair, on the couch, sitting up on the side of the bed, or leaning against a wall. Despite the restlessness, patients usually have the impression that sleep has been continuous or interrupted only by a few trips to the bathroom. A few patients describe repeated awakenings and complain mainly of insomnia.

Tiredness, sleepiness, and a sense that sleep is not refreshing are characteristic symptoms of sleep apnea, often accompanied by impaired memory and concentration. The sleepiness often increases gradually over several years as patients gain weight. Some patients feel mentally dull or disoriented each morning. Daytime sleepiness is usually most apparent after lunch, while driving or reading, or in other boring sedentary situations. Patients often minimize difficulties with sleepiness and describe it as no worse than in colleagues or peers. With more severe apnea, patients may fall asleep on the telephone or during sexual intercourse and may have episodes of "automatic behavior" during which complex activities are performed such as driving for miles with no recollection. Although daytime

sleepiness is common, its absence does not rule out OSA.

Other common symptoms include irritability, impotence or reduced libido, and dry mouth. Symptoms of gastroesophageal reflux may be present if the repeated episodes of negative intrathoracic pressure associated with apneas lead to passage of gastric contents through the lower esophageal sphincter.

In children, snoring and restless sleep are common complaints, along with poor attention, decreased school performance, enuresis, and hyperactivity. Daytime sleepiness is often less pronounced than in adults unless apnea is severe.

On physical examination, patients are often obese and have thick necks. Long narrow facies, high arched palate, retrognathia, an enlarged edematous uvula, prominent tonsils, and redundant pharyngeal tissue are other common findings. Patients with severe obstructive sleep apnea may have findings consistent with right-sided heart failure.

OSA occurs in 10 to 40 percent of obese persons and in at least 25 percent of patients with hypertension. In untreated severe OSA, the prevalence of hypertension may be as high as 50 percent. A number of other disorders contribute to the development of OSA (see [Table 54-7](#)).

Central sleep apnea, which is much less common than obstructive sleep apnea, is a disorder in which apneas occur but there is no associated attempt to breathe. The disorder may be idiopathic, or it may be caused by congestive heart failure or brain stem pathology. Many patients have both central sleep apnea and obstructive sleep apnea, presumably because activation of upper airway afferents during airway occlusion leads to inhibition of attempts to breathe.

Differential Diagnosis. Loud snoring with gasping or choking sounds, witnessed apneas, restless sleep, hypertension, and neck circumference greater than 16.5 inches are useful predictors of OSA, but a definitive diagnosis usually requires polysomnography. Among children, snoring or noisy breathing, daytime mouth breathing, and parental observation of apneas and struggles to breathe are suggestive symptoms. The absence of snoring and obesity does not rule out OSA in either adults or children. In patients with excessive daytime sleepiness, other diagnostic considerations include narcolepsy, idiopathic hypersomnia, periodic limb movement disorder (PLM), central sleep apnea, and the insufficient sleep syndrome. The differential diagnosis of nocturnal choking and gasping includes gastroesophageal reflux, nocturnal asthma, congestive heart failure, nocturnal panic attacks, and sleep-related laryngospasm.

Evaluation. A nocturnal polysomnogram with monitoring of sleep stage, airflow, respiratory effort, electrocardiogram, leg movements, and body position is the most commonly used tool for diagnosis. If upper airway resistance syndrome is suspected, intraesophageal pressure measurements should be obtained as part of the polysomnogram. The polysomnogram helps determine the presence and type of apnea, assess the relation of breathing disturbance to sleep stage and body position, determine the severity of hypoxemia and sleep disturbance, and identify cardiac arrhythmias. Apneas and hypopneas usually last 10 to 30 seconds and typically are followed by transient arousals. During REM sleep, apneas and hypopneas are usually longer, sometimes as long as 2 to 3 minutes, and are more likely to be associated with hypoxemia and cardiac arrhythmias. There are usually reduced amounts of stages 3 and 4 sleep and REM sleep. With mild OSA, apneas may occur only after alcohol ingestion or only when the patient is supine. With severe OSA, apneas occur continuously throughout the night and in all body positions.

In patients with high pretest probability of moderate or severe OSA, a home-monitoring study may be sufficient for diagnosis. A variety of home-monitoring devices are available; the simplest types measure only a single variable, such as oxygen saturation, whereas more complex devices may record as many channels as a typical laboratory polysomnogram. Home-monitoring studies cost less than laboratory studies, but they do not allow for visual observation, correction of artifacts or faulty sensors, or therapeutic interventions. It is also more difficult to assess mild sleep apnea. Nonetheless, it is likely that these devices will assume an increasing role for diagnosis due to the reduced cost.

Additional studies may be indicated in some patients. An MSLT helps assess the presence and severity of excessive

sleepiness. Although fiberoptic endoscopy of the upper airway, cephalometric radiographs, and magnetic resonance imaging can be used to assess airway anatomy, such studies during wakefulness are of limited value in determining the site of obstruction because airway dynamics differ in sleep and wakefulness. Arterial blood gases and pulmonary function tests are indicated if obesity-hypoventilation syndrome or other causes of hypoventilation are suspected but they are not needed for routine evaluation of suspected OSA.

Some patients described as loud snorers do not snore during sleep studies. In such cases, snoring may be intermittent and related to alcohol use, body position, or allergies. Loud snoring that cannot be verified with objective assessment is sometimes an indication of marital problems.

Management. The goal of treatment is to keep the airway open during sleep, which should lead to improved sleep, better oxygenation, and enhanced daytime alertness. Treatment for OSA depends on the severity of the disorder. There is little doubt that treatment is needed for severe OSA because it is associated with increased risks of motor vehicle accidents, stroke, myocardial infarction, cardiovascular death, and death while sleeping, if left untreated or treated ineffectively.^[19]^[20]^[21]^[22]^[23]^[24] For patients with a mild case of the disorder--those with fewer than 20 apneas plus hypopneas per hour of sleep, little or no nocturnal hypoxemia, mild or absent daytime sleepiness, and no serious cardiac arrhythmias--the health benefits of treatment are less certain, and it is unknown at present whether asymptomatic patients with mild sleep apnea need to be treated.

The introduction in the 1980s of continuous positive airway pressure (CPAP) administered via a nasal mask revolutionized the management of OSA.^[25] Nasal CPAP functions as an air splint to maintain positive intraluminal pressure in the upper airway. Although nasal CPAP can be used by children as well as by adults and is effective in 80 to 90 percent of patients, the proportion who use CPAP on a regular basis is substantially less. If nasal obstruction prevents the use of nasal CPAP, treatment with decongestants, steroid inhalers, septoplasty, or other forms of nasal surgery may be required. Other factors that may prevent the use of CPAP or reduce its benefit include a poorly fitting or uncomfortable mask, sinus infections, claustrophobia, chronic mouth breathing, incomplete efficacy, and lack of motivation. The more expensive bilevel positive airway pressure (BPAP) devices provide different pressures during inspiration and expiration, and are sometimes better tolerated, particularly by patients with claustrophobia. Other problems associated with nasal CPAP include noise from the machine, air swallowing, allergic rhinitis, and discomfort from misdirection of airflow into the eyes. Barotrauma to the lungs is extremely rare.

For patients who cannot tolerate CPAP or prefer not to use it, a number of other treatments may be used. Removal of enlarged tonsils and adenoids is often successful in children and sometimes in adults. Uvulopalatopharyngoplasty (UPP) with removal of the uvula, portions of the soft palate, and redundant pharyngeal tissue eliminates snoring in more than 80 percent and produces improvement of OSA in about 50 percent of patients, but complete resolution of sleep apnea is uncommon. Laser-assisted UPP is a staged outpatient procedure that eliminates snoring in about 60 percent of patients but is probably less effective for OSA than standard UPP. Maxillofacial surgery, with advancement of the mandible, the maxilla, or both, appears to be beneficial for selected patients. Orthodontic appliances that advance the tongue or mandible can improve airway patency during sleep, reduce snoring, and decrease the frequency of respiratory events during sleep, but they rarely eliminate sleep apnea completely. Weight reduction is often helpful, but it may be difficult to achieve. Protriptyline at doses of 5 mg at bedtime may provide some benefit in mild cases. For some patients with mild OSA, avoidance of precipitating factors such as sleep deprivation, evening alcohol use, sedative medications, and the supine sleeping position is the only treatment needed. Whatever treatment is used, the outcome should be assessed with a sleep study because many patients experience more subjective than objective improvement.

Prognosis and Future Perspectives. Some patients develop increasingly severe apnea with age, but worsening of the condition may be due to weight gain. The natural history of sleep apnea in the absence of weight gain is unknown. Habitual snoring remits in as many as 35 percent.

Restless Legs Syndrome and Periodic Limb Movement Disorder

Restless legs syndrome (RLS) is characterized by unpleasant sensations of the legs that are worse in the evening and at night, and that are relieved by movement.^[1] Most patients with RLS also have movements of the legs that occur periodically at 20- to 30-second intervals for minutes to hours during sleep. Although the term nocturnal myoclonus sometimes is used to describe these movements, they usually are not sudden lightning-like movements. Rather, they typically last for about 1 second and consist of extension of the great toe with variable degrees of ankle extension, knee extension, and hip extension or flexion. With PLM disorder, periodic movements occur during sleep but the unpleasant evening and nighttime sensations are absent. Arousals associated with the PLMs may lead to complaints of insomnia or daytime sleepiness, or the disorder may be asymptomatic.

Pathogenesis and Pathophysiology. Although the pathophysiological basis for RLS and PLMs is unknown, disinhibition of a CNS pacemaker that affects reticular excitability may contribute. The similarity of PLMs to the extensor response to plantar stimulation (Babinski's sign) or to a triple flexion response suggests that pyramidal or dorsal reticulospinal tract dysfunction is involved.^[26] Functional dopamine or opiate insufficiency, perhaps related to abnormal iron metabolism, may also play a role. Abnormal sensory input may be a factor in some patients.

Epidemiology and Risk Factors. The prevalence of RLS is about 2 to 5 percent for the adult population and increases with age. Men and women are affected equally, and symptoms begin after age 40 in most patients. About one third to one half of patients report that other family members are affected, and in some families, the syndrome occurs in a pattern consistent with an autosomal dominant inheritance. Periodic limb movements without waking

symptoms of RLS occur in about 5 percent of persons between ages 30 and 50 years and in 30 to 45 percent or more of persons older than 65 years of age.^[27]

Clinical Features and Associated Disorders. Patients with RLS complain of a gradual buildup of a subcutaneous crawling, pulling, itching, aching, or pins-and-needles sensation that affects the muscles or bones of the calves and thighs. As the sensation builds, the associated urge to move gradually becomes irresistible and movement provides temporary relief. Most patients have insomnia with difficulty getting to sleep and frequent awakenings during which they may flex and extend the legs, repeatedly turn over in bed, or get out of bed and walk. About 80 to 90 percent of patients with RLS have PLMs, usually during light NREM sleep, that contribute to awakenings and arousals.

During the day and especially during attempts to remain still, many patients fidget, swing their legs, or have movements that are similar to the extensor movements during sleep. Apart from the movements, neurological examination is usually normal.

In PLM disorder, the condition is associated with arousals that lead to sleep disruption and complaints of insomnia or daytime sleepiness, but the sensory symptoms and waking dyskinesias that accompany RLS do not occur. Although severely affected patients may produce movements throughout sleep, PLMs may also be entirely asymptomatic, causing no disruption of sleep patterns, and are sometimes brought to medical attention either as an incidental finding on a polysomnogram or because the spouse is unable to sleep owing to the leg jerks and kicks.

RLS and PLMs may be induced or aggravated by a variety of conditions, including iron deficiency, anemia, and chronic renal failure. Peripheral neuropathy may be a factor in some cases, although peripheral nerve function is clinically normal in most affected patients. Symptoms occur in 10 to 20 percent of pregnant women and usually resolve postpartum. Other disorders that may be associated with PLMs or RLS include venous disease, degenerative CNS disorders, and vitamin deficiency.

Differential Diagnosis. The diagnosis of RLS is based on the history. The essential elements are the urge to move associated with sensory phenomena in the legs, motor restlessness, and exacerbation at rest and in the evening and night.^[28] The differential diagnosis may include akathisia, peripheral neuropathy, claudication, and leg cramps. With akathisia caused by phenothiazines, there is restlessness of the body and a compulsion to move, but the sensory component is less than with RLS and it is usually not exacerbated at night. Neuropathic dysesthesias are usually more distal than proximal, are felt more on the surface than in deeper structures, and are not relieved by movement. Claudication is brought on by exercise and relieved by rest, which is the reverse of the pattern with RLS. Leg cramps are associated with palpable tightness of muscles that does not occur with RLS.

Differential diagnosis of PLMs includes sleep starts and a variety of other movements during sleep. Sleep starts are vigorous myoclonic jerks of the extremities or trunk that occur at sleep onset but do not recur periodically. Most other types of movements and behaviors during sleep are not periodic.

Evaluation. Evaluation of patients with suspected RLS should include complete blood count, and serum iron and ferritin levels. Renal function tests and electromyography and nerve conduction studies are indicated only in selected patients. Polysomnography is useful for suspected PLM disorder.

Management. Evening and bedtime doses of levodopacarbidopa or dopaminergic agonists provide the most benefit in RLS and PLM disorder.^[29] Some patients require additional doses during the night or controlled-release formulations. Unfortunately, some patients develop tolerance and require increasing doses, whereas others develop increased daytime symptoms of restless legs. If necessary, levodopa-carbidopa can be given around the clock to such patients. Temporary withdrawal and reinstitution of therapy a few weeks later may improve efficacy.

Benzodiazepines, particularly clonazepam, can be used either alone or in combination with dopaminergic agents for RLS and for PLM disorder. Daytime sedation, tolerance, and loss of efficacy are the major problems encountered with these drugs. Opiates such as propoxyphene, codeine, and hydrocodone also reduce the unpleasant sensations and can be used alone or in combination with dopaminergic agents and benzodiazepines.^[30] Clonidine, baclofen, carbamazepine, and gabapentin are sometimes helpful.

For patients with PLMs without RLS, it may be difficult to determine the extent to which PLMs contribute to daytime symptoms. The decision to treat PLMs depends on the frequency of movements and associated arousals and on the clinical assessment of the degree to which other sleep disorders contribute to symptoms.

Prognosis and Future Perspectives. RLS has a variable course. Some patients have long periods of relative stability, whereas others worsen with age. Permanent remissions are rare.

CHRONOBIOLOGICAL DISORDERS

People who sleep at the wrong time of day or who cannot sleep at the right time of night often have one of the six major chronobiological disorders: jet lag syndrome, shift work sleep disorder, DSPS, advanced sleep phase syndrome, non-24-hour sleep-wake disorder, and irregular sleep-wake pattern disorder. ^[1]

Pathogenesis and Pathophysiology. Circadian rhythm disturbances are caused by a shift in the usual phase relation between the internal biological clock and the desired sleep-wake schedule. The suprachiasmatic nucleus of the hypothalamus functions as the biological clock. In the absence of entraining influences, the output of the nucleus has a period slightly longer than 24 hours. Thus, persons living in temporal isolation adopt a 24.5- to 25-hour sleep-wake schedule and cycle in and out of phase with the external environment. The phase of the biological clock can be shifted by only a few stimuli of which the most potent is bright light. ^[31] Bright light exposure helps maintain synchronization between the internal clock and the external world, but the phase shifting effects of light are limited in most circumstances to no more than 2 hours each day. The retinohypothalamic pathway, the primary afferent tract to

the suprachiasmatic nucleus, mediates the effects of light on circadian rhythms. Intensity, duration, and timing of light exposure determine its effect on the phase of the circadian system. Light pulses just before or during the first half of the dark phase produce phase delays, whereas light pulses during the second half of the dark phase or just after the end of the dark phase produce phase advances. Melatonin, a pineal hormone that is secreted mainly at night in humans, appears to have phase-shifting properties that are opposite to the effects of bright light: Melatonin administered in the afternoon produces phase advances, whereas melatonin given in the morning produces phase delays.

With east-west jet travel or with changing work schedules, most persons attempt to shift their schedule of sleep and wakefulness quickly to meet the social demands of the new schedule, but the internal clock cannot adjust and sleep-wake patterns are disrupted. Night workers also sleep about 1 to 1.5 hours less than day workers, and their attempts to sleep at night when they are not working often prevent them from synchronizing the internal clock to the night shift schedule. As the internal clock shifts by about 1 hour per day after a phase advance--such as an eastbound flight--and by 1.5 hours per day after a phase delay--such as a westbound flight, it may be several days before sleep-wake patterns and the internal clock shift to the new schedule. ^[32], ^[33]

Phase shifts also may occur during weekends if bedtimes and rise times are delayed, at least in part because of altered timing of light exposure. In patients with DSPS, ^[34] phase delays induced by sleeping later are not corrected during the week. Adolescence, the usual time of appearance of DSPS, is associated with increased sleep needs but social factors and greater independence usually prevent earlier bedtimes. As a result, many adolescents sleep later on weekends and develop DSPS. Leaving home for college may exacerbate DSPS because parents can no longer act as backups to the alarm clock. In *advanced sleep phase syndrome*, the pattern is the opposite, with excessively early bedtimes and early awakenings due to phase advance of the biological clock.

Degeneration or destruction of the suprachiasmatic nucleus or its effector pathways is the usual cause of *irregular sleep-wake pattern disorder*. *Non-24-hour sleep-wake disorder* is usually caused by retinal, prechiasmal, or chiasmal lesions that interrupt the retinohypothalamic tract. Although most affected persons are blind, chiasmal lesions that interrupt the retinohypothalamic tract may cause the syndrome even when visual loss is incomplete. Without retinal input, the internal clock moves in and out of phase with the environmental clock. When the phase difference is small, patients may be able to maintain sleep hours close to the societal norm, but when the phase difference is large, synchronization cannot be maintained and sleep times become highly irregular. Prolonged periods of wakefulness lasting up to 40 to 50 hours may be followed by sleep periods of 12 to 20 hours and then resumption for a few days of a relatively normal schedule.

Epidemiology and Risk Factors. Circadian rhythm sleep disorders are common. Jet lag symptoms affect the majority of persons who fly across five or more time zones. Sleep disruption is a problem for a large proportion of the more than 20 million shift workers, particularly for older workers during the days and nights following a shift change. DSPS may affect as many as 7 percent of urban adolescents. The other disorders are less common. The irregular sleep-wake pattern disorder occurs mainly in institutionalized persons with severe static or progressive encephalopathies. The non-24-hour sleep-wake disorder appears to be a major cause of sleep-wake complaints in blind persons.

Clinical Features and Associated Disorders. Symptoms of jet lag, which may last as long as 7 to 10 days after trips across five or more time zones, include difficulty falling asleep or remaining asleep in the new environment, along with sleepiness during the new daytime. Symptoms, which are usually worse with eastward flight than with westward flight, may be exacerbated by sleep loss and alcohol use during the flight. Chronic jet lag with sleepiness, sleep disruption, malaise, irritability, and reduced performance may occur in airline personnel and in other frequent jet travelers. Night workers and those who work rotating shifts often develop sleep problems similar to jet lag because an 8-hour shift in the sleep schedule produces effects similar to flight across eight time zones. Nighttime sleep on weekends may prevent shifts in phase to match the new schedule and may exacerbate sleep problems during the week. Adolescent patients with DSPS have difficulty falling asleep at night and difficulty waking up on time when they try to maintain a conventional sleep-wake schedule. Patients with advanced sleep phase syndrome complain of evening sleepiness and early morning awakening. Sleep onset between 6 and 9 PM and awakening between 1 and 3 AM are typical.

With the irregular sleep-wake pattern disorder, sleep episodes of varying length occur at irregular intervals. Patients or caretakers complain of difficulty falling asleep, difficulty remaining asleep, and daytime somnolence. The picture is often complicated by nocturnal agitation and by the use of sedatives or antipsychotic medications to control the agitation.

Patients with the non-24-hour sleep-wake disorder may complain of difficulty falling asleep in the evening, difficulty waking up in the morning, or difficulty staying awake during the day. Cyclical fluctuation in severity of the complaints is typical because sleep problems are much greater when the phase difference between the temperature rhythm and the desired sleep-wake schedule is high.

DSPS may be the initial manifestation of depression in adolescents. In adults with poor social adaptation, the syndrome may provide secondary gain as a means to reduce or avoid social interaction. Irregular sleep-wake syndrome is often associated with encephalopathy and non-24-hour sleep-wake syndrome with blindness.

Differential Diagnosis. The differential diagnosis of chronobiological disorders includes most of the other disorders that cause insomnia or sleepiness. Inadequate sleep hygiene and chronically insufficient sleep often contribute to sleep disturbance in shift workers and night workers; temporal association of sleep disturbance with night or rotating shift work and remission during vacations is suggestive of shift work sleep disorder. Depression, marital or family problems, job dissatisfaction, or other psychosocial factors should be considered in a permanent shift worker who develops sleep problems after years of stable functioning.

DSPS that presents in adolescence is sometimes misdiagnosed as narcolepsy, depression, chronic fatigue, or as a learning disorder. Knowledge that sleepiness occurs mainly in the morning and continuous restful sleep occurs when patients go to bed late and arise late helps the clinician arrive at the correct diagnosis.

