HISTORY AND DEFINITIONS

Consciousness represents the core of our experience as human beings, and its alterations challenge our concepts of self and the meaning or value of life. For the physician, and especially the clinical neuroscientist, these alterations are among the greatest dilemmas, because the disorders that produce them often require swift diagnosis and management based primarily on the physical examination and most probable etiologies. The ancients, at least as far back as the Egyptians at the time of the Edwin Smith surgical papyrus, recognized that the brain was the seat of consciousness. However, the anatomical structures and physiological processes involved in awareness were not elucidated until the middle of the 20th century. The classic studies of Moruzzi and Magoun^[1] established the importance of the midbrain reticular formation as the driving force of consciousness. McNealy and Plum^[2] applied these concepts in their clinical observations, which were published in the 1960s, on patients with mass lesions. With some modifications by Ropper^[3] in recent years, their discussion of the anatomy of lesions altering consciousness, as amplified in the classic text by Plum and Posner,^[4] remains the foundation for analysis of the patient with altered consciousness. The other major source of insight into mechanisms of consciousness comes from the study of patients with epilepsy, particularly by Penfield and Jasper^[5] and by Gloor.^[6] The various theories used to explain loss of awareness during complex partial seizures and absence seizures have helped elucidate the interaction of the cortex and the reticular system.

For the purposes of this book, *consciousness* describes that set of neural processes that allow an individual to perceive, comprehend, and act on the internal and external environments. It is usually envisioned in two parts: *arousal* and *awareness*. Arousal describes the degree to which the individual appears to be able to interact with these environments; the contrast between waking and sleeping is a common example of two different states of arousal. In contrast, awareness reflects the depth and content of the aroused state. Awareness is dependent on arousal, because one who cannot be aroused appears to lack awareness. Awareness does not imply any specificity for the modality of stimulation. This stimulation may be external (e.g., auditory) or internal (e.g., thirst). *Attention* depends on awareness and implies the ability to respond to particular types of stimuli (modality-specific).^[7]

Many terms that describe gradations of consciousness populate the clinical literature. *Stupor* refers to a condition in which the patient is less alert than usual but can be stimulated into responding. *Obtundation* describes a patient who appears to be asleep much of the time when not being stimulated. This eyes-closed state is not electroencephalographic (EEG) sleep, however. Stuporous or obtunded patients respond to noxious stimuli by attempting to deflect or avoid the stimulus. The *comatose* patient lies with eyes closed and does not make an attempt to avoid noxious stimuli. Such a person may display various forms

of reflex *posturing* (defined later), but does not actively try to avoid the stimulus. After a period of coma, some patients may enter a *vegetative state*, in which the patient's eyes open and close, and the patient may appear to track objects about the room and may chew and swallow food placed in the mouth. However, the vegetative patient does not respond to auditory stimuli and does not appear to sense pain, hunger, or other stimuli. This is a state in which there is arousal but no awareness.

Delirium has been redefined in recent years by the psychiatric community through the *Diagnostic and Statistical Manual of Mental Disorders*. In this publication, delirium is defined as "a disturbance of consciousness that is accompanied by a change in cognition that cannot be better accounted for by a preexisting or evolving dementia. The disturbance develops over a short period of time, usually hours or days, and tends to fluctuate during the course of the day. There is evidence from the history, physical examination, or laboratory tests that the delirium is a direct physiological consequence of a general medical condition, substance intoxication or withdrawal, use of a medication, or toxin exposure, or a combination of these factors."^[8]

Many other terms have been applied to gradations of consciousness but lack consistent definitions and usage. For this reason, one should eschew their employment and concentrate on clearly describing what the patient does spontaneously and in response to auditory, visual, and somatic stimulation. This discipline results in clearer communication among the clinicians caring for the patient.

CLINICAL HISTORY

Although the physician confronted with a patient whose alertness is reduced must be prepared to proceed without any external information, knowledge of the patient's history frequently provides important clues regarding the etiology of the problem and the initial approach to management. When an observer can provide the history of the present illness, immediate therapy for likely causes can be instituted. Even when only fragmentary information is available, such data allow the clinician to focus the evaluation more closely and, it is hoped, reach a diagnosis in a more timely fashion.

A history of trauma or underlying medical disease is important to establish, and a list of medications may suggest important intoxication or drug reactions. If the change in consciousness occurred suddenly, a cardiac or primary neurovascular event should be considered, whereas a subacute or slow decline in function may suggest other medical or metabolic causes. Any details on the immediate events surrounding the altered consciousness may help in isolating possible environmental factors, and knowledge of prior events of a similar nature leads the clinician to consider etiologies of a recurrent nature, like epilepsy. Particularly important information on associated medical or neurological signs that occurred just before the loss of consciousness, such as vomiting, altered speech or confusion, hemiparesis, or chest pains, are directly applicable to forming a list of possible diagnoses.

ANATOMY OF CONSCIOUSNESS AND ATTENTION

Anatomy of Arousal

Arousal requires the interplay of both the reticular formation and the cerebral hemispheres. The reticular components necessary for arousal reside in the midbrain and diencephalon; the pontine reticular formation is not necessary for arousal. The midbrain may be viewed as a driving center for the higher structures; loss of the midbrain reticular formation (MRF) produces a state in which the cortex appears to be waiting for the command or ability to function. This is manifested electroencephalographically as alpha coma, in which the resting electrical activity of the cortex appears relatively normal but cannot be altered by external or internal stimuli. This ascending midbrain reticular activating system extends upward into the hypothalamus to the thalamus. It receives collaterals from and is stimulated by every major somatic and sensory pathway directly or indirectly. Because of its many cellular components, this system is best regarded as a physiological rather than a precise anatomical entity. Nonetheless, at least three principle paths project out of the midbrain -- one to the thalamic reticular nucleus and then to the cortex, one to the hypothalamus and then on to the basal forebrain and limbic system, and a third to the brain stem median raphe and locus caeruleus with consequent diffuse cortical projections.^[9]

The precise mechanism of diencephalic involvement in arousal is uncertain. Information from the midbrain reticular formation passes to the thalamic reticular nucleus, through which these signals must pass in order to allow the cortex to function. The thalamic reticular nucleus acts predominantly to inhibit the cerebral cortex via outflow tracts that traverse numerous other thalamic nuclei. By increasing or decreasing thalamic inhibitory mechanisms on the cortex, the ascending reticular system from the midbrain provides a gating mechanism to enhance or diminish neuronal activation.^[10]

Disorders that distort the normal anatomical relationships of the midbrain, diencephalon, and cortex appear to impair arousal by interrupting the flow of information from the midbrain to the cortex. However, it is likely that the diencephalon plays a more active role in the control of arousal than simply that of a conduit. For example, in the prion disorder known as fatal familial insomnia (see [Chapter 44](#)), dysfunction of neurons in the anterior and ventral thalamic nuclei interfere with normal sleep-wake cycling to diminish or even completely prevent sleep.

Because of the diffuse anatomical substrate of arousal, little is known of the specific neurochemistry involved in the maintenance of arousal. It appears, however, that central acetylcholine and monoamine systems (noradrenaline and serotonin) have received the most attention. Cholinergic receptors exist at many levels of this system; antimuscarinic drugs often depress consciousness, and the centrally active cholinesterase inhibitor physostigmine reverses anticholinergic encephalopathy, both observations suggesting a direct role of the cholinergic system. Likewise, norepinephrine and serotonin are neurotransmitters in numerous areas

of the brain stem reticular formation and may serve as direct or indirect chemical components of arousal pharmacology.^[11]

Although older discussions of this material have stressed the role of downward shift of the midbrain in the production of coma, current concepts of pathological anatomy have been revised by the availability of computed tomography (CT) and magnetic resonance imaging (MRI). It is now clear that in patients with lateralized masses, the horizontal displacement of the diencephalon is more closely correlated with the degree of altered awareness than the vertical displacement. In patients with diffuse brain swelling, caudal vertical displacement of the diencephalon is important, but the actual mechanism of coma may relate more to elevated intracranial pressure (ICP), which compromises cerebral perfusion, than the actual movement. Terminally, both lateral masses and diffuse supratentorial brain swelling displace the brain stem caudally, separating it from the basilar artery (which remains fixed to the clivus).

Loss of function of both cerebral hemispheres interferes with normal arousal mechanisms. However, over days to weeks following a severe global cortical injury (e.g., hypoxia), the central nervous system appears to re-establish some degree of arousal. This is clinically apparent in the vegetative state, in which the patient manifests sleep-wake cycling. This condition appears to represent arousal without awareness, and is histopathologically characterized by loss of the cortex with preservation of brain stem and diencephalic reticular structures.

In summary, two primary types of lesions depress the level of arousal, either direct brain stem-diencephalic dysfunction involving the reticular formation and nuclei or bilateral cerebral dysfunction. Unilateral cortical lesions should not impair arousal function unless there is secondary compression or compromise of the other hemisphere or reticular structures, as sometimes occurs with herniation syndromes.

Anatomy of Awareness

Awareness implies that the individual is not only alert but is cognizant of self and surroundings. Interaction of the cerebral cortex and the reticular system is required for the individual to be aware. Analysis of patients in the vegetative state and the study of anencephalic infants provide a picture of reticular system function in the absence of the cerebral cortex. The opposite problem, that of understanding the function of the cortex in the absence of reticular system control, is difficult to study. First, almost all lesions damaging the midbrain or thalamic reticular structures also impair motor output, and second, although the cortex appears electroencephalographically to be idling, there is no electrical technique by which one can determine whether the cortex is aware. A few case reports suggest that olfactory stimulation (which does not require transit through the midbrain or thalamus to reach the cortex) may produce an EEG change, and patients in alpha coma due to a midbrain lesion will rarely alter this EEG pattern. These are the only suggestions that external stimuli can alter cortical function in the absence of reticular system driving. With current techniques, scientists are not able to examine whether the cortex of an individual with a reticular system lesion is able to perceive any internal state (e.g., hunger).

Anatomy of Attention

Attention to specific aspects of the perceived universe depends on both awareness as a general property and on the specific anatomical structures that mediate the sensory phenomena involved. In order to attend to a particular stimulus, the pathways required for its perception must be functional (e.g., the visual system must carry information from the retina to the occipital cortex for visual attention to occur). Each primary sensory modality has one or more principal cortical regions that must function in order to attend to a stimulus (e.g., primary somatosensory cortex in the postcentral gyrus), but the presence of these areas alone is not sufficient for attention. Lesions affecting the more posterior portion of the nondominant parietal lobe, for example, produce extinction of the contralateral stimulus when stimuli are presented simultaneously on each side of the body. A lesion at the occipitoparietal junction produces a similar defect in visual perception of bilateral stimuli. With larger lesions, the patient appears to have increasingly more substantial deficits in awareness of the contralateral half of the universe, including the self.

EXAMINATION OF CONSCIOUSNESS AND ATTENTION

Directed Neurological Examination

OVERVIEW

The examination of the patient with altered consciousness begins by ensuring that the patient's vital signs and basic biochemistry are adequate to support brain function. It is essential to ensure that blood pressure, respiration, and oxygen saturation are adequate and that the patient is not hypoglycemic or thiamine deficient before proceeding with the examination outlined later. In many situations (e.g., emergency departments), naloxone is also administered at this point to reverse any putative effects of opiates. The empirical use of flumazenil to antagonize potential benzodiazepine intoxication as a routine measure is controversial because of the risk of provoking seizures or status epilepticus, especially in patients with mixed benzodiazepine and cyclic antidepressant overdoses.

The initial goals of the examination of the patient with apparent altered consciousness are first to determine whether the patient is conscious and then, in patients with altered awareness, to determine whether or not the reticular system is functional. Because altered awareness requires either reticular system dysfunction or bilateral hemispheric dysfunction, testing the structures immediately adjacent to the reticular system provides the major clues regarding the etiology of altered consciousness and

TABLE 1-1 -- CLINICAL FINDINGS WITH DIFFERENT LEVELS OF CENTRAL NERVOUS SYSTEM DYSFUNCTION

Dysfunction	Response to Noxious Stimuli	Pupils	Eye Movements	Breathing
Both cortices	Withdrawal	Small, reactive	Spontaneous conjugate horizontal movements; if none, cervico-ocular or vestibulo-ocular reflexes can be elicited	Posthyperventilation apnea or Cheyne-Stokes respiration
Thalamus	Decorticate posturing	Same as above, unless the optic tracts are also damaged	Same as above	Same as above
Midbrain	Decorticate or decerebrate posturing	Midposition, fixed to light	Loss of ability to adduct. Both eyes may be deviated laterally (wall-eyed) (CN III damaged)	Usually same as above; potential for central reflex hyperpnea
Pons	Decerebrate posturing	Usually small; may exhibit bilateral pinpoint pupils (especially with midline pontine hemorrhage); Horner's syndrome with lateral lesions	Loss of conjugate horizontal movements with retained vertical movements and accommodation. Often eyes are deviated medially (CN VII damage)	May exhibit central reflex hyperpnea, cluster (Biot's) breathing, or apneustic breathing
Medulla	Weak leg flexion (or none)	Usually small; Horner's syndrome with lateral lesions	Usually no effect on spontaneous eye movements; may interfere with reflex responses; rarely, nystagmus	Rarely, ataxic respiration; apnea if respiratory centers involved

thereby determines the direction of subsequent investigations. The major findings on examination and their expected anatomical correlates are presented in [Table 1-1](#). These correlations are with the level of *dysfunction*, which may involve a substantially larger portion of the nervous system than the degree of actual *damage*.¹²

The findings on these examinations are often summarized by use of the Glasgow Coma Scale.¹³ Because the verbal response of intubated patients is difficult to assess, one either ignores it (assigning it a value of T, for intubated) or imputes a score based on the examiner's estimate of what the patient could do. Although the results of this evaluation are frequently presented as the sum of the values, this practice is of limited utility. This procedure is of value in indicating the severity of head injury, in which a total score of 3 to 8 indicates severe trauma, 9 to 13 moderate trauma, and 14 to 15 mild trauma. However, the real utility of the score is to provide a simple way of detecting changes in the examination over time, with good inter-rater reliability, in circumstances of global cerebral dysfunction (e.g., trauma, intoxication). The score has limited utility in patients with focal neurological dysfunction.

At all times in the initial examination of the patient with suspected impaired awareness, the examiner must recall that the patient may in fact be capable of sensing and remembering. Although noxious stimuli may be required for an adequate examination, the minimum necessary stimulation should be employed, and the examiner should always be cognizant of the need for explanation of procedures, especially potentially painful ones. This caveat should carry over from the first encounter with the patient throughout the course of treatment. Attempts to communicate the level of sedation in patients is particularly problematic. For patients who are intoxicated or therapeutically sedated, the scale proposed by Ramsay and colleagues is commonly used ([Table 1-2](#)).¹⁴

ASSESSMENT OF AROUSAL

Observation of the Patient's Ambient State. A great deal can be learned by watching the patient before the formal examination. Is the patient lying still in bed when not stimulated (required for the diagnosis of coma), or does he or she exhibit spontaneous movements? Evaluation of the patient's spontaneous movements often yields information of localizing and lateralizing significance. An externally rotated leg in a comatose patient is frequently evidence of corticospinal tract dysfunction due to a contralateral hemispheric lesion. Do the eyes open spontaneously, and are there other facial movements? Minor facial or extremity twitching is frequently the only physical finding in patients suffering from nonconvulsive status epilepticus. Is there evidence of trauma to the head or the rest of the body?

The examiner next asks the patient to follow verbal commands. Early in the examination, ask the patient to open the eyes and look up; this will detect patients with pontine lesions that prevent all other somatic motor output (the locked-in syndrome; see later). Such patients may appear comatose but are not, and care must be taken to recall that they are alert and cognizant, and have intact auditory and somatosensory systems despite their brain stem disorder.¹⁵

Pupillary Responses to Light. The parasympathetic reflex arc begins in the retina, traverses the base of the brain, runs through the midbrain, and returns to the pupil

TABLE 1-2 -- SEDATION SCALE

Level	Patient's State
1	Awake, anxious and agitated, or restless
2	Awake, cooperative, oriented, and tranquil
3	Awake but responds to commands only
4	Appears asleep (this is not true sleep) but responds briskly to a light glabellar tap or a loud auditory stimulus
5	Appears asleep, and responds only sluggishly to a light glabellar tap or a loud auditory stimulus
6	Appears asleep, with no response to stimuli

From Ramsay MA, Savage TM, Simpson BR, Goodwin R: Controlled sedation with alphaxalone-alphadolone. *BMJ* 1974;2:656-659.

(see [Chapters 8](#) and [9](#)). Disorders altering pupillary constriction typically affect the midbrain or the third cranial nerve. Compression of the superior colliculus (e.g., by a pineal region mass) interferes with input to the pretectal nuclei, resulting in pupils that are large (because the sympathetic system is not affected), unreactive to

light, and sometimes displaying *hippus*. Lesions affecting the area of the Edinger-Westphal nucleus and the origins of the third cranial nerves are the most important, because this area is adjacent to the superior pole of the midbrain reticular formation. Because the descending sympathetic efferent fibers also traverse this portion of the brain stem, dysfunction produces pupils that are midposition (4 to 6 mm in diameter), unreactive to light, and frequently slightly irregular. Such pupils are an ominous finding, usually indicating that coma is due to structural damage affecting the upper midbrain, and unless its etiology can be reversed quickly, the patient's coma is usually irreversible. Because the pupillary constrictor has a muscarinic, rather than a nicotinic, acetylcholine receptor, it is not affected by drugs given to block neuromuscular transmission. However, it is affected by systemic antimuscarinic drugs (e.g., atropine), so one must be cautious about interpreting the examination if such agents are being used.

Unilateral loss of pupillary constriction in the comatose patient may rarely indicate subarachnoid hemorrhage from an internal carotid aneurysm that compresses the third nerve at the origin of the posterior communicating artery. Much more commonly, such a finding indicates the presence of a mass lesion that has shifted the diencephalon laterally. Although older studies suggested that this finding arose from compression of the third cranial nerve by the herniating temporal lobe, the unilaterally dilated pupil appears to develop before actual movement of the medial temporal structures over the tentorial edge. Ropper's work demonstrates that unilateral pupillary dilation results from traction on the third nerve produced when the diencephalon, being pushed away from an expanding lateral mass, pulls the midbrain with it. Because the third cranial nerve is tethered anteriorly at the cavernous sinus, the nerve ipsilateral to the mass is subjected to stretching and the pupil dilates. Early in the course of this process, therapies that decrease the degree of shift (e.g., administration of mannitol) can reverse the pupillary dilation.

The sympathetic pathways begin in the hypothalamus, descend through the brain stem and spinal cord to the first thoracic level, and then exit the central nervous system to traverse the face and reach the pupil. Most sedative drugs produce bilateral small pupils by antagonizing sympathetic outflow at the hypothalamic level; other agents, such as opiates, appear to have an additional effect of stimulating the parasympathetic system, resulting in very small (pinpoint) pupils. Lesions affecting the sympathetic system below the midbrain do not directly affect consciousness.

Conjugate Eye Movements. The position and movements of the eyes are observed, and certain easy-to-administer procedures are undertaken to evaluate the integrity of the cerebral hemisphere and brain stem. The neural pathways for the control of horizontal conjugate eye movements are outlined in Figure 1-1 (Figure Not Available). Cortical control originates in the frontal gaze centers (Brodmann's area 8), and descending fibers controlling horizontal conjugate gaze cross the midline in the lower midbrain region and descend to

Figure 1-1 (Figure Not Available) Conjugate vision pathways; nuclei and paths are shaded to include those important to left conjugate gaze: fibers from the right frontal cortex descend cross the midline, and synapse in the left paramedian pontine reticular formation (PPRF). Fibers then travel to the nearby left cranial nerve VI nucleus (to move the left eye laterally) and then cross the midline to rise in the medial longitudinal fasciculus (MLF) to the right cranial nerve III nucleus (to move the right eye medially). In addition to the cortical influence on the left PPRF, there is vestibular influence. With cold water placed in the left external ear canal, the crossed pathway from the right vestibular nucleus to the left PPRF predominates and drives the eyes conjugately to the left. This procedure tests the integrity of the brain stem circuit that includes the vestibular nucleus, the PPRF, and cranial nerves III and VI and the MLF. If the eyes move to the side of cold water infusion, the brain stem from medulla to midbrain must be functioning. (From Weiner WJ and Goetz CG [eds], *Neurology for the Non-Neurologist*, 3rd ed. Philadelphia, J.B. Lippincott Company, 1994.)

the paramedian pontine reticular formation (PPRF) in the pons. The systems producing conjugate eye movements in the conscious and unconscious states vary slightly. Conscious horizontal conjugate eye movements depend on the PPRF for their coordination, whereas such movement in the unconscious patient appears to bypass this region and depend directly on the abducens nuclei for their coordination. Because these small structures are directly adjacent to each other and are caudal to the portion of the reticular formation necessary for consciousness, this distinction is not usually of consequence. The region of PPRF and adjacent neurons is thus the major area of confluence of pathways controlling horizontal eye movements.

from the PPRF project to the nearby abducens nerve (cranial nerve VI) nucleus and thereby stimulate movements in the lateral rectus muscle of the eye ipsilateral to the PPRF and contralateral to the frontal gaze center. In addition, fibers from the abducens nerve nucleus cross the midline and ascend the median longitudinal fasciculus (MLF) to the medial rectus nucleus of the oculomotor nerve (cranial nerve III) in the midbrain. This activation stimulates adduction of the eye ipsilateral to the frontal gaze center, and conjugate gaze is thus completed. Because this system overlaps in space with the midbrain reticular formation, conjugate gaze examination is of vital importance in the comatose patient. In contrast to the pupillary constrictors, these muscles have nicotinic neuromuscular junctions and are therefore susceptible to neuromuscular junction blocking agents.

By following the pathways outlined in the figure, the consequences of lesions at various levels of the neuraxis can be deduced. Stimulation of fibers from the frontal gaze center of one cerebral hemisphere results in horizontal, conjugate eye movements to the contralateral side. If one frontal gaze center or its descending fiber tract is damaged, the eyes drift toward the involved cerebral hemisphere due to unopposed action of the remaining frontal gaze center. For example, a destructive lesion in the right cerebral hemisphere, involving descending motor fibers and frontal gaze fibers, causes a left hemiplegia, with head and eyes deviated to the right. In other words, the eyes appear to look at a destructive hemispheric lesion and look away from the resulting hemiplegia.

By contrast, a destructive left pontine lesion, for example, damages the left PPRF and surrounding region. The eyes, therefore, cannot move to the left and tend to deviate to the right. Because descending pyramidal tract fibers cross the midline in the medulla, damage to the pyramidal tract fibers in the pons on the left results in a right hemiplegia. Thus, the eyes appear to look away from a destructive pontine lesion but look toward the hemiplegia.

If the abducens nerve or nucleus is destroyed, there is a loss of abduction of the ipsilateral eye (cranial nerve VI palsy). With destruction of the tract of the medial longitudinal fasciculus, disconjugate gaze results, with loss of adduction of the ipsilateral eye (same side as the tract of the MLF). Abduction of the contralateral eye is preserved, but there is nystagmus in the awake patient. This type of disconjugate gaze abnormality is also termed internuclear ophthalmoplegia. The pathways for vertical eye movements are less well understood. Lower centers likely exist in the midbrain (pretectal and tectal) regions.

If a patient cannot follow verbal commands, two useful tests are employed to determine brain stem integrity. They activate the PPRF and subsequent pathways, not by cortical stimulation but rather by vestibular alterations. An oculocephalic or cervico-ocular (or doll's eyes) reflex is performed by turning the patient's head rapidly in the horizontal or vertical planes and by noting the movements or position of the eyes relative to the orbits. This test obviously should not be performed if a cervical neck fracture is suspected. If the pontine (horizontal) or midbrain (vertical) gaze centers are intact, the eyes should move in the orbits in the direction opposite to the rotating head. An abnormal response (no eye movement on moving the head) implies pontine or midbrain dysfunction and is characterized by no movement of the eyes relative to the orbits, or an asymmetry of movements.

Horizontal oculocephalic maneuvers are a relatively weak stimulus for horizontal eye movements. If a doll's eyes reflex is present, it is not necessary to continue with oculocephalic testing. If, however, the doll's eyes reflex is lacking, ice water calorics should be performed, because ice water is a stronger stimulus than oculocephalic maneuvers.

Oculocephalic responses (ice water calorics) are reflex eye movements in response to irrigation of the external ear canals with cold water. The head is raised to 30 degrees relative to the horizontal plane, and the external canals are inspected for the presence of cerumen or a perforated tympanic membrane. Fifty to one hundred milliliters of cold water is instilled into the canal (waiting 5 minutes between each ear), and the resulting eye movements are noted. Ice water produces a downward current in the horizontal semicircular canal and decreases tonic vestibular output to the contralateral PPRF. Simplistically, one can think of this as an indirect means of stimulating the ipsilateral PPRF. Hence, after cold water instillation, there should be a slow, tonic, conjugate deviation of the eyes toward the irrigated ear if the brain stem is intact. In a comatose patient, there is a loss of the past-phase nystagmus, and only tonic deviation of the eyes is seen if appropriate pontine-midbrain areas are intact. Thus, if nystagmus is noted in a seemingly unconscious patient, the patient is not truly comatose.

Thus, a lack of oculocephalic responses suggests pontine-midbrain dysfunction. Ice water calorics can help differentiate between the conjugate gaze weakness, or paralysis caused by either cortical (cerebral hemisphere) or brain stem (pontine) damage. Oculocephalic responses should not be altered in patients with only hemispheric pathology other than the loss of nystagmus.

Movement of the ipsilateral eye toward the irrigated ear but no movement of the contralateral eye suggests an abnormality of the contralateral MLF.

Although tradition dictates that the head be elevated 30 degrees (in order to place the horizontal semicircular canal in a vertical orientation, thereby maximizing the effect of gravity on endolymphatic movement), the superiority of this position over others has not been solidly demonstrated.

Breathing Patterns. Various respiratory patterns have localizing significance in the patient with altered consciousness. These patterns are recognizable by bedside observation. Before proceeding to detailed analysis of the respiratory pattern, the examiner should be certain that the upper airway is intact. If it is not, endotracheal intubation should be performed immediately unless the patient has an advance directive prohibiting this maneuver. The respiratory pattern can be easily assessed

after intubation, recognizing the confounding effects of drugs given to facilitate the procedure and the increased work of breathing required by the smaller diameter of the new airway.

The respiratory pattern is determined by observation but should be interpreted in the light of arterial blood gas results. Tachypnea should be interpreted differently in patients who are hypoxic than in those who are normoxic. In the analysis of blood gas results, recall that the brain stem

TABLE 1-3 -- RESPIRATORY PATTERNS IN PATIENTS WITH ALTERATIONS OF CONSCIOUSNESS

Pattern	Description	Localization	Comments
Posthyperventilation apnea	Apnea for more than 10 seconds after 5 deep breaths	Bilateral hemispheric dysfunction	Normally, the cerebral cortex triggers another breath within 10 seconds regardless of the PaCO ₂
Cheyne-Stokes respiration	Rhythmic waxing and waning of respiratory amplitude	Bilateral hemispheric dysfunction	1. Periods of "apnea" are actually times when the respiratory amplitude is too low to measure, but the respiratory rhythm is unchanged; 2. Congestive heart failure prolongs the reflex arc (blood leaving the lungs takes longer to reach the brain stem than is normal) and may produce this finding without any neurologic dysfunction
Central reflex hyperpnea (CRH) (formerly called central neurogenic hyperventilation)	Continuous deep breathing	Bilateral hemispheric (e.g., trauma), lower midbrain, upper pons, possibly medulla	When present in patients with brain stem lesions or subarachnoid hemorrhage, CRH is most commonly due to the hypoxia that accompanies neurogenic pulmonary edema. True central neurogenic hyperventilation is rare.
Apneustic respiration	Prolonged inspiratory time ("inspiratory cramp")	Pons	Does not support adequate ventilation (true for all following patterns as well). Isolated lesions at these levels do not produce coma.
Cluster (Biot's) breathing	Clusters of breaths punctuated by apnea	Lower pons	
Ataxic respiration	Infrequent, irregular breaths	Lower pons or upper medulla	
Ondine's curse	Failure of involuntary respiration with retained voluntary respiration	Medulla	
Apnea	No respiration	Medulla down to C4; peripheral nerve (e.g., acute inflammatory polyneuropathy), neuromuscular junction (e.g., myasthenia gravis), muscle	

is primarily concerned with the maintenance of pH and PaO₂, not PaCO₂. Thus, compensation for a metabolic acidosis produces a pattern resembling central reflex hyperpnea, but the arterial blood gas analysis shows a pH below 7.35, which is indicative of a primary metabolic problem, such as diabetic ketoacidosis. The anatomical correlations of the major respiratory patterns are found in [Table 1-1](#), and the patterns themselves are summarized in [Table 1-3](#).

Motor Examination. The level of neurological dysfunction is often best defined by the motor examination. If the patient responds to noxious stimuli by any defensive maneuver, such as withdrawal from the stimulus, that patient is not truly comatose. Such a response may be seen in patients whose examinations otherwise suggest no cortical function, presumably because a noxious stimulus powerfully evokes an arousal response. Stereotyped posturing (spontaneous or induced) indicates that the cerebral cortices are no longer in command of the motor system.^[16] The physiological levels of dysfunction are summarized in the motor component of the Glasgow Coma Scale ([Table 1-4](#)).

Experiments in animals led to the concepts of *decorticate* and *decerebrate* rigidity. These terms have produced endless confusion, and these states are perhaps better called by the labels used in the Glasgow Coma Scale: decorticate rigidity is abnormal flexion, and decerebrate rigidity is abnormal extension. Physiologically, these states reflect loss of higher motor control functions, either leaving the rubrospinal system in command (in flexor posturing) or ceding control to the vestibulospinal and reticulospinal systems (in extensor posturing). These postures do not mean that the higher control centers have been destroyed but indicate that they are not functioning. Patients with lateral mass lesions may demonstrate flexor posturing on one side of the body and extensor posturing on the other (usually the side contralateral to the mass; see [Chapter 15](#)).

ASSESSMENT OF AWARENESS

Although the comatose patient, by definition, does not manifest spontaneous eye opening (except in association

TABLE 1-4 -- GLASGOW COMA SCALE

Item	Response	Score
Verbal response	Oriented	5
	Confused	4
	Inappropriate words	3
	Incomprehensible	2
	None	1
Eye opening	Spontaneous	4
	To speech	3
	To pain	2
	None	1
Motor	Obeys commands	6
	Localizes pain	5
	Withdraws	4
	Abnormal flexion	3
	Abnormal extension	2
	None	1

with the vertical eye movements that may accompany a suppression-burst EEG pattern), the presence of spontaneous eye opening and even conjugate eye movements does indicate awareness; these findings are part of the vegetative state, in which the patient has arousal without awareness. Thus, testing for awareness must involve observation for the response to various stimuli and is not practically separable from testing for attention, because inattention to the stimuli chosen could be misinterpreted for unawareness (e.g., failure to respond to verbal commands on the part of a deaf patient). The patient who appears to be awake (i.e., aroused) but fails to attend to any stimuli (internal or external) is identified as lacking awareness.

ASSESSMENT OF ATTENTION

Tests of attention must include several modalities and be presented from both sides of the patient in order to avoid misinterpreting disorders of primary sensation or attention as disordered awareness. Typically, verbal, visual, and somatosensory stimuli are employed. Descriptions of the available tests for attention take up major portions of neuropsychology texts and are beyond the scope of this chapter. Only the basic principles commonly used in bedside screening of patients with impaired consciousness are discussed here.

Patients who are unable to respond to verbal commands (e.g., owing to receptive aphasia) may be able to direct themselves toward a voice or other sound (usually presented contralateral to the nondominant hemisphere). Assessing the response to visual stimuli may require passive eye opening (e.g., in patients with nondominant parietal lesions who have a transient apraxia of eyelid opening). Standardized tests of attention (e.g., the trailmaking test) are valuable in following patients over time, especially in assessing their response to therapy.

Associated Neurological Findings

Cerebral. The scope of potential physical findings related to lesions of the cerebral cortex in patients with altered awareness is itself the subject of several texts. Rather than attempting to perform specific tests of cortical function in these patients, one should concentrate on (1) using the neurological examination to identify lateralized lesions that may be affecting consciousness by shifting the diencephalon, and (2) detecting focal dysfunction that may be misinterpreted as altered consciousness (e.g., a patient with receptive aphasia who is misdiagnosed as confused or psychotic).

Cranial Nerves. In addition to the eye movements discussed earlier, the cranial nerve examination is crucial for the detection of brain stem lesions. Fundoscopic examination may also provide a clue to the presence of elevated ICP. Conscious patients may exhibit nystagmus with a variety of intoxications. In anyone with a confusional state, detection of altered eye movements should prompt consideration of Wernicke's encephalopathy (see [Chapter 40](#)).

Motor/Reflexes/Cerebellar/Gait. Asterixis is a nonspecific sign of bilateral cortical dysfunction. Hemiparesis indicates a lesion of the upper motor neuron paths and may suggest either a contralateral cortical or paramedian brain stem lesion. Quadriplegia suggests a midline brain stem lesion. Signs of cerebellar dysfunction are unusual in patients with cerebellar infarcts or hemorrhages, which alter consciousness by producing brain stem compression or obstructive hydrocephalus. Finding cerebellar dysfunction or abnormal gait in a confused patient should raise the possibility of nutritional deficiencies (e.g., Wernicke's encephalopathy, vitamin B₁₂ deficiency) or intoxications (see [Chapters 39](#), [40](#), and [55](#)).

Autonomic Nervous System. Autonomic instability can be both a cause and an effect of coma. In lesions affecting the descending sympathetic pathways from the hypothalamus to the brain stem, Horner's syndrome with a mildly constricted pupil ipsilateral to the lesion can be seen. Whereas diencephalic lesions are particularly associated with erratic changes in autonomic stability, the most common causes of coma with marked dysautonomia are intoxication and drug overdose (see [Chapters 38](#) and [55](#)).

Neurovascular System. Because cardiac and vascular disease are commonly associated with coma, a thorough examination of these systems is essential. Arrhythmias, specifically atrial fibrillation, are associated with emboli that can shower the cortices and provoke multifocal bilateral cerebral dysfunction, leading to coma. The large vessels of the neck should be examined for evidence of carotid disease. The fundoscopic examination likewise complements the neurovascular examination in detecting disease that affects central nervous system vasculature.

Associated Medical Findings

Beyond measuring vital signs and detecting evidence of trauma, the general physical examination is most important for clues to systemic disorders that may alter consciousness. In the initial evaluation, detection of nuchal rigidity and skin lesions are the most important portions of the examination, because they may indicate the presence of bacterial meningitis (or, with nuchal rigidity, either subarachnoid hemorrhage or cerebellar tonsillar herniation). Other points of importance include evidence of hepatic disease, especially jaundice and signs of portal hypertension. An irregular cardiac rhythm raises the suspicion of systemic embolism, which may alter consciousness by producing a brain stem infarct or large bilateral cortical infarcts. Hematomas or purpura raise the possibility of platelet or coagulation disorders and may be associated with intracranial bleeding or conditions such as thrombotic thrombocytopenic purpura. Edema may reflect cardiac, hepatic, renal, or nutritional disorders.

EVALUATION GUIDELINES

The use of neurodiagnostic studies in patients with altered consciousness with specific syndromes is outlined in [Table 1-5](#).

Neuroimaging. Neuroimaging studies should be selected based on the patient's history and the initial examination. If a structural lesion is suspected, an emergent CT scan should be obtained to guide therapy. Patients with

TABLE 1-5 -- USEFUL STUDIES IN THE EVALUATION OF DISORDER OF LEVEL OF CONSCIOUSNESS

Syndrome	Neuroimaging	Electrophysiology	Fluid and Tissue Analysis	Neuropsychological Tests
Bilateral cortical dysfunction; confusion and delirium	Usually normal; may show atrophy; rarely bilateral chronic subdural hematoma or evidence of herpes simplex encephalitis; dural enhancement in meningitis, especially neoplastic meningitides	Diffuse slowing; often, frontally predominant intermittent rhythmic delta activity (FIRDA); in herpes simplex encephalitis, periodic lateralized epileptiform activity (PLEDS)	Blood or urine analyses may reveal etiology, CSF may show evidence of infection or neoplastic cells	In mild cases, difficulty with attention (e.g., trailmaking tests); in more severe cases, formal testing is not possible
Diencephalic dysfunction	Lesion(s) in or displacement of diencephalon; also displays mass displacing the diencephalon	Usually, diffuse slowing; rarely, FIRDA; in displacement syndromes, effect of the mass producing displacement (e.g., focal delta activity, loss of faster rhythms)	Usually not helpful	Usually not obtained
Midbrain dysfunction	Lesion(s) in the midbrain or displacing it	Usually, diffuse slowing; alpha coma; evoked response testing may demonstrate failure of conduction above the lesion	Rarely, platelet or coagulation abnormalities	Usually not performed
Pontine dysfunction	Lesion(s) producing syndrome; thrombosis of basilar artery	EEG: usually normal; evoked responses usually normal	Rarely, platelet or coagulation abnormalities	Usually not performed
Medullary dysfunction	Lesion(s) producing dysfunction	EEG: normal; brain stem auditory and somatosensory evoked responses may show conduction abnormalities	Rarely, platelet or coagulation abnormalities	Usually not performed
Herniation syndromes	Lesion(s) producing herniation; appearance of perimesencephalic cistern	Findings related to etiology	Findings related to etiology	Usually not performed
Locked-in syndrome	Infarction of basis pontis	EEG and evoked potential studies: normal	Findings related to etiology	Usually not performed
Death by brain criteria	Absence of intracranial blood flow above the foramen magnum	EEG: electrocerebral silence; evoked potential studies may show peripheral components (e.g., wave I of brain stem auditory evoked response) but no central conduction	Absence of hypnosedative drugs	Not done
Psychogenic unresponsiveness	Normal	Normal	Normal	Helpful after patient "awakens"

CSF, Cerebrospinal fluid; EEG, electroencephalogram, FIRDA, frontally predominant intermittent rhythmic delta activity; PLEDS, periodic lateralized epileptiform activity.

bilateral hemispheric dysfunction do not usually benefit from emergent CT scanning. Although MR imaging is almost always superior in quality to CT, the pulse sequences currently employed may not detect all cases of acute intracranial bleeding. CT scanning is usually faster and more readily available in emergent circumstances.^[17] Positron emission tomography may be useful in the study of vegetative patients but is not widely available.

Electrophysiology. An EEG is indicated in most patients with altered consciousness at some point in their evaluation, usually after a structural lesion has been excluded, because the history and examination are inadequate to detect many cases of nonconvulsive status epilepticus. Patients in whom supratentorial structural lesions are present but are not adequate to explain the patient's state based on their location and size should also have an EEG performed.

Some EEG findings in patients with encephalopathy are characteristic; for example, frontally predominant rhythmic delta activity (FIRDA) and triphasic waves are common in metabolic disorders. An alpha coma pattern indicates either a midbrain lesion, anoxia, or hypnosedative drug overdose. In the setting of a hypnosedative drug overdose, the patient has a good prognosis for recovery. An unexpectedly normal EEG, with alpha blocking on passive eye opening and normal sleep-wake cycling, should alert the physician to the likelihood of psychogenic unresponsiveness. The EEG may also provide clues to otherwise unexpected diagnoses, such as subacute spongiform encephalopathy, which may come to medical attention in the guise of an acute encephalopathy. Evoked response studies are of limited value in these patients, and although abnormalities may be present (see [Table 1-5](#)), these studies seldom contribute diagnostically or therapeutically useful data in this population.^[18]

Fluid and Tissue Analysis. Although the concept of routine tests has fallen from favor in laboratory medicine circles because of pressure from third-party payors, the patient with unexplained bilateral hemispheric dysfunction should indeed have a battery of screening tests to allow the physician to detect treatable etiologies rapidly. At a minimum, these tests should include a complete blood count with differential, platelet estimate or count, prothrombin time, partial thromboplastin time, serum osmolality, and serum and urinary screening for drugs of abuse.

If oral drug ingestion is considered a possibility, gastric aspiration for analysis of the contents and removal of remaining

unabsorbed drug is indicated. If the patient's airway protective reflexes are compromised, endotracheal intubation should be performed first. Induction of vomiting is no longer recommended in the emergency department because it may interfere with the use of activated charcoal to bind drugs. This substance may be used routinely unless acetaminophen ingestion is suspected, because it will interfere with the absorption of acetylcysteine as well.

Cerebrospinal Fluid. Cerebrospinal fluid (CSF) analysis is crucial in some conditions that alter consciousness (e.g., suspected meningitis) and is irrelevant in others. Thus, the decision to perform a lumbar puncture is based on the entire clinical picture. If bacterial meningitis is suspected and the physician believes that an imaging study should precede the lumbar puncture in these patients, then appropriate antibiotic therapy should be started before the patient is sent for the imaging study. Pneumococcal and meningococcal meningitides may be so rapidly fatal that even a brief delay in instituting antibiotic treatment should not occur.

Subarachnoid hemorrhage, either as a single event or as a repeated phenomenon, can also be diagnosed by lumbar puncture. The pattern of red blood cells and various pigments helps in establishing whether a patient with a known subarachnoid hemorrhage and a new onset of depressed level of consciousness has rebled or suffered another event like vasospasm.

In many instances of altered level of consciousness, ICP changes due to an intracranial mass lesion, ventricular obstruction, or other causes. As discussed in [Chapter 26](#), ICP reflects the net effect of static and dynamic forces affecting the intracranial contents. In the clinical context of decreased intracranial compliance, relatively small changes in volume have the potential to effect dangerous changes in pressure when the ICP is already elevated. Therefore, sudden and nonlinear rises in pressure are particularly important to control through ICP monitoring. Whereas in the normal brain, the perfusion pressure (mean arterial pressure minus mean ICP) must drop below 40 mm Hg before cerebral blood flow is impaired, in the damaged brain, the determinate pressure is less clear. Furthermore, often pressure increases are not distributed evenly throughout the cranium, and compartmentalized, very high pressure areas may not be accurately recorded by ICP monitoring. These features are particularly problematic in the instance of focal lesions with risks of herniations.

Neuropsychological Tests. Although most focal cortical abnormalities should be detected by the bedside neurological examination, formal neuropsychological testing may be valuable for detecting focal neurological dysfunction in patients who are thought to have diffuse disorders. This may be especially valuable in patients who present with an acute encephalopathy but do not improve, or in whom subsequent information indicates that a more chronic dementing process may be present.

CLINICAL SYNDROMES

Syncope

Syncope refers to rapid, transient loss of consciousness that is most commonly due to cardiovascular problems (e.g., dysrhythmias) but that may also be a reflection of autonomic disturbances. These autonomic disturbances are frequently drug induced but may include such conditions as Shy-Drager syndrome. The other major differential diagnostic concern for the neurologist is a seizure presenting as loss of consciousness. The patient's history is essential in distinguishing conditions of inadequate cerebral blood flow from seizures.

Many patients with syncope of cardiac or autonomic origin have a brief tonic spasm when they lose consciousness, and a minority have a tonic-clonic seizure. This situation appears to be more common in children and young adults, and may be exacerbated if the patient is not allowed to become recumbent during the period of hypotension. The congenital syndromes of QT interval prolongation (e.g., Romano-Ward syndrome) are frequently misdiagnosed as a primary seizure disorder instead of a cardiac arrhythmia. Analyses of patients undergoing induced ventricular fibrillation as part of a cardiac electrophysiological study reveal a high incidence of seizures in this setting.^[19] EEG should be reserved for cases in which there is a reason in the history or findings on examination to suspect seizures or in which the cardiac and autonomic evaluations have not yielded a diagnosis. Other than seizures or rare autonomic neuropathies, primary neurological disorders are extremely unlikely to cause syncope.