Evaluation. The history and sleep logs provide the most useful information for diagnosing circadian rhythm sleep disorders. Maintenance of a sleep log for 2 to 4 weeks is usually sufficient except for patients with the non-24-hour sleep-wake pattern, whose cyclical sleep patterns may only be revealed after several weeks of maintaining sleep logs. In DSPS, sleep logs show sleep onset and awakening from sleep that are much later than the social norm. Bedtimes and wakeup times are often even later on weekends. Sleep logs in patients with irregular sleep-wake patterns show no consistent sleep times: There may be several 2- to 4- hour sleep periods scattered over the 24-hour period, with marked variability in the timing and duration of sleep from one day to the next.

If sleep apnea or narcolepsy is suspected, polysomnography and MSLT may be helpful but MSLT interpretation is difficult if the patient has not been on a regular schedule. Psychiatric assessment is indicated if depression appears to be a contributing factor.

Management. Appropriate scheduling of sleep and of exposure to bright light are the keys to management of circadian rhythm sleep disorders. To minimize jet lag, the pretravel sleep schedule should be shifted 1 to 2 hours closer to the destination schedule. Although hypnotic use during the trip may minimize in-flight sleep loss, the potential for effects on memory and cognition must be considered, especially in the elderly. After travel, correctly timed exposure to bright light and immediate adoption of the new time zone schedule help reduce symptoms. At present, melatonin, which may be beneficial for jet lag, is not available in the United States except as an unregulated health food supplement.

Treatment of shift work sleep disorder depends on the frequency of shift changes, the direction of shift rotation, the desired schedule during nights of work, and the daytime obligations of the shift worker.^[35] Shift rotations from days to evenings to nights tend to be better tolerated than rotations in the opposite direction. Although sleep is usually best for night workers who sleep during the day 7 days per week, most persons are unwilling to spend days off asleep. A biphasic sleep schedule with a 2- to 3-hour nap in the afternoon and 4 to 6 hours of sleep in the morning after work is sometimes the best option. Bright light at night and dark bedrooms in the daytime are beneficial, but daytime sedative use is usually of no value.

For DSPS, the patient should be instructed to advance the times of going to bed and arising from bed by about 15 minutes each day or two beginning with the usual weekend sleep times. Alternative approaches with more rapid phase shifts are quicker, but they are more socially disruptive and require strong motivation. Once the desired schedule is achieved, it must be rigorously maintained 7 days per week. Morning bright light is helpful, but patients should understand that the schedule is the most critical element.

Although DSPS almost always can be treated effectively with strict scheduling, psychosocial factors often interfere with the planned treatment. Awakening in time to get to school often has become a focus for conflict between the parents and the patient, and many patients, particularly those with depression, lack the motivation to maintain the schedule. Failure to attempt even a minimal shift in schedule is usually an indication of major family discord, depression, or poor motivation.

Advanced sleep phase syndrome can be treated with daily 15-minute delays in bedtime and evening exposure to bright light. Treatment of the irregular sleep wake pattern disorder is difficult, although morning exposure to bright light, increased daytime activity, and prohibition of morning and evening naps may be helpful. Management of the non-24-hour sleep-wake syndrome is also difficult, but blind patients who retain some retinal input to the suprachiasmatic nucleus benefit from appropriately timed exposure to high-intensity bright light.^[36]

PARASOMNIAS

Parasomnias are disorders in which the chief complaint is related to undesirable physical and mental phenomena that occur mainly or exclusively during sleep. Twenty-three parasomnias are recognized (Table 54-8). This chapter reviews some that are of particular interest to neurologists.

Arousal Disorders

Pathogenesis and Pathophysiology. The arousal disorders--confusional arousals, sleepwalking, and sleep terrors--are grouped together based on the hypothesis that impaired ability to arouse fully from slow-wave sleep is responsible for the phenomena. The disorders, which are most common during childhood when the amount of slow-wave sleep is at its peak, probably exist on a continuum. Confusional arousals are associated with low levels of motoric and autonomic activation; sleepwalking with motoric activation but little autonomic activation; and sleep terrors with pronounced autonomic, emotional, and motoric activation. The variable activation patterns lead to considerable overlap between the three syndromes.

Epidemiology and Risk Factors. Children are affected more than adults with a peak incidence between ages 4 and 10 years; however, onset in adulthood can occur. About 1 to 6 percent of children have recurrent sleep terrors. An increased prevalence in first-degree relatives suggests that genetic factors may play a role. In susceptible persons, sleepwalking and sleep terrors may be precipitated or aggravated by stress, sleep deprivation, fever, sleep apnea, and noise.

Clinical Features and Associated Disorders. Sleep terrors are episodes of fearful agitation with decreased responsiveness and inconsolability that begin abruptly, usually from slow-wave sleep in the first third of the night. Severe episodes are often accompanied by screaming and attempts to leave the bed or the room. Patients may fall down stairs and may react violently to attempts to restrain them. After several minutes the patient calms down and

TABLE 54-8 -- PARASOMNIAS

Disorder	Key Features
Confusional arousals	Sudden arousals, usually from slow-wave sleep, associated with confusion and disorientation
Sleepwalking	Arousal with complex motor behavior, usually from slow-wave sleep; walking, running, talking, and eating may occur
Sleep terrors	Sudden arousal, usually from slow-wave sleep, with fearful agitated behavior, often with screaming or crying and inconsolability
Rhythmic movement disorder	Stereotyped repetitive rhythmic movements--such as head-banging, head-rocking, and body-rolling during light sleep and transitions between sleep and wakefulness
Sleep starts	Sudden myoclonic jerks at sleep onset of the trunk, head, or extremities
Sleep talking	Talking during sleep, usually during arousals
Nocturnal leg cramps	Painful cramps of the foot or calf that produce awakenings
Nightmares	Frightening dreams
Sleep paralysis	Paralysis occurring at the onset or end of sleep or during nocturnal awakenings
Impaired sleep-related penile erections	Impaired or absent penile erections during REM sleep
Sleep-related painful erections	Painful erections occurring during REM sleep
REM sleep-related sinus arrest	Periods of cardiac asystole during REM sleep
REM sleep behavior disorder	Dream-enacting behavior with loss of the normal muscle atonia during REM sleep
Sleep bruxism	Stereotyped repetitive grinding of the teeth during sleep or during arousals from sleep
Sleep enuresis	Incomplete bladder control during sleep beyond the expected age for bladder control
Sleep-related abnormal swallowing syndrome	Impaired swallowing of saliva during sleep
Nocturnal paroxysmal dystonia	Brief stereotyped episodes of sudden dystonic posturing and ballistic movements, arising from NREM sleep
Sudden unexplained nocturnal death syndrome	Sudden death during sleep in healthy young adults
Primary snoring	Snoring without sleep apnea
Infant sleep apnea	Sleep apnea in infants
Congenital central hypoventilation syndrome	Hypoventilation during sleep that is not due to primary lung disease or respiratory muscle weakness
Sudden infant death syndrome	Sudden unexplained death in infancy
Benign neonatal sleep myoclonus	Irregular myoclonic jerks of the trunk and extremities during NREM sleep in neonates

REM, Rapid eye movement; NREM, nonrapid eye movement.

returns to sleep. Morning recall is usually absent, although some patients have a vague recollection of a terrifying situation such as suffocation and occasional patients recall more elaborate dreamlike experiences.

Sleepwalking is characterized by complex automatisms during sleep typified by getting out of bed and walking. Some subjects eat; others attempt to leave the home through a door or window. Patients sometimes sit or stand in bed without getting out of bed. Although sleepwalkers often respond inappropriately, they sometimes follow instructions to return to bed.

Confusional arousals are brief episodes associated with talking, moaning, or agitation that rarely require treatment.

Although sleep terrors and sleepwalking may be precipitated by stress in susceptible individuals, most affected children do not have severe psychopathology. Arousal disorders appear to be increased in Tourette's syndrome, post-traumatic stress disorder, and children with violent, abusive families.

Differential Diagnosis. The differential diagnosis of arousal disorders includes sleep-related epilepsy, REM sleep behavior disorder (RBD), nightmares, confusional states, and nocturnal delirium. Although the patient's history is often sufficient for diagnosis, symptoms of screaming, walking, running, and vague, frightening perceptions may accompany nocturnal complex partial seizures. Atypical presentations that suggest the possibility of seizures include onset in adulthood; multiple nightly episodes; stereotyped behaviors with chewing, swallowing, and salivation; and poor or no response to medications. The RBD occurs mainly in adults and is usually associated with dream recall; the vague recollections that accompany some episodes of sleep terrors are usually fragmentary without the plot or story that characterizes dream mentation. Behavior may, however, be similar to that observed with sleep terrors, and some patients have a so-called overlap syndrome with elements of sleep terrors and RBD.

In hysterical dissociative phenomena, such as fugue states and multiple personalities, the patient is not asleep and behavior is purposeful, more complex, and longer

lasting. The EEG is consistent with waking state.

Evaluation. For otherwise normal children with typical behaviors of sleepwalking or sleep terrors that occur during the first third of the night, the diagnosis can usually be made based on clinical criteria. When the diagnosis is uncertain, polygraphic monitoring with simultaneous video monitoring is indicated for 1 or 2 nights, particularly if the events are occurring several times per week. If nocturnal seizures are a consideration, several additional EEG channels should be included in the recording montage, along with a video recording of the patient and the capability to record or play back activity at a sufficient paper speed to identify interictal and ictal epileptiform activity.^[40] Standard polysomnographic recording techniques used for identifying sleep apnea are generally insufficient for a definitive diagnosis.

Polysomnographic monitoring usually demonstrates the onset of sleep terror episodes during stage 3 or 4 sleep. The electroencephalogram (EEG) during the episode may show rhythmical delta activity or other nonwaking patterns, whereas the EEG shows waking activity during psychogenic dissociative episodes and REM sleep activity during the RBD. Psychiatric evaluation is indicated if a dissociative disorder is suspected as many patients have severe psychopathology.

Management. Sleep terrors and sleepwalking usually

improve with age and resolve before adolescence. Treatment may be required if the associated behaviors are potentially injurious or if the behavior is excessively disruptive to the family. Good sleep hygiene with regular sleep hours and adequate amounts of nocturnal sleep are important initial recommendations. Ground floor bedrooms, window locks, and absence of sharp objects or toys on the bedroom floor are other useful measures. If injuries have occurred or appear likely to occur, treatment of the patient at bedtime with imipramine, diazepam, or clonazepam is usually effective. Hypnosis or other behavioral treatments may be helpful for some patients, and psychiatric treatment is indicated when the disorder is linked to significant psychopathology.

Prognosis and Future Perspectives. Episodes tend to decrease in frequency and severity during adolescence. The natural history of adult-onset arousal disorders is unknown.

REM Sleep Behavioral Disorder

Normal REM sleep is associated with skeletal muscle atonia interrupted by irregular muscle twitches. With the RBD, the muscle atonia that accompanies REM sleep is incomplete and patients have motor automatisms in which they appear to act out their dreams.^[39]

The RBD occurs mainly in older persons and is more common in men than in women. Patients with Parkinson's disease, Alzheimer's disease, multi-infarct dementia, multiple system atrophy, olivopontocerebellar degeneration, narcolepsy, and focal brain stem lesions are at increased risk for RBD, but over half of patients have no major abnormality on neurological examination or MRI. Some studies have suggested that the disorder may be an early marker or risk factor for Parkinson's disease.

The disorder may begin fairly abruptly, or it may be preceded by months of progressively increasing nocturnal movements, vocalizations, and disturbing dreams. Presenting complaints include nocturnal shouting, violent behavior with "acting out" of dreams, and injuries during sleep to the patient or bed partner.^[41] During the episodes, which usually last a few minutes, behavior may be limited to talking, laughing, and waving of the arms or it may include punching, kicking, or jumping out of bed. Some patients have a so-called Jekyll and Hyde syndrome with quiet peaceable behavior during the day that contrasts with the swearing and violence that accompanies REM sleep.

The timing and duration of episodes parallel the distribution of REM sleep across the night. Some patients have complex behaviors with virtually every REM period, whereas others have the behaviors less than once per week. Episodes usually do not occur during naps or during the first hour of sleep because REM sleep is uncommon at these times. Patients can usually be awakened from an episode without the confusion or difficulty arousing that characterizes sleep terrors.

Dream mentation and dream-enacting behaviors are uncommon with other disorders associated with complex motor activity during sleep ([Table 54-9](#)). The recurrence of episodes at approximately 90-minute intervals, and the rapid return to full alertness on awakening are also useful distinguishing features.

Polysomnography with simultaneous audio and video monitoring and additional channels for limb movement monitoring is indicated when RBD is suspected. On polysomnography, the atonia that normally accompanies REM sleep is disrupted by periods of increased tone and increased phasic muscle activity, even during REM periods that are not associated with disruptive behavior. One night of recording is usually sufficient, but sometimes two nights are required. Brain imaging, daytime EEG, or neuropsychological tests may be indicated in patients with abnormal neurological examinations, but they are not needed in patients with idiopathic RBD.

In 80 to 90 percent of patients, behavior is eliminated or reduced to minor movements and vocalizations with bedtime doses of clonazepam, which appears to be more effective than other benzodiazepines. Incomplete atonia persists during REM sleep even with treatment. If clonazepam is ineffective or not tolerated, imipramine, levodopa-carbidopa, diazepam, temazepam, clonidine, or carbamazepine are occasionally useful.

Idiopathic RBD disorder is a chronic disorder with few if any remissions. A substantial proportion of patients who are otherwise neurologically normal at the time of presentation develop Parkinson's disease over the next several years.

Hypnogenic Paroxysmal Dystonia

The clinical characteristics of hypnogenic paroxysmal dystonia (also called nocturnal paroxysmal dystonia) closely

TABLE 54-9 -- CAUSES OF EPISODIC NOCTURNAL COMPLEX MOTOR ACTIVITY

Disorder	Stage of Sleep or Wakefulness in which Episodes Arise
Sleepwalking	NREM sleep, usually slow-wave sleep
Sleep terrors	NREM sleep, usually slow-wave sleep
Partial complex seizures of temporal lobe origin	Usually NREM sleep
Partial complex seizures of frontal lobe origin	Usually NREM sleep
Hypnogenic paroxysmal dystonia	Usually NREM sleep
Panic disorder	NREM sleep
REM sleep behavior disorder	REM sleep
Nightmares	REM sleep
Nocturnal delirium	Wakefulness
Dissociative episodes	Wakefulness
Malingering	Wakefulness

REM, Rapid eye movement; NREM, nonrapid eye movement.

resemble partial seizures originating in the supplementary motor area, and in most patients, the attacks are epileptic.^{[42], [43]} Unusual cases with long-lasting attacks are presumed to be caused by a basal ganglia disturbance.

The disorder is rare. Lesions of the supplementary motor area or of mediobasal regions of the frontal lobe appear to be the major risk factors.

Patients with this disorder have brief spells of ballistic choreoathetoid movements and dystonic postures that arise abruptly from NREM sleep. The violent movements are usually bilateral, but they may predominate on one side and the patient usually is awake with eyes open during the episode.

Differential diagnosis includes partial seizures of temporal lobe origin, sleep terrors, nocturnal dissociative disorder, and RBD. Although the bizarre behaviors may suggest a psychiatric disorder, the abrupt onset from sleep, the highly stereotyped behaviors, and the absence of dream mentation and dream-enacting behaviors are helpful distinguishing features. Sleep terrors rarely occur more than 3 to 4 times per night, whereas episodes of hypnogenic paroxysmal dystonia often occur 10 to 40 times per night.

Polysomnography with video-EEG monitoring is the most useful diagnostic test.^[40] The documentation of abrupt onset from sleep with stereotyped behavior is usually sufficient to exclude psychiatric causes, but definitive determination of whether the episodes are epileptic is often difficult. In some cases, ictal discharges may be recorded from frontal regions, but it may be necessary to record dozens of episodes over the course of several nights before a focal ictal discharge is revealed. In some cases, intracranial electrode placement is required.

Epileptic and nonepileptic forms may respond to carbamazepine and other antiepileptic agents, but as in other patients with seizures of frontal lobe origin, some patients show no response to any anticonvulsant.

The course is variable. Spontaneous remissions may occur that last for years, even when the disorder is epileptic. Other patients have numerous nightly episodes that are refractory to all treatments. Daytime seizures sometimes develop.

SLEEP ABNORMALITIES IN NEUROLOGICAL DISORDERS

Sleep Disordered Breathing and Neuromuscular Diseases

Breathing disturbances in neuromuscular diseases are due to weakness of respiratory muscles or upper airway muscles, or both. Respiratory muscle weakness is usually severe in Duchenne's muscular dystrophy and also occurs in myotonic dystrophy, limb-girdle dystrophy, polymyositis, poliomyelitis, amyotrophic lateral sclerosis, myasthenia gravis, and congenital myopathies.

Weakness of the diaphragm is the most important cause of respiratory disturbance during sleep. Diaphragmatic workload increases in NREM sleep owing in part to airway narrowing caused by decreased tone in upper airway muscles, in part to sleep-related changes in lung mechanics and respiratory muscle activation, and in part to the increased load associated with the horizontal position. With neuromuscular disorders, weakness of upper airway muscles may further reduce airway diameter, leading to increased respiratory load. Diaphragm workload increases even further during REM sleep, because accessory muscles of respiration are inhibited and the diaphragm must perform almost all of the work of breathing. The increased workload during sleep may lead to diaphragm fatigue with hypoxia, hypercapnia, acidosis-induced muscle dysfunction, and progressively worsening hypoventilation during the latter portion of the night.

Weakness of upper airway muscles may also lead to obstructive apneas and hypopneas, but weakness of inspiratory muscles may prevent generation of sufficient force to produce snoring.

Obesity, kyphoscoliosis, and other factors that increase work of breathing may precipitate sleep-related hypoventilation in patients with diaphragm weakness. Patients with bulbar symptoms are at increased risk for upper airway obstruction during sleep. Although patients with daytime respiratory symptoms are at greatest risk, many patients without daytime complaints have significant sleep-related hypoventilation.

Patients may complain of frequent awakenings, nocturnal dyspnea or restlessness, inability to sleep supine, or morning headaches. Patients with marked diaphragm weakness may be unable to sleep in a bed and may sleep in a chair or on the couch. Daytime sleepiness is usually not a prominent complaint until sleep disturbance is severe. In occasional patients with motor neuron disease or myopathy, sleep complaints caused by nocturnal hypoventilation are the initial manifestation of the neuromuscular disease.

Other causes of sleep disturbance, including periodic limb movements and the effects of medications, must be considered. Patients with progressive disorders may have sleep disturbance caused by depression.

Evaluation should include spirometry obtained in the sitting and supine positions because patients with diaphragm weakness may have a pronounced reduction in vital capacity when they are supine. Arterial blood gases, assessment of diaphragm motion with fluoroscopy, and complete pulmonary function testing are helpful in selected patients. Polysomnography allows assessment of breathing in REM and NREM sleep in various body positions and sleep stages. Measurement of end-tidal pCO_2 , which can be performed as part of the recording, provides a quantitative assessment of ventilation.

Weight reduction may produce marked benefits if obesity has led to decompensation of marginal pulmonary function during sleep. Nocturnal oxygen may be beneficial if hypoventilation is not severe, but it must be administered cautiously in patients with daytime hypercapnia because of the risk of precipitating respiratory failure in patients whose breathing is dependent on hypoxic drive. For patients with upper airway obstruction, nasal CPAP is excellent treatment and if hypoventilation is not reversed with CPAP, BPAP devices that provide a higher pressure during inspiration than during expiration can be used, especially for patients with expiratory muscle weakness. Negative pressure cuirass ventilators and intermittent positive pressure ventilation can be used if additional ventilatory support

is needed. Tracheostomy combined with positive pressure ventilation may be needed for some patients. The prognosis depends on the underlying neuromuscular disorder.

Sleep Disorders Associated with Degenerative Disorders of the Central Nervous System

Degenerative neurological diseases can lead to sleep disturbance through effects of the disease on neuronal systems involved in sleep-wake regulation, on systems involved with regulation of breathing during sleep, or on systems involved with motor control during sleep. Degenerative processes that affect the suprachiasmatic nucleus or the retina may produce circadian rhythm disturbances. Obstructive sleep apnea may occur if weakness, spasticity, or rigidity affect bulbar muscles, and central or obstructive apneas may occur if respiratory control systems of the lower brain stem are involved. Patients who have degenerative processes that affect motor systems are at increased risk for PLM disorder, RLS, and RBD.

Degenerative disorders may also cause sleep disturbance due to the effects on sleep continuity of immobility, discomfort, and nocturnal disorientation. Depression and the effects of psychoactive medications also contribute to sleep problems in many patients, but sleep disturbance is also common in unmedicated nondepressed patients.

Frequent awakenings scattered throughout the night represent the most common pattern of sleep disturbance in these patients. Awakenings combined with disorientation in demented persons often lead to the so-called sundown syndrome with nocturnal wandering, confusion, and agitation. This problem is highly stressful to family members and is a major cause of institutionalization of the demented elderly.^[44],^[45] Daytime somnolence, often caused by nocturnal sleep disruption, may exacerbate difficulties with memory and attention.

Obstructive and central sleep apneas and irregular respiratory patterns during sleep are common in patients with autonomic disturbances, in those with bulbar symptoms, and in those with degeneration of pontomedullary systems involved in the coordination of breathing.^[46],^[47]

For the patient with a degenerative neurological disorder and sleep complaints, the differential diagnosis may include direct and indirect effects of the disease, medication effects, poor sleep hygiene with excessive time in bed, circadian rhythm sleep disorders, RLS and PLM disorder, sleep-related breathing disorders, sundowning, and RBD.

The history is the most important element for diagnosis. The relation of the onset of sleep disturbance to the onset of the degenerative disorder helps determine whether the two are related. For patients with insomnia or disruptive nocturnal behavior, the frequency and duration of awakenings should be noted, along with the times of naps and medications. Mood should be assessed because depression is a common contributor to sleep disturbance in this population. A sleep log may provide evidence of a circadian rhythm disorder and also helps quantify the sleep disturbance and its effect on the caregiver. Sleep laboratory evaluation may be required in some cases, particularly if sleep apnea, PLMs, or RBD are suspected.

The management of disturbed sleep in patients with degenerative disorders requires a determination of the severity of sleep disturbance and its probable causes, an assessment of the impact of disrupted sleep on the patient and family, and a consideration of the benefits and drawbacks associated with particular treatments. Although the underlying pathology usually cannot be halted or reversed, there may be elements contributing to disordered sleep that can be ameliorated or removed. Good sleep hygiene with a regular sleep-wake schedule, exposure to bright light in the morning, and minimal amounts of time spent in bed during the day are important first steps. Morning and evening naps should be avoided in most patients, but afternoon naps may help some patients obtain more total sleep. Caffeine and alcohol should be eliminated, and psychoactive medications should be minimized.

Sleep-related breathing disturbances should be treated to the greatest extent possible, particularly in patients with autonomic disturbances because they appear to be at high risk for death during sleep.^[48] Obstructive sleep apnea may respond to treatment with nasal CPAP. Although the CPAP apparatus may be manageable initially, its use may become impossible as the degenerative disorder progresses, particularly if dementia is a prominent symptom. In most patients with advanced disease, the complications associated with tracheostomy outweigh its benefits.

Disruptive nocturnal behavior that is due to RBD usually responds to treatment with clonazepam in patients who can tolerate the medication, but it is a difficult symptom to manage when the condition is due to other causes. Benzodiazepines exacerbate nocturnal confusion and impair memory in the demented. Some patients

benefit from low doses of thioridazine, butyrophenone, or sedating tricyclics but their anticholinergic properties may worsen cognitive disturbance.

HISTORY AND DEFINITIONS

Adverse reactions to prescription or over-the-counter medications are a frequent cause of neurological morbidity and patient hospitalization. Therefore, it is essential that the possibility of an iatrogenic condition be considered in any patient presenting with acute, subacute, or chronic neurological symptoms. Identification of the responsible agent is simple when neurological symptoms are highly characteristic of the offending agent. However, in most cases, symptoms of intoxication are nonspecific and mimic neurological entities, or they exacerbate pre-existing neurological disease. Some effects relate directly to neurotoxicity, and others are secondary to damage of other organ systems such as renal or hepatic.

The nervous system may be adversely affected by several mechanisms. There may be interference with energy production necessary to maintain normal neural structure and function; exposure to foreign material may result in allergic or other immunological phenomena; drugs may affect the nervous system through their effects on neurotransmitters; the offending agent may interfere with nerve nutrition through involvement of the nutrient vessels; and alterations in acid-base balance or in ionic concentrations may occur. Advances in molecular biology research techniques are being applied to understanding the biochemical foundations of toxic reactions and to identifying subjects at risk of intoxication.

receptors at the level of the limbic system, forebrain, and basal ganglia. They also have antihistaminergic, anticholinergic, and anti- α_1 adrenergic properties. Many newer agents have some affinity for 5-HT₂ serotonin receptors as well (clozapine, risperidone). As a class, they are associated with a variety of important neurological complications. These can be classified as acute, subacute, and chronic side effects ([Table 55-2](#)).

ENCEPHALOPATHY

Neuroleptics may cause a toxic confusional state, especially in the elderly, and confusion occurs more frequently with the low-potency, high-anticholinergic activity subclass (chlorpromazine, thioridazine, mesoridazine). These drugs can also produce profound sedation, especially with initiation of therapy. ^[1]

*Neuroleptic malignant syndrome can occur as an acute, subacute or chronic side effect of neuroleptics.

SEIZURES

Neuroleptics also lower the seizure threshold and have been associated with exacerbation of pre-existing epilepsy as well as the de novo appearance of seizures.

NEUROLEPTIC MALIGNANT SYNDROME

The pathogenesis of neuroleptic malignant syndrome (NMS) is not completely understood. Alterations in dopaminergic transmission, changes in sympathetic outflow, alterations in central serotonin metabolism, and abnormalities in muscle membrane function have been implicated. NMS has been associated with all groups of neuroleptics, although high-potency agents, specifically haloperidol and fluphenazine, have been most frequently cited. NMS tends to occur with the initiation of treatment or increases in dose and is more common with depot forms of neuroleptics. Affective disorder, concomitant lithium carbonate administration, psychomotor agitation, dehydration, exhaustion, and mild hyperthermia seem to increase susceptibility toward this condition. ^[1]

The principal features of NMS are hyperthermia, muscle rigidity, autonomic dysfunction, and mental status changes. Laboratory findings include elevated creatine kinase, polymorphonuclear leukocytosis, elevated aldolase, alkaline phosphatase, lactic dehydrogenase (LDH), alanine aminotransferase (ALT), and aspartate aminotransferase (AST), hypocalcemia, hypomagnesemia, low iron, proteinuria, and myoglobinuria. ^[1] Approximately 40 percent of patients with NMS develop medical complications that may be life threatening. NMS is a clinical diagnosis based on the presence of the proper historical setting and the characteristic constellation of signs. Disorders with similar features include malignant hyperthermia, heat stroke induced by neuroleptics, lethal catatonia, other drug reactions, and vascular,

infectious, or postinfectious brain damage.

NMS is a potentially fatal disease, and a high index of suspicion is required for early recognition and intervention.

Treatment includes ceasing of the offending agent, providing supportive measures, and administering dantrolene or bromocriptine or a combination of the two.

ACUTE DYSTONIA

Acute neuroleptic-induced dystonia can be seen early in the course of neuroleptic therapy or with dose increases. It is often seen following a single parenteral dose of neuroleptics. The manifestations can be diverse, although the most typical clinical signs involve oculogyric crises and opisthotonic posturing. Risk factors include young age, male gender, and use of high-potency neuroleptics. ^[1] Acute dystonic reactions are self-limited, and if they are left untreated, they usually subside within 24 hours. Parenteral administration of anticholinergics, such as benztropine or diphenhydramine, offers immediate relief in the majority of cases, but oral anticholinergics should be continued for a few days until the causative neuroleptic is cleared.

ACUTE AKATHISIA

Akathisia is a severe form of restlessness associated with the need to move. Typically the patient paces incessantly in place and cannot sit down without continual volitional movement of the legs or feet. The pathophysiology of the syndrome is not well understood but may relate to the development of acute imbalance between the dopaminergic and cholinergic systems. This neuroleptic side effect usually occurs within the first days of therapy or with dose increases, and it resolves with withdrawal of the neuroleptic agent. Anticholinergics, amantadine, beta blockers, clonidine, and benzodiazepines have also been used with variable success. ^[1], ^[2] Late-onset akathisia may be a form of tardive dyskinesia (TD; see later) and may be more difficult to treat.

PARKINSONISM

Neuroleptic-induced parkinsonism is the result of striatal dopaminergic underactivity due to dopaminergic D₂ receptor blockade. Clinically, it cannot be distinguished from idiopathic Parkinson's disease, although its development occurs as a subacute syndrome within the first weeks of drug introduction or drug-dosage increase. Parkinsonian symptoms resolve over a few weeks to 6 months after stopping the causative agent or with the use of antiparkinsonian drugs. Proposed risk factors for development of neuroleptic-induced parkinsonism are female gender, older age, and the use of high-potency agents. ^[1], ^[2] Treatment consists of discontinuing or reducing the dose of the offending agent. A lower-potency neuroleptic or one of several novel neuroleptics that lack prominent striatal receptor blockade, like clozapine, can be substituted. Anticholinergics, amantadine, and electroconvulsive therapy are also possible treatments.

TARDIVE DYSKINESIA

TD usually appears after several months or years of treatment with antipsychotic medications and almost never before 3 months. No consistent neuropathological changes have been seen in patients with TD, and the predominant hypothesis for its genesis is denervation supersensitivity of the striatal dopamine receptors following chronic blockade. ^[1] Risk factors for the development of TD include old age, female gender, presence of affective disorders, history of neuroleptic-induced parkinsonism, presence of organic brain disease, high-potency neuroleptics, sufficient duration of treatment with neuroleptics, and possibly the use of anticholinergic medications, previous electroconvulsive treatment, and drug holidays.

In addition to the well-known oral-buccal-lingual masticatory movements and generalized chorea, dystonia, akathisia, tics, and myoclonus have been described. Once TD has appeared, its peak severity is reached rapidly and is often maintained. Following neuroleptic withdrawal, TD may transiently worsen, but this exacerbation is short lived. TD resolves in up to 33 percent of patients within 2 years after discontinuation of the offending agent. ^[1]

At present, prevention is the treatment of choice for TD. Therefore, neuroleptics should be used only when specifically needed and at the lowest possible doses. Once TD develops, the causative agent should be discontinued, if possible. Alternatively, the patient should be switched to an atypical neuroleptic like clozapine, which not only does not regularly cause TD but may even improve its symptoms. ^[2] If neurological impairment, disfigurement, or discomfort exists, treatment with the dopamine depleters reserpine or tetrabenazine should be considered. Noradrenergic antagonists (propranolol, clonidine), gamma-aminobutyric acid (GABA) agonists (clonazepam, diazepam, valproate, baclofen), botulinum toxin injections, and to a lesser degree, vitamin E, buspirone, and calcium channel blockers have been used with variable success. ^[1], ^[2]

Antidepressants

TRICYCLIC ANTIDEPRESSANTS

Tricyclic antidepressants (TCAs) act by blocking primarily norepinephrine or serotonin reuptake and also affect the cholinergic and histaminergic systems ([Table 55-3](#)). They have a narrow therapeutic index and can be associated with significant central nervous system (CNS) toxicity. Risk factors for CNS toxicity include plasma level, type of TCA, and concomitant administration of other psychotropic drugs. ^[1]

Sedation is a very common side effect of TCAs and is most prominent when drug therapy is initiated or when the dose is increased. Sleep in TCA-treated patients is associated with a decrease in rapid eye movement (REM) sleep and may result in a hangover. ^[1] Confusional states and delirium occur particularly in the elderly or in those treated with high doses, concomitant administration of neuroleptics or antiparkinsonian medications. Confusion also occurs especially with the use of TCAs with high anticholinergic activity (amitriptyline, imipramine). ^[1], ^[2] Anticholinergic effects of TCAs are also responsible for memory impairment, especially in the elderly. TCAs can exacerbate the naturally occurring tendency for depressed patients to become manic and are responsible for a rare but unusual difficulty

TABLE 55-3 -- ACTION OF TRICYCLIC ANTIDEPRESSANTS

+++ , significant; ++ , moderate; + , low, +/- , inconsistent.

in articulation that resembles stammer and has been called speech blockade. ^[1]

TCAs lower the seizure threshold and may be associated with an increased risk of seizures in individuals who have a history of epilepsy or who are predisposed to have seizures. For imipramine, the most frequently studied tricyclic, the literature indicates a seizure rate of between 0.3 and 0.6 percent at effective doses. In

general, seizures are observed after long-term treatment with high doses of TCAs or after a rapid increase in dose. [1]

A high-frequency postural and kinetic tremor may be present in as many as 10 percent of patients treated with imipramine. Myoclonus, akathisia, and choreoathetoid movements are additional rare side effects seen with TCAs. [1], [2]

TCAs are one of the most common causes of drug-related death in the United States. The signs and symptoms of TCA overdose are cardiovascular instability, CNS depression, and anticholinergic toxicity. TCA-induced drowsiness and coma can be reversed by the cholinergic agonist physostigmine. [2]

SELECTIVE SEROTONIN REUPTAKE INHIBITORS

The selective serotonin reuptake inhibitors (SSRIs) are potent and selective inhibitors of serotonin reuptake at the presynaptic terminal. They are considered first-line therapy for depression because of their prescribing ease and superior side effect and safety profile. SSRI-induced side effects are usually transient and rarely result in discontinuation of the medication. In addition, they appear to be safer than TCAs when an overdose occurs.

The major side effects of the SSRIs referring to the CNS include nausea, headache, dry mouth, insomnia and somnolence, agitation, nervousness, sweating, dizziness, tremor, and sexual dysfunction. [1] Fluoxetine is often associated with anxiety, nervousness, insomnia, and anorexia. Paroxetine, fluvoxamine, and nefazodone are associated with sedation. Sexual dysfunction manifests itself as ejaculatory delay in men and anorgasmia in women. There have been reports suggesting that fluoxetine can induce or exacerbate suicidal tendencies, and several mechanisms have been proposed. However, because suicide is an important feature of depression, it is difficult to draw conclusions, whereas on the other hand, it is difficult to exclude the possibility that suicidal ideation occurs as a rare adverse reaction with some drugs. [2]

SSRIs have been shown to inhibit the cytochrome P-450 system both in vitro and in vivo and, therefore, to result in increased levels of drugs that are substrates of cytochrome P-450 as well (i.e., TCAs). There has been debate over whether the combination of SSRIs and monoamine oxidase inhibitors (MAOIs) or TCAs can lead to the serotonin syndrome, characterized by hyperpyrexia, myoclonus, rigidity, hyperreflexia, shivering, confusion, agitation, restlessness, coma, autonomic instability, low-grade fever, nausea, diarrhea, diaphoresis, flushing, and rarely, rhabdomyolysis and death. [1] This occurrence is probably uncommon but should be watched for and immediately handled with supportive care and drug withdrawal if it occurs. Several case reports in the literature suggest that SSRIs can produce extrapyramidal symptoms in the form of akathisia, dyskinesia, acute dystonia, and deterioration in Parkinson's disease, but controlled clinical studies are needed to determine the validity of these observations.

MONOAMINE OXIDASE INHIBITORS

Monoamine oxidase is an intramitochondrial enzyme responsible for the breakdown of intracellular dopamine, norepinephrine, and serotonin. MAOIs inhibit monoamine oxidase, resulting in an increase in the concentration of monoamines in the synapse. Therefore, when patients taking MAOIs ingest vasoactive amines in foods and beverages (cheese, chocolate, pickled herring, chicken livers, caviar, broad beans, wine, beer), or take certain medications (amphetamines, ephedrine, reserpine, L-dopa, tryptophan), the vasoactive amines are not catabolized but enter the bloodstream and are taken up by the nerve terminals (Table 55-4). The result is a cataclysmic syndrome consisting of sudden severe headache, stiff neck, profuse sweating, mydriasis, neuromuscular irritability, extreme hypertension, and cardiac arrhythmias. The most effective treatment is phentolamine, or sodium nitroprusside, and for less severe cases, chlorpromazine. [1], [2], [3], [4] When MAOIs are taken in combination with TCAs in high doses or in overdose, or when MAOIs are taken with the narcotic analgesic meperidine, a severe condition of hyperpyrexia can occur. [5]

The MAOIs cause odd mixtures of sedation and stimulation. All three available drugs--tranylcypromine, phenelzine, and isocarboxazid--can cause insomnia, daytime sedation, aberrant changes in the sleep-wake cycle, and

1127

suppression of rapid eye movement sleep. In some patients, tranylcypromine can have amphetamine-like effects such as tremor and heightened locomotion activity about 1 hour after each dose, but it also causes sedation. This and other drugs in the group can produce mild euphoria as a prolonged effect. [7]

Other side effects include myoclonic jerks, paresthesias of the extremities, and sexual dysfunction.

LITHIUM CARBONATE

Lithium carbonate is indicated for the treatment of mania and for maintenance therapy in patients with a history of bipolar disorder. The majority of patients suffer side effects at therapeutic doses, although most patients classify them as mild. A fine postural or intentional tremor occurs in up to 80 percent of patients on lithium therapy. This side effect may resolve spontaneously, respond to a decrease in dose, or be treated with beta-adrenergic blockers. [1] Case reports have described choreiform movements or parkinsonism associated with lithium treatment.

Poor memory, loss of concentration, fatigue, muscle weakness, slowed reaction time, and lack of spontaneity are common during the course of treatment. These side effects cannot be consistently related to drug serum levels, duration of treatment, dose, age, or other variables. A toxic confusional state may occur in the absence of signs of toxicity and at relatively low serum lithium levels. This is characterized by disorientation, confusion, lack of continuity of thought, memory loss, lability of

mood, and reduced comprehension. The symptoms are preceded by a steady or precipitous rise in oral lithium dose, often within the first weeks of treatment, but may occur at serum lithium levels as low as 1.0 mEq/L. The condition usually remits within a few days following reduction or withdrawal of the dose. [1]

Lithium intoxication manifests itself with nausea, vomiting, diarrhea, tremor, drowsiness, ataxia, muscle twitching, and slurred speech. As intoxication advances, ataxia, alteration of the level of consciousness, and eventually, seizures and coma occur. Until recently, it was thought that patients who survived severe lithium intoxication suffered no permanent neurological damage. However, reports indicate that the basal ganglia and the cerebellum can be permanently damaged following lithium intoxication. [1]

Finally, lithium has been associated with syndromes similar to myasthenia gravis, NMS, lowering of the seizure threshold, pseudotumor cerebri, headaches, polyneuropathy, and downbeating nystagmus.

BENZODIAZEPINES

Benzodiazepines potentiate GABA action in the nervous system and act on the spinal cord as well as in many areas within the brain, including the cerebellum, the limbic system, and the cerebral cortex. Although the therapeutic index of benzodiazepines is 10 to 30 times that of the barbiturates and hence their absolute toxicity is less, adverse reactions are seven times more frequent with benzodiazepines. [1] This statistic apparently relates to the vast number of patients consuming these agents.

The most frequent toxic symptoms are increased drowsiness or paradoxical excitation. After large doses, exacerbation of depression and antisocial behavior have been reported. Withdrawal seizures can occur as well. Encompassing the range from subtle cognitive impairments to frank delirium, toxicity due to benzodiazepines is associated with impairment of immediate and delayed memory, psychomotor performance, and rebound insomnia.

Physiological dependence on benzodiazepines is accompanied by a withdrawal syndrome that is typically characterized by sleep disturbance, irritability, increased tension and anxiety, panic attacks, hand tremor, sweating, difficulty in concentration, nausea, weight loss, palpitations, headache, muscular pain, and stiffness. Factors that contribute to the development of withdrawal symptoms are primarily dose, duration, concurrent medication, and pharmacokinetics of individual drugs. The shorter-acting drugs can produce a more intense withdrawal syndrome following chronic administration. [10] No specific treatment exists for the withdrawal syndrome, which commonly lasts for up to 6 weeks, although tapering the benzodiazepine dose, sedative antidepressants, or the substitution of a longer-acting benzodiazepine may help.

Even short-term benzodiazepine use can lead to the development of tolerance, necessitating larger doses of drug to be administered.

ANESTHETICS

Inhalational General Anesthetics

HALOTHANE, ENFLURANE, ISOFLURANE, AND SEVOFLURANE

Halothane, a halogenated hydrocarbon, was first synthesized in 1951. It was introduced into clinical practice in 1956 in the United Kingdom and in 1958 in the United States. It quickly replaced the other volatile agents because

it was nonflammable, easy to administer, and relatively safe. Halothane, enflurane, isoflurane, and sevoflurane depress cerebral metabolism, with isoflurane having the greatest effect.^[11] Electrical activity of the cerebral cortex recorded by a fronto-occipital electroencephalogram (EEG) shows progressive replacement of fast, low-voltage activity by slow, high-amplitude waves as anesthesia gets deeper.^[12] Since cerebral blood flow generally increases during halothane anesthesia, cerebrospinal fluid (CSF) pressure increases. After several hours of anesthesia with halothane, the changes in cerebral blood flow and metabolism return to normal. Recovery of mental function after anesthesia with halothane is not complete for several hours.^[12]

Tonic-clonic activity and spike and wave EEG complexes have been reported with enflurane anesthesia. Deepening anesthesia and hyperventilation may exacerbate these phenomena. This excitatory action of enflurane does not appear to be associated with aggravation of seizures in epileptic patients; nevertheless, enflurane is best avoided in such patients.^{[11], [12]}

Rarely, the induction of anesthesia with halothane or any of the other halogenated inhalational anesthetics triggers an uncontrolled hypermetabolic reaction in the skeletal muscle of susceptible patients. There is defective uptake of Ca^{2+} by the sarcoplasmic reticulum resulting in elevation of intracellular free Ca^{2+} levels. The resultant syndrome of malignant hyperthermia has an incidence of 1 in 12,000 and a mortality rate of 24 percent.^[11] It is more common in men and children, in association with various myopathies, and in genetically susceptible individuals. The order in which available agents cause malignant hyperthermia is halothane, which is greater than enflurane, which, in turn, is greater than isoflurane. The concomitant use of suxamethonium and gallamine, neuroleptics, infection, stress, heat, and alcohol tend to increase the risk of malignant hyperthermia. Larach and colleagues demonstrated that generalized muscle rigidity that occurs as a result of an anesthetic is a valuable, but not absolute, predictor of a patient's susceptibility to malignant hyperthermia, its presence being associated with an 18-fold increase in risk of being susceptible, as determined by subsequent muscle biopsy testing.^[13]

Clinically, there is a rapid rise in body temperature, generalized muscular rigidity, high metabolic rate with increased oxygen consumption and carbon dioxide production, tachycardia, tachyarrhythmias, metabolic acidosis, and hyperkalemia. The most reliable method of diagnosis is by muscle biopsy and in vitro contracture tests with halothane and caffeine.^[12] Treatment consists of cessation of known triggering agents, supportive measures, and the administration of dantrolene.