Bilateral Cortical Dysfunction

Confusion and delirium are common in hospitalized patients, especially the elderly. In this setting, drugs prescribed for the patient must be considered the first candidates for causing this state. Other common possibilities include nutritional disorders and withdrawal from alcohol or other hypnosedative agents. Even seemingly subtle changes in the patient's medication regimen, such as accidental discontinuation of a thyroid replacement medication, can lead to a metabolic encephalopathy with depressed consciousness. Patients in intensive care units (ICUs) are sometimes thought to develop delirium because of sleep deprivation, but this concept of ICU psychosis has come under attack in recent years, because almost all such patients have other reasons for acute confusion.

Diencephalic Dysfunction

Disorders of the diencephalon may affect consciousness either directly, by interfering with reticular system function, or indirectly, by producing endocrine disorders. These conditions may develop slowly, as with anterior pituitary syndromes resulting in hypothyroidism or cortisol deficiency, or rapidly, as with osmoregulatory disorders. The lesions producing these problems may also affect the cerebral cortex, as in the case of neoplasms, and produce seizures or other focal neurological disorders. Patients with structural diencephalic lesions may have toxic downward eye deviation, small pupils, decorticate posturing, and Cheyne-Stokes respirations as an archetype, although varying combinations of signs may appear.

Midbrain Dysfunction

The classic midbrain syndrome associated with depressed consciousness involves midsized pupils, often unilateral cranial nerve III paresis with compensatory forced adduction (wall-eyes) and retractive nystagmoid movements. Decerebrate or decorticate posturing can occur, and a severe respiratory alkalosis can arise from central neurogenic hyperventilation. Rarely, patients with midbrain dysfunction can actually remain awake but have an altered state termed peduncular hallucinosis of L'hermitte. In this situation, the patient experiences intense visual hallucinations in a clear sensorium. These phenomena have been likened to dreams in an awake state, and disrupted brain stem pathways involved in sleep-wake physiology may be implicated in this remarkable syndrome.

Pontine and Medullary Dysfunction

Hemorrhage into the basis pontis frequently extends rostrally into the midbrain and appears to produce coma by interference with midbrain reticular function. This condition is associated with pinpoint pupils, presumably reflecting both parasympathetic irritation as well as sympathetic outflow disruption. Importantly, however, most patients presenting in coma with pinpoint pupils are suffering from an opiate overdose and not specific pontine dysfunction. Naloxone quickly reverses opiate pupillary changes but has no effect on pontine lesions. Patients with pontine lesions that cause coma from involvement of midbrain reticular dysfunction may also have a flaccid hemiparesis or paraparesis, irregular respirations termed apneustic, and a variety of extraocular palsies. These problems may include conjugate deviation of the eyes toward the hemiparetic body if the PPRF has a lesion, unilateral or bilateral sixth nerve palsies or an internuclear ophthalmoplegia if the MLF has a lesion. Cold caloric testing usually clarifies the ocular dysfunction.

Primary pontine lesions without midbrain involvement may mimic coma as the "locked-in" syndrome by interrupting almost all efferent pathways from the cerebral cortex. Infarction of the basis pontis disrupts the corticospinal tracts (producing tetraplegia), the PPRF and abducens nuclei (eliminating conjugate horizontal eye movements), and the facial nerves in their course around the abducens nuclei (resulting in complete facial paralysis). Because the MRF is spared, however, the patient is awake and alert; and because the sensory pathways have migrated to a posterior position in the pons, both the auditory and somatosensory systems are functional. The only voluntary motor act of which the patient is capable is conjugate vertical eye movements. When the patient is not actively moving the eyes, spontaneous vertical movements known as ocular bobbing may develop.

Although this condition was previously emphasized because of the possibility that a sentient patient would mistakenly be judged comatose, the advent of thrombolytic therapy for cerebrovascular diseases mandates that these patients be identified rapidly so that they may be considered for intravenous recombinant tissue plasminogen activator (rt-PA) treatment. At present, studies of intra-arterial thrombolysis are in progress.

The locked-in state is occasionally mimicked by severe neuropathic disorders (e.g., acute inflammatory polyneuropathy, the Guillain-Barre(c) syndrome) and other widespread peripheral disorders.

Herniation Syndromes

Herniation occurs when the brain is subjected to pressure gradients that cause portions of it to flow from one intracranial compartment to another. Although the brain has substantial elasticity, the arteries and veins responsible for its blood supply are relatively fixed in space, producing a risk that brain shifts will cause the moving portions to lose their blood supply. In the case of lateral herniation, the hernia itself may compress or distort vessels, similarly disrupting blood flow. Herniation also appears to produce dysfunction in important white matter pathways, such as those connecting the MRF to the thalamus, probably via geometrical distortion of the pathways themselves. Extracerebral structures, particularly the third cranial nerve, are also susceptible to distortion when the brain shifts.

The classic herniation syndromes are well established in the clinical neurosciences; recent advances in imaging have changed some of our understanding of their pathological anatomy, but their clinical symptoms remain important.

Central Herniation Syndrome. Central herniation occurs when diffuse brain swelling (e.g., after trauma) or a centrally located mass causes the diencephalon to move caudally through the tentorial notch. Dysfunction of the reticular formation and cerebral hypoperfusion due to ICP elevation are the leading hypotheses explaining alteration of consciousness in this setting. Diencephalic dysfunction initially produces small reactive pupils because of loss of sympathetic output from the hypothalamus. At this stage, decorticate (flexor) posturing may be present spontaneously or is frequently elicited by noxious stimuli. As the midbrain begins to fail, the pupils enlarge to midposition, and posturing becomes decerebrate (extensor). Attempts to elicit horizontal eye movements may reveal failure of adduction with either cervico-ocular reflex (COR) or vestibulo-ocular reflex (VOR) testing; however, this is often only present briefly. Eventually, if the patient is breathing spontaneously, tidal volume decreases and the respiratory rhythm becomes irregular.

The initial cardiovascular response to diminished brain stem perfusion, regardless of etiology, is hypertension. In this setting, bradycardia is a reflex response to the systemic hypertension that is commonly seen in children but is less common in adults. There may be a tendency for bradycardia to occur more commonly in patients with posterior fossa masses, but this observation is confounded by the higher incidence of posterior fossa tumors in children. Respiratory disturbances, the third

component of Cushing's triad, reflect the anatomical considerations discussed earlier and are not part of the same reflex system as the cardiovascular responses. In some clinical settings, such as head injury with diffuse brain swelling, spontaneous hyperventilation is commonly noted but its etiology remains obscure.

Lateral Mass Herniation (Uncal or Hippocampal Herniation) Syndrome. Although concepts of herniation due to an expanding lateral cerebral mass have changed in the past decade, there is a consistent sequence of physical findings that develops. The initial signs are usually those related to the mass itself (e.g., contralateral hemiparesis); as the diencephalon begins to shift away from the mass, consciousness begins to diminish, and an ipsilateral third cranial nerve palsy develops in about 85 percent of patients. When the third nerve is compressed against the tentorial notch, the pupillary fibers, located most peripherally in the nerve, are primarily damaged and the prominent sign is a large pupil. The remaining patients develop either simultaneous bilateral third nerve palsies or, on occasion, an isolated contralateral third nerve palsy. These findings presumably follow from the distortion of third nerve anatomy described earlier, although the bilateral disturbance may also relate to midbrain ischemia as the brain stem begins to move away from the basilar artery. Imaging studies (CT or MRI) performed early in this process do not show transtentorial movement of the temporal lobe; this feature occurs later in the process, accounting for its implication as the cause of third nerve dysfunction in autopsy studies. Early in this process, the most common finding on imaging studies is an *enlargement* of the perimesencephalic cistern ipsilateral to the mass.

As lateral displacement of the midbrain continues, the contralateral corticospinal tract (in the cerebral peduncle) is compressed against the edge of the tentorium. This produces an *ipsilateral* hemiplegia, called the *Kernohan's notch* phenomenon. If the herniation process continues, the diencephalon and the ipsilateral temporal lobe may actually herniate downward through the tentorial notch. Because the uncus (containing the amygdala) and the hippocampus are the most medial portions of the temporal lobe, they are the first structures to cross the tentorial edge; this accounts for the older terms of *uncal* or *hippocampal* herniation. Movement of the more posterior aspects of the medial temporal lobe may compress the posterior cerebral artery (or arteries), producing ischemia in the medial temporal lobe and sometimes in the occipital lobe.

Subfalcine Herniation Syndrome. Herniation of the medial frontal structures (e.g., the cingulate gyrus) beneath the falx is commonly observed in patients with frontal lobe masses. Most of these patients present with signs related either to the mass itself or to the global increase in ICP that accompanies it. Rarely, this subfalcine herniation causes ischemia in the distribution of the anterior cerebral arteries.

Cerebellar Tonsillar Herniation Syndrome. Posterior fossa masses produce most of their findings by compression of the brain stem and cranial nerves, and by obstructive hydrocephalus. As the pressure gradient across the foramen magnum increases, however, the cerebellar tonsils may be pushed into, and eventually through, the foramen. This compresses the medulla and may produce apnea by inducing dysfunction in the medullary respiratory centers. Before losing consciousness, patients with cerebellar tonsillar herniation may complain of a stiff neck.

Upward Transtentorial Herniation Syndrome. Expanding posterior fossa masses usually herniate caudally because the obstructive hydrocephalus they produce prevents a pressure gradient across the tentorial opening. If these patients undergo ventriculostomy for relief of hydrocephalus, however, the possibility of upward herniation of the contents of posterior fossa into the diencephalic region exists. Many neurosurgeons prepare the patient for an emergent posterior fossa decompression just before performing the ventriculostomy in case this problem occurs.

Persistent Vegetative State

Following a severe brain insult, usually traumatic or anoxic, the comatose patient with a relatively intact brain stem usually begins to show the signs of the vegetative state discussed earlier.^[20] The prognosis for further recovery to at least the level of ability to understand and follow commands varies with the mechanism of injury and with the age of the patient. In general, patients who remain in a vegetative state 3 months after an anoxic injury are expected to persist in that state indefinitely. Patients in a vegetative state at the time of hospital discharge after head trauma have an almost 50-percent likelihood of some further recovery over the next 12 months, and a small number regain consciousness between 12 and 36 months. However, the prognosis for functional recovery, in the form of returning to work or to school, is much worse. Although about one third of trauma patients younger than 30 years of age who awaken after prolonged vegetative state meet these goals, only some patients older than 30 years of age do so.

Death by Brain Criteria

The ability to transplant organs successfully led to the need of criteria for brain death, and national and international definitions have been developed. Many now argue that current criteria are restrictive and should be expanded to include patients who have no reasonable chance of regaining consciousness.^[21] If this change is to be made, a substantial shift in societal thinking about life and death may need to precede it. However, in North America, death by brain criteria is still considered to be irreversible loss of brain function, including that of the brain stem. The single exception to this rule appears to be in the area of osmolar control, and diabetes insipidus is not required for this diagnosis.

At present, most jurisdictions recognize the existence of death by brain criteria, but its precise definition varies with local practice. In general, the first stage in pronouncing death by brain criteria is a *permissive diagnosis*; that is, there must be a diagnosis adequate to explain death of the brain, including the brain stem. This need not be an etiological diagnosis; for example, a massive intracerebral hemorrhage qualifies as a permissive diagnosis, even if the etiology of the hemorrhage is unknown. This requirement helps exclude cases of hypnosedative overdose, in which the patient may appear dead but still recover. Importantly, this criterion does not require demonstration of an anatomical lesion, and a history of prolonged anoxia, for example, would suffice. One then proceeds to demonstrate that

TABLE 1-6 -- SELECTED ETIOLOGIES ASSOCIATED WITH CHANGES IN LEVEL OF CONSCIOUSNESS

Etiological Category	Selected Specific Etiologies	Chapter
	STRUCTURAL DISORDERS	
Developmental	Hydrocephalus: obstructive or nonobstructive Neural tube defects Segmentation, cleavage defects Neuronal migration defects Posterior fossa abnormalities, Dandy-Walker, Chiari malformations	28
Degenerative and compressive	Paget's disease	29
	HEREDITARY AND DEGENERATIVE DISORDERS	
Storage diseases: Lipidoses, glycogen disorders, and leukoencephalopathies	Neuronal ceroid lipofuscinosis, especially NCL-2 Cerebrosidoses, especially type II Leukodystrophies, especially Canavan's disease (neonatal form) and Krabbe's disease	30
Amino/organic acidopathies, mitochondrial enzyme defects, and other metabolic errors	Aminoacidopathies, especially maple syrup urine disease, urea cycle disorders, propionie acidemia, methylmalonic acidemia Mitochondrial enzyme defects, especially Leigh's disease, Alpers disease MERFF, MELAS, fatty acid oxidation disorders	31
Chromosomal abnormalities and neurocutaneous disorders	Conditions associated with generalized seizures, especially tuberous sclerosis and Sturge-Weber syndrome	32

The degenerative dementias	Alzheimer's disease (late) Pick's disease (late)	33
Movement disorders	Multiple system atrophy with syncope Huntington's disease (late)	34
Ataxias	Dandy-Walker syndrome Chiari malformations Multiple system atrophy with syncope	35
Degenerative motor, sensory, and autonomic disorders	Amyotrophic lateral sclerosis (late)	36
ACQUIRED METABOLIC AND NUTRITIONAL DISORDERS		
Endogenous metabolic disorders	Electrolyte dysfunction, sodium, potassium, chloride, calcium Hormonal imbalances: especially thyroid, corticosteroids, and glucose metabolism	38
Exogenous acquired metabolic disorders of the nervous system: toxins and illicit drugs	Solvents including methyl alcohol, ethylene glycol, carbon tetrachloride Organophosphates and organochlorides Illicit drugs, including cocaine, amphetamine analogs and opioids	39
Nutritional deficiencies and syndromes associated with alcoholism	Alcohol stupor and withdrawal Vitamin deficiencies, including thiamine, B ¹² , folic acid, and biotin	40
INFECTIOUS DISORDERS		
Viral infections	All causes of viral meningitis and viral encephalitis	41
Nonviral infections	All organisms causing bacterial meningitis or encephalitis Abscesses with increased intracranial pressure	42
Transmissible spongiform encephalopathies	Kuru, Creutzfeldt-Jakob, Gerstmann-Straussler-Scheinker syndromes and fatal familial insomnia	43
HIV and AIDS	AIDS encephalopathy, AIDS dementia complex (late), dysautonomia from neuropathy or myelopathy, progressive multifocal leukoencephalopathy	44
NEUROVASCULAR DISORDERS	Unilateral strokes with secondary edema. Bilateral strokes or showering of emboli, brain stem strokes, subarachnoid hemorrhage	45
NEOPLASTIC DISORDERS		
Primary neurological tumors	Unilateral tumors with secondary edema. Bilateral cerebral or primary brain stem tumors. Metabolic alterations, especially involving calcium	46
Metastatic neoplasms and paraneoplastic syndromes	Unilateral tumors with secondary edema. Bilateral cerebral or primary brain stem tumors. Metabolic alterations, especially involving calcium	47
DEMYELINATING DISORDERS		
Demyelinating disorders of the central nervous system	Multiple sclerosis (rare) Devic's disease	48
Demyelinating disorders of the peripheral nervous system	Guillain-Barre syndrome (with dysautonomia)	49
AUTOIMMUNE AND INFLAMMATORY DISORDERS	Autoimmune cerebritis including giant cell arteritis, primary CNS arteritis, and hypersensitivity arteritis and autoimmune induced dysautonomic states from peripheral nervous system involvement including polyarteritis and Wegener's granulomatosis. Systemic lupus erythematosus can affect either central or peripheral systems	50
TRAUMATIC DISORDERS	Cortical contusion, epidural hematomas, subdural hematomas Traumatic hematomas, post-traumatic epilepsy	51
EPILEPSY	All seizures associated with loss of consciousness, i.e., primary and secondary generalized seizures and all complex partial seizures with an alteration in consciousness	52
HEADACHE AND FACIAL PAIN	Complicated migraine, basilar migraine	53
SLEEP DISORDERS	Obstructive sleep apnea	54
DRUG-INDUCED AND IATROGENIC NEUROLOGICAL DISORDERS	Drugs associated with hypotension or seizures	55

AIDS, Acquired immunodeficiency syndrome; CNS, central nervous system; MELAS, mitochondrial myopathy, encephalopathy, lactic acidosis and stroke-like episodes; MERFF, mitochondrial encephalopathy with ragged red fibers; NCL-2, neuronal ceroid lipofuscinosis type 2.

there is no detectable function above the level of the foramen magnum. Any sign of brain stem-mediated function, such as decerebrate posturing, eye movements, pupillary response to light, or coughing, negates the possibility of the diagnosis of death by current brain criteria. Brain stem testing includes an apnea challenge. [22]

Apnea testing involves observing the brain stem response to hypercapnia without producing hypoxemia. In order to prevent hypoxemia, a period (e.g., 20 minutes) of ventilation with 100 percent oxygen is required before starting the test. Although acidosis, rather than hypercapnia, is the real afferent trigger for ventilation, a PaCO₂ of 60 mm Hg (50 mm Hg in the United Kingdom) is usually the endpoint for this test. In order to reach this endpoint before hypoxemia supervenes, it is advisable to regulate ventilation during the period of preapneic oxygenation so that the PaCO₂ reaches 40 to 45 mm Hg before apnea begins. This period should also be used to ensure that the patient's core temperature is adequate (e.g., above 32 degrees C), and that the results of assays for hypnosedative agents, if indicated, show that intoxication is not the cause of the patient's apparent lack of reflex responses.

Even though the patient has been adequately preoxygenated, some method of supplemental oxygen delivery is still necessary. This may be accomplished either by placing a suction catheter near the carina with a 10 L/min oxygen flow, or by using a continuous positive airway pressure (CPAP) circuit with 10 cm H₂O pressure. A CPAP circuit does not provide ventilation, so it does not interfere with observation for spontaneous respirations. Even with one of these methods employed, some patients with cardiorespiratory dysfunction may not tolerate the approximately 10 minutes of apnea necessary to raise the PaCO₂ to 60 mm Hg without becoming hypoxemic and hypotensive. In this circumstance, a confirmatory test may be necessary.

Apnea is then allowed under observation until the PaCO₂ reaches 60 mm Hg by arterial blood gas analysis. Although it may be possible to predict this point by

following the trend in end-tidal CO₂ (PetCO₂) measurements, there is enough discrepancy between arterial blood PaCO₂ and PetCO₂ to indicate use of the arterial measurement. Visual observation is the standard method for detecting respiratory movement; this may be supplemented by airway pressure monitoring. Any respiratory movement negates the diagnosis of apnea. However, if the patient remains apneic despite a PaCO₂ of 60 mm Hg, the diagnosis of apnea is confirmed, and the patient, having met the other conditions cited as prerequisites, is declared dead by brain criteria.

If the patient is unable to tolerate the apnea test, or if some portion of the examination cannot be performed (e.g., trauma has rendered the face too swollen to examine the eyes), then a confirmatory test is necessary if the patient is to be diagnosed as dead. This is usually indicated only for potential organ donors, because there is no requirement that death be diagnosed in order to withdraw supportive measures, but at times may be helpful for the patient's family. Tests of cerebral perfusion (e.g., radionuclide angiography or conventional contrast angiography) are usually employed to show that blood does not flow intracranially above the foramen magnum. In some areas, transcranial Doppler blood flow velocity measurements are considered adequate for this purpose. Electrophysiological studies, such as EEG, have been used for this purpose but are prone to both false-positive (e.g., artifacts that cannot be distinguished from cerebral activity with certainty) and false-negative (due to hypothermia or hyposedative drug intoxication) results (see [Chapter 24](#), [Fig. 24-4](#)).

Psychogenic Unresponsiveness

This category includes patients who have a diagnosable psychiatric condition, such as catatonia or conversion disorder, and those who are malingering. The differential diagnosis of these conditions is beyond the scope of this chapter, but a few diagnostic points are important in order to raise the physician's suspicion of a psychogenic disorder. These conditions share two characteristics not seen in patients with neurological reasons for coma: First, they have the COR and VOR responses characteristic of awake patients and develop nystagmus and vomiting to cold caloric challenge. Second, their EEGs are not indicative of coma.

GENERAL MANAGEMENT GOALS

Beyond the initial stabilization of the patient and the detection of conditions that require immediate specific treatment, the management of patients with altered consciousness is primarily supportive. The responsibility to protect patients from harm runs the gamut from keeping the confused ambulator from wandering away to endotracheal intubation and mechanical ventilation. Making an etiological diagnosis as rapidly as possible may permit specific treatment ([Table 1-6](#)).

DEFINITIONS

Sleep occupies approximately one third of the adult life. Although the function of sleep is not understood, the inherent necessity for sleep is widely recognized and is present in almost all mammals. The notion that sleep is a time of rest and brain inactivity persisted until the 20th century when electrophysiological techniques were applied to the study of sleep. Thereafter sleep was found to be a dynamic process, with the cyclical recurrence of different stages. The discovery of rapid eye movement (REM) sleep by Aserinsky and Kleitman in 1953^[1] was a major advance in sleep research, stimulating physiological and clinical studies of sleep. Sleep is divided into two types: REM and non-rapid eye movement sleep (NREM).^[2]

REM sleep cycles on and off throughout the night. In a young adult, the first REM period occurs approximately 90 to 100 minutes after sleep onset, following an initial period of NREM sleep. The first REM period is the shortest of the night. Successive REM periods are of progressively longer duration, with the longest REM period occurring in the early morning hours. In infancy, 50 to 80 percent of total sleep time consists of REM sleep. By age 2 years and through adulthood, the percentage of REM sleep falls to approximately 20 to 25 percent of total sleep time.

REM sleep is divided into tonic and phasic events, and has several characteristic features. The tonic REM events include (1) cortical desynchronization, with mixed frequency, fast activity on electroencephalography (EEG), similar to that observed in the waking state; (2) hippocampal synchronous theta activity that also occurs in waking; and (3) muscle atonia that is present in all but respiratory and ocular muscles, and marked by a reduction in chin and limb electromyographic activity. The phasic components of REM sleep include the following features: (1) rapid eye movements, horizontal and vertical, occurring in bursts during REM; (2) muscle twitches punctuating the muscle atonia; (3) ponto-geniculo-occipital spikes (PGO) not observable on routine polysomnography (PSG); and (4) autonomic nervous system lability with fluctuations in respiratory rate, heart rate, and blood pressure.^[3]

NREM sleep is divided into four stages: Stages 1 and 2 are considered light sleep. Stage 1 occupies 2 to 5 percent of sleep time and is marked by slow rolling eye movements, low voltage, mixed frequency EEG, and a low arousal threshold. Stage 2 makes up approximately 45 to 55 percent of total sleep time and is marked by the presence of K complexes and sleep spindles on EEG recordings. K complexes are composed of an initial sharp component followed by a slow component. Sleep spindles are episodically occurring rhythmical complexes occurring with frequency of 7 to 14 cycles per second grouped in sequences lasting 1 to 2 seconds. Spindles can occur alone or superimposed on K complexes. Although spindles are a feature of Stage 2 sleep, they may also be present in Stage 3 and Stage 4 NREM sleep, and can even be found in REM sleep.