NITROUS OXIDE

Nitrous oxide (N_2O), or so-called laughing gas, was first used as a dental anesthetic. Although when it is used by itself it produces a light level of anesthesia, when it is used to supplement more potent anesthetics, it reduces the dose requirements for those other agents. However, its euphorogenic properties, ready availability, and low cost have contributed to its popularity as a recreational gas. Human nitrous oxide toxicity is associated with its occupational, iatrogenic, and recreational use.

Nitrous oxide toxicity is due to inactivation of methionine synthase, a vitamin B_{12} -dependent enzyme, resulting in defective biosynthesis of DNA and myelin in nervous tissue. Monkeys exposed to 15 percent nitrous oxide develop the biochemical changes and neurological signs of vitamin B_{12} deficiency very rapidly. Morphologically, their spinal cords show degeneration of both the myelin sheaths and axis cylinders in the posterior columns and in the lateral and anterior corticospinal and spinocerebellar tracts.^[14]

Nitrous oxide is more likely to produce megaloblastosis or subacute combined degeneration-like clinical presentation when it is used repetitively or for periods longer than 3 hours or in individuals with vitamin B_{12} deficiency. Occupational exposure of medical and dental personnel during its use as an analgesic is not likely to produce adverse neurological effects except in vitamin B_{12} -deficient individuals or in those routinely exposed to high nitrous oxide levels.^[15] An epidemiological survey of over 30,000 dental personnel occupationally exposed to nitrous oxide found an incidence of neurological complaints of less than 2 percent in the population at risk.^[14] In the elderly, in whom subclinical vitamin B_{12} deficiency reportedly ranges from 7.3 to 21 percent, the frequency of neuropathic symptoms after anesthesia due to nitrous oxide may be underrecognized.^[16]

Clinically, nitrous oxide neuropathy presents with numbness, paresthesias, ataxia, and clumsiness in the extremities. Many but not all of the symptoms resolve with time if exposure is discontinued. With further exposure, weakness, gait disturbance, impotence, and loss of sphincter control can occur.^[14] Administration of folic acid or methionine have been shown to protect against megaloblastosis and neurotoxicity occurring following nitrous oxide administration.^[15]

Tension pneumocephalus can follow any intracranial neurosurgical procedure if nitrous oxide has been used. Following dural closure, the increase in volume due to nitrous oxide can result in pressure changes that may lead to seizures, brain stem herniation, and death. Discontinuing nitrous oxide at the time of dural closure can prevent tension pneumocephalus. Nitrous oxide can expand air emboli in the blood stream. In patients undergoing posterior fossae exploration in the sitting position, nitrous oxide increases the risk of air emboli and should be avoided.^[14]

Local Anesthetics

When they are applied locally, local anesthetics reversibly block the action potentials responsible for nerve conduction. The most commonly used local anesthetics are cocaine, lidocaine, bupivacaine, chloroprocaine, etidocaine, mepivacaine, prilocaine, ropivacaine, procaine, and tetracaine. Local anesthetics entering the systemic circulation produce adverse effects primarily on the CNS. Usually, when they are administered locally, they cannot reach sufficient systemic concentrations to interfere with the function of organs where conduction or transmission of impulses occurs.^[17] Nevertheless, when systemic absorption

occurs after topical use of local anesthetics, as is the case in children when tetracaine, adrenaline, and cocaine (TAC) is applied to mucous membranes, CNS toxicity has been described.^{[18], [19]}

The first sign of systemic toxicity following administration of local anesthetics is drowsiness, followed by tremor, restlessness, convulsions, and ultimately, CNS depression with respiratory failure.^[20] Lidocaine and cocaine can produce changes in mood and behavior. Finally, local anesthetics can affect neuromuscular transmission. This effect is due to blockade of the ion channel of the acetylcholine receptor.^[17]

Epidural and Spinal Anesthesia

Epidural anesthesia is administered by injecting local anesthetic into the epidural space and can be performed in the sacral hiatus or in the lumbar, thoracic, or cervical regions of the spine. Spinal anesthesia follows the injection of local anesthetic into the CSF in the lumbar space. Significant differences between epidural and spinal anesthesia are that the dose of local anesthetic used in epidural anesthesia can produce high concentrations in blood following absorption from the epidural space, and that there is no zone of differential sympathetic blockade with epidural anesthesia; thus the level of sympathetic block is close to the level of sensory block.^[17]

Probable causes of neurological complications following epidural and spinal anesthesia include trauma, the nature of the injected material, infection, vascular lesions, or pre-existing pathology. The incidence of transient paralysis following epidural anesthesia is 0.1 percent, and the incidence of permanent paralysis is 0.02 percent.^[21] Neurological sequelae after spinal anesthesia are rare as well. Neurological complications of spinal or epidural anesthesia tend to be more severe in the

presence of spinal stenosis.

During the administration of epidural anesthesia, damage to a single nerve can occur and is the most frequent complication. Paresthesia with or without motor weakness is the presenting symptom, and the majority of patients recover completely. Paraplegia, resulting from myelopathy or cauda equina syndrome, can occur secondary to epidural hematoma or abscess, adhesive arachnoiditis, or anterior spinal artery occlusion. An epidural hematoma or abscess should be suspected if severe backache appears in combination with weakness and hypoalgesia of the lower extremities. Signs and symptoms of extradural abscess may be delayed for several days until the abscess has developed. Adhesive arachnoiditis may result from inadvertent subarachnoid administration of toxic chemicals or chemical contamination of anesthetic solutions. Chemical contaminants such as detergents or antiseptics act as irritants and induce a meningeal reaction that may progress to constrictive adhesive arachnoiditis. Clinically, gradual progressive weakness and sensory loss of the lower extremities occurs beginning several weeks to months after the procedure. Precontrast and postcontrast magnetic resonance imaging (MRI) scans are usually sufficient to diagnose arachnoiditis. Spinal cord infarction is usually associated with prolonged arterial hypotension and can occur whether or not epinephrine was added to the local anesthetic. ^[21] ^[22] ^[23] Finally, dural puncture may cause severe and prolonged headache because of leakage of CSF into the extradural space. The incidence of dural puncture is about 1 percent. ^[22] Fortunately, most patients never develop a spinal headache or the problem resolves spontaneously in a few days. The use of an extradural injection of autologous blood (a so-called blood patch) is usually effective in treating spinal headaches.

The neurological syndromes that appear after spinal anesthesia are similar to the ones described following epidural anesthesia. The most benign is aseptic meningitis, characterized by high fever, headache, nuchal rigidity, and photophobia. Symptoms usually appear within 24 hours of spinal anesthesia, and recovery occurs spontaneously within several days to a week. ^[21] Cauda equina syndrome is characterized by urinary and fecal incontinence, localized sensory loss in the perineal area, and varying degrees of leg weakness. These symptoms are evident after the effect of anesthesia has worn off and may be permanent or may show gradual regression over weeks or months. Single nerve injury, lumbosacral polyradiculopathy, adhesive arachnoiditis, spinal cord ischemia, and postural headache can occur under circumstances similar to the ones described for epidural anesthesia.

Spinal anesthesia is sometimes regarded as contraindicated in patients with pre-existing disease of the spinal cord. Although there is no experimental evidence to support this hypothesis, it is prudent to avoid spinal anesthesia in patients with progressive diseases of the spinal cord. ^[17]

DRUGS USED TO TREAT MYASTHENIA GRAVIS

Cholinesterase Inhibitors

Cholinesterase inhibitors interfere with the hydrolysis of acetylcholine at the cholinergic synapses. Peripherally active agents have been the mainstay of myasthenic treatment until the advent of immunosuppressive therapy in the 1960s. Pyridostigmine bromide and neostigmine bromide are the most commonly used cholinesterase inhibitors. Pyridostigmine bromide is preferred because it has fewer gastrointestinal side effects and a longer duration of action.

Side effects of cholinesterase inhibitors result from overstimulation of the cholinergic system at the level of the muscarinic receptors of the smooth muscle, the nicotinic receptors of the skeletal muscle, the autonomic glands, and the CNS. Signs of cholinergic excess include nausea, abdominal cramps, excessive secretions, and bronchospasm. This syndrome is distinct from myasthenia gravis and is usually diagnosed accurately. However, because overstimulation can lead to subsequent depolarization blockade and enhanced weakness, exacerbation of myasthenia and cholinergic crisis can be dangerously confused. In situations in which there is a question of too much or too little cholinesterase inhibition, edrophonium (Tensilon) given in 1-mg increments may be helpful. More likely, however, admission to an intensive care unit for transient cessation of cholinesterase inhibition is needed to elucidate whether the dose should be raised or lowered.

It has been suggested that chronic administration of cholinesterase inhibitors may damage the neuromuscular junction. This concern is based in part on the chronic effects on the neuromuscular junction known to occur in animals after large doses of prostigmine and reported decrease in improvement after thymectomy when the use of cholinesterase inhibitors increased. Nevertheless, the latter was a retrospective review, and therefore, there is no evidence that would discourage the use of cholinesterase inhibitors to treat myasthenia gravis when needed. ^[24]

Glucocorticosteroids

Neurological side effects of glucocorticosteroids are well described and may be as serious as the diseases being treated. Neuropsychiatric disorders and myopathy are common. Most of the neurological sequelae are often related to dosage and duration of therapy and may be reversible by modification of the drug regimen. ^[25] Glucocorticosteroid use can be associated with a broad spectrum of neuropsychiatric disorders, ranging from emotional lability and anxiety to confusion, mood disorders, and psychosis. Behavioral symptoms usually begin within 5 to 14 days of starting steroids, but they may also occur during withdrawal of therapy. With the exception of multiple sclerosis, pre-existing neurological disease does not appear to increase the risk of steroid-induced mental status abnormalities. Alternate-day steroid therapy may decrease the overall incidence of behavioral changes, although it may rarely induce a cyclic behavior, with mania occurring on high-dose days and depression occurring on low-dose days.

Steroid myopathy is probably the most common drug-related disorder of muscle. There are two forms of myopathy: a common, well-known, chronic form involving type II fiber atrophy, and a rare acute form that occurs during treatment for status asthmaticus and may be associated with rhabdomyolysis. The exact incidence of the more typical chronic myopathy is uncertain, but in one series of patients with rheumatic disease, it was reported to be 7 percent. ^[25] The syndrome consists of insidious onset of painless, symmetrical proximal muscle weakness and atrophy, with the lower extremities involved first. Bulbar muscles are spared, but the diaphragm may be involved. The time of onset is variable, and the symptoms may begin from several weeks to several months after beginning treatment. The serum creatinine kinase is normal and electromyography (EMG) reveals short-duration, low-amplitude motor unit action potentials. Muscle biopsy shows type II atrophy, and electron microscopy reveals glycogen accumulation and enlarged mitochondria. Treatment consists of tapering and discontinuing the offending agent or substituting another steroid. The uncommon acute myopathy has been reported mainly in asthmatic patients who are receiving IV steroids, paralytic agents, and mechanical ventilation. The pathogenesis is unclear. ^[25]

Steroid-induced deposition of fat in the epidural space occurs in patients taking more than 40 mg of prednisone for at least 4 months. Most of these patients are already cushingoid when consequent neurological symptoms occur. The earliest and commonest feature is low back pain, and depending on the level of the lipomatosis, signs of myelopathy, cauda equina syndrome, or radiculopathy may develop. MRI can be a very useful diagnostic tool. Fat appears to be hyperintense on T₁-weighted images and less intense on T₂-weighted images, in contrast with inflammatory processes, which are brighter on T₂-weighted images. Unless it is contraindicated, laminectomy has been the treatment of choice. Further studies are needed to clarify the response to steroid tapering without surgical decompression before the onset of significant myelopathy. There have been isolated reports of corticosteroid-induced lipomatosis in the perineural spaces of peripheral nerves, leading to entrapment neuropathies. ^[25]

Increased intracranial pressure has been associated with steroid use, and the vast majority of cases involve male children. No particular dose has been implicated, but the duration of treatment is usually prolonged. Symptom onset generally occurs after discontinuation, tapering, or change in the type of steroid. Signs and symptoms are consistent with elevated intracranial pressure: headache, nausea, vomiting, papilledema, and diplopia with abducens nerve palsy. The disorder is usually self-limited. Patients have improved after changing the type or dose of steroids (using lower or higher dose) or lumbar puncture. ^[25]

Glucocorticosteroids have been reported to enhance physiological tremor. Propranolol can be useful in controlling this movement disorder if steroid withdrawal is not possible. Intrathecal administration of glucocorticosteroids can be associated with sterile meningitis, arachnoiditis, and pachymeningitis. Epidural steroids can have the same complications because the epidural and subarachnoid spaces are not totally separate but communicate via arachnoid villi and epidural veins. Additionally, inadvertent sub-arachnoid injections occur during about 2.5 percent of epidural attempts. ^[25]

Azathioprine

Side effects due to azathioprine (the nitroimidazole derivative of 6-mercaptopurine) can be classified as toxic (myelosuppression, hepatotoxicity) and idiosyncratic (fever, rigors, arthralgias, pneumonitis, and gastrointestinal symptoms). Although the toxic effects are due to 6-mercaptopurine, the hypersensitivity reactions are believed to be caused by the nitroimidazole moiety.

Azathioprine toxicity can occur during long-term treatment of myasthenia gravis. ^[26], ^[27] Among 104 treated patients with myasthenia gravis, side effects occurred in 35 percent and included, in decreasing frequency, hematological, 18 percent; gastrointestinal, 13 percent; infectious, 13 percent; and elevation of liver enzymes 6 percent. The medicine was discontinued temporarily in 11 percent of the patients. In five patients, a malignant tumor was diagnosed, but a causal relationship seemed likely in only one. ^[26] Neurological toxicity is rare with azathioprine. Two patients with recurrent meningitic reactions following azathioprine ingestion have been presented in the literature; they were being treated for lupus of the CNS. ^[28]

TABLE 55-5 -- CENTRAL NEUROTOXICITY OF ANTIBIOTICS

Cochlear/vestibular damage	Aminoglycosides Erythromycin Minocycline Vancomycin

Cyclosporine

Neurotoxicity is a well-recognized sequela of cyclosporine, and the most common complications are tremor and altered mental status. Cyclosporine neurotoxicity can occur in one in 10 patients after liver transplantation. Behavioral signs include acute psychosis, restlessness, wide mood swings with inappropriate crying and laughing, cortical blindness, visual hallucinations, stupor, and akinetic mutism. Additionally, seizures, extrapyramidal symptoms, action myoclonus, and quadriparesis have been reported. In patients with neurological signs, cyclosporine levels are usually outside the normal range, and after lowering the dose or withholding administration, neurotoxicity clears in most cases. MRI abnormalities are consistent with cortical or white matter high-signal changes and may relate to demyelination or edema.^[29] Although the mechanism of cyclosporine neurotoxicity has not been fully elucidated, one theory suggests that hypocholesterolemia may result in upregulation of the low-density lipoprotein receptors, which increases intracellular transport of cyclosporine. Access may be particularly high in the white matter with a relatively high density of low-density lipoprotein receptors. Another theory implicates endothelin, a potent vasoconstrictive neuropeptide, in combination with breakdown of the blood-brain barrier, resulting in local ischemia. Other possible etiological mechanisms of cyclosporine neurotoxicity include hypomagnesemia, hypertension, aluminum overload, and high-dose methylprednisolone administration.^[29] Both the clinical manifestations and the neuro-imaging abnormalities of cyclosporine neurotoxicity usually resolve with a reduction or discontinuation of cyclosporine.^[29]

ANTIBIOTICS (Tables 55-5 and 55-6)

Antibacterial Agents

PENICILLINS, CEPHALOSPORINS, AND IMPENEM

Historically, radiculitis, paraplegia, hemiplegia, and convulsions occurred after penicillin was administered into the CSF, but because this route of administration has been abandoned, such reactions are exceedingly rare. The neurotoxic clinical manifestations of penicillins, cephalosporins, and imipenem include myoclonus, seizures, confusion, hallucinations, encephalopathy, nystagmus, and agitation. Imipenem, cefazolin, and benzyl penicillin are the most epileptogenic.^[31] These drugs antagonize the inhibitory neurotransmitter GABA. Risk factors for neurotoxicity are high-dose intravenous use (e.g., greater than 30 to 40 million units of benzyl penicillin per day), decreased renal function, abnormal blood-brain barrier, cardiopulmonary bypass, age more than 50 years, pre-existing disease of the CNS, concurrent use of drugs that may lower the seizure threshold (such as theophylline or ciprofloxacin), and concomitant use of nephrotoxic drugs. Blockade of a system for transporting the beta lactams out of the CSF in diseases causing meningeal inflammation adds to the risk of increased meningeal antibiotic penetration during inflammation.

Penicillin gluteal injection may cause sudden and irreversible paraplegia. The actual incidence of such a complication is not known, but there have been eight cases reported in the literature. The proposed mechanism is accidental injection intra-arterially, causing distal spasm and the upstream ascent of penicillin with ensuing embolic or spastic occlusion, or both, of the anterior spinal artery. Treatment of this complication is unsatisfactory, but it can be prevented by giving injections in the lateral thigh^[32]

Penicillins and cephalosporins have also been reported to cause recurrent aseptic meningitis.^[33] Ampicillin has been reported to aggravate weakness in myasthenia gravis. Intrathecal beta lactams have the potential to cause adhesive arachnoiditis.^[31]

Gentamicin	+	++	++
Tobramycin	+	+	+
Amikacin	++	+	++
Netilmicin	++	+	+++

+++ , very common; ++, moderately common; +, rare.

AMINOGLYCOSIDES

The toxicity of all aminoglycosides is similar--mainly ototoxicity and neuromuscular blockade (Table 55-7). Acute ototoxicity is based on calcium antagonism and blockade of ion channels, and chronic mechanisms are related to tissue-specific toxicity of a noxious metabolite. The frequency of ototoxicity ranges from 2 to 4 percent in retrospective studies and up to 25 percent in studies with specialized testing. The incidence and severity of damage appear to increase with patient age, total drug dose, and concomitant use of other ototoxic drugs.^[34] Auditory toxicity is more common with the use of amikacin and kanamycin, whereas vestibular toxicity predominates following gentamicin and streptomycin therapy. Tobramycin is associated equally with vestibular and auditory damage. Cochlear toxicity is more often silent, as the hearing loss first affects the high frequencies (greater than 4000 Hz) before involving the speech frequencies. Cochlear toxicity presents clinically as deafness, tinnitus, and ear pain, whereas vestibular toxicity presents as ataxia, dizziness, vertigo, chronic sense of imbalance, nystagmus, or oscillopsia.^[31] Routine audiometry or studies of auditory brainstem evoked responses can be used to monitor ototoxicity. Monitoring vestibular toxicity is complex and needs even more specialized testing.^[31] Aminoglycoside hearing loss is usually irreversible and may even progress following discontinuation of drug therapy.^[34] Careful monitoring of peak and trough levels, especially in high-risk groups, helps prevent toxicity.

A potentially fatal neurotoxic effect of all aminoglycosides is neuromuscular blockade, due in part to a curare-like effect of the aminoglycosides and also to a competition with calcium by these antibiotics. This side effect is related to dose and serum level. Aminoglycosides are relatively contraindicated in both presynaptic (e.g., botulism) and postsynaptic (e.g., myasthenia gravis) disorders of neuromuscular transmission.^[31] They may further potentiate ether and other drugs used to induce muscular relaxation during anesthesia. Neomycin and netilmicin are the most toxic, and tobramycin and kanamycin are the least toxic. Sudden or prolonged respiratory paralysis due to aminoglycosides may be reversed by calcium infusion, cholinesterase inhibitors, and aminopyridines.^[31]

SULFONAMIDES

Sulfonamides inhibit the synthesis of tetrahydrofolic acid, the one-carbon donor needed for the synthesis of methionine, serine, and purines. Although they are

associated with low incidence of neurotoxicity, a variety of adverse reactions can occur during therapy. ^[1] Recurrent aseptic meningitis is a well-recognized side effect of sulfonamide therapy, more specifically trimethoprim-sulfamethoxazole, and presents clinically with episodes of headache, nuchal rigidity, confusion, and myalgias. CSF analysis may show low glucose levels with or without pleocytosis; however, this study is not a reliable method to differentiate antibiotic-induced meningitis from partially treated bacterial meningitis. ^[33]

In addition, headache, fatigue, tinnitus, generalized convulsions, optic neuritis, agraphia, aphasia, stammering, teleopsia, macropsia, polyneuritis, and myelopathy can occur with sulfonamides. Euphoria, nausea, vomiting, somnolence, poor concentration, and impairment of judgment may be observed on the second or third day of treatment. The pathophysiology of the neurotoxic signs may relate to a drug-induced hypersensitivity reaction, because they often occur in the context of serum sickness or drug-induced vasculitis. Pathologically, a variety of lesions have been reported in fatal cases, including focal necrosis and demyelination of the cerebral white matter, hypothalamus, and pons, as well as hemorrhages in the fourth ventricle, brain stem, cerebral gray matter, and nuclear structures. ^[1], ^[31], ^[35]

QUINOLONES

Seizures have been reported with ciprofloxacin as well as other quinolones, and the use of nalidixic acid, the first clinically useful quinolone, is contraindicated in patients with a history of epilepsy. In vitro studies suggest that the epileptogenic effect of the quinolones may be due to inhibition of GABA binding to its receptor site in the brain. This effect seems to be related to quinolone concentrations at the receptor site (dose related) and to particular substituents in quinolone structure. Simultaneous use of theophylline or nonsteroidal anti-inflammatory drugs may increase the risk for quinolone-associated toxic effects on the CNS, as the combination has an additive inhibitory effect on GABA sites. ^[36]

CNS side effects are seen in 1 to 4 percent of patients but are usually minor, including dizziness or mild headache. Quinolones have been reported to cause tremor, restlessness, hallucinations, delirium, psychosis, and benign intracranial hypertension, especially in high-dose therapy. ^[36] Especially in cases of renal impairment, the dose should be carefully monitored to avoid CNS toxicity.