Stages 3 and 4 sleep are considered deep or slow-wave sleep (SWS). SWS is prominent in youth and diminishes in the elderly. SWS is present for approximately 10 to 20 percent of sleep time and is predominate in the first part of the night. The arousal threshold is high in SWS. The EEG feature of SWS is the delta wave. Delta waves are high voltage (75 microvolts or more) waves with a frequency range of 0.5 to 4 Hz. Stage 3 sleep is defined as sleep consisting of 20 to 50 percent delta waves, and Stage 4 is defined as greater than 50 percent delta waves.^[4], ^[5]

CLINICAL HISTORY

Obtaining a detailed clinical history is especially important when diagnosing a sleep disturbance because routine physical examination is often not revealing during the waking hours. From the history, age of onset, duration and progression of the sleep complaint, and the general classification of the type of sleep disturbance is usually obtained. The International Classification of Sleep Disorders categorizes sleep disturbances as (1) dyssomnias or disorders that result in insomnia or excessive sleepiness; (2) parasomnias or disorders of arousal, partial arousal, or sleep stage transition; and (3) sleep disorders associated with medical or psychiatric disorders.^[1] The dyssomnias include the intrinsic sleep disorders arising from bodily malfunctions such as psychophysiological insomnia, obstructive and central sleep apnea, restless legs syndrome (RLS), and periodic limb movement disorder (PLMD). Examples of parasomnias include sleep walking, sleep terrors, sleep talking, nightmares, REM sleep behavior disorder (RBD), bruxism, and enuresis. Sleep disorders associated with medical and psychiatric conditions include those secondary to mood disorders, alcoholism, neurological disorders such as parkinsonism and dementia, and gastroesophageal reflux.^{[2], [3]}

Sleep complaints often involve three areas of sleep disturbance: (1) the perceived inability to obtain sufficient sleep (insomnia), (2) the presence of excessive sleepiness or fatigue during the day (excessive daytime somnolence [EDS]), and (3) the occurrence of unusual events during sleep (parasomnias) (see the section entitled Clinical Syndromes). The clinical history should investigate each of these areas because there is often overlap among them.

The first part of the interview examines the quantity and quality of sleep: The hour of bedtime and final awakening, the latency from bedtime to onset of sleep, events that delay sleep onset, number and duration of nocturnal awakenings, activities during the night, and perceived sleep quality are obtained by patient history. Is there a variation in the timing of sleep from day to day? Those who work or attend school may sleep less during the week, then sleep much longer when their activities are not structured during the weekend.^[4] Shift workers or those who work in the evening or at night may find it very difficult to obtain a consistent timing and duration of sleep. They may be always fighting the circadian clock, which keeps internal rhythms and levels of alertness set to a 24-hour cycle.^[5] Patients with neurodegenerative diseases often have internal clocks that no longer function effectively. Sleep and wakefulness may occur haphazardly around the clock or may be reversed, with most sleep coming during the daylight hour.^[6] Withdrawal from pharmacological agents, especially those that cause sedation, is another possible cause of sleep disruption.

A sleep diary is a useful adjunct to the patient history. The patient completes a sleep diary every day for a consecutive 14-day period. This daily record of the patient sleep cycle provides the clinician with an indication of the timing and quantity of sleep obtained. This method is particularly useful in diagnosing sleep phase shifts, and timing of insomnia. Patients with delayed phase sleep may show an inability to fall asleep until late at night, with a corresponding late awakening. Likewise, patients with phase advanced sleep may fall asleep easily at an early hour but awaken early in the morning. In particular, sleep diaries allow for an assessment of spontaneous sleep patterns during weekends or vacation periods, when the necessity to accommodate a work or school schedule is not present. Actigraphy is a useful adjunct to a sleep diary. A wrist actigraph is worn by the patient for 2 weeks and continually records physical activity. Although it does not specifically record sleep, periods of quiescence suggesting sleep time, punctuated by periods of muscle activity can be stored in the actigraph and later retrieved. In conjunction with a sleep diary, actigraphy is a powerful tool in estimating routine sleep patterns at home.^[7]

The evaluation of sleep quality relies on the subjective perception of sleep. Several scales have been developed to assess overall sleep quality. Some of these scales have been validated.^[8] The structured interview provides insight into several domains of sleep quality. How well does the patient sleep? Does the patient feel that sleep is troubled or insufficient? Good sleep satisfies several criteria: (1) it is sufficient--providing for adequate alertness and a feeling of vitality during the day, (2) it is efficient--easily initiated, continuously maintained, and not excessively prolonged, and (3) it is convenient--occurring during a period of time when the patient would not need or prefer to be awake, which is usually at night but may vary for those with other life demands, such as a nighttime job.

An evaluation of the presence and severity of daytime sleepiness is a vital part of the sleep interview. Patients whose sleep is significantly disrupted or fragmented,^[9] or those who simply do not get enough sleep may be sleepy during the daytime. Typically, EDS manifests as nodding off or napping during quiet, passive activities, such as reading, watching television, or listening to a lecture. In more severe cases, sleep may occur during active periods such as while eating, talking, or driving a motor vehicle. When EDS is severe, it can impair the quality of life and even lead to life-threatening situations, such as falling asleep while driving. In contrast to the EDS arising from nocturnal sleep disruption, narcoleptic patients may have attacks of sleep in which REM sleep occurs.

In determining whether or not there are unusual events during sleep, interview of the bed partner or family members who are able to observe sleep may be essential. A variety of abnormal events during sleep may impair sleep quality, cause patient discomfort, or interrupt the sleep of the bed partner. Snoring or gasping during sleep may be a sign of respiratory difficulties or sleep apnea. Unusual sleep-related movements can indicate the presence of or PLMD, nocturnal epilepsy, or RBD. Other behaviors may suggest the presence of sleep walking (somnambulism), sleep talking (somniloquy), tooth grinding (bruxism), or attacks of eating in a fuguelike state (nocturnal eating disorder).^[10]

Events occurring before sleep onset may provide clues to the cause of insomnia. Good sleep hygiene, which can help sleep quality, involves consistent calming activities before sleep.^[11] Poor sleep hygiene may interfere with the ability to sleep. These activities include caffeine and nicotine intake, late-day napping, exercising immediately before bedtime, and using the bed to read, watch television, or

work. Alcohol intake at bedtime may shorten sleep latency but often causes sleep fragmentation later in the night, with early morning awakening. Patients may report sensory phenomenon in the legs or arms when they lie down to sleep. These sensations may be described as tingling, tightness, crawling sensations or pain. These sensations may be severe enough to interfere with sleep onset and may be relieved only with movement of the limbs, or walking. This history suggests that the diagnosis of RLS. PLMD is frequently associated with RLS and may cause disruption of sleep once sleep is obtained. A prominent jerk just at sleep onset that runs through most of the body, sometimes associated with a sensation or illusion of falling, is a hypnic jerk and is experienced by most people on occasion.^[12]

Psychological states at the time of sleep onset are important to assess in patients with insomnia. Patients reporting excessive worries, ruminations over daytime problems, and anxiety may find that despite feeling sleepy, these intrusive thoughts cause alertness and prevent sleep onset. They may feel increased muscle tension. The duration and triggering factor for the insomnia is important to obtain. Patients experiencing transient insomnia related to particular life events may benefit from treatment strategies inappropriate for the patient with chronic, recurrent insomnia. Depression and anxiety are psychiatric disorders that are strongly associated with sleep disturbances. A psychiatric assessment may provide useful clues to the presence of these potentially treatable causes of insomnia.

Medical conditions may also interfere with normal sleep. Patients with rheumatoid arthritis may be awakened by pain. Patients with neuromuscular disease may awaken because of respiratory difficulty. Patients with Parkinson's disease may awaken because their medications have worn off and they are uncomfortable and unable to shift posture. Prostate disorders may lead to frequent awakenings to urinate during the night

Neuromuscular disorders, Parkinson's disease, multisystem atrophies, lung disease, obesity, acromegaly, or thyroid disease can all be associated with respiratory disturbances in sleep.^[13] Different medical and neurological conditions, including iron deficiency, uremia, and peripheral neuropathy, are associated with RLS and PLMD.^[14] Neurodegenerative disorders, such as Alzheimer's disease, may result in a breakdown of the circadian clock, which regulates the alternation of sleep and wakefulness. Tic disease may lead to parasomnias in children. Patients with Parkinson's disease, as well as those with neurodegenerative disease or brain stem strokes, may have RBD, in which dreams can be acted out with injurious consequences.^[15]

A history of hallucinations either at sleep onset (hypnogogic) or on awakening from sleep (hypnopompic), sleep paralysis (the inability to voluntarily move upon awakening), sleepiness during the day, or cataplexy (sudden loss of muscle tone during wakefulness) may indicate a diagnosis of narcolepsy, particularly if onset occurred during youth, adolescence, or young adulthood.^[16]

Ingestion of medication is a particularly important part of the clinical history. There are many medications that cause drowsiness during the day or disrupted sleep at night. In severe cases, this disruption may lead to lethargy, confusion, or forgetfulness. Although sedative and hypnotic medications, particularly those with long half lives, are usually recognized as a cause of daytime sleepiness, there are numerous additional agents that have a similar effect, including antihistamines, neuroleptic agents, antihypertensives, anticonvulsants, antiparkinsonian medications, antidepressants, analgesics, and muscle relaxants. Elderly patients, especially those with hepatic or renal insufficiency, may be particularly susceptible to medication side effects because a drug or its active metabolites may accumulate owing to impaired metabolism or excretion. Alcohol, ingested near the sleeping hour, may help induce sleep, but later in the night, after several hours of sleep, alcohol may cause

awakenings and sleep disruption. Alcohol also worsens most respiratory problems in sleep.

Antiparkinsonian medications may cause vivid dreams and nightmares. The benzodiazepines and barbiturates may suppress SWS, decrease the amount of REM sleep, and exacerbate sleep apnea. With chronic use, these agents often lose their efficacy, and sudden discontinuation frequently causes rebound insomnia. Stimulants used for attention deficit disorder and in narcolepsy may cause insomnia. Dopamine-blocking agents including metoclopramide can aggravate RLS, whereas antidepressants, including tricyclic compounds and serotonin reuptake inhibitors, may activate PLMD.

A family history of sleep disturbance may suggest particular sleep disorders. In particular, RLS is inherited as an autosomal dominant disorder. ^[2] Narcolepsy and sleep apnea are other sleep disorders with strong hereditary origins. Fatal familial insomnia is a rare disorder in which family history is essential for a correct diagnosis ([Chapter 43](#)). ^[2]

[PreviousNext](#)

ANATOMY OF NORMAL SLEEP

Physiological Function of Sleep

Sleep evolves during life and changes with maturation and aging. During infancy, 16 to 18 hours a day are spent sleeping, with sleep-wake states initially occurring every 3 to 4 hours. By 6 months of age, a more prolonged sleep period occurs during the night. REM sleep time occupies as much as 80 percent of sleep time in the newborn, with a steady decrease until only approximately 20 percent of sleep is REM in the adult. Sleep spindles appear at approximately 2 years of age. During adolescence, sleep requirement increases, and the sleep pattern is one of phase delay.^[8] Because school schedules do not allow for late awakening, the most common cause of daytime sleepiness in this age group is insufficient sleep. In adulthood, the need for sleep is relatively constant. With aging, sleep tends to become more fragmented, and night sleep may decrease with a corresponding increase of daytime napping. With aging, the amount of SWS decreases. Although REM sleep time remains stable with aging, the pattern of REM sleep seen in the young adult with progressively longer REM periods is not observed in the elderly, who have REM sleep equally distributed over the course of the night.^[22]

The function of sleep remains elusive.^[23] Most sleep is NREM sleep, comprising 80 percent of total sleep time in

the adult. The most critical part of NREM sleep occurs early at night, when most SWS occurs. SWS is deepest, most difficult to interrupt, and most refreshing. During recovery from sleep deprivation, SWS is the first to rebound.^[24] The decline in the proportion of SWS with aging is possibly related to the overall deterioration of sleep, resulting in an increase in sleep complaints that characterize the older population. Third, for humans, primarily diurnal animals, sleep typically occurs at night. Whatever else sleep does, it likely reduces activity at the time when a diurnal, visually dependent animal cannot function effectively and thereby conserves resources. In evolution, the development of sleep as a block of reduced activity at night likely made that time available for other purposes. Functions that would be impaired by daylight activity could be shifted into the sleep period and integrated with the sleep state. As a result, many of the plausible functions of sleep may be adaptations to the reduced nocturnal activity that sleep ensures. Fourth, there may be no one single function of sleep but a group of different functions. As one summary statement to a recent publication of the proceedings of a conference on the function of sleep stated, "Research and speculation on the functions of sleep have yielded many viable possibilities."^[25] Functions may vary in importance depending on the individual's age or activities, and none of these functions may be unique to sleep. The following section presents some of the plausible functions suggested for NREM sleep.

Metabolic and Thermoregulatory Functions

Animal studies with rats have suggested that during sleep deprivation, energy expenditure increases while temperature and weight drop until body systems begin to fail, beginning with the endocrine and immune systems.^[26] This and other studies have led to the proposal that sleep conserves energy loss through thermoregulation: When core body temperature decreases during sleep, heat loss to the environment is minimized. Similar studies have understandably not been performed in humans, but humans also show lowered body temperature during sleep. A different interpretation of temperature changes begins with the observation that sleep in general and deeper NREM sleep in particular are increased when the body is heated^[27]; therefore it is suggested that sleep functions to allow the shedding of excess accumulated heat.^[28] This approach emphasizes not the decreased rate of heat loss in sleep due to decreased core temperature but the reduced rate of heat production due to slowed metabolism. Sleep may be the prime period for anabolic activity. In primates, growth hormone, whose effects can be manifest at all ages in humans, is primarily secreted during the periods of deepest SWS early in the night.^[29] In several studies of growth in children with growth disorders, it was found that total sleep correlated with rate of growth, suggesting that disrupted sleep could inhibit growth.

Restorative Neural Functions

In the brain, there is evidence, although it is not yet conclusive, that overall RNA transcription and protein synthesis is relatively most prominent during deep SWS. This activity may have particular importance for synaptic function. Even considering the alternation of SWS and REM sleep, when brain activity is often as high as during the waking state, it has been suggested that SWS allows for a recovery from so-called activity debts. It has been hypothesized that the brain uses the materials produced and stored during SWS. The decline of cognitive function with sleep deprivation provides some evidence of these restorative or supportive functions of sleep. Other possible related functions are a restoration of balance at the synaptic level. Neurons relatively quiescent during the waking period can be activated at night during both NREM and REM sleep, so that the entire network does not become imbalanced.^[30] Alternatively, SWS may be used to restore a functional balance, as of emotional states in the limbic system.

Continued Processing of Waking Experience

Insofar as REM sleep is linked to synaptic changes that consolidate memories, that consolidation may depend on earlier processes in SWS. There is some evidence that SWS responds to learning situations in animals and may share a role, perhaps beyond mere provision, in consolidating memories.^[31]

NEURONAL CIRCUITS

Circadian Rhythms

The timing and rhythmicity of the sleep-wake cycle is matched to the solar day-night cycle in humans. This rhythmical pattern is generated internally but is modified by environmental factors, in particular the light-dark cycle. The endogenous nature of the circadian rhythm is verified by the persistence of these rhythms when environmental conditions are held constant. For example, a human kept in isolation without access to a clock or a periodic light-dark cycle will maintain a regular sleep-wake cycle. Although the rhythm is maintained, the periodicity of the sleep-wake cycle under this free-running condition is approximately 25 hours. However, under the influence of the environmental light-dark cycle, this rhythm is entrained to 24-hour solar day. The environmental cues that are able to entrain the internal clock mechanism are called zeitgebers. The most potent zeitgeber for sleep-wake rhythms in most organisms is light.

The Suprachiasmatic Nucleus

The anatomical structure serving as the internal circadian rhythm generator is the suprachiasmatic nucleus (SCN) of the anterior hypothalamus. ^[32], ^[33] Lesions of the SCN in rodents abolish circadian rhythmicity, and disconnection of the SCN from the rest of the brain also results in a loss of circadian rhythms in the brain in spite of

continued fluctuations within the SCN. Furthermore, in animals with ablations of the SCN, transplantation of fetal SCN tissue restores circadian rhythm.

Entrainment of these neurons occurs via the visual pathways linking photoreceptors of the retina to the SCN. There are two pathways: (1) a direct pathway called the retinohypothalamic tract (RHT) and (2) an indirect pathway called the geniculohypothalamic tract (GHT). Photoreceptors in the retina transduce light into nerve impulses and transmit information to ganglion cells, which are distributed over the entire retina. The cell processes of the ganglion cells make up the RHT, which travels through the optic nerve and optic chiasm. In the chiasm, two thirds of the axons cross and one third remain uncrossed. The RHT projects directly to the SCN. Collateral processes from the RHT continue in the optic tract to the lateral geniculate complex. From the lateral geniculate, the GHT projects to the SCN as the indirect pathway.

Efferent fibers from the SCN project to intrahypothalamic areas, encompassing the preoptic area, paraventricular nucleus, retrochiasmatic area, dorsomedial area and extrahypothalamic sites, including the thalamus, basal forebrain and periaqueductal gray. From these areas information is further relayed to the effector organs for particular biological rhythms.

In addition to controlling the circadian variability of the sleep-wake cycle, the SCN creates variability in locomotor activity, food intake, water intake, sexual behavior, core body temperature, and hormonal levels. Thus, cortisol is highest in the early morning hours between 4:00 to 8:00 AM, and thyroid-stimulating hormone increases just before sleep. Hormones both influence and are influenced by the circadian clock.

The Pineal Gland and Melatonin

The pineal gland is a neuroendocrine gland that synthesizes and secretes melatonin (N-acetyl-5-methoxytryptamine). ^[34] The afferent input to the pineal gland is transmitted from the retinal photoreceptors through the SCN and sympathetic nervous system. The circadian rhythm of melatonin is controlled by the SCN but is strongly entrained by light. The two effects of light are, first, to regulate melatonin secretion in accordance with diurnal light-dark cycles and, second, to suppress melatonin if given in brief intense pulses. Melatonin secretion increases during the night, reaching a peak level between 2:00 and 4:00 AM, then gradually falls during the latter part of the night, and is present at very low levels during the day. Exogenous melatonin has been used with some success to avoid jet lag and may be useful for treatment of phase-shifted sleep and sleep disturbance due to shift work. Melatonin is available through health food stores and has received strong public attention. However, at this time, there are no proven indications for melatonin.

NREM Sleep

Sleep spindles usually arise from the gamma-aminobutyric acid (GABA)-ergic neurons in the reticular thalamic nucleus. These neurons have intrinsic oscillations with spontaneous slow depolarization on which rhythmical spikes are superimposed and serve as drivers for thalamocortical projection neurons. Dissection of the reticular thalamic region from the thalamocortical region or specific kainic acid lesions of reticular thalamic nuclei eliminates spindles. On scalp recordings, spindles occur maximally over the frontal and vertex areas. Depth electrode recordings in humans show that thalamic spindles are earlier and more frequent than those recorded on the scalp. Spindles occurring in the frontal leads may also originate in the supplementary cortex. ^[35]

The defining feature of Stages 3 and 4 sleep is the delta or slow wave. Thalamocortical cells are capable of generating delta waves, but other areas are involved as well, as shown by lesions of the anterior hypothalamus, preoptic region, and basal forebrain, all of which can abolish delta waves.

REM Sleep

The anatomical substrates for the different components of REM sleep are as follows:

1. An important substrate is cortical desynchronization. The origin of the mixed frequency activity is the mesencephalic reticular formation. The reticular cells fire about 15 seconds before activation of cortex, and their projections extend to the intralaminar nuclei of the thalamus with widespread projections to cortex.
 2. Hippocampal theta activity is highly synchronous activity with a frequency of 5 to 10 Hz, which is generated in the dentate and medial entorhinal cortex. It involves the rostral pontine reticular formation in the area of the nucleus pontis oralis.
 3. Muscle atonia, except for respiratory and ocular muscles, is a tonic event of REM sleep. Electrical stimulation studies have shown that muscle atonia occurs following activation of the medullary magnocellular reticular nucleus and the rostral nucleus pontis oralis. Muscle paralysis arises at the spinal cord level, from a centrally mediated hyperpolarization of the alpha motor neurons through the action of the inhibitory neurotransmitter glycine.
 4. Muscle twitches are superimposed on the tonic muscle paralysis. The twitches arise from descending excitatory impulses, which transiently overcome motor neuron inhibition.
 5. Rapid eye movements are another phasic event of REM sleep. Horizontal eye movements arise from burst neurons in the parabducens reticular formation in the pons, and vertical eye movements are associated with activation of the midbrain reticular formation. Positron emission tomography has shown that REM-related eye movements involve cortical areas similar to those used during wakefulness.
 6. PGO activity is a phasic feature of REM sleep, generated in the pons and projected through the lateral geniculate body and other thalamic nuclei to the occipital cortex. PGO activity is of two types--type one occurs independent of eye movements, and type 2 occurs simultaneously
-

with eye movements. PGO spike activity has been associated with fragmentary images or dreams.