METRONIDAZOLE

Metronidazole, a nitroimidazole derivative, is used for anaerobic and protozoal infections, as well as for the treatment of Crohn's disease. It is generally well tolerated, but it is associated with minor, transient adverse side effects. However, peripheral neuropathy is a potentially serious effect associated with the use of metronidazole. The mechanism of metronidazole peripheral neuropathy is undetermined, but the drug binds to the RNA of rat nerve cells, which may diminish protein synthesis and lead to subsequent nerve degeneration.

113

Neuropathy is particularly prevalent in patients who receive more than 2 g/day, a total dose of 50 g or more, and a treatment duration of at least 30 days. In long-term administration, 10 to 50 percent of patients develop a sensory neuropathy that is predominantly distal and symmetrical. Sensory deficits are prominent, with the sural and peroneal nerves most often affected. ^[35] The paresthesias and discomfort associated with metronidazole neuropathy usually improve when metronidazole is discontinued or the dose is decreased. Symptoms gradually subside within 4 to 48 months following drug cessation. Rarely, neuropathic symptoms persist for an extended duration, worsen, or are irreversible. ^[35] These atypical clinical courses may be related to metronidazole-induced nerve degeneration.

Metronidazole has rarely been associated with seizures in humans. It is believed that the total cumulative dose of metronidazole is more closely associated with seizure potential than the serum level. ^[37] Confusion, irritability, depression, headache, optic neuropathy, and aseptic meningitis have been reported as drug complications. ^[35] These rare complications can be associated with large doses or prolonged administration, and they disappear rapidly with cessation of the drug.

ERYTHROMYCIN AND NEWER MACROLIDES

Macrolides are among the safest anti-infective drugs in clinical use. An uncommon neurological side effect is temporary hearing loss. Whereas erythromycin-induced hypoacusis is a dose-dependent effect, its occurrence in patients otherwise free from predisposing factors suggests that it is idiosyncratic. ^[38] Usually, this reaction has occurred during treatment with 4 g or more of the lactonate derivative of oral erythromycin. Because erythromycin is metabolized by the liver, patients with hepatic abnormalities may be at higher risk for this ototoxic reaction. Tinnitus rather than a distinct difficulty hearing is the usual complaint. ^[1] This adverse reaction is reversible with dose reduction or discontinuation, and in patients with impaired renal or liver function, a lower prescribed daily dose may prevent or reduce its development. The new macrolides azithromycin and clarithromycin have not been found to cause ototoxicity. ^[31]

Erythromycin interacts with carbamazepine, causing carbamazepine levels to increase rapidly when erythromycin is introduced. Careful monitoring of the carbamazepine blood level and clinical symptoms of toxicity should be performed in patients receiving both drugs. Worsening of weakness in patients with myasthenia gravis, through a possible presynaptic mechanism, is generally mild, although respiratory failure may be precipitated. ^[31]

TETRACYCLINES

Vestibular toxicity has been reported in approximately 50 percent of patients receiving minocycline, a tetracycline derivative. Toxicity is more common in women, and the incidence is estimated to be at 70 percent. Although vestibular toxicity is more likely in patients with pre-existing vestibular disease, many patients have no such history. The symptoms begin a few days after the initiation of treatment and consist of lightheadedness, dizziness, loss of balance, nausea, and extreme vertigo. The reaction is transient, and even in the most severe cases, it resolves within few days. ^[36], ^[39]

Pseudotumor cerebri occurs in both adults and infants taking tetracyclines, but infants are more susceptible. The syndrome is characterized by headache, papilledema, elevated CSF pressure, and bulging fontanels in infants. Signs and symptoms disappear within a few days after drug discontinuation, although papilledema may persist for weeks. ^[35], ^[39] The intravenous administration of tetracyclines has rarely been reported to exacerbate myasthenia. This may be the result of magnesium in the diluent, binding of calcium by non-protein-bound tetracycline, or direct action at the neuromuscular junction. ^[31]

NITROFURANTOIN

Nitrofurantoin therapy has been associated with polyneuropathy. Generally seen with prolonged therapy, neuropathy can occur as early as the first week of treatment. It is usually subacute, begins in the distal extremities with paresthesias, and tends to ascend progressively to involve the motor system with weakness and areflexia. Although this polyneuropathy clinically resembles Guillain-Barre syndrome, the spinal fluid is usually normal, except for 25 percent of patients, in whom there is a slight increase in protein without pleocytosis. When neuropathy is recognized, drug withdrawal is essential, although 10 to 15 percent of patients do not improve, and 15 percent have only partial recovery. The prognosis appears to relate to the extent of the neuropathy at the time of drug withdrawal but not to the total dose exposure or the duration of therapy. ^[1], ^[35]

Antituberculous Drugs

ISONIAZID

Isoniazid inhibits the phosphorylation of pyridoxine and chelates whatever pyridoxal phosphate remains. Because pyridoxal phosphate is a co-factor that is important to the GABA system, it has been hypothesized that the centrally diminished GABA activity may relate to the pathophysiology of isoniazid-induced seizures. In chronic toxicity, isoniazid predominantly inhibits the phosphorylation of pyridoxine to induce a peripheral neuropathy. ^[1]

The incidence of pyridoxine-associated polyneuropathy is 0.2 to 2 percent, and the clinical features include numbness and tingling of the feet with diminished or absent deep tendon reflexes and occasional optic neuropathy. Isoniazid-associated neuropathy can be prevented by concomitant administration of pyridoxine, 50 mg/day. ^[31] In patients not receiving pyridoxine, high-risk groups for neuropathy include slow acetylators, adults, alcoholics, malnourished individuals, and those receiving more than 5 mg/kg/day.

Acute isoniazid intoxication due to overdosage is associated with generalized seizures, ataxia, psychosis, and coma. Metabolic acidosis, hyperglycemia, and aciduria may accompany

the acute neurological syndrome. Pyridoxine should be administered immediately, along with standard anticonvulsant and supportive measures. Because seizures are a complication of isoniazid therapy, the drug is not recommended for patients with pre-existing seizure disorder if another drug can be chosen. When isoniazid is required in patients who are already receiving phenytoin, the phenytoin dose has to be adjusted because isoniazid decreases its clearance. ^[1], ^[31]

More unusual isoniazid-related neurotoxic syndromes include drug-induced lupus with meningitis, psychosis, obsessive-compulsive disorder, and acute mania.

RIFAMPIN

Rifampin may induce an encephalopathy with features suggestive of a psychosis. Other rare adverse reactions are dizziness, headache, drowsiness, confusion, inability to concentrate, and ataxia. ^[31] Rarely, paresthesias and pain suggestive of peripheral neuropathy are reported. ^[35]

ETHAMBUTOL

Optic neuropathy has been associated with ethambutol treatment. This appears to be a demyelinating process, and the reason for the optic nerve's sensitivity to this drug is unknown. Symptoms are seen in as many as a third of patients taking doses of 35 mg/kg/day for 6 months. Doses of 25 mg/kg/day are safe for not more than 2 months, and the safe maintenance dose is 15 mg/kg/day. Toxicity is manifested by impairment of visual acuity, loss of color discrimination, constricted visual fields, and central and peripheral scotomata. The drug should be stopped at the first sign of visual change, and recovery can be anticipated, although it may take weeks to months. ^[40] Other side effects include mild peripheral neuropathy and a metallic taste in the oral cavity. ^[35]

Antifungal Drugs

AMPHOTERICIN B

Encephalopathy, occasionally with parkinsonian features, can be associated with intravenous administration of amphotericin B. Autopsy examination of afflicted patients discloses diffuse noninflammatory degeneration of the white matter, characterized by demyelination and infiltration by foamy macrophages. The leukotoxic effect of amphotericin B is related to its binding to myelin and an increase in membrane permeability, resulting in leakage of intracellular components. ^[41] Clinically, the patients develop a subacutely evolving neurological disorder characterized by personality change and confusion, rapidly progressing to akinetic mutism. Neuroimaging studies disclose diffuse nonenhancing lesions of the cerebral white matter that include hypodensity on computed tomography (CT) and increased signal on T₂-weighted MRI. Amphotericin-associated leukoencephalopathy can be fatal, although there have been cases of slow recovery after discontinuation of the drug.

POLYMYXIN B

The incidence of neurotoxicity from parenteral polymyxin B averages 7 percent. Polymyxin has both presynaptic and postsynaptic effects, and it can worsen neuromuscular weakness, leading to respiratory failure, particularly in patients with renal failure or in combination with other drugs known to block neuromuscular transmission. ^[31] The various adverse effects of polymyxins include paresthesias, peripheral neuropathy, diplopia, dysphagia, ototoxicity, muscle weakness, dizziness, ataxia, seizures, and confusion. ^[1], ^[31]

Antimalarials

CHLOROQUINE

Chloroquine, once considered too toxic for humans, has been the antimalarial of choice for 40 years. Although a range of serious CNS effects has been documented during chloroquine therapy, the incidence is unclear. ^[42] Abnormal involuntary movements including torticollis, blepharospasm, and dystonic tongue protrusion have been reported during chloroquine therapy, especially in patients younger than 30 years of age. ^[1] Headache, nausea, and tinnitus with progressive hearing loss, optic nerve dysfunction, seizures, psychosis, mania, and myasthenic syndrome have also been reported.

When used chronically, as in rheumatoid arthritis, chloroquine has been implicated in the development of peripheral neuropathy, cranial nerve palsies, and myopathy. The peripheral neuropathy is a distal sensorimotor polyneuropathy that is reversible after drug withdrawal. ^[1]

ANTINEOPLASTIC CHEMOTHERAPY ([Table 55-8](#))

Alkylating Agents

NITROGEN MUSTARD MECHLORETHAMINE

Nitrogen mustard (NM) administered intravenously in a dose of 0.4 mg/kg is not usually associated with neurotoxicity. Hemiplegia, coma, chills, and fever, with increased intracranial pressure and CSF pleocytosis, however, were reported in one patient 7 days after each of two standard intravenous doses of NM (0.4 mg/kg).^[43] On both occasions the signs and symptoms subsided after therapeutic measures to decrease intracranial pressure. When the patient died four years later, from unrelated reasons, a gross and microscopical examination of the brain revealed focal areas of gliosis with loss of neurons. Massive intravenous injections of NM have caused hearing loss, and vertigo, presumably from damage to the eighth cranial nerve, seizures, somnolence, and confusion.^[44] Intracarotid NM injection has been associated with hemiplegia, seizures, coma, and death.^[45] One pathological study showed diffuse cerebral edema, which was greater on the side of the injection, and

extensive gliosis and demyelination, presumably from a previous injection.^[4]

CYCLOPHOSPHAMIDE

One of the most widely used alkylating agents, cyclophosphamide, is associated with very little neurological toxicity. Rapid intravenous infusion of cyclophosphamide has been associated with facial or scalp burning, oropharyngeal tingling, nasal congestion, rhinorrhea, sneezing, and lacrimation. These uncomfortable sensations of the skin and mucous membranes occur more frequently than was previously noted, and changing infusion duration or the concentration of cyclophosphamide, or administering anticholinergics intranasally, can result in variable degrees of improvement.^[49]

Inappropriate secretion of antidiuretic hormone has occurred rarely and is exacerbated by the high fluid loading required in high-dose cyclophosphamide therapy to prevent renal toxicity. Biopsy-proven progressive multifocal leukoencephalopathy (PML) has been described in a man treated with cyclophosphamide and prednisone for Wegener's granulomatosis. On discontinuation of immunosuppression, dramatic recovery took place.^[46]

CHLORAMBUCIL

Seizures have rarely been reported with chlorambucil administration. They occur almost exclusively in children, in the setting of overdosage or nephrotic syndrome. They consist of myoclonic seizures followed by generalized tonic clonic seizures. The EEG can show paroxysmal discharges that continue for several days after seizure activity.^[4] Although the drug is generally considered to be non-neurotoxic, acute CNS abnormalities consisting of lethargy, ataxia, seizures, and coma have been reported with overdose.^[44] Progressive multifocal leukoencephalopathy has occurred in a patient with rheumatoid arthritis after treatment with chlorambucil. Of interest is that progressive multifocal leukoencephalopathy can develop as a late complication, even after the medicine is stopped.^[47]

THIOTEPA

Owing to its low neurotoxicity, thiotepa, an intravenously administered alkylating agent, is one of the few anticancer drugs that can be injected into the CSF. In one series of 10 patients with meningeal leukemia and carcinomatosis treated with multiple courses of intrathecal thiotepa, clinical neurotoxicity developed in only two.^[4] This neurotoxicity consisted of progressive myelopathy, manifested as progressive lower extremity weakness, back and leg pain, areflexia, and sensory deficits. EMG revealed diffuse lower motor neuron abnormalities. The histopathological changes in the spinal cord were localized to the white matter and consisted of demyelination and gliosis of the posterior columns and the nerve roots of the cauda equina.^[48]

BUSULFAN

Generalized seizures are a frequent side effect of high-dose busulfan (total dose 16 mg/kg) as part of a preparative regimen for allogeneic bone marrow transplantation. No neurological deficits are found after the episodes, and there are no recurrences. Maintenance of therapeutic blood concentrations of anticonvulsant prophylactic regimens is recommended.^[49] There has been one case of busulfan administration associated with the development of myasthenia gravis, although the relationship among the myasthenia, the busulfan, and the leukemia was not clarified.^[4]

Antimetabolites

METHOTREXATE

Methotrexate is a competitive inhibitor of dihydrofolate reductase, acting primarily during DNA synthesis (S-phase) as an antifolate antineoplastic drug. It prevents two primary reactions, the conversion of folic acid to tetrahydrofolic acid and the conversion of tetrahydrofolic acid to folinic acid, therefore blocking DNA, RNA, and protein synthesis by limiting the availability of reduced folates. [1], [44], [50] As an oral or intravenous drug in the usual prescribed doses, methotrexate is a neurologically safe agent. It has limited ability to cross the blood-brain barrier, and the CSF concentration is less than 10 percent of that in plasma after oral or parenteral administration. When given intrathecally or in higher doses, however, methotrexate is associated with a number of neurological syndromes. Proposed mechanisms of methotrexate neurotoxicity include depletion of cerebral reduced folates, reduced cerebral protein, altered blood-brain barrier permeability, and impaired neurotransmitter synthesis. [44] The risk of neurotoxicity is increased with increasing total intrathecal methotrexate dose, prolonged elevated CSF methotrexate levels, concurrent radiation therapy, or systemic high-dose methotrexate therapy. Toxicity is also more frequent and severe in younger patients

1196

and when methotrexate is used as treatment for meningeal tumor rather than for prophylaxis. [44]

Acute methotrexate neurotoxicity includes an acute chemical meningitis with fever, headache, nuchal rigidity, and CSF leukocytosis. This condition is usually mild to moderate; begins within hours of intrathecal administration; lasts for 1 to 3 days, although it may persist for 2 weeks; resolves spontaneously; and does not recur with subsequent therapy. [1], [44], [50] An acute stroke-like encephalopathy with seizures, confusion, hemiparesis, and coma may complicate high-dose methotrexate (more than 1 g/m²) in as many as 15 percent of patients. [44] Other acute complications that occur within hours of intrathecal administration are acute transverse myelopathy with paraplegia, which may be permanent, and transient radiculopathies, possibly related to epidural or subdural injection, or the development of hematomas. [44], [50] Accidental intrathecal methotrexate overdose may produce an ascending myelopathy and necrotizing leukoencephalopathy. [44] Doses of 50 mg or less probably produce few serious sequelae. A moderate overdose (50 to 100 mg) without early CSF drainage may produce an acute chemical meningitis. Massive overdose (more than 500 mg) causes myelopathy and encephalopathy, which may be fatal. Intensive systemic support, high-dose leucovorin, and alkaline diuresis, plus rapid CSF drainage and ventriculolumbar perfusion, may permit survival and recovery of neurological function.

Delayed neurotoxicity from repeated intrathecal or intraventricular methotrexate is more frequent than acute intoxication, and encephalopathy is the most important late effect. Pathologically, this is a leukoencephalopathy, with areas of coagulative necrosis, demyelination, and mineralizing microangiopathy. Clinically, it is characterized by progressive personality and intellectual decline, dementia, hemiparesis, and sometimes seizures. MRI and CT usually show extensive, patchy white matter lesions. The long-term effects of the treatment (or prophylaxis) of childhood leukemia and brain tumor include behavioral changes, poor school performance, memory loss, intellectual decline, growth retardation, hormonal disturbances, and abnormal CT scans. Although radiotherapy may account for many of these complications, intrathecal methotrexate alone may produce intellectual and behavioral problems or exacerbate those produced by radiotherapy. [44]

5-FLUOROURACIL

5-Fluorouracil is a fluorine-substituted analog of the pyrimidine uracil. It inhibits the enzyme thymidylate synthetase, blocking DNA synthesis by reducing thymidine monophosphate formation. It is associated with a characteristic cerebellar syndrome in 1 percent of patients when the recommended doses are used. When doses exceed the usual recommendations, the incidence of this cerebellar syndrome may be as high as 3 to 7 percent. The mechanism of 5-fluorouracil neurotoxicity is unknown, but its conversion to fluocitrate and fluoacetate in the CNS with subsequent inhibition of the Krebs cycle has been postulated. [44], [50], [51] Concomitant administration of alpha-interferon, cisplatin, leucovorin, or thymidine potentiates the toxic effects. [44]

Clinically, 5-fluorouracil induces pancerebellar dysfunction, characterized by the acute or subacute onset of gait ataxia, limb incoordination, dysarthria, nystagmus, and, sometimes, diplopia. The symptoms are usually controlled by dose reduction or increase in intervals between treatments. Although the syndrome is reversible, cases of re-emergence after subsequent treatment have been reported. [44], [50], [51]

Other neurotoxic reactions associated with 5-fluorouracil include encephalopathy, as well as a parkinsonian syndrome in 40 percent of patients. [51] The encephalopathy is usually mild to moderate but can range from lethargy to coma with high-dose infusions. All of the neurological symptoms associated with 5-fluorouracil are usually reversible on cessation of the drug, and no pathological changes have been noted in the brain at postmortem examination. [51]

CYTOSINE ARABINOSIDE (CYTARABINE)

Cytosine arabinoside is an analog of pyrimidine nucleosides and readily crosses the blood-brain barrier. The drug destroys proliferating cells as an S-phase-specific cytotoxic agent. In many animals, in which cellular proliferation is active in the external granular layer of the cerebellum, cytosine arabinoside selectively destroys this layer and causes disarrangement and abnormal arborization of the Purkinje cells. [52]

Although the drug has little neurotoxicity following usual intravenous doses, in high doses it can cause an acute cerebellar syndrome in up to 14 percent and less commonly seizures and encephalopathy. When given intrathecally, it may result in myelopathy or cauda equina syndrome that is incompletely reversible. Combined intrathecal cytarabine and cranial irradiation may lead to necrotizing encephalopathy. Intravenous therapy may cause a peripheral neuropathy. [52] The incidence and severity of neurotoxicity increases with increasing dose (more than 18 g/m²/course), increasing age (being rare in patients younger than 20 years of age, occurring in 3 percent of those from 20 to 50 years of age, and in 19 percent of those older than 50 years of age), and following subsequent rather than initial courses. [44] Symptoms of neurotoxicity typically begin 6 to 8 days after the initiation of cytosine arabinoside with nystagmus and ataxia, peak over the following 2 to 3 days (confusion, somnolence, ataxia, dysarthria, and sometimes seizures or coma), start to improve within 1 week, and resolve completely within 2 weeks in most patients. [44] Cerebellar atrophy may be seen on CT or MRI, and pathological changes are remarkable for Purkinje cell loss, reactive Bergmann's gliosis, and occasionally, demyelination.

Natural Products

VINCA ALKALOIDS

Vincristine and vinblastine are alkaloid derivatives of the periwinkle plant, whose major and dose-limiting toxicity is neurological. The mechanism of action of these agents is probably related to inhibition of microtubule formation in the mitotic spindle, resulting in an arrest of dividing cells at the metaphase stage. Peripheral neuropathy is almost

1197

universal in patients receiving these drugs, and neurotoxicity is attributed to the inhibition of axoplasmic transport by their effect on axonal microtubules. [43], [44] Patients with pre-existing neuropathy (diabetic, familial, compressive, or nutritional) may have more severe neuropathy. Generally, the longer the exposure, the more numerous and severe the neuropathic side effects.