7. Autonomic nervous system lability, with profound sympathetic activation and fluctuations in respirations, heart rate, and blood pressure, involves the parabrachial nuclei of pons. Other features of REM sleep include penile erections not associated with sexual stimulation or dream content and thermoregulatory suspension leading to a pseudopoikilothermic state. Additionally, there is an increase in cerebral metabolism and blood flow as compared with NREM sleep. ^[36]
^[37] ^[38]

The regulation of REM sleep is primarily at the level of the brain stem, with REM-on and REM-off nuclei. ^[39] In the model of neuronal interactions as outlined by McCarley, there are 4 steps in the REM cycle. ^[4] Although the putative trigger zone initiating REM sleep is not identified, the activity of brain stem areas during REM sleep has been studied, both electrically and pharmacologically. Brain stem nuclei with activity immediately preceding and persisting during REM sleep are the cholinergic cells in the dorsolateral tegmentum: the lateral dorsal tegmental (LDT) and the pedunculopontine tegmental (PPN) nuclei. These two nuclei comprise the main concentration of brain stem cholinergic neurons. ^[40] The projection areas of these nuclei include the basal ganglia; the limbic areas, including the preoptic area; the thalamic areas, including the lateral geniculate nuclei; and the cortical areas. The PPN plays a role in numerous feedback loops, involving locomotion, and rhythmical functions, specifically control of sleep-wake cycles and generation of REM sleep. The cholinceptive REM triggering zone located in the paramedian

reticular formation receives input from LDT and PPN. Inhibition of these REM-on nuclei appears to arise from nearby REM-off cells, primarily the serotonergic neurons of the dorsal raphe and adrenergic neurons of the locus coeruleus.

The reciprocal-interaction model proposed by Hobson posits that control of REM sleep arises from anatomically distributed and neurochemically integrated populations of cells. This model is summarized by McCarley as involving four steps: (1) Positive feedback of REM-on neurons through excitatory interconnections with reticular neurons. (2) Excitation of REM-off neurons by REM-on neurons mediated through cholinergic pathways, although the reticular formation may actually be the origin of this process. (3) Inhibition of REM-on neurons by REM-off neurons located in the dorsal raphe and locus coeruleus. (4) Inhibitory feedback of REM-off neurons through recurrent collateral or some other method of serotonin and norepinephrine feedback. ^[3]

The neuroanatomical areas involved in the generation of REM sleep have largely been identified through transections at different levels in the neuraxis. In transections separating the forebrain from the brain stem, REM sleep features are recorded caudal to the cut. These features include atonia, rapid eye movements, PGO spike bursts, and REM-like activation of the reticular formation. However, in this transection, thermoregulatory control is lost with an inverse relationship between temp and amount of REM sleep. Transections between the locus coeruleus and the red nucleus, separating the pons from the midbrain, results in atonia, PGO spike bursts, rapid eye movements, and activation of the reticular formation in a rhythmical pattern caudal to the transection. Transections between the medulla and the pons result in a regular cycle of REM above the transection, with the exception of the generation of muscle atonia. Taken together, these experiments provide evidence that REM sleep is generated primarily in the pons. ^[36]

REM sleep is the form of sleep in which many dreams occur. When awakened during an episode of REM, the sleeper will report the contents of the dream approximately 85 percent of the time. The function of dreaming has remained elusive. Both physiological (related to memory and learning) and psychological roles have been proposed. ^[41]

NEUROCHEMICAL ANATOMY

The primary neurotransmitters for circadian rhythm generators are as follows. SCN neurons are mostly GABAergic. The neurotransmitter released from the RHT is glutamate, which affects both *N*-methyl-D-aspartate (NMDA) and non-NMDA receptors in the SCN. The putative neurotransmitters of the indirect pathway, GHT, are GABA and neuropeptide Y. Cholinergic agonists like carbachol also have an effect on activity of the SCN, and their administration shifts the activity of the SCN in a manner similar to that of light exposure. Less pronounced effects on SCN activity have been described following clonidine, an alpha-2 receptor agonist. The SCN also receives nonentrainment afferents from serotonergic projections of the median and dorsal raphe nucleus of the midbrain and histaminergic projections from the posterior hypothalamic tuberomammillary neurons. Vasopressin, neurophysin, and vasoactive intestinal polypeptide are important neurotransmitters in some of these efferent pathways from the SCN. The neurotransmitter from the SCN to the pineal is norepinephrine. ^[32]

The neurochemical constituents involved in the generation and maintenance of REM and NREM are listed in [Table 2-1](#). Neurochemically, REM sleep is associated with an increase in cholinergic activity and a reduction in noradrenergic and serotonergic activity. ^[39] ^[40] ^[41]

EXAMINATION OF THE PATIENT WITH SLEEP-WAKE CYCLE COMPLAINTS

Neurological Examination

Cerebral. The neurological examination focuses on the general state of alertness. Patients may appear sleepy or even nod off during the examination if EDS is severe. Cognitive and psychological functioning is assessed for evidence of dementia or depression, both of which are associated with sleep pattern disruption. Excessive anxiety, fears, and concerns are frequent causes for insomnia, and clues to these problems may reveal themselves during cerebral assessments of memory, concentration, and attention.

Cranial Nerves. Cranial nerve lesions indicate brain stem pathology. Disorders of REM sleep, including narcolepsy and RBD, may reflect focal pathology in the pons, so

TABLE 2-1 -- ACTIVITY OF SUBPOPULATIONS OF CELL GROUPS DURING WALKING, SLOW-WAVE SLEEP AND REM SLEEP

Nucleus	Primary Neurotransmitter	Waking Activity	Slow-Wave Sleep	REM Sleep
Pedunculo-pontine nucleus (PPN)	Acetylcholine	Increased	Decreased	Increased
Locus coeruleus	Norepinephrine	Increased	Increased	Decreased
Raphe nucleus	Serotonin	Increased	Increased	Decreased
Substantia nigra	Dopamine	Increased	Decreased	Increased

Reprinted from Garcia-Rill E The pedunculo-pontine nucleus Prog Neurobiol 1991;36; 363-389, with permission of Elsevier Science.

specific attention to pontine cranial nerve function (trigeminal, abducens, facial, and vestibulocochlear) are essential. Bulbar dysfunction in the form of dysphagia, hoarseness, and dyspnea can occur in neuromuscular disorders and myopathies. In checking for the gag reflex, the upper airway can be examined, and a reddened palate and uvula are suggestive of snoring.

Motor/Reflexes/Cerebellar/Gait. Several disorders of the motor system are associated with sleep alterations. Strength should be examined, specifically the strength of the neck and respiratory muscles. Patients with myopathies, neuropathies, and neuromuscular junction disease can have significant chest wall weakness. In acute or chronic demyelinating polyneuropathy (Guillain-Barre(c) syndrome), tendon reflexes are lost and there may be additional bulbar cranial nerve weakness. In patients with myasthenia gravis, initial inspiration and expiration volumes may be normal, but repeated testing demonstrates rapid fatigability and poor aeration. In the condition multiple system atrophy, a diffuse degenerative condition with numerous areas of the nervous system affected, typical signs include parkinsonism in the form of bradykinesia and rigidity and gait dysfunction, along with cerebellar dysfunction-like dysmetria, ataxia, or tremors. Spinocerebellar atrophies are also associated with sleep disruption, and their motor signs are predominantly limb, trunk, and gait ataxia, along with sensory neuropathies. Whereas most movement disorders resolve during sleep, patients with tics may have significant sleep disruption from continuing tics, and patients with Parkinson's disease have difficulty going to sleep because of stiffness and shaking as well as further difficulty staying asleep. In addition, they have a frequent problem with vivid dreams and sleep fragmentation, and they may have RBD associated with injurious behaviors.

Sensory. A number of neuropathies are associated with sleep alterations, and hence the sensory examination, including both position and vibration testing for myelinated fiber function and pain and temperature testing for unmyelinated fiber function should be performed. RLS can be frequently exacerbated by neuropathy, and diabetes mellitus and spinocerebellar atrophies have characteristic neuropathic findings.

Autonomic Nervous System. Central sleep apnea is the loss of respiratory airflow associated with a loss of respiratory muscle effort. It is thought to arise from alterations in the functioning of chemoreceptors monitoring hypoxic and hypercapnic influences on respiration. Patients should be examined for waking respiratory difficulties and cardiac functioning, in particular for congestive heart failure. Neuromuscular diseases likewise may predispose to episodes of sleep apnea, as can autonomic nervous system instability. Patients should be assessed for evidence of orthostatic hypotension and examined for those disorders with autonomic nervous system involvement, including multiple system atrophy, Guillain-Barre(c) syndrome, and diabetes.

Neurovascular System. A general cardiac and vascular examination reveals signs of cardiac failure and blood pressure, specifically signs of pulmonary hypertension that is frequently associated with obstructive sleep apnea.

Associated Medical Findings

The physical examination in a patient with a suspected sleep disorder focuses on several features. To assess for physical abnormalities associated with obstructive sleep apnea, particular attention is directed toward examination of height, weight, and blood pressure. Abnormalities of the upper airway, including enlarged tonsils, tongue, or low palate, can indicate possible airway obstruction. A reddened uvula and palate may be associated with loud snoring. Retrognathia and a small pharyngeal opening may also be seen in patients with sleep apnea.

EVALUATION GUIDELINES

There are a variety of laboratory tests that directly or indirectly may apply to the evaluation of sleep and sleep disorders ([Table 2-2](#)).

Neuroimaging. Neuroimaging is not usually necessary during the evaluation of a primary sleep disorder. If patients present with additional neurological symptoms and signs, or the clinical history is atypical, magnetic resonance imaging may be helpful.

Electrophysiology. Routine EEG may be indicated when a diagnosis of sleep-related seizures is suspected. Likewise, electromyography may provide valuable information if peripheral neuropathy is suspected associated with RLS, or if neuromuscular disorders are thought to be predisposing to sleep apnea. The standard test of sleep is overnight PSG. PSG is an overnight recording of sleep, monitoring EEG, eye movements, chin muscle tone, muscle activity of the limbs, electrocardiogram, respiratory effort, nasal airflow, and oxygen saturation. During polysomnography, a patient is closely monitored by a technician

TABLE 2-2 -- USEFUL STUDIES FOR THE INVESTIGATION OF SLEEP-WAKE CYCLE DISORDERS

	Neuroimaging	Electrophysiology	Fluid and Tissue Analysis	Neuropsychological Tests	Other Tests
Insomnia	Focal abnormality in post-traumatic, atrophy in degenerative diseases	PSG to indicate whether secondary to other sleep disorder EMG evidence of peripheral neuropathy in some patients with RLS	Metabolic or drug screening	Dementia, depression, anxiety, or other psychiatric disorder	Sleep diary for sleep patterns Forced immobilization test to assess for restless legs syndrome
EDS	Focal abnormalities, brain stem abnormality in central sleep apnea	PSG assessing for nocturnal sleep disorder (sleep, apnea, PLMD) Multiple sleep latency test with shortened latency with or without REM onset naps EMG showing neuromuscular disease	Arterial blood gas showing hypoxia, chronic carbon dioxide retention HLA blood typing Serological evidence of viral infection	Dementia, depression, anxiety, or other psychiatric disorder Reduced attention	Daytime sleepiness scales Sleep diary Oximetry Pulmonary function tests Cephalometry Pharyngeal examination
Parasomnia	Focal abnormality in brain stem area, thalamus, or hemisphere causing nocturnal seizure Brain stem/cerebellar atrophy consistent with multiple system atrophy	PSG with videotaping to show the behaviors and the stage of sleep during which they occur Electroencephalography for nocturnal seizures	Evidence of multiple sclerosis in CSF, prior viral infection	Dementia Psychological disturbances, post-traumatic stress disorder	None needed
Circadian disorders		Wrist actigraphy, PSG	None needed	Assessment for anxiety, depression	Sleep diary, employment history

CSF, Cerebrospinal fluid; EDS, excessive daytime somnolence; EMG, electromyography; HLA, human leukocyte antigen; PLMD, periodic limb movement disorder; PSG, polysomnography; REM, rapid eye movement.

who is present throughout the night. Videotaping abnormal sleep behaviors is possible. PSG testing provides objective data concerning sleep latency, sleep efficiency, sleep staging, severity and type of sleep apnea, periodic limb movements, and parasomnias. PSG is of more limited usefulness in the evaluation of insomnia, unless insomnia arises from a primary sleep disorder, such as sleep apnea. The major drawback to PSG is the need to sleep in a controlled environment. For some patients, the strange surroundings reduce the ability to sleep normally, and obtaining an accurate sleep recording requires 1 night of adaptation before the actual recording night. Moreover, PSG is very labor intensive and expensive. Despite these drawbacks, PSG remains the most reliable test for certain sleep disturbances.

Fluid and Tissue Analysis. In patients with sleep apnea, obtaining a baseline arterial blood gas may be essential in guiding treatment. In patients with suspected narcolepsy, HLA blood typing may be descriptively interesting but does not confirm or eliminate a diagnosis. Obtaining other tests will depend on the individual case. Extensive fluid and tissue analysis is seldom necessary for most primary sleep disorders, but thyroid tests and drug screens should be obtained in most cases.

Neuropsychology Tests. Neuropsychology testing is useful for determining the presence and severity of cognitive impairment and mood disorders.

Other Tests. *Sleep diaries* allow a continuous subjective report of sleep. Patients are given a 2-week log, with each day divided into 30-minute or 60-minute intervals. Patients are instructed to fill out the log three to four times per day, indicating the time asleep for the previous 6- to 8-hour period. Patients can comment about their sense of alertness on awakening each morning and record unusual daytime or nighttime events. Sleep logs are inexpensive and convenient. Logs can provide valuable information about the circadian pattern of sleep and allow for an indefinite recording period. The drawback to sleep logs is the inaccuracy of self-report of sleep time and the inability to diagnose sleep disturbance. Sleep logs are a useful screening tool and can provide follow-up information for phase shifted sleep and insomnia.

Wrist actigraphy measures movement of the wrist, consisting of a movement detector and memory storage. A wrist actigraph is approximately the size of a large watch and is worn continuously at home. When the recording period is complete, the stored movement data is transferred to a computer for analysis. Interpretation of actigraphic records assumes that movement is reduced during sleep compared with wakefulness. Patients who lie still but are awake for prolonged periods of time will have their sleep time overestimated. Similarly, patients with excessive movements during sleep may be considered to be awake and have an underestimate of sleep time. According to the American Sleep Disorders Association practice parameters, actigraphy serves as a useful adjunct to history, examination, and subjective sleep diary for the diagnosis and treatment of insomnia, circadian-rhythm disorders, and excessive sleepiness. However, actigraphy is not indicated for the routine diagnosis of any sleep disorder.^[42]

The multiple sleep latency test (MSLT) consists of five 20-minute nap opportunities, with each nap separated by 2 hours. The patient is lying down in a darkened room and instructed to try to sleep. The time before any sleep is recorded for each nap, and the mean sleep latency for all five naps is then determined. Patients with a mean sleep latency of less than 5 minutes are considered to have pathological sleepiness; those with a mean sleep latency between 5 and 10 minutes are borderline, and those with a mean latency greater than 10 minutes are normal. During the naps, sleep is staged. If REM sleep occurs during two or more naps, the MSLT is consistent with a diagnosis of narcolepsy, provided other causes of sleep-onset rapid eye movements have been excluded. The MSLT test is accurate if performed the day following overnight PSG. Sleep deprivation from the night before or drugs that suppress REM may yield deceptive results. The MSLT is indicated for assessment of narcolepsy, severity of EDS due to obstructive sleep apnea, other nocturnal sleep disturbances, and idiopathic hypersomnia.^[43]

Ambulatory or portable sleep monitoring allows for recording of sleep in the patients home. It is less expensive than laboratory PSG and more convenient for patients. Portable monitors have been the most widely used tool for the assessment of sleep apnea. The limitations of portable monitoring include the variability in commercially available monitors. Recording channels may be limited, making a complete assessment of sleep problematic. There is no technician present in an unattended study to adjust for malfunctioning equipment or to reapply faulty or loose electrodes. According to the American Sleep Disorder Association's guidelines, portable monitoring is indicated only for patients who cannot be studied in the sleep laboratory or for follow-up studies when the diagnosis has already been established by standard PSG.^[44]

CLINICAL SYNDROMES INVOLVING THE ANATOMY OF SLEEP (Table 2-3)

Insomnia

The insomnias encompass a number of different disorders in which there is difficulty falling asleep or maintaining consolidated sleep, or the problem of awakening early in the morning before adequate sleep is obtained. The definition of adequate sleep varies between individuals, with some perceiving 5 hours as sufficient and others feeling that 8 or 9 hours of undisturbed sleep is necessary to be rested and alert the following day. The history is crucial to determining the possible etiologies of insomnia.^[45]^[46]^[47]^[48]

Sleep-onset insomnia refers to a prolonged latency from the time of going to bed until falling asleep. In psychophysiological insomnia, the patient may complain of feelings of anxiety, tension, worry, or persistent reflections over the problems of the past or future because they lay in bed to sleep. In acute insomnia, there may be an inciting event, such as the death or illness of a loved one, that is associated with the onset of insomnia. The pattern may become established over time, and the patient is left with a recurrent, persistent insomnia. In time, they may become apprehensive as they lie down to sleep, fearing that the struggle to obtain sleep will commence again. The greater the effort

TABLE 2-3 -- SELECTED ETIOLOGIES OF DISORDERS AFFECTING THE SLEEP-WAKE CYCLE

Etiological Category	Specific Etiologies	Chapter
Developmental structural disorders	Enuresis from structural anomalies	28
Degenerative and compressive structural disorders	Obstructive sleep apnea; upper airway resistance syndrome	29
The degenerative dementias	Alzheimer's disease	33
Movement disorders	Parkinson's disease, multiple systems atrophy; dopa-responsive dystonia; hyperkinetic movements: tics, chorea, dystonia, tremor, hemiballism, hemifacial spasm, myoclonus of cortical origin	34
Degenerative motor, sensory, and autonomic disorders	Duchenne muscular dystrophy; myotonic dystrophy, limb-girdle dystrophy; amyotrophic lateral sclerosis	36
Inherited muscle, neuromuscular, and neuronal disorders	Congenital myopathies	37
	Kleine-Levin syndrome	38
Endogenous metabolic disorders	Thyroid diseases	
Nutritional deficiencies and syndromes associated with alcoholism	Alcoholism	40
Transmissible spongiform encephalopathy	Fatal familial insomnia	43
Demyelinating disorders of the peripheral nervous system	Guillain-Barré syndrome	49
Autoimmune and inflammatory disorders	Rheumatoid arthritis; polymyositis, myasthenia gravis	50
Traumatic disorders	Post-traumatic hypersomnia	51
Epilepsy	Sleep epilepsy; nocturnal paroxysmal dystonia	52
Headache and facial pain	Sleep-related headaches	53
Sleep disorders	Narcolepsy; REM sleep behavior disorder; restless legs syndrome; periodic limb movement disorder; primary insomnia; sleep walking, sleep talking; bruxism	54
Drug-induced and iatrogenic neurological disorders	Antidepressants; hypnotic-dependent sleep disorder; stimulant-dependent sleep disorder	55

expended in trying to sleep, the more elusive sleep becomes. Watching the clock as each minute and hour passes only increases the sense of urgency, further confounding efforts to sleep. The bed may eventually be viewed as a battleground, and sleep is achieved more easily in a foreign environment.

Some patients report an inability to fall asleep quickly that arises from physical discomfort as they lie down. Patients with Parkinson's disease may observe stiffness and an inability to roll over in bed; patients with RLS may report unusual sensations of tightness, tension, creeping, or tingling in their calf muscles that is relieved only by movement; pain from arthritis, neuropathy, or muscle injury may be enhanced at night.

Patients with poor sleep hygiene may complain of sleep-onset insomnia. Late-day napping, caffeine and nicotine intake, exercising in the hours immediately before bed, or late night meals may all be factors contributing to insomnia. Using the bedroom and bed to work, read, eat, or watch television may also interfere with the ability to fall asleep.

Circadian rhythm disorders may also present as sleep-onset insomnia.^[49] Patients with irregular sleep hours, such as shift workers or international travelers, are continuously fighting their inherent circadian rhythms. In particular, travel in an eastward direction may provoke an inability to sleep at the desired times in the new time zone. Adolescents are often phase delayed or so-called night owls, preferring a later bedtime and awakening time. In some individuals, this pattern may carry over into adulthood, causing significant problems with maintaining an acceptable job schedule and may be perceived as sleep-onset insomnia rather than phase-delayed sleep.

Insomnia may arise secondary to neurological or psychological disorders.^[50]^[51]^[52] Patients with dementia may have difficulty falling asleep at night. In some, there may even be a reversal of the normal day-night sleep cycle in which the patient is awake and wandering about throughout the night hours and napping intermittently throughout the day. Certain psychiatric disorders, such as major depression or bipolar disorder may be the cause of insomnia. Particularly in the acute manic or hypomanic phase, there may be significant problems with sleep onset. Schizophrenic patients may also report sleep onset insomnia.

Drugs may interfere with ability to sleep.^[53] Some agents, such as stimulants and antiparkinson drugs, may be directly associated with insomnia. Other drugs may cause insomnia when they are discontinued. In particular, the discontinuation of chronic hypnotic treatment may cause severe rebound insomnia. Establishing the pattern of medication intake and the association of medications with the onset of insomnia is vital to establishing this factor as the cause of insomnia.

Sleep fragmentation refers to an inability to maintain sleep over the night with frequent nocturnal awakenings and variable ability to fall back to sleep. Sleep may be disturbed by a variety of causes. Alcohol intake before bed, while promoting sleep onset, often causes disruption of sleep toward the end of the night. Primary sleep disorders may disrupt nocturnal sleep. PLMD may cause a patient to awaken without being aware of the cause. Sleep apnea, likewise, may cause sleep fragmentation in a patient who reports that initial sleep latency is short. A patient with sleep apnea may awaken with choking, or a sense of being unable to breathe. PSG is usually necessary to diagnose these causes of insomnia.

Medical and neurological conditions, including nocturia, cardiac disease, rheumatoid arthritis, fibromyalgia, and neuromuscular diseases may also cause sleep fragmentation.

Insomnia may also present as early-morning awakening.

Patients with this type of insomnia complain that they wake up for no reason at an early hour in the morning and are not able to reinitiate sleep. This type of insomnia is often seen in patients with major depression and is a frequent complaint of the elderly. In phase-advanced sleep, the major sleep period occurs early with bedtime and final awakening hours before desired.

Excessive Daytime Somnolence

EDS indicates the occurrence of abnormal sleepiness during the normal waking hours.^[54] EDS may be associated with inadequate nocturnal sleep and can arise secondary to insomnia. EDS can also occur independently of insomnia.^[55] Primary sleep disorders, such as sleep apnea and PLMD, may disrupt nocturnal sleep, leading to sleep deprivation and EDS. Often, patients with these disorders have frequent arousals punctuating the night but are unaware of these events. During the day, they report a susceptibility to falling asleep. When the condition is mild, inadvertent napping may occur only during sedentary activities during the normal nadirs in daytime alertness in the afternoon or evening. As EDS becomes more severe, patients may report nodding off during active periods, such as driving a car or when conversing. Narcolepsy is characterized by a propensity to sleep during the day. Sometimes, these periods may present as microsleeps in which there is a sudden but momentary lapse of consciousness. During these short periods, automatic behaviors may occur and observers may not realize that the patient is asleep. Sleep attacks, with the unexpected, cataclysmic onset of sleep, are also seen. Patients with narcolepsy may experience REM sleep and report the occurrence of dreams during these daytime naps. EDS may be the sole clinical manifestation of narcolepsy in some patients, occurring without associated cataplexy, hallucinations, or sleep paralysis.

EDS may also indicate primary hypersomnia.⁵⁶ Idiopathic hypersomnia is a neurological disorder in which nocturnal sleep is prolonged but not refreshing. Daytime naps may be long and unsatisfactory. Patients may sleep for periods of up to 20 hours a day. PSG shows a relatively normal sleep architecture compared with the more disturbed sleep seen in narcolepsy. The multiple sleep latency test demonstrates pathological sleepiness, but REM sleep does not occur during the two or more naps. Hypersomnia may also be secondary to medical conditions such as viral infections, especially mononucleosis and encephalitis, or hydrocephalus. It is usually necessary to obtain a PSG in order to distinguish among the disorders leading to EDS.

Parasomnias

The term parasomnia refers to a group of disorders of arousal, partial arousal, and sleep-stage transition. A feature of many of the parasomnias is the occurrence of abnormal muscle activation behaviors occur during sleep. These behaviors may be associated with REM or NREM sleep. Behaviors occurring predominantly during the first third of the night are likely to be related to Stages 3 and 4 sleep because this is the time of night when SWS predominates and are largely considered disorders of arousal. Somnambulism or sleep walking, sleep terrors, and confusional arousals are commonly occurring parasomnias during SWS. Usually, these disorders affect children and adolescents, and resolve during adulthood. However, these disorders may carry over into adulthood or arise secondary to medications. Sleep walking may result in significant sleep-related injuries because patients may walk through windows or fall down stairs during their nocturnal wanderings.

Sleep complaints that occur during the transition from wakefulness to sleep often affect otherwise healthy individuals and include sleep starts, sleep talking, and rhythmical movement disorders such as head banging, body rocking, and head rolling. The hallmark of this group of disorders is their occurrence at sleep onset, with some also occurring during wakefulness.

The parasomnias associated with REM sleep include nightmares, sleep paralysis, and RBD.^[18] REM-related parasomnias are more likely to occur later in the night, when REM sleep predominates. RBD usually affects older men, in contrast to the other REM- and NREM-related parasomnias. RBD may occur as an idiopathic disorder or arise secondary to neurological disorders in which there is pathology involving brain stem nuclei. RBD is considered a primary disorder of REM sleep that parallels oneiric activity in animals following selective lesions of the pontine nuclei controlling motor atonia. Patients with narcolepsy, another disorder of REM sleep, may also show features of RBD.

Sleep enuresis and bruxism are classified as parasomnias but are distinguished by their lack of complex-associated behaviors.

Additional sleep-related behavior disorders that may be confused with those described earlier include paroxysmal nocturnal dystonia and nocturnal epilepsy. These disorders appear as paroxysmal, stereotyped behaviors with sudden onset and resolution reflecting abnormal cortical activity rather than alterations in brain stem centers controlling REM sleep, or arising from NREM sleep.

Circadian Rhythm Disorders

This group of disorders involves a disruption of the inherent circadian pattern of wakefulness and sleep.^[37] Jet lag arises from transmeridian flights of long duration, usually through at least three time zones, and reflects the adaptation necessary to reset the internal rhythm to the day-night cycle of the destination. Jet lag is enhanced by the sleep deprivation that usually occurs before a prolonged trip, loss of sleep, and altered conditions during flight. Depending on the distance traveled, recovery may take as long as 7 days, especially for eastward travel.

In contrast, shift workers are required to change their major sleep period without the reinforcement of external light-dark cycles and in the absence of social patterns that conform to their new sleep schedule. Following a single change in shift, 2 weeks may be needed for readjustment. However, often shift workers are required to change their schedules every 2 to 4 weeks, and frequently are progressively

changed from night to afternoons to morning shifts. Thus, they may have a chronic desynchronization with their circadian clock.

Finally, there are so-called natural night owls and morning larks who are most comfortable with their major sleep period either later or earlier than can accommodate socially acceptable daytime activities, such as work or school.

Mood is defined as "the sustained internal emotional state of a person" ^[1] and is broadly divided into three realms: elevated, normal, or depressed. There are an enormous number of subclassifications within each of these subdivisions, and normal mood includes several gradations of elevation or depression. *Affect* generally refers to the external expression of emotional content and may coincide or be at odds with a patient's mood. The terms mood congruent and mood incongruent are used to describe these forms of emotional or affective expressions. Some authors use the term affect to describe a subject's emotional state at a particular instant, ^[2] but this is a more obscure usage. Two basic mood abnormalities, depression and mania, are recognized, and these occur on a continuum from normal to the clearly pathological. While minor symptoms may be an extension of normal sadness or elation, more severe symptoms are associated with discrete syndromes (affective disorders) that appear to differ qualitatively from normal processes. *Depression* is defined as a morbid sadness, dejection, or melancholy, whereas *mania* is a disordered mental state of extreme excitement. Both have accompanying emotional and cognitive and motoric features.

Emotional experience connotes the whole range of human feelings, including anxiety, fear, apathy, euphoria, depression, sadness, anger, and grief as well as how the person experiences these various feelings, which are not mutually exclusive. Thus, most individuals constantly experience a wide variety of feelings of variable intensities that vary over time. *Emotional expression*, or affect, may be mood congruent, accurately reflecting the person's inner state, or incongruent, when the subject appears to be very happy or sad but in fact feels quite the opposite. Emotional expression has an enormous range, which is obviously wider in some people than in others. This range may be normal, expanded, or *restricted*, allowing little chance for either happy or sad emotions to be displayed. When expansive, emotional expression is amplified at both ends of the mood spectrum. *Flattened* affect is a lack of emotional display, and *labile* affect is an emotional state that changes rapidly and is out of proportion to changes in the situation. It is important to note that emotional experience and emotional expression are quite different. One can appear to be emotionally detached and have little concern or interest in the situation, when in fact one is greatly moved. Such a discordance between apparent and true emotion may be highly adaptive in some situations and cultures and not at all pathological.

Other terms involved in disorders of emotion and mood include *apathy*, which is a lack of feeling or indifference. A *bulia* is a general behavioral slowing and lowered activity that may be associated with an inability or refusal to speak. *Akinetic mutism* is defined as the presence of a condition in which the patient appears awake and may follow the examiner with his or her eyes but lacks spontaneous motor and verbal responses. *Anxiety* is an uncomfortable and unjustified sense of apprehension that may be diffuse and

unfocused and is often accompanied by physiological symptoms. An *anxiety disorder* connotes significant distress and dysfunction due to the anxiety. *Fear* can also produce the symptoms of anxiety, but, in contrast to anxiety, its cause is obvious and understandable.

Thought is in many ways unrelated to mood or emotions. Thought is evaluated in terms of the "process" or mechanics of thinking and also in terms of the content. In schizophrenia, one deals with "loosened" thought processes. *Psychosis* is a broad term defined variably in different places, but generally it implies a severe mental illness characterized by a loss of contact with reality leading to severe impairments in personal and social functioning. Psychosis is distinguished from delirium, in which there is an impairment of consciousness associated with an organic cause.

Hallucinations, hallucinosis, illusions, and delusions are terms that are frequently misused, leading to incorrect diagnoses, particularly by nonpsychiatrists. *Hallucinations* are false sensations that arise without a stimulus. Visual hallucinations appear real and are seen clearly in the light. They may be unformed like geometric shapes, or formed, simulating people, animals, or objects. Auditory hallucinations are sounds, such as voices or music, that are indistinguishable from real sounds. *Hallucinosis* refers to the presence of hallucinations in an otherwise normal mental state, without confusion, disorientation, or psychosis. Generally, hallucinations are experienced as real, whereas in hallucinosis the sensations are quickly interpreted as false. Hallucinations occur in every sensory realm, so that smells, taste, tactile sensations, and so on, may all occur. *Illusion* refers to an altered or misperceived sensation that is transformed, such as perceiving a lamp as a person. *Delusion* refers to a false and irrational belief that is unalterable by rational discourse. Typical delusions may include grandiosity, in which the patient believes he or she has great powers, or paranoia, in which the patient believes he or she is being followed. Hallucinations and delusions occur in a wide variety of psychoses including manic-depression and organic states.

Hallucinations and delusions are considered *positive symptoms*, meaning that they are extra or additional features superimposed upon normal behavior. This concept was pioneered by Hughlings Jackson, who considered positive symptoms a "release" phenomenon, in which inhibitory control is lost. Other positive symptoms include bizarre behavior, pressured speech, and thought disorder. In contrast, *negative symptoms* refer to loss of affect, diminished thought, anhedonia (diminished interest and enjoyment), and diminished attention. Jackson attributed negative symptoms to a loss of neurons leading to a direct loss of function.

Obsessive thoughts are unwanted and bothersome recurrent ideas, images, and impulses that intrude upon a patient and cannot be pushed out of consciousness. A *compulsion* is an irresistible need to perform an activity. Obsessions and compulsions usually go together. *Rituals* are a sequence of stereotyped behaviors that must be performed and often have a symbolic meaning.

CLINICAL HISTORY

The basic structure of the history and examination for a mood, emotion, or thought disorder is no different from that used for any medical or neurological problem. The only variation lies in how the history is obtained and how the patient answers questions and relays the clinical information. The process of response may therefore be even more important than the content of the historical details themselves. Another difference is that historical data, in a patient with a disorder of mood, emotion, or thought, often need corroboration or explication by third parties. The examiner should also obtain information about the premorbid state of the patient, including his or her development and environment, as important background on which to view the patient's current state. Personality changes are crucial indicators of mood and should be sought from family members. Progressive irritability or social withdrawal may be markers of depression, whereas new gregariousness and socializing may reflect a "decline" into mania. Finally, the time frame of the behavioral changes determines whether the event is acute, subacute, or chronic.

The presence of certain features typical of mood, emotion, or thought disorders must be pursued in a manner similar to that used for historical evaluation for any neurological or medical condition. Important details are evaluated so that pertinent positive and negative elements of the history supporting a diagnosis can be supplied. The clinician should know the symptoms of the illnesses considered in the differential diagnosis so that he or she can be sure that all pertinent questions have been asked. The history for a person with an affective illness must take into account both the mood state itself and the multiple somatic manifestations of mood disorders. Important questions about both depression and mania must be asked.

Depression is often associated with vegetative symptoms including disturbances of sleep and appetite, and loss of interest or pleasure in almost everything. Depressed people may state that they sleep excessively or insufficiently. They may note a loss of appetite or weight, or eat excessively. Because most depressed people lose energy and develop easy and excessive fatigue, these symptoms should be inquired about. Although some patients become agitated, as if they were manic, most generally do not apply this energy in useful, purposeful activities. Patients may note that their thinking ability and attention span are reduced and that their decision-making capability has plummeted. The patient may exhibit low self-esteem and feelings of guilt and may be absorbed by thoughts of death. The depressed mood may not be perceived by the patient or even by associates and may be manifested only by irritability. A sexual history is important because sexual drive may be markedly decreased as well.

Special care must be taken in the particular situation of a potentially suicidal patient, and the topic should be addressed forthrightly. Depressed patients should always be questioned about their potential for suicide. A history of suicide attempts, a family history of suicide, a suicide note, and a history of impulsive behavior are all significant risk factors.

When mania is encountered, the patient or family may note that the patient's need for sleep has declined and that the sleep schedule has changed dramatically. There may be a history of going without sleep for a few days and impaired judgment. This impaired judgment may have led

to the undertaking of huge projects based on an inflated belief in one's own power to control the outcome. The history may include details about money because large amounts may have been spent. Excessive or inappropriate sexual activity is also common.

When a patient has apathy or abulia, there is a near complete loss of feeling, initiative, movement, and thought. Very little historical information can be obtained directly from the patient, and the physician will have to rely on other family members or caretakers. In contrast, patients with anxiety and anxiety disorders often describe feelings of tension, irritability, or apprehension and may be mildly distractible during the interview. The presence of concomitant autonomic symptoms should be inquired about, including palpitations, diarrhea, cold clammy extremities, sweating, urinary frequency, insomnia, fatigue, and trembling.

Patients with psychotic disorders have a history of a grossly impaired sense of reality, often coupled with emotional disabilities. The violence-prone patient must be assessed in a safe situation, and the potential for violence should be openly acknowledged. Questions should be asked about previous episodes and the reason for the current violent outburst or threat. The interview situation must be stable and under control, with security personnel present, if necessary. During the interview, the patient may talk and act in a bizarre fashion, demonstrate delusions, or have illusions and hallucinations. During the conversation, the interviewer should note disturbances of both thought form and content. Abnormalities of thought include a loosening of associations with tangential topics of conversation. The flow of thoughts does not follow the usual orderly sequence that leads from one idea to another. Rather, it takes peculiar leaps that are difficult for listeners to follow both because the sequence is idiosyncratic and because the expressed thoughts may appear unrelated to the preceding thoughts. In addition, the content of thoughts may be bizarre. The patient may disrupt the flow of thoughts by including irrelevant information. New words, or neologisms, may be used that have no meaning. Disturbances of thought content, or delusions, may be bizarre, persecutory, or of grandeur. The patient may state that he or she believes he or she can control events through telepathy or may be convinced that there are "meanings" behind events and people's actions directed toward him or her.

Illusions are typically visual but may also be auditory or tactile. With visual illusions, the patient or family may note that the person may look at an object or person and see something other than what is actually there. The examiner should give specific examples, such as looking at a coat hanging in the closet or a light pole or lamp and perceiving a person, or looking at a bush and perceiving an animal. Similar examples involving sounds and tactile stimulation should be inquired about. Hallucinations should also be inquired about, and all sensory modalities should be investigated. Hallucinations may be unformed shapes or colors or formed images of people, animals, and objects. The images may be familiar or unfamiliar and may include relatives or friends who are living or dead, children, babies, or lilliputian figures. Threatening or frightening hallucinations may also occur and should be inquired about.

In the investigation of obsessive-compulsive behavior, the examiner should ask whether the patient experiences repeated images or ideas that are intrusive. Patients may note that these thoughts are unwanted, distressing, and occasionally frightening or violent, and that they are powerless to stop them. The examiner should ask whether the patient ruminates endlessly on certain thoughts such as whether the patient locked the door or performed other activities. The existence of rituals or compulsions should be sought. Patients should be asked if they must count, touch, or clean something to ward off unwanted happenings or to satisfy an obsession. These activities may consume a patient's whole day, rendering him or her unable to complete any necessary task.

Patients with impulse dyscontrol or aggression may not offer any complaints, yet family members may relate a detailed account. The spouse or relatives may note the patient's impulsiveness in everyday activities and an inability to resist performing inappropriate activities both at home and in public. The clinician should inquire about the use of both inappropriate words and physical actions. Additionally, family members should be asked about the presence of sudden outbursts or episodes of rage involving destructive behavior to property, abusive actions involving others, or self-mutilation.

In all settings of disorders of mood, emotion, and thought, a complete drug history is essential to uncover possible organic precipitants of behavioral changes. A medical and neurological review of systems is also crucial. Various medical conditions such as infections and endocrinopathies may present with disorders of mood, emotion, and thought, and other physical findings associated with these disorders may be helpful in arriving at the correct diagnosis. Neurologically, patients should be asked whether they have experienced asymmetrical weakness, numbness, memory problems, dysgeusia, or seizure activity, which may indicate a structural, metabolic, or infectious cause of the presentation. Finally, a family history provides important diagnostic information, since certain mental illnesses, including affective disorders, tend to be hereditary.

ANATOMY OF MOOD, EMOTION, AND THOUGHT

The neuroanatomic structures related to human mood, emotion, and thought function are complex, and research in this area is still under development. The association of various brain regions with particular functions is based primarily on studies of lesions and, more recently, on functional neuroimaging. Although generalizations based on these isolated cases are somewhat precarious, extended observations based on series of cases are somewhat more reliable. Additionally, although the findings of animal studies are highly reproducible, they do not necessarily apply to human behavior. Early experiments on dogs and other animals demonstrated that decortication produced rage behavior when the animal was presented with previously nonthreatening stimuli. Later work in cats showed the importance of an intact diencephalon (thalamus and hypothalamus)

in eliciting this response. If these lower structures were also damaged, strong emotional displays were not elicited. Other experiments on the hypothalamus of the cat demonstrated that when certain areas were stimulated, marked behavioral alterations were produced, including not only behavioral displays but also concomitant physiological changes appropriate to the behavior. For example, the cat displayed piloerection and hissing and baring of teeth with associated elevations of blood pressure, heart rate, and respiration.

Primary alterations in mood, emotion, and thought in humans have also been associated with abnormalities in certain regions of the brain and have primarily focused on the "limbic system" and on the temporal lobe and the frontal lobes.

Limbic System

The term limbic lobe was coined by Broca in 1878 to describe a series of structures that envelop the brain stem. The word limbic is derived from *limbus*, meaning border in Latin, and the limbic system encompasses the amygdala, hippocampus, septum, cingulate gyrus, cingulate cortex, hypothalamus, epithalamus, anterior thalamus, mammillary bodies, and fornix. The limbic system has rich connections throughout the brain, particularly with the primary sensory cortices, including the rhinencephalon for smell, the autonomic nervous system via the hypothalamus, and memory areas. Papez, in 1937, was first to use clinical information obtained from patients with brain tumors in support of his proposed limbic mechanism of emotion and memory. Since that time, others have reported a correlation of abnormalities of this region with disorders of emotion, mood, and thought.

Starkstein and colleagues studied 11 patients with manic syndromes associated with brain injuries and demonstrated that secondary mania correlated with the presence of either anterior subcortical atrophy or a focal lesion of a limbic or limbic-connected region of the right hemisphere. Follow-up studies of additional patients along with analysis of other cases of secondary mania from the literature indicated that the causative brain lesions were located mainly in limbic and limbic-related areas that have connections with the frontal lobes. More recently, positron emission tomography (PET) studies performed on subjects experiencing transient sadness with recall of unhappy memories showed bilateral activation of paralimbic structures, whereas happy memories were associated with a widespread reduction in cortical cerebral blood flow.

The limbic system has also been implicated in such thought disorders as schizophrenia. In one study reporting magnetic resonance imaging (MRI) and cerebral blood flow studies in twins who were discordant for schizophrenia, the hippocampal area of nearly all affected individuals was smaller. Additionally, a number of well-controlled observations of postmortem brain samples of schizophrenics revealed a decrease in the size of the region including the amygdala, the hippocampus, and the parahippocampal gyrus.

AMYGDALA

The amygdala, a core part of the limbic system, has been the focus of particular research attention in the evaluation of mood and emotion. This structure, named for its almond shape, sits medially in the anterior temporal lobe above the hippocampal formation. It consists of two main nuclear regions and about a dozen individual nuclei, each with distinct cytological and histochemical features. The amygdala is in contact with the tail of the caudate nucleus, but it is dissimilar from this region from both structural and evolutionary viewpoints. Afferent inputs to the amygdala are varied and include projections from the olfactory cortex, hypothalamus, and thalamus. The two major efferent projections from the amygdala are the stria terminalis and the ventral amygdalofugal pathway. The former supplies the hypothalamus, the nucleus accumbens, and the bed nucleus of the stria terminalis. The latter projects to the hypothalamus, dorsal medial nucleus of the thalamus, and the cingulate gyrus. The amygdala also projects in a reciprocal fashion to brain stem nuclei involved in the autonomic changes that accompany fear and stress-related responses. Projections to somatosensory cortex and most of the temporal lobe have also been demonstrated.

The connections between the amygdala and the hypothalamus and visceral brain stem nuclei explain the complex physiological responses that occur with mood changes in general, specifically fear and the "fight or flight" response. Stimulation experiments in animals produce a variety of autonomic responses. The most common response is an accelerated respiratory rate with shallow breathing associated with increases or decreases in blood pressure and pulse. Gastric motility may increase or decrease, and urination as well as defecation may be induced. Piloerection, pupillary changes, salivation, and altered body temperature may also occur. These autonomic changes may result from sympathetic or parasympathetic systems. The amygdala is additionally implicated in modulation of the hypothalamic control over food intake. Lesions of the basolateral nucleus of the amygdala or bilateral destruction of the amygdala induces hyperphagia. Stimulation of the basolateral nucleus causes decreased appetite and arrest of feeding behavior.

In 1939, Kluver and Bucy described primates with bilateral anterior temporal lobectomies, including removal of the uncus, amygdala, and part of the hippocampus. These animals became tame, and they lost the responses of fear and aggression. They mouthed all objects, regardless of how familiar or inappropriate, and they ate everything, including nonfood items. Sexual behavior increased dramatically for appropriate and inappropriate targets, and self-stimulation also occurred. A visual agnosia combined with an inability to screen out unimportant visual stimuli caused the animals to react to all stimuli in their visual field. Subsequent studies revealed that damage to the amygdala was the most important source of these behaviors. These data suggest that the amygdala gives sensory stimuli affective and motivational significance. In other experimental models, aggression has been provoked by stimulation of the amygdala, hypothalamus, and fornix and inhibited by stimulation of the frontal lobes.