The earliest and most consistent objective manifestation of vincristine neurotoxicity is suppression of the Achilles tendon reflex. This is followed rapidly by losses of other reflexes, distal symmetrical sensory loss (pin and temperature more than vibration and proprioception), weakness, footdrop, and muscle atrophy. Autonomic neuropathy with constipation, ileus, urinary retention, impotence, or postural hypotension may occur. Cranial neuropathy occurs, usually involving the oculomotor nerve, often causing bilateral ptosis. Affected nerves include the abducens, trigeminal, facial, and recurrent laryngeal nerves, the latter resulting in hoarseness or stridor. Nerve conduction velocities are normal, because the process is an axonopathy. [1], [43], [44], [51] A painful myopathy may occur in children. Vincristine does not cross the blood-brain barrier, so CNS toxicity is rare, although seizures may develop as a result of inappropriate secretion of antidiuretic hormone. [51] Vinblastine has similar neurotoxic reactions but only at doses that are usually not prescribed because of concomitant severe hematological reactions. [51]

L-ASPARAGINASE

L-Asparaginase is an enzyme that hydrolyzes asparagine to aspartic acid and ammonia, depleting asparagine and inhibiting protein synthesis. When it was first

introduced, the drug was used at high doses that produced an acute encephalopathy that proved to be dose limiting. At usually prescribed doses, the encephalopathy is not seen.^[51]

Because L-asparaginase inhibits protein synthesis, plasma protein deficits occur, including those involved in coagulation and fibrinolysis. Decreased levels of fibrinogen, factor IX, factor XI, plasminogen, antithrombin III, protein C, protein S, alpha₂-antiplasmin, histidine-rich glycoprotein, and alpha₂-macroglobulin also occur.^[52] L-Asparaginase has been linked to hemorrhagic and thrombotic cerebrovascular complications, including cortical infarction, capsular infarction, intracerebral hemorrhage, hemorrhagic infarction, and cerebral venous and dural sinus thrombosis. During treatment, progressive prolongations in PT, PTT, and thrombin time are seen. In patients who have had complications resulting from L-asparaginase and who require further treatment, therapy to prevent subsequent complications is controversial. Fresh frozen plasma alone or with low-dose heparin or antithrombin III has been proposed.^[53] Because fresh frozen plasma lessens the decrease in coagulation proteins normally seen with L-asparaginase, it is a reasonable treatment for patients with thromboembolic complications from the medicine.

Antibiotic Antineoplastic Agents

BLEOMYCIN

The existence of pure bleomycin toxicity has not been established, because the drug is ordinarily used in conjunction with other chemotherapeutic agents. Mental status changes and peripheral neuropathy have been reported with bleomycin therapy, although no pathological changes have been associated in brain or peripheral nerves in such patients. In animals, cochlear damage has been demonstrated, although there is no comparable clinical evidence in humans.^[1]

ADRIAMYCIN AND ACTINOMYCIN D

Adriamycin and actinomycin D produce no neurological side effects in humans in the usually prescribed doses, and when administered systemically, the drugs do not enter the CSF. Adriamycin can produce a severe form of myelopathy and encephalopathy after accidental intrathecal injection. Experimentally, it can produce cerebral damage after intracarotid injection, and anterior horn cell loss after direct injection into a peripheral nerve.^[44]

Actinomycin D causes tremors, myoclonus, seizure, ascending myelopathy, and encephalopathy when it is injected into the CSF in animal models. In pathological studies, demyelination and necrosis have been found in the brain.^[1]

Other Chemotherapeutic Agents

NITROSOUREAS

The nitrosoureas include BCNU (carmustine), CCNU (lomustine), methyl-CCNU (semustine), PCNU, and ACNU. As alkylating agents, they bind DNA, produce interstrand and intrastrand cross-links and carbamoylated proteins. They readily cross the blood-brain barrier and have little or no neurotoxicity at the usual dose regimens used (BCNU IV 200 mg/m² or 80 mg/m²/day for 3 days). Encephalopathy with confusion and seizures may follow high doses of the drug (BCNU IV 600 to 800 mg/m² or more).^[44] Several patients developed multifocal neurological abnormalities 3 to 12 weeks following high doses of BCNU (1500 to 3000 mg) followed by autologous bone marrow transplantation to rescue the bone marrow from the drug toxicity. Postmortem examination revealed foci of coagulative necrosis.^[51] Intracarotid BCNU (usually 100 to 200 mg/m²) can produce severe local pain in the ipsilateral face, eye, and head during infusion and, sometimes, retinopathy, blindness, or ocular necrosis. Intracarotid infusions above the ophthalmic artery may prevent ocular toxicity. A severe ipsilateral encephalopathy with seizures, hemiparesis, progressive neurological deficits, and cerebral necrosis (pathologically similar to radiation necrosis) has been described following intracarotid BCNU administration.^[44] Concurrent cranial radiotherapy and intracarotid BCNU may increase the risk of neurotoxicity.

CISPLATIN

Cisplatin most likely acts by binding to DNA, forming intrastrand and interstrand cross-links. Cisplatin neurotoxicity is common and dose limiting. Ototoxicity is a dose-limiting complication, occurring most commonly at doses

118

of 120 mg/m² or more. Direct toxicity of the drug on the organ of Corti appears to be the cause of the induced deafness, because nystagmus and vertigo have rarely been reported. Deafness is more common in elderly patients and is exacerbated by radiation therapy to the head. The patient cannot hear high-frequency sounds; the hearing loss is bilateral and largely reversible, but it can be permanent. Deafness often begins within 3 to 4 days of the initial treatment and slowly improves over the succeeding weeks after treatment is stopped. The combination of slow infusion and pretreatment with intravenous hydration and often mannitol to enhance renal excretion has reduced the problem of ototoxicity.^{[35], [44], [51]}

Peripheral neuropathy is a second prominent complication and involves predominantly large fibers. It is dose related and cumulative (with a total dose usually more than 300 to 600 mg/m²). Symptoms may begin or progress even after cisplatin has been stopped.^[44] Encephalopathy with confusion and seizures can occur, especially with high doses, but may be due to fluid or electrolyte disturbances that accompany cisplatin therapy, such as hyponatremia, hypocalcemia, and hypomagnesemia. Cerebral herniation with severe headache, increasing hemiparesis, seizures, coma, and death has been reported in patients with large intracranial tumors receiving cisplatin, possibly due to overhydration and electrolyte disturbances producing cerebral edema and seizures.^{[1], [44]} Finally, retinopathy and cranial neuropathy occasionally follow cisplatin therapy.

PROCARBAZINE

Procarbazine is a weak MAOI that acts primarily as an alkylating agent. High-dose intravenous or intracarotid procarbazine can produce severe encephalopathy. At usual oral doses (60 to 150 mg/m²/day), a mild reversible encephalopathy (drowsiness, confusion, agitation) or peripheral neuropathy (paresthesias, reduced deep tendon reflexes, and muscle aches) develop in as many as 20 percent of patients.^[44]

Because of its monoamine oxidase inhibition, procarbazine can predispose the patients receiving it to a variety of drug interactions, including synergistic sedative effects with phenothiazines, barbiturates, and narcotics, as well as alcohol intolerance. The caution advised with other MAOIs regarding the tyramine effect with cheese or wine has not been a clinical problem with procarbazine.^{[1], [43], [44]}

HEXAMETHYLMELAMINE

Hexamethylmelamine can act as an alkylating agent or as an antimetabolite. It has both central and peripheral neurotoxic effects. In the usual doses administered (8 mg/kg/day), neurological problems are seen in up to 20 percent of patients. The clinical manifestations include encephalopathy (confusion, agitation, hallucinations, parkinsonism) and peripheral neuropathy (distal sensory loss, weakness). In the case of the peripheral neuropathy, pyridoxine may be beneficial.^{[1], [44]}

CARDIAC DRUGS ([Table 55-9](#))

Digitalis

Adverse effects on the CNS occur in 40 to 50 percent of patients with clinical digitalis toxicity and may develop before, with, or after signs of cardiac toxicity. Neurological complications include nausea, vomiting, visual disturbances, seizures, confusion, delirium, mania, hallucinosis, and syncope. Explanations for the high frequency of neurotoxicity with digitalis have been inadequate, and the few pathological studies compiled have not demonstrated consistent lesions. ^[1]

The most frequent and often the first neurotoxic reaction is nausea due to direct stimulation of the medullary chemoreceptor trigger zone. Nausea associated with digitalis toxicity is often accompanied by vomiting, and when vomiting is chronic, it may lead to malnourishment and cachexia. The incidence of digitalis-related visual disturbances has been estimated at 40 percent. Clinically, it presents with blurred vision, scotomas, diplopia, defects of color vision, and amaurosis. Electrodiagnostic and labeled tracer studies have implicated retinal dysfunction in the pathogenesis. ^[54]

Seizures are most commonly seen in the pediatric population. The mechanism by which digitalis induces seizures has been postulated to involve inhibition of membrane ATPase and subsequent neuronal irritability. Confusion, delirium, mania, and hallucinosis have been reported in as many as 15 percent of patients with digitalis toxicity. ^[1] Although the mechanism for the symptoms is unknown, they are not the result of altered cardiac function. On the other hand, transient cognitive changes that are believed to be due to intermittent cerebral hypoperfusion can resemble transient global amnesia or be manifested as syncope.

Beta Blockers

Neuropsychiatric symptoms occur frequently during treatment with beta blockers. The pharmacology of CNS side effects is unclear, although presynaptic and postsynaptic adrenergic inhibition has been implicated, as has serotonergic antagonism. ^[1] Nonselective beta blockers seem to

cause CNS-related side effects to a greater extent than beta₁-selective blockers. ^[55] It is unclear to what degree lipophilicity is responsible for this kind of side effect. Lassitude or insomnia and depression are the most common reactions, although vivid dreams, nightmares, hypnagogic hallucinations, and psychotic behavior have been reported with high doses (more than 500 mg/day of propranolol). Pre-existing major psychiatric illness and hyperthyroidism may predispose to the above-mentioned symptoms.

Calcium Channel Blockers

Calcium channel blockers, particularly flunarizine and cinnarizine, have been associated with dystonia, parkinsonism, akathisia, and TD. Theoretical explanations for these events include the inhibition of calcium influx into striatal cells and direct dopaminergic antagonistic properties. In addition, the chemical structures of flunarizine and cinnarizine, which are related to neuroleptics, may explain the greater incidence of such side effects with these agents compared with those of calcium channel blockers available in the United States. Suggested risk factors appear to be advanced age and a family history of tremors or Parkinson's disease, or both. ^[56] The onset and type of presentation is unpredictable. The long-term evolution was assessed in a prospective follow-up study of 32 patients with diagnoses of calcium channel blocker-induced parkinsonism. Eighteen months following discontinuation of the offending agent, 44 percent of the patients had depression, 88 percent had tremor, and 33 percent still had criteria for diagnosis of parkinsonism. ^[57]

Angiotensin-Converting Enzyme Inhibitors

The incidence of CNS effects with angiotensin-converting enzyme (ACE) inhibitors is similar to that of beta blockers. The precise role of ACE in the CNS is not well defined. Mild lethargy, sedation, and fatigue are the most common complaints. ^[58] As opposed to beta-blockers, ACE inhibitors appear to have the lowest association with depression and, therefore, are the drugs of choice when depression is a risk.

Approximately 2 to 4 percent (depending on renal function and dose) of 100 patients on captopril develop diminution or loss of taste perception. This sign is reversible and usually resolves within 2 to 3 months, even with continued drug administration.

Nitrates

The major problem with nitrate therapy is headache. According to proposed mechanisms, nitric oxide is the common mediator in experimental vascular headaches. Nitroglycerin produces a throbbing or pulsating sensation in many patients and an overt headache in many others. Often, the headaches attenuate or disappear with time, but 15 to 20 percent of patients are not able to tolerate long-acting nitrates because of headache. Patients should be encouraged to use analgesics during the initial days or weeks of nitrate therapy and should be educated as to the nature of this problem and its probable resolution with time. ^[59]

Nitroglycerin therapy can cause dose-related increases in intracranial pressure, which, in rare cases, can result in clinically overt syndrome. Finally, the hypotensive effects of nitroglycerin can result in dizziness and lightheadedness or even syncope.

Antiarrhythmic Agents

AMIODARONE

Amiodarone is a di-ionated benzofurane derivative used primarily in the treatment of refractory ventricular and atrial arrhythmias. Amiodarone can be toxic for almost every organ in the body, including the central and peripheral nervous systems, especially when taken at high doses for long periods of time. The most common neurotoxic findings include tremor, ataxia, proximal muscle weakness, and wasting. Tremor usually appears early in the course of therapy and is usually a bilateral 6- to 10-Hz action tremor of the arms, which is indistinguishable from essential tremor. It can involve all limbs and may be asymmetrical, although to date it has not been reported to be unilateral. Rarely, the tremor is associated with parkinsonian features. Other manifestations of basal ganglia dysfunction that have been reported in association with amiodarone include myoclonus, hemiballismus, and dyskinesias of the extremities and orofacial area. Basal ganglia dysfunction associated with amiodarone is dose related, and reversibility is inversely related to duration of therapy. ^[60]

LIDOCAINE

Lidocaine is widely administered parenterally and topically. It is oxidized to active and inactive metabolites by hepatic enzymes in the cytochrome P-450 mixed oxidase system. Toxic effects of lidocaine occur frequently and involve the cardiovascular system and CNS. Although lidocaine-associated CNS effects can be seen with other local anesthetics, lidocaine is far more common as the causative drug, and this relates to its rapid absorption across the blood-brain barrier. The high frequency of toxicity is probably due to a diffuse excitation of neuronal systems and begins as altered behavior. ^[1] At concentrations less than 6 µg/ml, dizziness, drowsiness, paresthesias, and visual disturbances predominate; confusion, dysarthria, coma, convulsions, cardiac arrhythmias, and respiratory arrest are more often seen at concentrations greater than 6 µg/ml. The toxicity of lidocaine can be viewed as a self-enhancing phenomenon: If administration is not terminated immediately, a marked respiratory acidosis results, which creates more of the active, ionized form of the drug. ^[61] Treatment focuses on adequate oxygenation and support because the half-life of bolus lidocaine given immediately is 6 to 8 minutes. However, because repeated injections change the kinetics of lidocaine and prolong its half-life to approximately

90 minutes, more long-lasting effects can be seen. ^[61] Although most reports of adverse reactions involve intravenous lidocaine, toxic signs have also been reported with topical or oral use.

QUINIDINE

Quinidine is present in the cinchona bark, along with quinine and other alkaloids. Nervous system manifestations are usually not significant, but with overdosage or in susceptible individuals, quinidine causes a type of intoxication similar to that of quinine. The corresponding clinical syndrome, namely cinchonism, is manifested as headache, nausea, vomiting, blurring of vision, transient visual obscurations, and ringing of the ears. [61] The visual symptoms are short lived but can be confused with visual transient ischemic attacks or the visual accompaniments of migraine. More persistent quinidine amblyopia is the result of direct damage to the retinal ganglion cells. [62] Finally, there have been two case reports of dementia associated with chronic quinidine use, which reversed after drug discontinuation. [63]

[PreviousNext](#)

DIETARY COMPOUNDS AND MISCELLANEOUS DRUGS

Caffeine

Caffeine and other xanthine derivatives, including aminophylline, are CNS stimulants that excite all levels of the CNS, with the cortex being the most sensitive. Caffeine increases energy metabolism throughout the brain but decreases cerebral blood flow, inducing a relative brain hypoperfusion. The drug activates noradrenaline neurons and may act as a second messenger at dopamine receptors to affect the local release of dopamine. Mobilization of intracellular calcium and inhibition of specific phosphodiesterases occurs at high, nonphysiological concentrations of caffeine. The most likely mechanism of action of methylxanthine is the antagonism at the level of adenosine receptors.

Caffeine's psychostimulant action on humans is often subtle and difficult to detect. Its effects on learning, memory, performance, and coordination are related to methylxanthine-induced arousal, vigilance, and fatigue. An increased awareness of the environment or hyperesthesia may be an unpleasant experience to some patients. The patient becomes loquacious and restless, and often complains of ringing in the ears and giddiness. In high doses, xanthines affect the spinal cord, resulting in increased reflex excitability, tremulous extremities, and tense muscles. Caffeine clearly alters sleep patterns, and if taken within 1 hour of attempted sleep, it increases sleep latency, decreases total sleep time, and worsens the subject's estimate of sleep quality. Less time is spent in stage 3 and 4 sleep and more in stage 2 sleep. Xanthine-associated seizures are seen as a complication of aminophylline therapy, especially when the drug is administered intravenously. They are usually generalized but can be focal. Cessation of the use of products containing caffeine can cause a withdrawal syndrome that includes headaches, drowsiness, fatigue, decreased performance, and in some instances, nausea and vomiting. These symptoms begin within 12 to 24 hours after the last use of caffeine, peak at 20 to 48 hours, and last approximately 1 week.

Nicotine

Nicotine increases circulating levels of norepinephrine and epinephrine, and it stimulates the release of striatal dopamine. It exerts stimulant effects through specific nicotinic receptors, whose activation may facilitate dopaminergic transmission centrally. Nicotine has been reported to affect a number of neurological diseases, such as spinocerebellar degeneration, multiple system atrophy, multiple sclerosis, tic disorders, parkinsonism, and myoclonic epilepsy.

Nicotine, despite being a powerful stimulant, has no major therapeutic application. Its high toxicity and presence in tobacco smoke give nicotine a considerable medical importance, however. Clinically, tremors and convulsions are major neurological signs of nicotine intoxication. Respiration is stimulated, and vomiting is induced. Nicotine also has marked antidiuretic activity resulting from direct hypothalamic stimulation. If nicotine is acutely ingested, it can be fatal at approximately 60 mg of the base product. Autonomic overactivity with dilated pupils, irregular pulse, sweating, and muscle twitching are characteristic signs of nicotine toxicity. Coma may supervene rapidly, although convulsions are usually not present. If death occurs, it is due to paralysis of respiratory muscles. Cardiac arrhythmias are significant and are another potential cause of demise. Chronic intoxication due to nicotine, consisting of nausea, vomiting, dizziness, and prostration, occurs among tobacco pickers or croppers. The illness lasts intermittently between 12 and 14 hours and clears, only to recur when workers return to work. There are no mortalities or long-term sequelae, however. During the 1973 harvesting season, an estimated 9 percent of the 60,000 tobacco growers in North Carolina reported illnesses.

Vitamins

These vital trace substances are generally associated with vitamin deficiency syndromes, but because health enthusiasm has reached passionate proportions for many individuals, physicians are encountering neurotoxic syndromes from overdosage. The first recognized toxicity of vitamins was related to the fat-soluble vitamins, but water-soluble vitamins have been found to be harmful at times when they are ingested in large quantities.

VITAMIN A

Vitamin A toxicity results in a syndrome of increased intracranial pressure, headaches, blurred vision, and sixth nerve palsy. On fundoscopic examination, gradual papilledema develops. The mechanism whereby increased intracranial pressure develops is not known, although biochemically, the vitamin stimulates the synthesis of glycoproteins

and mucopolysaccharides, which may alter fluid balance centrally. The generally recommended daily vitamin A allowance is 5000 IU, and toxicity occurs with intake as little as four times that dose. Similar toxicity has been noted with one of the vitamin A-like substances, *cis*-retinoic acid, when used for acne in a person taking recommended intakes of vitamin A. In addition there is considerable evidence of the teratogenic effects of vitamin A in the mouse, rat, hamster, and guinea pig. Malformations include cleft palate, fused ribs, spina bifida, meningocele, hydronephrosis, and heart and genitourinary abnormalities.

VITAMIN D

Massive amounts of vitamin D mobilize bone calcium and phosphorus. Where there is bone demineralization and degeneration, nerve root and spinal cord compression can occur. Meningeal symptoms and trigeminal neuralgia are two additional reported findings without clear pathogenesis. Trigeminal neuralgia may relate to bony foraminal changes. Alterations in the calcium balance in the form of hypercalcemia can produce metastatic calcifications in the brain with resultant mental retardation or a clinical picture of generalized weakness, muscle aches, cramps, and mild metabolic encephalopathy. When renal impairment occurs, progressive secondary encephalopathy, not directly related to the vitamin, develops. Vitamin D, like vitamin A, is a teratogen, and when the vitamin consumed in large amounts by pregnant women, it can produce specific abnormalities of the facies, brain, heart, and kidney of the fetus.

VITAMIN E

Excessive vitamin E ingestion may produce subtle signs and symptoms of toxicity, such as easy fatigability, muscle weakness, headache, and delayed wound healing. Symptoms usually disappear with cessation of excessive intake. Increased bleeding tendencies have also been reported with large amounts of vitamin E, but no intracranial bleeding has been reported as resulting from it. No toxic effects have been reported at doses of 800 IU daily. Even with supraclinical doses, associated with high levels of plasma tocopherol, ventricular CSF levels are exceedingly low.

THIAMINE

Effects of excess thiamine on the CNS include nervousness, convulsions, headache, weakness, trembling, and neuromuscular paralysis. The decreased use of thiamine, especially parenterally for various functional disorders, appears to have resulted in a reduction of toxic reactions.

PYRIDOXINE

Pyridoxine, previously considered benign, has been found to have direct toxic effects on the peripheral nervous system. Animals treated with high doses of pyridoxine develop vacuolation and degeneration of dorsal root and ganglion cells, along with a widespread degeneration of sensory nerve fibers. When consumed in daily doses of 2 g or more, it has been reported to produce a syndrome consisting of difficulty walking with lightning-like dysesthesias in the back. Numbness of the extremities occurs, and most important, facial dysesthesias, so uncommon with most toxic neuropathies other than trichloroethane, quickly develop. Areflexia, stocking-and-glove sensory loss, and profound sensory ataxia with preserved strength are typical. On EMG, marked slowing of the sensory nerve conduction is seen with normal motor conduction. Treatment consists of cessation of pyridoxine, and in some cases there is a dramatic, although often slow, recovery.