Amygdala damage in humans usually occurs in patients undergoing elective surgery for controlling epilepsy, and in such cases these regions are presumed to be abnormal before ablation. Decreased aggression, increased placidity, or no emotional changes result. In one case of amygdectomy, the patient lost the ability to interpret facial emotions as well as the emotions conveyed by the nonverbal aspects of speech. In contrast, amygdala stimulation in humans has produced fear, confusion, amnesia, and altered awareness.

TEMPORAL LOBE

Emotional attributes have also been associated with temporal lobe abnormalities in humans, even when the nature, localization, and extent of the abnormalities have been unknown. Most of these data involve epileptics with known seizure foci of the temporal lobe. Researchers have posited that patients with temporal lobe epilepsy who have not undergone surgery may have a "temporal lobe personality." In such studies, patients with right temporal lobe abnormalities have been thought to be more introspective and "obsessive," and those with left temporal lobe defects have been said to be extroverted and often concerned with "personal destiny." Additional features perceived to be more common in temporal lobe epileptics than in normal controls include emotionality (more intense and sustained emotional response), euphoria, sadness, anger, guilt, hypermoralism, religiosity, hypergraphia, and passivity. These studies have been criticized on methodological grounds but suggest that emotionality, mood, and thought processes involve temporal lobe function albeit in complicated and still poorly understood ways.

Various reviews and long-term follow-up studies of patients with epilepsy who have undergone temporal lobectomies have led to several conclusions about the temporal lobe and psychotic behavior. Most reports suggest that when psychosis is present preoperatively, no improvement is demonstrated following the operation. In fact, psychosis may actually develop postoperatively, especially when the surgery involves the right temporal lobe. Postoperative depression and both early and late suicide are also reported as possible complications of temporal lobectomy. Improvement, however, may occur in other behaviors, particularly excessive aggression, irritability, and social misconduct.

FRONTAL CORTEX

Mood, emotions, and thought also involve structures outside the limbic system, and the frontal lobes in particular have a major role. The famous 1868 case of Phineas Gage, in which the subject survived an explosion in which a metal bar 3 cm wide by 1 meter long went through his left frontal lobe but then demonstrated a marked alteration in personality, clearly indicated the importance of the frontal lobe in behavior.

The frontal cortex of interest can be divided into three major domains: precentral, prefrontal, and limbic. The precentral cortex is composed primarily of the motor strip and premotor cortex. Further anterior is the prefrontal cortex, which is the largest region of the frontal lobe and includes the anterior pole. The prefrontal cortex may be further divided into mesial, dorsal, and orbital parts. The orbitofrontal region of the cortex is one of the main limbic efferent channels to the hypothalamic-hypophysial complex and the visceral motor system. The prefrontal cortex has connections with the association, premotor, and limbic cortices as well as with the amygdala, hippocampus, and dorsomedial thalamic nuclei. Although the prefrontal cortex projects to the striatum, it does not receive reciprocal fibers from this structure. Cummings has proposed three major circuits connecting the frontal lobes with the subcortical structures, providing a framework for understanding the role of the frontal lobes in behavioral disorders.^[12] Based on analyses of lesions, the dorsolateral prefrontal-subcortical circuit appears to be involved with executive function (see [Chapter 5](#)). This type of function includes the process of supervising other brain functions related to developing and implementing a plan. The orbitofrontal-subcortical circuit is necessary for social behaviors and inhibition of inappropriate activities, and lesions of this area have been associated with obsessive compulsive disorders. Finally, the medial frontal-subcortical circuit is involved with motivation; consequently, lesions of this region have been associated with apathy syndromes.

Lesions of the frontal lobe may cause different behavioral syndromes depending on their location, depth, and size. Bilateral disturbances of the frontal lobes, particularly slowly developing abnormalities such as tumors, can cause significant intellectual and affective decline that simulates the signs of Alzheimer's disease or other dementing disorders. Bilateral ventromedial frontal lobe damage produces inappropriate, uncontrolled histrionic displays of affect, with laughing or crying fits that are not precipitated by obvious stimuli and are unrelated to the subject's mood.^[13] More commonly, frontal lobe lesions in humans cause a dulling or shallowness of response or a lability of mood, classically termed witzelsucht. This term refers to the inappropriate jocularity and facetiousness seen with such disorders. The humor is quite changeable, and the affect may be labile. There is a loss of pleasure but no depressed affect, as seen in patients with affective disorders. Increased volatility, especially in patients with orbital lesions, has led to hypotheses that dysfunction of the frontal-orbital cortex may be involved in mania, especially when the right hemisphere is involved.

Other focal lesions of the frontal cortex have also been associated with mood and emotion abnormalities. In a selected group of right-handed patients with a single stroke lesion in either the right or left hemisphere and no previous psychiatric history, Robinson and associates found that the severity of depression in these patients was significantly increased in those with left anterior lesions as opposed to any other location.^[14] Additionally, the severity of depression correlated significantly with the proximity of the lesion to the frontal pole in the left anterior group. Patients with a right hemisphere lesion showed the reverse. These findings caused the authors to suggest that the location of the intrahemisphere lesion is in some way related to mood disorders in stroke patients, and the neuroanatomy of the biogenic amine-containing pathways in the cortex might explain the graded effect.

Figure 3-1 (Figure Not Available) Catecholamine biosynthetic pathways (Reproduced with permission from Siegel GJ, Agranoff BW, Albers RW, Molinoff PB: *Basic Neurochemistry*, 5th ed. New York, Raven Press, 1994.)

In the presence of frontal lobe dysfunction, patients are often impulsive and have little insight into their difficulties. They are also characterized by a lack of originality and creativity, an inability to focus attention, recent memory problems, and a tendency to display inappropriate emotional reactions (disinhibitions).^[13]

Investigations of patients with thought disorders such as schizophrenia have also consistently shown frontal lobe dysfunction. Morphological and imaging studies in these patients have shown other abnormalities including ventricular enlargement with atrophy involving the amygdala, parahippocampal gyrus, and superior temporal gyrus.^[15] Single-photon emission computed tomography (SPECT) and PET have further revealed the presence of low metabolic rates in medial frontal regions^[16] and in the dorsolateral prefrontal cortex.^[17]

Subcortical Structures

Mood and affective changes are seen in patients with subcortical dementia syndromes resulting from a disconnection between the frontal lobes and the basal ganglia. Behavior has been investigated in patients with certain specific disorders including Parkinson's disease (PD), progressive supranuclear palsy (PSP), and Huntington's disease. In each, the pathology has been located primarily in the basal ganglia, and all patients have had associated disorders of affect and cognition. Parkinson's disease and PSP patients are often depressed or apathetic and may develop delusions and hallucinations with drug therapy. These patients, particularly those with PSP, may demonstrate a pathological affect known as pseudobulbar affect, whereby they intermittently exhibit primary emotional displays in response to trivial stimuli. This situation is also seen in any condition causing bilateral lesions involving the bulbar regions of the neocortical motor system or its descending connections. Patients with Huntington's disease also become depressed, impulsive, and often psychotic. The clinicopathological correlation is complicated by the fact that our understanding of the pathology of each of these disorders is still incomplete, and it is not at all clear that cortex is spared. Other investigators have shown that secondary mania is associated with subcortical lesions of the white matter of the right frontal lobe, the right anterior limb of the internal capsule, and the right head of the caudate.

Recently, investigators have become interested in the role of the cerebellum in nonmotor function, including mood and executive function.^[18] A syndrome of mutism and behavioral disturbances has been reported in some children after cerebellar resections, and several case reports have described "cortical type" behavioral disturbances resulting from purely cerebellar lesions.^[19]

Pharmacological Neuroanatomy

A number of neurotransmitters, specifically the catecholamines (norepinephrine and dopamine) and serotonin, are closely related to mood, emotion, and thought disorders.^[20] Catecholamines are formed in brain, chromaffin cells, sympathetic nerves, and sympathetic ganglia from tyrosine, their amino acid precursor (Fig. 3-1 (Figure Not Available)). Tyrosine is taken up from the bloodstream and concentrated within the brain and other sympathetically innervated tissue via active transport. In the brain, tyrosine undergoes a series of chemical transformations, resulting in the formation of norepinephrine and dopamine. The conversion of tyrosine to dihydroxyphenylalanine (dopa), the first and rate-limiting step in this process, is controlled by tyrosine hydroxylase. This enzyme is stereospecific and requires molecular O₂, Fe²⁺, and tetrahydropteridine as cofactors. The second enzyme involved in catecholamine biosynthesis is dopa decarboxylase, which requires pyridoxal phosphate (vitamin B₆) as a cofactor and converts dopa to dopamine. Dopamine-beta-hydroxylase

utilizes molecular oxygen in the presence of ascorbic acid to convert dopamine to norepinephrine. In the adrenal medulla, norepinephrine can be further N-methylated by the enzyme phenylethanolamine-N-methyl transferase, forming epinephrine. Although it is largely restricted to the adrenal medulla, low levels of this enzyme have been noted in the mammalian brain.

The degree of sympathetic activity does not influence endogenous levels of norepinephrine. Studies have demonstrated that accelerated norepinephrine biosynthesis secondary to enhanced sympathetic activity is due to an increase in the activity of existing tyrosine hydroxylase and is not the result of increased enzyme synthesis. Tyrosine hydroxylase is inhibited by catechols and catecholamines, presumably within the neuron. When increased impulse flow causes more transmitter to be released and metabolized, the levels of intraneuronal norepinephrine are reduced, resulting in increased activity of tyrosine hydroxylase. More recently, several experiments have demonstrated that electrical stimulation of both central and peripheral catecholamine neurons results in an allosteric activation of tyrosine hydroxylase that persists following termination of the stimulation. This suggests that short-term mechanisms in addition to depletion of catecholamines are operative in altering tyrosine hydroxylase activity during increased neuronal activity. After prolonged increases in activity of catecholaminergic neurons, tyrosine hydroxylase formation is induced; however, this process appears to be nonspecific and also results in increased levels of dopamine-beta-hydroxylase levels.

Most norepinephrine is located within highly specialized subcellular particles, or granules, in sympathetic nerve endings of the CNS. Adenosine triphosphate (ATP)

likewise is contained in the granules. These vesicles serve as a depot for dopamine and oxidize this transmitter to norepinephrine. By storing the transmitters, the vesicles retard their diffusion out of the neuron and protect them from destruction by intraneuronal monoamine oxidase (MAO). The release of catecholamines can be influenced by direct local action at nerve terminals by catecholamines themselves as well as by prostaglandins, vasoactive amines, angiotensin II, acetylcholine, and polypeptides. Beta-2-adrenoceptors are believed to facilitate the release of norepinephrine, possibly by stimulation of adenylate cyclase, which leads to increased levels of cyclic adenosine monophosphate (cAMP), followed by rises in intracellular Ca^{2+} concentrations.

The major enzymes involved in the metabolic degradation of catecholamines are MAO and catechol- O-methyl transferase (COMT) (Fig. 3-2 (Figure Not Available)). Monoamine oxidase converts catecholamines to their corresponding aldehydes, which are then rapidly metabolized, generally through oxidation by aldehyde dehydrogenase to the corresponding acid. Monoamine oxidase is predominantly located in the outer membrane of mitochondria with possible microsomal localization. Extraneuronal MAO exists; however, it is predominantly an intraneuronal enzyme. In the human brain, at least two forms of MAO, type A and type B, have been identified. Certain agents have been shown to specifically inhibit these enzymes, including clorgyline, a specific type A inhibitor, and deprenyl, a selective type B inhibitor.

The second enzyme, COMT, is thought to be predominantly extraneuronal and requires S-adenosyl methionine and Mg^{2+} to become active. In peripheral sympathetic neurons, the aldehyde intermediate produced by MAO can be oxidized to the corresponding acid or reduced to glycols.

Figure 3-2 (Figure Not Available) Degradative pathways of norepinephrine. COMT, Catechol-methyltransferase (Reproduced with permission from Siegel GJ, Agranoff BW, Albers RW, Molinoff PB: Basic Neurochemistry, 5th ed. New York, Raven Press, 1994.)

Oxidation usually exceeds reduction, and vanillylmandelic acid is the major metabolite of norepinephrine and is detectable in the urine. In the CNS, reduction of the intermediate aldehyde formed by MAO predominates, and the major metabolite of norepinephrine found is 3-methoxy-4-hydroxy-phenylethylglycol. Dopamine is metabolized to dihydroxyphenylacetic acid (DOPAC) through intraneuronal MAO following reuptake (Fig. 3-3 (Figure Not Available)). When released, dopamine is also metabolized to homovanillic acid (HVA) through the actions of COMT and then MAO. In humans, the major dopaminergic brain metabolite is HVA, and accumulation of this metabolite in the brain or cerebrospinal fluid can be used as an index of functional activity of this transmitter system. There are lesser amounts of DOPAC and 3-methoxytyramine in human brain tissue. Catecholamines released by neurons are subsequently taken up via a saturable membrane transport process that is dependent on temperature and requires energy. This process is also sodium dependent and can be blocked by the inhibition of $\text{Na}^+ - \text{K}^+$ -activated ATPase.

There are two major groups of norepinephrine neurons within the CNS. The first, the locus coeruleus, is a compact bilateral cluster of approximately 12,000 large neurons in the caudal pontine central gray matter. Fibers from these cells form three major ascending noradrenergic tracts, including the central gray dorsal longitudinal fasciculus, the central tegmental, and the ventral tegmental-medial forebrain bundle tracts. These fibers innervate all cortices, specific thalamic and hypothalamic nuclei, and the olfactory bulb. A fourth tract ascends to innervate the cerebellar cortex, while the fifth fascicle descends into the mesencephalon and spinal cord; although they are largely ipsilateral, approximately one quarter of these fibers cross in some animals.

These central norepinephrine neurons have been thought to be involved in many neurophysiological functions, including learning, memory, sleep-wake cycle regulation, anxiety, and nociception, as well as in affective psychoses. In the catecholaminergic theory of affective disorders it is hypothesized that depression may be related to a deficiency of catecholamine at important CNS receptors, whereas mania is associated with an excess catecholaminergic state. This hypothesis originally resulted from the observation that MAO inhibitors produced mood elevation, and, in contrast, drugs that depleted brain amines such as reserpine could produce depression. Furthermore, agents such as MAO inhibitors, tricyclic antidepressants, and stimulants that are effective in treating depression interact with brain catecholamine receptors and increase the availability of monoamines. More recent studies have shown that long-term treatment with some of these agents affects receptor numbers and causes physiological and behavioral changes in sensitivity to monoamine agents. Furthermore, there is a decrease in the number and sensitivity of postsynaptic beta-adrenergic receptors and an increase in sensitivity of central alpha-adrenergic receptors.

The CNS dopaminergic system is complex, and a proposed schema divides the anatomy into three systems including ultra-short, intermediate-length, and long-length systems.^[19] The ultra-short systems encompass the interplexiform amacrine and periglomerular olfactory dopamine cells, which are unrelated to mood, emotion, or thought processes. The intermediate-length systems include the tuberohypophysial (connecting the arcuate and periventricular nuclei to the intermediate lobe of the pituitary and median eminence), the incertohypothalamic neurons (linking the dorsal-posterior hypothalamus with the dorsal anterior hypothalamus-lateral septal nuclei), and the medullary periventricular dopamine group (in the area of the dorsal motor nucleus, nucleus tractus solitarius, and periaqueductal gray). The long-length system connects the ventral tegmental and substantia nigra with the caudate-putamen (nigrostriatal) and limbic cortex-limbic system (mesocortical-mesolimbic). This long-length system is important in motor control and in mood, emotion, and thought processes.

Although dopamine synthesis and transmitter dynamics are shared by all dopamine cells, their physiology, pharmacology, and regulatory properties vary with location. Early investigations suggested that there were two broad classes of dopamine receptors (D_1 and D_2 classes); however, recently multiple additional subtypes have been identified (two D_1 and four D_2 classes). The D_1 receptors mediate dopamine-stimulated increases of adenylate cyclase and

Figure 3-3 (Figure Not Available) Major metabolites of dopamine. MAO, monoamine oxidase; COMT, catechol-methyltransferase; HVA, homovanillic acid; DOPAC, 3,4-dihydroxyphenylacetic acid (Reproduced with permission from Siegel GJ, Agranoff BW, Albers RW, Molinoff PB: Basic Neurochemistry, 5th ed. New York, Raven Press, 1994.)

phosphoinositide turnover and are located in the striatum, nucleus accumbens, olfactory tubercle, and striatum. One D_1 receptor subtype, D_5 , has a pharmacological profile that is similar to that of D_1 and stimulates adenylate cyclase activity, but it displays a higher affinity for dopamine and is located primarily in the limbic system. The D_2 receptors mediate the inhibition of adenylate cyclase and modulate phosphoinositide metabolism, as well as inhibiting the entry of Ca^{2+} through voltage-sensitive channels and enhancing K^+ conductance in the dopaminergic neuron. These receptors are located in the striatum, nucleus accumbens, retina, substantia nigra, ventral tegmental area, and pituitary gland. The D_3 receptor, a D_2 subtype, is found in highest levels in the limbic brain structures. Another D_2 subtype, the D_4 class, resembles the D_2 and D_3 receptors pharmacologically but has a higher affinity for clozapine, the atypical antipsychotic, and is found in the amygdala, hippocampus, and hypothalamus. Drugs that have dopaminergic effects may act via dopamine receptor-mediated effects as well as by non-receptor-mediated effects on presynaptic function and by effects that are mediated indirectly by interaction with other neurotransmitter systems that subsequently affect dopamine neurons.

Abnormalities in dopaminergic homeostasis have been implicated in patients with psychotic disorders, particularly schizophrenia. These theories suggest that such abnormalities of thought result from too much dopaminergic activity. This hypothesis evolved from the observation that, except for clozapine, the efficacy and potency of antipsychotics are correlated with the ability to antagonize the D_2 receptor. Additionally, amphetamines and other drugs that increase dopaminergic activity are able to produce psychotic behavior. Whether the cause of psychosis is related to excessive dopamine release or hypersensitivity of the dopamine receptors is unclear, as is which dopaminergic systems or receptors are involved. Furthermore, there is at present no direct experimental evidence that excessive dopamine-dependent neuronal activity or elevated dopamine levels at central synapses occur in schizophrenics. Although a significant elevation in HVA levels in the cerebrospinal fluid (CSF) of patients taking antipsychotic medications has been demonstrated, no differences in HVA levels in brain or CSF in normal subjects and unmedicated schizophrenics have been found. Other neurotransmitters may also be involved in psychosis, including norepinephrine, serotonin, and some amino acids. How these various systems interact is a matter of continued speculation.

Brain serotonin makes up only about 2 percent of the body's serotonin, much more being present in platelets, mast cells, and enterochromaffin cells. In the brain, serotonin is synthesized by the uptake of tryptophan, which is then hydroxylated by tryptophan hydroxylase to form 5-hydroxytryptophan (5-HTP). This enzyme requires molecular oxygen, reduced pteridine, and a sulfhydryl-stabilizing substance. This first enzyme is the rate-limiting step. When synthesized, 5-HTP is then decarboxylated to serotonin via amino acid decarboxylase. Serotonin is deaminated by MAO, producing 5-hydroxyindoleacetaldehyde, which can be further oxidized to 5-hydroxyindoleacetic acid (5-HIAA) or reduced to 5-hydroxytryptophol.

Serotonin synthesis apparently is not influenced by the concentration of 5-HT itself. This has been demonstrated by the fact that when 5-HT catabolism is blocked, brain serotonin concentration increases to three times that of controls. Furthermore, when 5-HIAA efflux is blocked, levels of this metabolite continue to rise linearly. These findings suggest that the rate of initial synthesis may be limited only by the availability of substrate and cofactors, or by other mechanisms.

Serotonin-containing cells are concentrated in the pineal gland but are also found in discrete groups of cells in the midline regions of the pons and midbrain. The caudal cells project to the spinal cord and brain stem, while the rostral cell groups project to the limbic forebrain system, thalamus, neostriatum, and cerebellum. Raphe neurons receive dopaminergic input from the substantia nigra and the ventral tegmental area, norepinephrine input from the locus coeruleus, and other afferents from the hypothalamus, thalamus, and limbic forebrain. In the past decade, extensive pharmacological laboratory work has identified numerous serotonergic subsystems, including 5-HT_{1A-F}, 5-HT_{2A-C}, 5-HT₃, 5-HT₄, 5-HT_{5A-B}, and 5-HT₇. More recently, specific receptor antagonists have also been developed that allow more refined pharmacological and neurochemical analysis of behaviors that relate to serotonin.

A wide array of homeostatic functions has been suggested for the serotonergic systems, including sleep-wake cycles. Alterations in serotonergic function have also been suggested in patients with certain psychiatric conditions such as affective illness, aggressive states, and schizophrenia. Low levels of serotonin in brain have been associated with depression and suicide, and drugs that enhance serotonin activity act as antidepressants.

EXAMINATION OF MOOD, EMOTION, AND THOUGHT

Directed Neurological Examination

The directed neurological examination should begin with a mental status evaluation, which includes a psychiatric assessment. This part of the examination actually begins during the history and may be expanded in a more formal fashion. The mental status examination should include assessments of level of alertness, orientation, and attention. Stupor may be organic in origin or psychiatric. Hypervigilant states may develop with delirium tremens as well as with drug overdoses, such as amphetamine, phencyclidine, and cocaine, or with paranoid states in general. A fluctuating level of consciousness is more likely to be associated with an organic cause, and the presence of stupor will interfere with the remaining aspects of the cognitive examination. Sudden alterations in behavior, especially behavior with automatisms, may also suggest a seizure disorder; seizures of frontal lobe origin may be extremely bizarre, and sudden behavioral changes are often mistaken for psychogenic displays.

To assess mood one must ask how the patient feels, yet the affect is also directly displayed. The patient may appear sad and tearful or ebullient and inappropriately expansive. The way the patient is dressed and presents herself or himself is important but is often overlooked. A slovenly

appearance in a recently high-performing individual is a cause for concern, even if the subject scores well on tests of memory and the simple routine tasks demanded in an office cognitive examination. The way questions are answered is a significant aspect of the emotional evaluation. The examiner should notice whether the patient volunteers information or conceals it. Additionally, it should be noted whether questions are answered in a normal time frame or if there are delays that require several prompts to obtain an answer. Furthermore, the answers may be incomplete or minimally helpful, and the prosody of the speech may convey emotions or the lack of them.