When low to moderate doses of pyridoxine are added to the diet of a parkinsonian patient receiving levodopa, without carbidopa supplementation (e.g., Sinemet), it will precipitously cause an exacerbation of the disease. Pyridoxine is a co-factor for dopa decarboxylase and enhances the systemic conversion of dopa to dopamine: Because dopamine cannot cross the blood-brain barrier, this enhanced peripheral synthesis of dopamine in fact diminishes central delivery of dopa for effective antiparkinsonian therapy. When sufficient carbidopa is added to levodopa (usually at least 100 mg/day), this pyridoxine toxicity is probably insignificant.

Monosodium Glutamate

In 1968, Kowk, a Chinese physician, described a transient neurological syndrome that occurred when he ate at American-Chinese restaurants. He suggested that monosodium glutamate could be the provoking agent because this product is used widely in Chinese restaurants to enhance the flavor of food. The pathophysiology of the syndrome has been suggested to relate to glutamate. As an excitatory agent, glutamate may alter synaptic transmission. Some authors suggest that the symptoms of monosodium glutamate syndrome may relate to cholinergic overstimulation or non-neurological vascular mechanisms. The syndrome has three major symptoms, occurring within 15 minutes after ingestion of Chinese food and lasting approximately 1 hour: a dysesthetic facial pressure, burning dysesthesias over the trunk, and chest pain. Headache, which may be migrainous in quality, is more frequently seen in patients with a prior history of headaches. Other vague symptoms such as malaise and lightheadedness may accompany the triad. It is not fully established that monosodium glutamate is, in fact, the causative agent. Therefore important contributing influences may also be the vehicle, whether the subject has been fasting, and whether a load of carbohydrate accompanies the ingestion of monosodium glutamate.^[1]

Sex Hormones and Contraceptive Agents

Female hormones in the form of oral contraceptives or postmenopausal replacement therapy have become widely prescribed. It is clear that oral contraceptives increase by 3 to 8 times the risk of stroke in women taking them. Oral

contraceptive-associated strokes can occur in any vascular distribution. Factors predisposing to cerebrovascular disease in women on birth control pills include the use of compounds containing high levels of estrogen, multiparity, and a change in migraine headache pattern. Of probable but less certain importance are previous thrombotic or embolic disease and hypertension. Inherited resistance to activated protein C, which is caused by a single factor V gene mutation, is a frequent risk factor for thrombosis. Activated protein C resistance was found to be highly prevalent in women with a history of thromboembolic complications during pregnancy or use of oral contraceptives. The gene defect is common in the general population, and the question is raised as to whether it would be reasonable to perform general screening for activated protein C resistance early during pregnancy or before prescription of oral contraceptives.^[71]

Chorea is another serious problem related to oral contraceptives. The involuntary movements appear days or weeks after starting birth control pills and may be more frequent in patients with a prior history of Sydenham's chorea. The chorea starts abruptly and may involve only one side of the body.^[72] A similar phenomenon occasionally occurs during pregnancy when a woman develops severe involuntary movements that spontaneously resolve when the pregnancy ends (chorea gravidarum). Birth control chorea may disappear within 48 hours of cessation of the medication, although the abatement can take longer.

Whereas pseudotumor cerebri can occur in patients taking oral contraceptives, other conditions that may cause blurring of the optic disc are papilledema related to venous sinus obstruction or retrobulbar optic neuritis, which also occurs in patients on birth control pills. Vascular headaches may also appear for the first time or suddenly change in pattern when oral contraceptives are started. Common migraine may become classic migraine, with patients experiencing symptoms or signs of focal cerebral dysfunction at the onset of the headache. In cases in which migraines either appear for the first time, increase in frequency, or become focal, cessation of oral contraceptives is suggested. On the other hand, a subgroup of headache patients find relief of headache pain while taking oral contraceptives. These headaches may have a close relationship to menstruation, and while on the oral contraceptives, the patient has minimal pain.

Chelating Agents

2,3-DIMERCAPTOL-1-PROPANOL

2,3-Dimercaptol (British antilewisite [BAL]) was synthesized during World War II as an antidote for arsenic-containing lewisite gas. This compound has also been found to be effective against the toxic manifestations of arsenic, mercury, gold, antimony, and other heavy metals. With doses of 2.5 mg/kg of body weight, toxic symptoms develop in less than 1 percent of individuals; with twice that dose, there is a 50 to 60 percent increase in the occurrence of intoxication. Symptoms appear within 10 to 20 minutes after injection of the drug and subside within 50 to 90 minutes. The usual reaction consists of headache, burning sensations in the mouth and eyes, muscular aches, paresthesias, pain in the teeth, lacrimation, salivation, rhinorrhea, and profuse sweating. Restlessness, anxiety, and general agitation may also develop, with progression in some instances to generalized convulsions and stupor. Abdominal pain, apprehension, blepharospasm, piloerection, tachycardia, and palpitations may also occur. Because of the transient nature of the toxic symptoms, no treatment is needed in BAL poisoning. Twenty-five milligrams of ephedrine sulfate given before the injection of BAL may lessen the incidence of toxic reactions.^[1]

PENICILLAMINE

The most commonly encountered neurotoxic effect of penicillamine is loss or abnormality of taste, which has been correlated with high doses and long duration of therapy.^[1] Hypogeusia occurs in 25 to 30 percent of patients at doses of 1 g daily within 6 weeks. It may be reversible by decreasing the dosage or discontinuing of the drug and may not occur at all in dosages of 500 mg or less. Zinc infiltration of taste receptors has been postulated as causing the hypogeusia induced by penicillamine.

Dermatomyositis and polymyositis characterized by typical tender proximal muscle weakness with elevation of muscle enzymes may occur during penicillamine therapy. Another neurological side effect of penicillamine therapy, especially in rheumatoid arthritis patients, is a myasthenic syndrome. This can start as ptosis, diplopia, or dysphagia but progresses to generalized weakness if early signs go undetected. The edrophonium test usually confirms the clinical suspicion, and laboratory studies demonstrate autoantibodies to acetylcholine receptors. Withdrawal of the drug and treatment with cholinesterase inhibitors reverse the weakness over several months.^[73]

Cholesterol-Lowering Agents

CLOFIBRATE

Clofibrate, an aromatic monocarboxylic acid, is capable of inducing myotonia in humans and experimental animals and is clinically significant because it is widely used to reduce serum triglyceride levels. The mechanism by which it induces myotonia is believed to be through a decrease in chloride conductance.

LOVASTATIN AND PRAVASTATIN

Lovastatin and pravastatin are HMG-CoA reductase inhibitors that are effective cholesterol-lowering agents used in the treatment of hypercholesterolemia. They can induce myotonia by blocking chloride channels on the muscle membrane.^[74]

NEUROLOGICAL SEQUELAE OF DIAGNOSTIC AND THERAPEUTIC PROCEDURES

Coronary Artery Bypass Graft Surgery

Coronary artery bypass graft (CABG) surgery is the most frequently performed cardiac surgery in North America,

with nearly 400,000 procedures performed annually in the United States and Canada.^[75] Early retrospective studies of open heart surgery found that stroke and anoxic encephalopathy were common postoperative neurological complications occurring in more than 20 percent of patients. Improvement in surgery and extracorporeal circulation may have initially reduced the frequency of permanent, disabling neurological sequelae. Nevertheless, subsequent prospective studies have shown that neurological complications account for the major adverse sequelae of this procedure. Because these problems can be severe, they must be taken into account when decisions are weighed as to whether medical or surgical therapy would be more appropriate in a given case.

CENTRAL NERVOUS SYSTEM COMPLICATIONS

Stroke as a complication of CABG procedures occurs in 0.9 to 5.9 percent of cases.^[76] Most territorial infarcts result from macroemboli from diseased valves, left ventricular thrombus, or atheromatous emboli from a rigid ascending aorta. Stroke occurs more frequently with valvular heart surgery than with coronary artery bypass grafting operations. A permanent neurological disability after valve replacement occurs in 5 to 10 percent of patients. In contrast, the risk of a severe disability complicating CABG surgery is less than 2 to 5 percent.^[76], ^[77] The difference is due to the greater risk of cardiac macroemboli with operations that require opening of the heart chambers. Removal or repair of diseased, calcified mitral or aortic valves is associated with the dispersion of tissue and surgical debris in the cardiac chambers. Extracranial carotid artery disease is often suggested as an important cause of stroke during CABG surgery. This theory proposes that severe carotid occlusive disease, combined with intraoperative hypotension, results in cerebral ischemia. However, most perioperative strokes occur in the absence of carotid occlusive disease or have their onset in the postoperative period. Most studies have failed to demonstrate a correlation between perioperative stroke and asymptomatic carotid artery stenosis. Nevertheless, it is common practice in some hospitals to perform a prophylactic staged or combined carotid endarterectomy in asymptomatic patients discovered to have carotid stenosis.^[78] Although CABG surgery frequently results in a tendency for bleeding (as a result of heparin administration, low fibrinogen levels, and thrombocytopenia induced by hemodilution and sequestration) and occasional disseminated intravascular coagulation, intracranial hemorrhage is an infrequent cause of stroke.^[79]

Attempts to prevent neurological sequelae after cardiac surgery have focused on improved surgical and cardiopulmonary bypass techniques, as well as identifying the high-risk patient. Age, preoperative stroke (within 3 months), severe aortic atheroma, opening of cardiac chambers, and sustained mean arterial pressure of less than 30 to 40 mm Hg are probable risk factors for postoperative neurological sequelae. Less proven but still possible risk factors are prolonged cardiopulmonary bypass, severe carotid or cerebrovascular disease, postoperative atrial fibrillation, congestive heart failure, and diabetes mellitus.^[75], ^[76]

Minor cognitive impairment following CABG procedures occurs in as many as 75 percent of patients tested 8 days postoperatively and may be present in up to a third of patients, even 1 year after surgery. These patients show a reduction of one standard deviation in neurocognitive testing postoperatively.^[75] The pathogenesis of the cognitive decline following CABG is believed to be secondary to disseminated brain microemboli occurring during cardiac surgery. An alkaline phosphatase map of the afferent cerebral microvasculature has revealed thousands to millions of focal, small capillary and arteriolar dilatations in patients and dogs who have recently undergone CABG. These capillary and arteriolar dilatations are usually empty, suggesting that gas bubbles or fat emboli are a prime cause. Some authors believe that membrane oxygenators and 40- μ arterial line filters are an essential part of protecting the brain against microembolic events, although this remains to be proved in practice.^[75]

The global encephalopathy that can follow heart surgery varies from confusion to coma or a psychotic delirium. Nonmetabolic coma is a rare complication of open heart surgery, occurring in less than 1 percent of patients. It may be due to global anoxia-ischemia, massive stroke, or multiple strokes. On the other hand, the incidence of clinically detectable diffuse encephalopathy varies from 3 to 12 percent.^[75] Post-CABG encephalopathy is often multifactorial and can be related to medications, hypoxia, fever, sepsis, metabolic derangements, hemodynamic instability, and intensive care unit psychosis. These patients may be slow to emerge from anesthesia, are often agitated or restless, and have poor visual fixation, small reactive pupils, and occasionally, Babinski sign. Improvement usually occurs during the first postoperative week. In otherwise uncomplicated cardiac surgery, disseminated microemboli during extracorporeal circulation may be the cause of this encephalopathy.^[76] Seizures occur in less than 1 percent of patients and can accompany coma, encephalopathy, or delirium, or they may occur independently. The vast majority occur within the first 24 hours after surgery.

PERIPHERAL NERVOUS SYSTEM COMPLICATIONS

In a prospective analysis of 412 consecutive patients undergoing coronary bypass surgery, 55 (13 percent) developed new peripheral nervous system complications postoperatively.^[79] The most common complication was brachial plexopathy, occurring in 23 patients. Most frequently the lower trunk or the medial cord of the brachial plexus was involved. The plexus injuries may be due to torsional traction, compression, or cannulation of the jugular vein. Male gender and hypothermia during surgery were associated with an increased risk. The usual clinical presentation involves intrinsic hand weakness and a decreased or absent triceps reflex. Sensory loss is sometimes present in the affected hand; some patients have prominent pain, and a minority of them have a Horner's syndrome. Most brachial plexus injuries are reversible within 1 to 3 months, implicating conduction block as the primary pathophysiological mechanism. Such injuries may be prevented by minimizing the opening of the sternal retractor, placing the retractor in the most caudal location, and avoiding asymmetrical traction. Unilateral phrenic nerve injuries with hemidiaphragmatic

paralysis occur in at least 10 percent of patients during open heart surgery and can be manifested as atelectasis or persistent singultus. Finally, mononeuropathies resulting from compression or trauma during surgery may involve the accessory, facial, lateral femoral cutaneous, peroneal, radial, recurrent laryngeal, saphenous, and ulnar nerves.^[78]

Cardiac Catheterization

CNS complications of cardiac catheterization are rare and occur in 0.1 to 1.0 percent of patients. The majority of these complications are focal neurological deficits, which are believed to result secondary to embolism from either manipulation of the guidewire or catheter flushing in the ascending aorta when the brachial route is chosen.^[76] Resolution of the focal deficits within 48 hours occurs in approximately half of the patients. In one big series, the carotid circulation accounted for 30 to 40 percent of focal deficits and consisted of hemiparesis, hemisensory deficits, and dysphasia. The vertebrobasilar circulation accounted for 60 percent of the deficits, with combinations of cortical blindness, hemianopic visual field defects, and intrinsic brain stem signs.^[76]

Percutaneous Transluminal Coronary Angioplasty

Focal neurological complications following percutaneous transluminal coronary angioplasty occur in 0.2 to 0.3 percent of patients and are similar to those seen in catheterization patients.^[76]

Cardiac Transplantation

Neurological complications recognized in the first weeks after cardiac transplantation are similar to those seen after routine coronary artery bypass surgery or heart valve repair ([Table 55-10](#)). They include cerebrovascular disease, anoxic-ischemic

TABLE 55-10 -- NEUROLOGIC COMPLICATIONS OF CARDIAC TRANSPLANTATION

Early Onset (first 2 weeks)

Anoxic-ischemic encephalopathy

Brachial plexopathy/mononeuropathy
 Cerebrovascular disease
 Metabolic encephalopathy/sepsis
 Psychosis
 Seizures
 Vascular headache
 Late Onset
 Cerebrovascular disorders
 Cyclosporine/prednisone toxicity
 Lymphoma
 Metabolic encephalopathy/sepsis
 Opportunistic infections
 Psychosis
 Seizures

encephalopathy, seizures, and peripheral nerve disorders. ^[79] Vascular headaches accompanied by nausea and vomiting may occur the first week after transplantation and are felt to be associated with a rapid shift from low preoperative to high postoperative mean arterial pressures. Psychotic behavior with hallucinations, delusional thought process, and disorganized behavior can occur during the first two weeks after transplantation or as a late complication. When it occurs in the first 48 hours and is accompanied by disorientation and impaired memory, it probably represents a behavioral response to intraoperative cerebral ischemia-hypoxia. If it begins 2 to 5 days after surgery, memory is preserved, and there is rapid resolution with environmental re-orientation, then a multifactorial intensive care unit psychosis may be present. If psychotic behavior presents 2 to 4 weeks following transplantation, then a full evaluation for an opportunistic infection is indicated. ^[79]

Immunosuppression remains the major cause of late neurological complications after cardiac transplantation. Opportunistic infections can occur as early as 2 weeks after surgery and immunosuppression, but usually there is an interval of at least a month. Focal meningoencephalitis or brain abscess, meningitis, and encephalitis are three common presentations of infections in cardiac transplant recipients. Aspergillus, *Toxoplasma gondii*, cryptococcus, listeria, candida, and nocardia are the most frequent nonviral organisms. The most frequent viral infections are caused by the herpesviruses, with cytomegalovirus being the most common. ^[76], ^[73] Aseptic meningitis has been reported in 5 percent of patients receiving OKT3 and presents as mental status and behavioral changes. ^[76]

The use of cyclosporine since the early 1980s has allowed significant lowering of corticosteroid requirements and has reduced the frequency of its side effects. There have been a number of neurological effects ascribed to cyclosporine, however, including tremor, lowered seizure threshold, confusion, muscle weakness, ataxia, paresthesias, visual hallucinations, and a leukoencephalopathy with cortical blindness. ^[76], ^[75] These neurotoxic side effects rapidly remit with reduction of the dose of cyclosporine. When seizures occur and anticonvulsants are indicated, selection of the best agent may be difficult because phenytoin, phenobarbital, and carbamazepine can decrease the blood levels of cyclosporine. Finally, immunosuppression predisposes the patient to the development of primary or secondary lymphoma of the brain.

Radiation Damage

Therapeutic radiation may affect the nervous system in two settings: (1) damage to neural structures or blood vessels when they are included in the radiation port, whether the cancer undergoing radiation therapy is within or outside the nervous system ([Table 55-11](#)); (2) secondary nervous system involvement when radiation causes new tumors to develop or when radiation damages endocrine organs that are necessary for nervous system function. The presence and severity of these reactions are governed by a number of factors, including the total radiation dose, the radiation fraction size, and the volume of tissue irradiated.

TABLE 55-11 -- RADIATION-INDUCED INJURY: DIRECT DAMAGE TO THE CNS

Time after Radiation	Clinical Findings	Mechanisms
Acute (minutes to days)	Brain Increased intracranial Pressure	Vasogenic edema
Early delayed (weeks to months)	Brain Diffuse: somnolence/lethargy Focal: simulates recurrent tumor Spinal cord Lhermitte's sign	Demyelination
Late delayed (months to years)	Brain Diffuse: dementia Focal: simulates recurrent tumor Spinal cord Transverse myelopathy Motor neuron syndrome	Glial and vascular damage

The age of the patient, the presence of pre-existing brain injury by tumor or surgery, infection, vascular disease due to hypertension or diabetes mellitus, and chemotherapy may influence the susceptibility of the patient to injury as well. ^[80]

PRIMARY BRAIN DAMAGE

Injury to the brain resulting from the radiosensitivity of normal brain tissue encompassed in the treatment volume can be classified as acute, early delayed, and late delayed reactions. Acute reactions occur during or immediately after the course of radiation therapy and typically develop in patients with increased intracranial pressure from primary or secondary brain tumors, particularly in the absence of corticosteroid coverage. Clinically, patients present with symptoms suggesting increased intracranial pressure or exacerbation of pre-existing neurological symptoms or signs. ^[81] The pathogenesis of the disorder is unknown, although it is thought to be due to radiation-induced edema secondary to blood-brain barrier breakdown. Acute symptoms are uncommon with dose-fractionation schedules consisting of 180 to 200 rad/day, given 5 days per week to a total dose of 6000 rad. Daily doses of up to 600 rad are well tolerated, but higher daily dose fractions should be administered with caution. Acute reactions, when they occur, are usually mild and transient. The above-mentioned situations have two implications for the clinician: First, patients with large brain tumors and signs of increased intracranial pressure should not receive more than 200 rad per fraction. Second, all patients undergoing brain radiation should be given dexamethasone, preferably at least 24 hours before starting radiation therapy.

Early delayed reactions occur a few weeks to a few months after radiation. The symptoms often simulate tumor progression, with accentuation of pre-existing signs and symptoms, or may present as somnolence and lethargy without lateralizing signs. The early delayed reaction is transient and usually associated with an uneventful recovery. Rarely, however, it can be fatal. This is more likely to occur following radiation of the posterior fossa resulting in brain stem encephalopathy. ^[80], ^[81] Pathologically, there is extensive demyelination with central necrosis, absence of oligodendroglia, and gliosis accompanied by minimal vascular change and

preservation of neurons and axons. The pathogenesis of the early delayed reaction is thought to be a temporary inhibition of myelin synthesis due to radiation-induced effects on the oligodendroglial cells. The turnover time of myelin is 5 weeks to 2 months, which corresponds to the latency and recovery time of the syndrome. The main significance of early delayed radiation injury lies in the need to differentiate this condition, which is transient and requires no therapy, from late radiation injury and tumor progression.

Late delayed reactions occur several months to years after treatment. Late delayed injury constitutes the major hazard of CNS exposure to therapeutic radiation. There are several theories as to the pathogenesis of late delayed brain injury. These theories include (1) vascular injury, (2) direct effect on glial cells, or (3) autoimmune demyelination. It is probable that several mechanisms are involved, and the importance of each depends on the radiation dose and the latent interval. Evidence suggests that demyelination is important in the early delayed reaction and that the effect on the small and medium arterioles becomes progressively more important with time. Histologically, the typical lesion is an area of coagulative necrosis in the white matter, with relative sparing of the overlying cortex. Microscopically, the most striking abnormalities are found in blood vessels, with hyalinized thickening and fibrinoid necrosis of the walls often associated with vascular thrombosis, vascular hemorrhages, and accumulation of perivascular fibrinoid material.

There is little information on the incidence of late radiation injury, because there is a paucity of prospective, well-controlled studies. The available data suggest that the risk of injury increases with doses in excess of 6000 rad delivered in 30 fractions over 6 weeks.^[81] The daily fraction size in addition to total dose has a substantial effect on the risk of inducing damage to the CNS. Concomitant administration of chemotherapeutic agents may potentiate radiation injury.

In patients who were treated for primary or metastatic brain tumors, symptoms of radiation damage usually recapitulate those of the brain tumor, leading the physician to suspect tumor recurrence. In patients irradiated for head and neck tumors, whose brains were included in the radiation portal, new focal neurological signs are the rule. When injury occurs at the site of an intracerebral tumor, it is not possible to differentiate the effects of radiation from those

1148

of residual or recurrent tumor on the basis of CT or angiographic findings. MRI provides no additional information that can be used to differentiate between lesions. In both conditions, an increase in tissue water content causes an increase in mobile proton density and prolongation of T₁ and T₂ relaxation times. These changes result in decreased signal in T₁-weighted images and increased signal in T₂-weighted and proton density images. Contrast enhancement, resulting from blood-brain barrier breakdown, can be seen as well. Diffuse white matter injury is seen as periventricular white matter lesions, appearing as high-signal areas on proton density and T₂-weighted images. These abnormalities are usually symmetrical and indistinguishable from the deep white matter changes seen in older people with risk factors for cerebral vascular disease.^[81],^[82] The CT, MRI, and angiographic picture of radiation necrosis cannot be differentiated from tumor recurrence. This differentiation is reliably achieved by fluorodeoxyglucose (FDG [¹⁸F]) PET examination, based on the decreased FDG accumulation in an area of necrosis.^[83]

Surgical resection of favorably situated focal lesions may result in considerable improvement or in complete recovery from the secondary effects of brain injury. After surgery, improvement most commonly occurs in patients with focal necrosis who have been irradiated for primary extra cranial lesions. Resection is of little value in patients with diffuse lesions or brain stem involvement. Corticosteroids may result in improvement or stability of neurological deficit by reducing brain edema, although they cannot reverse the ongoing process.^[81]

PRIMARY SPINAL CORD DAMAGE

Although there are no acute effects of radiation on the spinal cord, early delayed radiation myelopathy is common, especially after radiation of the neck. The patient develops Lhermitte's sign, which persists for weeks and months with spontaneous resolution; the sign is believed to be caused by demyelination of the posterior columns of the spinal cord.

Late delayed radiation myelopathy appears either as progressive myelopathy or a motor neuron syndrome. Radiation myelopathy usually presents as Brown-Sequard syndrome, which progresses to cause paraparesis or quadraparesis over weeks to months. Pathologically, there are areas of necrosis with a predilection for the white matter. Vascular changes are similar to those of the brain and sometimes can result in hemorrhage.^[84] The myelogram and MRI are usually normal, although in the acute phase, spinal cord swelling or contrast enhancement of focal lesions may be seen. Motor neuron syndrome characteristically follows pelvic radiation for testicular tumors. This is characterized by muscle weakness, accompanied by atrophy, fasciculations, and areflexia. There are no sensory, sphincter, or sexual changes. The symptoms progress over months to years and eventually stabilize.^[81]

CRANIAL AND PERIPHERAL NERVE DAMAGE

Radiation injuries to the cranial and peripheral nervous systems are rare. The risk of brachial plexus injury increases with total dose in excess of 6000 rad, with daily fraction sizes of 200 rad, and with the use of large daily fraction sizes. Optic nerve and chiasmal injury are major risks in patients with pituitary or paraspituitary tumors who are treated with high daily dose fractions. In patients with pituitary tumors, the use of fraction sizes of 180 to 200 rad, with the total dose limited to 4500 rad, minimizes the risk of such injury. The retina is sensitive as well, and clinically evident injury may occur with doses as low as 4600 rad when the whole retina is included in the radiation field.^[81]

SECONDARY INVOLVEMENT OF THE NERVOUS SYSTEM

Secondary involvement of the nervous system following head and neck radiation for tumors not involving the nervous system can result in the development of radiation-induced tumors years to decades later. These radiation-induced tumors can be meningiomas, sarcomas, gliomas, and malignant schwannomas. Lesions of large intracranial or extracranial blood vessels may also follow radiation therapy by years. The supraclinoid portion of the internal carotid artery is particularly vulnerable to the occlusive effects of radiation.

Finally, radiation of the head and neck can result in primary hypothyroidism, hypercalcemic hyperparathyroidism, and hypothalamic-pituitary dysfunction. Radiation-induced hypothyroidism can present as encephalopathy, ataxia, and peripheral neuropathy. Thyroid function should be part of the evaluation of every patient with neurological dysfunction who has undergone prior radiation to the head and neck.

Vaccinations

Worldwide vaccination programs have had unparalleled success during this century to reduce the incidence of serious infectious diseases. Neurological sequelae of vaccinations have been reported, although assigning a causative relationship for vaccine injuries is difficult because randomized double-blind placebo controlled studies have not been systematically conducted. There are five types of vaccines available: whole-killed organisms, live-attenuated viruses, toxoids or components, conjugated vaccines, and recombinant vaccines ([Table 55-12](#)).

TABLE 55-12 -- TYPES OF VACCINES

Killed organisms	Toxoids (Components)
Influenza	Acellular pertussis
Japanese Encephalitis	Diphtheria
Pertussis	Tetanus
Poliomyelitis (IPV)	Conjugated
Live-attenuated viruses	<i>Haemophilus</i> Influenza type B
Measles	Recombinant
Mumps	Hepatitis B
Poliomyelitis (OPV)	Smallpox

WHOLE-KILLED ORGANISMS

Vaccines composed of whole-killed organisms include the influenza, poliomyelitis (IPV), pertussis, and rabies vaccines. Administration of the inactive antigens provokes an immune response that creates immunity without causing the disease. Vaccines made from whole-killed organisms may cause a variety of immune-mediated reactions.

Pertussis. Standard pertussis vaccine prepared from killed whole cell *Bordetella pertussis* organisms has been in widespread use since the early 1950s.^[85] It has been effective in reducing the incidence of pertussis in the United States to low levels. Despite marked reduction in disease, the use of the vaccine has caused concern because of questions of encephalopathy resulting in permanent brain damage or death. Pertussis vaccine is ordinarily combined with diphtheria and tetanus toxoids (DPT), and all reported side effects are based on DPT and not pertussis vaccine alone. The Child Neurology Society, after reviewing the reports linking the whole cell pertussis vaccine and neurological illness, has issued a consensus statement concluding that the pertussis vaccine is associated with a short-term increased risk of seizures, most of which are febrile seizures, and complete recovery is expected. In regard to encephalopathy, the report concluded: "At present, there is no means by which a diagnosis of pertussis vaccine-encephalopathy can be established in an individual basis."

Influenza. Annual vaccination against influenza is constituted depending on the prevalent strains that are expected to appear in the United States the following year. A small increase in the incidence of Guillain-Barre syndrome has been reported after the 1976 vaccination against the so-called swine flu. The significance of this association was initially questioned but later confirmed.^[86]

Inactivated Poliomyelitis Vaccine. Inactivated poliomyelitis vaccine was introduced in 1955, is still preferred in most European countries, and is devoid of neurological complications. In spite of this safety, the vaccine is not used in the United States; at present, it is recommended only for immunocompromised individuals or for individuals living in households with immunosuppressed persons.

Rabies. The rabies vaccine used in the United States is both safe and efficacious. It is prepared by inactivated rabies virus grown on human diploid cells. Unfortunately, many underdeveloped countries continue to prepare the vaccine by growing inactivated virus in the brains or spinal cords of mature animals. The myelin basic protein present in this vaccine (Semple) is responsible for encephalomyelitis and polyneuritis.

LIVE-ATTENUATED VIRUSES

Vaccines composed of live-attenuated viruses include the measles, mumps, rubella, oral poliomyelitis, and varicella vaccines. They are intended to cause an asymptomatic infection. The immunity provided by these vaccines is lifelong, but they can occasionally cause symptomatic infection, sometimes with associated neurological involvement.

Measles-Mumps-Rubella (MMR). MMR vaccine may cause fever, rash, conjunctivitis, or other measles-like symptoms in the second week after immunization. A double-blind placebo-controlled crossover study of the MMR vaccine performed in twins living in the same household found that statistically significant differences between placebo and vaccine occur during the second week and can be attributed to the development of measles infection.^[87] Seizures can also occur during the second week following immunization and are almost always simple febrile seizures. The evidence is inadequate to accept or reject a causal relation between encephalopathy, subacute sclerosing panencephalitis, residual seizure disorder, sensorineural deafness, optic neuritis, transverse myelitis, or Guillain-Barre syndrome and MMR.^[88]

Reports have suggested an association with mumps vaccines and aseptic meningitis and sensorineural deafness. This is probably associated with the Urabe mumps strain, which is not used in the United States. Finally, with regard to the rubella vaccine, the Institute of Medicine concluded that there is insufficient evidence to indicate a causal relationship between the rubella vaccine and radiculoneuritis and other neuropathies.^[89]

Oral Poliomyelitis Vaccine. The oral poliomyelitis vaccine (OPV) consists of live-attenuated virus, and since its introduction in 1961, it has replaced IPV in the United States because it is easier to administer, confers intestinal as well as serum immunity, and can spread from immunized to nonimmunized persons. The main disadvantage of OPV is that it can cause paralytic disease in 1 of 2.5 million doses distributed. At present, all cases of poliomyelitis in the United States are vaccine related.^[90] High-risk groups are infants receiving their first dose and immunocompromised individuals who either receive the vaccine or are in contact with vaccine recipients. Finally, evidence favors acceptance of a causal relation between OPV and Guillain-Barre syndrome.^[88]

TOXOIDS

Toxoid vaccines include tetanus and diphtheria, and acellular pertussis. They are denatured bacterial toxins that prevent disease but not infection.

Tetanus and Diphtheria. Adverse reactions of diphtheria and tetanus immunizations cannot be assessed separately because they are always given together. Several reports have implicated DT in causing polyradiculoneuritis, brachial plexus neuritis, and acute transverse myelitis. The Institute of Medicine has reported that current evidence favors acceptance of a causal relation between diphtheria and tetanus toxoid and Guillain-Barre syndrome and brachial neuritis.^[88] It has also concluded that evidence rejects a causal relation between diphtheria and tetanus toxoid and encephalopathy and infantile spasms.^[88]

Acellular Pertussis. Acellular pertussis vaccines contain two or more denatured elements of *Bordetella pertussis* required for immunity but do not contain endotoxin. In a recent study, the five-component acellular pertussis vaccine has been found to have a favorable safety profile with sustained protection against pertussis. The two-component acellular vaccine and the whole-cell vaccine were less efficacious.^[90]

TABLE 55-13 -- NEUROLOGICAL COMPLICATIONS OF OBSTETRICAL AND GYNECOLOGICAL PROCEDURES AND SURGERY

Site and Injury	Mechanism	Symptoms
Spinal cord and nerve roots	Spinal or epidural anesthesia (hematoma, chemical injury, infarction)	Myelopathy/radiculopathy
Lumbosacral Plexus	Disproportion, large babies, midforceps use	Buttock/leg pain weakness: footdrop
Genitofemoral nerve	Pelvic surgery	Sensory loss: labia, femoral triangle
Ilioinguinal and iliohypogastric nerves	Surgery with low transverse abdominal incision	Sensory loss: suprapubic area, upper-medial thigh, anterior labial majus
Lateral femoral cutaneous	Inguinal lymphadenectomy	Sensory loss: anterior-lateral thigh
Pudendal nerve	Radical pelvic surgery	Sensory loss: clitoris, perineum, anus, incontinence
Obturator nerve	Lithotomy position, at the obturator foramen, pelvic surgery	Sensory loss: medial thigh, weakness: thigh abduction
Femoral nerve	Stirrups with thighs flexed and abducted and hip flexed and externally rotated, retractors	Sensory loss: anterior thigh, weakness: thigh flexion, reflex loss: patellar

Sciatic nerve	Stirrups, intramuscular injections, sacroiliac fossa bleeding	Sensory loss: lateral leg, foot weakness: foot flexion or extension, knee flexion, reflex loss: ankle
Common peroneal nerve	Lithotomy position, at the head of the fibula	Sensory loss: lateral and dorsum of the foot, weakness: footdrop and inversion

Obstetrical and Gynecological Procedures and Surgery

The peripheral nervous system can be injured in a variety of ways during pregnancy and delivery. Injury can occur at the level of the nerve roots, lumbosacral plexus, or individual peripheral nerves ([Table 55-13](#)).

The risk of injury to spinal cord or nerve roots from spinal or epidural anesthesia used for delivery is 0.1 percent or less. Various types of injury that have been described include epidural hematomas, chemical radiculitis or arachnoiditis, direct needle injury to the root, or spinal infarction secondary to hypotension. ^[91]

Lumbosacral plexus injuries occur during labor or delivery and can be easily confused with a herniated disc. They occur in fetal-pelvic disproportion or in primiparous patients with large babies that necessitate midforceps delivery. The anterior division of the lumbosacral trunk (L4 or L5) is compressed by the fetal head or the obstetric forceps against the pelvic brim. These patients often complain of buttock or leg pain, which intensifies with uterine contractions. A footdrop or weakness of the tibialis anterior is the most common finding. ^[92]

A number of isolated nerve lesions may occur as a complication of obstetrical maneuvers. The obturator nerve may be injured when the patient is in the lithotomy position, because of angulation as the nerve leaves the obturator foramen. Clinically, the patient has weakness of adduction of the thigh and sensory loss over the medial thigh.

The femoral nerve is injured when the thighs are markedly flexed and abducted or the hips are abducted and externally rotated. Results of the injury include impaired extension of the knee, impaired flexion of the thigh, sensory loss over the anterior thigh, and loss of the patellar reflex.

The saphenous nerve can be injured by pressure from leg braces when the patient is in the lithotomy position. The sciatic nerve can be injured when the patient is placed in stirrups on the obstetrical table or with a misplaced deep intramuscular injection. Clinically, the patient experiences sensory loss over the lateral leg and the whole foot, weakness of both dorsal and plantar flexion of the foot, and of the extension of the knee, and loss of the ankle jerk. Isolated tibial injury is uncommon. The common peroneal is usually compressed at the head of the fibula from the leg braces with the patient in the lithotomy position. ^[92] Clinically, the patient has footdrop and inversion and sensory loss on the lateral aspect and the dorsum of the foot.

Nerve injury is an infrequent complication of gynecological surgery (see [Table 55-13](#)). The most frequently reported injury has been to the femoral nerve, followed by the sciatic and the obturator nerves. ^[93] Stretch, compression, ligation, and transection are the most commonly reported intraoperative precipitators of symptoms, and postoperative scar formation may lead to entrapment symptoms at anatomical locations remote from the procedure.

Mechanisms of femoral neuropathy include self-retaining retractors, especially in thin patients with low transverse incisions and deep retractor blades; hyperflexion of the thigh; and control of bleeding deep in the pelvis and in the region of the psoas muscle. The clinical presentation is as described earlier.

Sciatic nerve injury can occur as a result of sacroiliac fossa bleeding, intramuscular injections, and the sacrospinous vaginal vault suspension procedure. Obturator nerve injury has been associated with pelvic surgery and specifically with pelvic lymphadenectomy.

Other less commonly encountered nerve injuries that may occur in association with gynecological surgery include

1149

the genitofemoral nerve, which may be injured during pelvic lymphadenectomy, and can result in numbness or tingling over the labia and the skin over the femoral triangle. The ilioinguinal and iliohypogastric may be severed during an operation using a low transverse abdominal incision. The clinical syndrome consists of numbness or tingling over the suprapubic region, the upper medial thigh, and the anterior part of the labium majus. Finally, the lateral femoral cutaneous nerve may be injured during an inguinal lymphadenectomy and the pudendal nerve may be injured during radical pelvic surgery or during the performance of the sacrospinous vaginal vault suspension. Damage of the lateral femoral cutaneous nerve results in paresthesias over the lateral aspect of the front of the thigh as far as the knee, and damage of the pudendal nerve results in urinary and fecal incontinence and paresthesias of the clitoris, labia, perineum, and anus.

In contrast to brachial plexopathy, radiation-induced neural damage to the lumbosacral plexus is a rare complication. Although a few permanent lumbosacral lesions have been reported in patients treated with conventionally fractionated external beam, this syndrome is more often seen in patients treated with intracavitary irradiation for cervical or endometrial carcinoma. ^[94]

Careful surgical technique is probably the most important factor in prevention of the above-mentioned complications. In addition, careful placement of the self-retaining retractor and careful positioning of the patient in stirrups is of paramount importance. With mild injuries, the prognosis for recovery is excellent, but recovery may be prolonged and incomplete if axonal degeneration has occurred. Recovery usually takes 4 weeks for the sensory function and 1 to 4 months for the motor function. Physical therapy, splinting or bracing to prevent contractures, and electrical stimulation are the usual treatment modalities used.

Critical Illness Polyneuropathy

The occurrence of muscle weakness in patients with sepsis and multiple organ failure managed in the intensive care unit has been recognized with increasing frequency in the last 15 years. This weakness is due to an axonal polyneuropathy, otherwise called critical illness polyneuropathy. It must be differentiated from myopathy or disturbance of the neuromuscular junction that can also occur in the intensive care setting. ^[95] Neither the cause nor the exact mechanism of critical illness polyneuropathy has been elucidated. Nutritional, toxic, metabolic, and vascular factors have all been proposed as likely causes, but none has been proved so far. ^[95]

The difficulty in examining critically ill patients may explain why this complication has only recently been recognized. The presence of encephalopathy or generalized edema can make the clinical diagnosis difficult to obtain. Predominantly proximal weakness can lead to quadriplegia. The facial muscles can be mildly weak, but the muscles of the eyes, tongue, and jaw are relatively spared. ^[96] Deep tendon reflexes are partially preserved. Nevertheless, the signs of limb weakness and loss of previously elicited tendon reflexes are not present in all patients, even those who are subsequently shown by electrophysiological studies to have a moderately severe polyneuropathy. ^[96]

Electrophysiological studies demonstrate acute axonal damage to the peripheral nerves. Signs of primary demyelination, such as marked slowing of nerve conduction velocities, prolongation of distal latencies, dispersion of compound muscle action potentials, conduction block, and increased F-wave latencies, are absent even in severe cases of polyneuropathy. ^[96] Parenchymatous axonal damage and marked neurogenic atrophy are constant features of nerve biopsy.

Before the recognition of critical illness polyneuropathy, these cases were usually misdiagnosed as acute demyelinating Guillain-Barre syndrome. The essentials for diagnosis of Guillain-Barre syndrome (e.g., absent reflexes, albuminocytological dissociation in the CSF, and evidence of demyelination in the electrophysiological studies), however, are not present in most critically ill patients with neuromuscular weakening failure. Furthermore, prolonged neuromuscular blockade following long-term treatment with muscle relaxant drugs; aminoglycoside antibiotics; neuromuscular blocking agents in combination with high-dose corticosteroids for treatment of life-threatening status asthmaticus; and infectious, metabolic, or toxic myopathies or neuropathies should be included in the differential diagnosis of weakness and prolonged dependence on the ventilator. ^[95], ^[96]

Sepsis and multiple organ failure still has a high mortality rate, even in fully equipped intensive care units. Clinical recovery from the neuropathy is rapid and nearly complete in those patients who survive, although it may appear to be incomplete on electrodiagnostic studies. Thus, neuropathy acquired during critical illness,

although causing a delay in weaning from ventilatory support and hospital discharge, does not worsen long-term prognosis. [95]

- [16 - Hypokinesia and Hyperkinesia](#)
- [17 - Coordination and Ataxia](#)
- [18 - Gait and Balance](#)
- [19 - Proprioception, Touch, and Vibratory Sensation](#)
- [20 - Pain and Temperature](#)
- [21 - Autonomic Nervous System](#)
- [22 - Neurovascular System](#)

Part 2 - NEURODIAGNOSTIC TOOLS

- [23 - Neuroimaging](#)
- [24 - Electrophysiology](#)
- [25 - Body Fluid and Tissue Analysis](#)
- [26 - Cerebrospinal Fluid and Intracranial Pressure](#)
- [27 - Neuropsychological Testing](#)

Part 3 - ETIOLOGICAL CATEGORIES OF NEUROLOGICAL DISEASES

- [28 - Developmental Structural Disorders](#)
- [29 - Degenerative and Compressive Structural Disorders](#)
- [30 - Storage Diseases: Neuronal Ceroid-Lipofuscinoses, Lipidoses, Glycogenoses, and Leukodystrophies](#)
- [31 - Aminoacidopathies and Organic Acidopathies, Mitochondrial Enzyme Defects, and Other Metabolic Errors](#)
- [32 - Chromosomal Abnormalities and Neurocutaneous Disorders](#)
- [12 - The Degenerative Dementias](#)
- [34 - Movement Disorders](#)
- [35 - Ataxias](#)
- [36 - Degenerative Motor, Sensory, and Autonomic Disorders](#)
- [37 - Inherited Muscle, Neuromuscular, and Neuronal Disorders](#)
- [38 - Endogenous Metabolic Disorders](#)
- [39 - Exogenous Acquired Metabolic Disorders of the Nervous System: Toxins and Illicit Drugs](#)
- [40 - Nutritional Deficiencies and Syndromes Associated with Alcoholism](#)
- [41 - Viral Infections](#)
- [42 - Nonviral Infections](#)
- [43 - Transmissible Spongiform Encephalopathy](#)
- [44 - Human Immunodeficiency Virus and Acquired Immunodeficiency Syndrome](#)
- [45 - Neurovascular Disorders](#)
- [46 - Primary Neurological Tumors](#)
- [47 - Metastatic Neoplasms and Paraneoplastic Syndromes](#)
- [48 - Demyelinating Disorders of the Central Nervous System](#)
- [49 - Demyelinating Disorders of the Peripheral Nervous System](#)
- [50 - Autoimmune and Inflammatory Disorders](#)
- [51 - Traumatic Disorders](#)
- [52 - Epilepsy](#)
- [53 - Headache and Facial Pain](#)
- [54 - Sleep Disorders](#)
- [55 - Drug-Induced and Iatrogenic Neurological Disorders](#)