The presence of a thought disorder will be conveyed during conversation and is independent of mood. When taking the history and examining patients, the clinician should look for "loose associations of thought" and the practice of skipping illogically from one idea to another seemingly unrelated idea. It should be observed whether a word with two meanings is used correctly the first time and then used incorrectly to develop an unrelated thought. A formal language examination may be helpful in distinguishing a thought disorder from an aphasia. But when the speech disorder is profound, the difference may be difficult to discern. There are certain features of psychotic speech that may be helpful and should be sought. Clanging, the use of similar sounding words together regardless of their meaning, is never present in aphasia, whereas dysarthria is not a feature of psychosis. Naming should not be impaired in thought disorder but is usually affected in aphasias. The examiner should note that many patients with thought disorders are either noncompliant and refuse to answer or may seem to purposefully misname things, requiring interpretation of the incorrect answers. Writing specimens of a psychotic subject should be obtained; they may be agrammatical or may contain neologisms, simulating aphasia. As in patients with some aphasias, the content of the speech of a patient with a thought disorder may be empty, and often, after a few minutes of monologue, the examiner may have no idea what information was conveyed. Thought-disordered speech may also be pressured and may be highly distractible. The clinician should note any figures of speech that may contain unusual allusions and references to bizarre or macabre things.

The examiner should also ask whether the patient is hearing or seeing things that aren't there and assess whether these hallucinations are interfering with complete cooperation. Delusions should be probed but not countered. Since the delusion is an irrational belief, argument over its logic is fruitless, but the examiner should not agree with it. Depending on the situation, either an explanation that the belief is a delusion but appears real to the patient can be given, or the clinician can simply take note of it and pass on to other subjects. In the case of drug-induced psychosis in Parkinson's disease, the most common delusion is of spousal infidelity, a problem that is often not shared with the neurologist owing to embarrassment by both the patient and the spouse. In this situation and occasionally in others, specific delusions should be asked about.

Associated Neurological Findings

Cranial Nerves. The cranial nerve examination is important for determining symmetry in general. Asymmetrical findings indicate a pathological process. The eye examination is the most important part of the cranial nerve examination. Gaze impersistence, an inability to maintain conjugate deviation of the eyes, may be seen in the side opposite a frontal lesion. Small pupils may suggest narcotic use. Anticholinergic overdose may cause large pupils. A left-sided field cut or cortical blindness may be associated with a mass or infarct and in addition will be associated with a denial of illness. A bitemporal field cut indicates a chiasmal lesion, which can occur in a patient with a pituitary tumor in the presence of emotional abnormalities. A superior quadrantanopia may accompany temporal lobe tumors or other disorders. Fundi can reveal papilledema or emboli, pointing to systemic disease. A Foster Kennedy syndrome, associated with a frontal meningioma, may present with behavioral changes, ipsilateral optic atrophy, and contralateral papilledema. Smell should also be tested in patients with behavioral abnormalities because it may be abnormal when orbital-frontal pathology is present.

Motor/Reflexes/Cerebellar/Gait. The motor examination may reveal several signs relevant to the assessment of mood and thought. Any abnormality such as a hemiparesis indicates an organic disorder. The finding of myoclonus or asterix generally indicates a metabolic or toxic disorder and occurs only rarely with focal lesions. Tremor at rest is seen with neuroleptic drug use or Parkinson's disease, and these should be considered. Rigidity and akinesia should also be assessed; they may accompany catatonia, neuroleptic use, or any parkinsonian syndrome. Catatonic akinesia may include waxy flexibility and abnormal sustained postures including one limb being stretched out for extended periods. Adventitious movements such as chorea may be seen and usually indicate tardive dyskinesia following chronic exposure to dopamine-blocking drugs. Alternative explanations include dyskinesias in the presence of psychosis in PD, Huntington's disease, Sydenham's chorea, or systemic lupus erythematosus. Stereotypic movements such as clapping, tapping, and rubbing may suggest autism or mental retardation or may be seen with schizophrenia. Deep tendon reflexes may be accentuated during stress or anxiety. A few beats of clonus at the ankles may be acceptable in these settings. A Babinski's sign, asymmetrical reflexes, or spastic tone should always suggest an organic process. "Frontal release" or "primitive" reflexes may occur as a normal finding, but these are commonly seen in patients with disorders of frontal lobe deterioration. The grasp reflex is normal in young children only and is always pathological in adults. Hoffman's sign and the palmomental reflex are common in the normal elderly, and their appearance can be interpreted as abnormal only if multiple frontal release signs are present or if their appearance is asymmetrical.

Sensory. The sensory examination is the most subjective part of the evaluation and can be difficult to interpret. The presence of a sensory abnormality triggers the same differential diagnosis as that used for a mentally normal person. It is important to test vibratory and position sensations in a patient with a mood or thought disorder. A sensory neuropathy should lead the clinician to assess nutritional problems (vitamin B₁₂ deficiency), infections (human immunodeficiency virus [HIV] and syphilis), hypothyroidism, or malignancy. The gait should also be checked. An

obviously factitious gait may cast doubt on the organicity of an unexplained mood, emotion, or thought abnormality encountered during other parts of the examination. However, gait ataxia and mood disorders may occur in the context of alcoholism and multiple sclerosis, and more rarely with hypothyroidism.

Autonomic Nervous System. The clinician should look for evidence of autonomic hyperactivity including the presence of palpitations, cold clammy extremities, sweating, sighing, trembling, or hypervigilance, which can be indicative of anxiety disorders, anxiety associated with neurological diseases, or drug withdrawal syndromes.

Neurovascular Examination. The neurovascular examination is rarely helpful in patients with mood, emotion, or thought disorders.

Associated Medical Findings

Assessment of vital signs, preferably performed prior to administration of medications, is very important. Fever should always be construed as a sign of organic disease and should trigger consideration of a spinal tap. In a patient taking a neuroleptic, fever may accompany the neuroleptic malignant syndrome and may warrant consideration of this diagnosis. Once the vital signs are known, the general physical examination should be performed with the aim of identifying contributory factors to a behavior disorder. The general appearance may reveal obesity or cachexia. Central obesity and hirsutism suggest endocrine derangements, whereas hair loss may indicate lupus, thyroid disease, or simply an unrelated skin condition. Weight loss may be evident by excessive skin folds or a cachectic appearance and may accompany depressive syndromes. Changes in skin color may suggest endocrine disorders or a neurocutaneous syndrome. Evaluation of the head may reveal evidence of trauma or gingival hyperplasia, indicative most likely of chronic phenytoin use or proptosis from hypothyroidism. Heart auscultation may reveal murmurs of

valvular disease. Both lupus and rheumatic fever may affect the heart valves and can cause a variety of neuropsychiatric syndromes. Subacute bacterial endocarditis, a chronic illness, may present with an abnormal mental state such as depression and mild dementia. Tachycardia may be observed in patients with anxiety and manic disorders. Abdominal examination may reveal evidence of liver disease. The extremities should be evaluated for intravenous track marks, the stigmata of the drug abuser.

[PreviousNext](#)

EVALUATION GUIDELINES (Table 3-1)

The tests that should be performed on patients with mood, emotion, or thought disorders depend on the clinical situation. Patients who present for the first time are obviously to be evaluated differently from patients who were once fully evaluated but have suffered a relapse. Patients with long histories, although perhaps never fully evaluated with modern techniques, may not require testing because the natural course of alternative diagnoses may preclude their consideration (e.g., in a 65-year-old with a 40-year history of schizophrenia, a frontal lobe tumor is not the cause of the behavioral disorder).

Neuroimaging. There are some who believe that all psychotic patients should have at least one brain imaging study. A magnetic resonance imaging (MRI) study is more sensitive than a computed tomography (CT) scan primarily because it reveals white matter disease with far greater sensitivity. The usefulness of these studies is questionable in "routine" disorders of mood, emotion, and thought, but in atypical cases, those of late onset, or when focal neurological signs are present, an imaging study is imperative. In general, imaging is done to look for evidence of masses or infarcts for which CT is adequate. Lesions causing such changes are usually large or multiple, and CT is satisfactory and much less costly than MRI. In patients who have had a prior brain imaging study for a behavioral disorder, repeat studies are unlikely to shed further light on a potential organic cause.

SPECT studies have been available for several years using the hexamethylpropylenamine-oxime (HMPAO) ligand to visualize brain metabolism, yet they have little diagnostic value for individual patients. In the future, as more ligands are developed, the prospect of depicting neurotransmitter or receptor densities throughout the brain is high. PET scans provide information about metabolism (glucose utilization), neurotransmitters, or receptors. Although several abnormalities have been found in a variety of disorders of mood, emotion, and thought, none occur with sufficient specificity to be diagnostic.

Electrophysiology. Electroencephalography (EEG) is helpful in the evaluation of seizure disorders and metabolic encephalopathy and, to a lesser extent, for documentation of regional physiological malfunctions. In patients with psychosis, the EEG should be normal, whereas metabolic disorders can cause disorganization and generalized slowing. The EEG can reveal physiological abnormalities that may not be reflected on structural imaging studies. Old trauma, a postictal state, or migraine headache may be associated with behavioral abnormalities and may cause focal EEG findings when the MRI is normal. Rarely, disorders of emotion, mood, or thought with "subclinical seizures" or complex partial status epilepticus may be diagnosed only with EEG. The use of evoked responses in neuropsychiatric disorders remains a research tool except when organic explanations such as multiple sclerosis are being actively considered.

Body Fluid and Tissue Analysis. "Routine" blood tests to assess for metabolic disorders are required for all patients with behavioral abnormalities. Sodium, glucose, creatine, blood urea nitrogen, calcium, liver function tests, and thyroid hormone levels are mandatory. Depending on the situation, other blood studies such as serum ammonia, ceruloplasmin, porphobilinogen, drug levels, prolactin and other hormones, toxicology screens, vasculitic studies, and HIV and syphilis serologic tests may be appropriate. Gastric lavage is useful in patients with suspected drug ingestion and possibly when one is looking for blood as a source of hepatic encephalopathy. Genetic testing can be done when Huntington's disease is considered likely. Because of the putative biological nature of many depressions, certain research-related tests have been developed, including the dexamethasone suppression test, measurement of urinary

IMPULSE DYSCONTROL SYNDROMES	Brain MRI/CT: Degenerative disorders, CNS tumors, trauma, encephalitis	Sleep-deprived EEG with nasopharyngeal electrodes	CBC, chemistries, adrenal studies, TFTs, CSF evaluation, toxicology	Luria Complex Motor Tasks (go no go); Wisconsin Card Sorting Test, California Verbal Learning Test; Behavioral Dyscontrol Scale; EXIT; MMPI-2; Frontal Lobe Personality Scale
ALTERED SEXUALITY SYNDROMES	Brain MRI/CT: Encephalitis, CNS tumors, hypothalamic lesions, trauma	EEG: Temporal lobe epilepsy	Prolactin, follicle-stimulating and luteinizing hormone levels, testosterone, estradiol, urine cortisol	MMPI-2

CBC, Complete blood count; TFTs, thyroid function tests; VDRL, venereal disease research laboratory test; CSF, cerebrospinal fluid; EEG, electroencephalography; MRI magnetic resonance imaging; CT, computed tomography; ESR, erythrocyte sedimentation rate; HIV, human immunodeficiency virus; EXIT, executive interview.

3-methoxy-4-hydroxyphenylglycol (MHPG), and the thyrotropin-releasing hormone stimulation test. Unfortunately, these studies are not useful in routine clinical practice. A drug screen for amphetamines and other psychoactive medications should be included in the evaluation of patients with appropriate clinical presentations.

Cerebrospinal Fluid. Cerebrospinal fluid must be examined when meningitis (infectious or carcinomatous) and encephalitis are being considered. Cell counts are elevated in patients with infectious or malignant meningitis. There is a polymorphonuclear predominance with bacterial etiologies and a mononuclear predominance with viral, fungal, or malignant causes. There is also an elevated protein and low (bacterial) and normal to low (viral or fungal) glucose levels. Special stains, cultures, and immunofixation studies should be obtained when indicated. A high-volume tap for cytological examination should also be pursued when carcinomatous meningitis is being considered in the presence of a known or suspected malignancy. A single large-volume tap may be negative, and multiple lumbar punctures may be required to effectively document or rule out the possibility of this diagnosis.

Neuropsychological Tests. Neuropsychological testing can be extremely helpful in the diagnosis, prognosis, and treatment of patients with disorders of mood, emotion, and thought and is especially useful for distinguishing "organic" dementia from nonorganic disorders such as the pseudodementia of depression, or

malingering. These tests may also help to identify and localize organic syndromes, contribute to the identification of borderline psychotic states, and provide baseline data on the patient's general and specific function. A large number of neuropsychological tests are

available, and the tester must choose the appropriate studies. The Wechsler Adult Intelligence Scale provides three separate IQ scores, and various subtests can provide clues to the presence of disorders of attention and thought (see [Chapter 27](#)). The Minnesota Multiphasic Personality Inventory can produce a general description of the patient's personality characteristics, but it is not useful diagnostically. Other tests that may at times be useful in the evaluation of patients with mood, emotion, and thought disorders include the Bender-Gestalt, Rorschach, thematic aperception, and draw-a-person tests (see [Chapter 27](#)).

[PreviousNext](#)

CLINICAL SYNDROMES (Table 3-2)

Affective Disorder Syndromes

Major depression has a lifetime prevalence of about 15 percent and is about 15 times as common as bipolar disorder (manic-depressive disorder). Major depression is about twice as common in women as in men in all countries and cultures and does not vary in occurrence among different races. It may occur at any age, but the majority of cases occur in adulthood. Studies suggest a genetic predisposition because there is an increased incidence of major depression and alcoholism in relatives of patients with this mood disorder. The diagnosis of depression is often overlooked, especially in patients with chronic neurological disease. The *Diagnostic and Statistical Manual*, 4th edition (DSM-IV) criteria for this diagnosis requires either that the patient have a depressed mood or that the patient have a sustained loss of interest and pleasure. Some depressed patients have a depressed affect or become withdrawn or irritable but do not admit to or complain of feelings of sadness. Almost all, however, complain of reduced energy and easy fatigability, and most have weight disturbances. Their clinical presentation can vary, however, from profound retardation and withdrawal to an irritable, unrelieved agitation. Other symptoms include a loss of interest in activities, diminished emotional bonds, preoccupation with death, guilt, and a sense of worthlessness. The patient may have somatic complaints with memory impairment, fatigability, insomnia, anorexia or hyperrexia, weight loss or gain, and impaired libido. A thought disorder may be present with delusions, but hallucinations are uncommon. Most patients have two or more attacks, and some have clear periods between episodes. Most attacks gradually build over a period of a week to a month, and if untreated may last from 3 to 8 months.

The differential diagnosis of depression includes primary psychiatric syndromes other than major depression such as behaviors associated with schizophrenia, generalized anxiety disorder, and obsessive-compulsive neuroses. Medical and neurological disorders either associated with or mimicking depression include malignancy, infections, medications (steroids, reserpine, levodopa, benzodiazepines, propranolol, anticholinesterases), endocrinological dysfunction (Cushing's disease, hypothyroidism, apathetic hyperthyroidism, diabetes), pernicious anemia, and electrolyte and nutritional disorders (inappropriate secretion of antidiuretic hormone, hyponatremia, hypokalemia, hypercalcemia). Depression is also associated with multiple sclerosis, Parkinson's disease, head trauma, stroke (particularly of the left frontal lobe), and Huntington's disease. Interictal changes in temporal lobe epilepsy may mimic depression, particularly with right-sided epileptic foci. Patients with diencephalic and temporal region tumors may also present with depressive symptoms. Equally important, depressive signs and symptoms may be incorrectly diagnosed as dementia, especially in the elderly population.

In patients with bipolar disorder, mania that is severe enough to compromise functioning must be present in addition to depression. The lifetime risk for developing bipolar disorder is 0.6 to 1.0 percent. While the type of inheritance is uncertain, there is a strong genetic influence. These manic periods usually develop over a few days and may be associated with hallucinations and delusions. The attacks are usually separated in time by months or years, but there may be more rapid cycling in a minority of patients. Symptoms consistent with mania include euphoria, emotional lability, irritability, and a demanding and egocentric demeanor. The patient may be loud and have word rhyming or pressured speech with a flight of ideas. He or she may demonstrate poor judgment, disorganization, and agitation, possibly accompanied by paranoia, delusions, or hallucinations.

The differential diagnosis of bipolar disorder includes other psychiatric syndromes including schizophrenia and personality disorders. Medical and neurological conditions that may be associated with mania or may be mistaken for bipolar disorder include CNS masses, infections (neurosyphilis, encephalitis), and hyperthyroidism. Steroids, cocaine, amphetamines, hallucinogens, baclofen, bromocriptine, pergolide, methylphenidate, and levodopa may all cause symptoms consistent with mania. Other neurological disorders that may include mania as part of their presentation include multiple sclerosis, head trauma, stroke, temporal lobe epilepsy, and Wilson's disease.

Pseudobulbar Palsy

Patients with pseudobulbar palsy demonstrate pathological laughing, crying, and grimacing, often following little or no stimulation. Spastic weakness of the lower cranial nerve muscles (cranial nerves V, VII, and IX through XII) may be noticed on examination with accompanying dysarthria. This syndrome may be seen in patients with upper motor neuron dysfunction including those with amyotrophic lateral sclerosis, multiple sclerosis, or bilateral cerebral infarction. Patients with progressive supranuclear palsy (PSP), Parkinson's disease, and other parkinsonian syndromes may have pseudobulbar palsy in addition to more classic signs and symptoms. Mutism associated with pseudobulbar symptoms has also been reported after the resection of posterior fossa tumors in children. [19] Most therapies are ineffective; however, trials of agents that modulate biogenic amines such as levodopa, amantadine, amitriptyline, and fluoxetine may ameliorate the paroxysms of abnormal affective behavior.

TABLE 3-2 -- SELECTED ETIOLOGIES ASSOCIATED WITH DISORDERS OF MOOD, EMOTION, AND THOUGHT

Etiological Category	Selected Specific Etiologies	Chapter
HEREDITODEGENERATIVE DISORDERS

Psychotic Syndromes

Psychosis does not describe a specific diagnosis and may be seen in patients with both primary psychiatric disease and drug intoxication and in the presence of certain medical and neurological conditions. Psychotic patients have alterations in the normal processes of thought that result in an impaired sense of reality, which may be linked to emotional and cognitive abnormalities. The patient with psychosis may talk and act in a bizarre fashion and demonstrate hallucinations. The hallucinations may occur in one or more sensory modalities including tactile (the sensation of bugs crawling on the skin), auditory (threatening, critical, or insulting voices), and visual (lilliputian figures or animals). Additionally, delusions in the presence of full wakefulness may occur. These may be systematized or fragmentary, and the content may be variable, but persecutory delusions are most common.

Schizophrenia is the most common psychotic illness, and in the United States there is a 1 to 1.5 percent lifetime prevalence of this disorder. The disorder is equally prevalent in men and women and tends to occur more frequently in urban populations and in lower socioeconomic groups. The peak age of onset in men is 15 to 25, while in women the peak occurs at 25 to 35 years of age. Numerous studies suggest that the inheritance of schizophrenia has a genetic component, which is most likely polygenetic. Fifty percent of monozygotic twins of schizophrenics develop the disorder compared with 10 percent of dizygotic twins. The diagnosis of schizophrenia is a clinical diagnosis because there are no pathognomonic findings. At present two or more of the following features must be present for a significant period of time during a 1-month period: delusions, hallucinations, disorganized speech, grossly disorganized or catatonic behavior, and negative symptoms. Only one of these is required if delusions are bizarre, if hallucinations consist of a voice keeping up a running commentary, or if two or more voices are conversing with each other. There are five subtypes of schizophrenia including paranoid, disorganized, catatonic, undifferentiated, and residual types. ¹

Schizophrenia is a chronic disorder, but many of the dramatic and acute symptoms subside over time. Most patients have low-level delusions and hallucinations and end up in psychiatric hospitals or supervised shelters. There is an improved prognosis when the onset occurs after age 30 and the active psychotic symptoms have a rapid onset. Additionally, good premorbid social and occupational function, the presence of a probable precipitant, and the absence of a family history are associated with an improved outcome. Although the biochemical cause of schizophrenia is unknown, most of the major hypotheses implicate central dopaminergic hyperactivity.

Schizophrenia should be differentiated from other primary psychiatric disorders that may have psychosis as a feature, including schizoaffective disorder, the major affective disorders, autism, malingering, and obsessive-compulsive disorder. Symptoms of psychosis can be caused by a large number of medical and neurological conditions and may be precipitated by legal and illicit drugs ([Table 3-3](#)). Psychosis and other psychiatric symptoms may present

early in the course of medical or neurological disorders, and the clinician must consider this in the differential diagnosis. Of note, a significant link has been established between temporal lobe tumors and psychosis, even if patients with epilepsy are not considered. Tumors of the limbic system, particularly the cingulate gyrus, amygdala-hippocampal region, and the area around the third ventricle, are also commonly associated with psychotic behaviors. Typically, patients with organic causes of psychosis have a higher amount of insight into the illness and are distressed by their symptoms. Clinicians should be aggressive in pursuing a medical or neurological cause of psychosis in patients with no diagnosed psychiatric disease, particularly if there are unusual symptoms, altered consciousness, or concomitant medical or neurological signs. Additionally, a concomitant medical or neurological condition may cause an exacerbation or recrudescence of psychosis in patients with an established psychiatric disease.

Apathy Syndromes

Patients with apathy demonstrate a lack of interest not only in their usual interests and hobbies but also in routine daily activities. Apathy may arise from unilateral or bilateral lesions of the caudate nuclei, bilateral lesions in the lenticular nuclei, or frontal lobe lesions. Apathy is a common aspect of Parkinson's disease and progressive supranuclear palsy and can be difficult to distinguish from depression. Bilateral cingulate lesions can produce akinetic mutism and abulia, but these lesions are not necessarily symmetrical, and one can be cortical while the other is subcortical. Abulia can cause mutism and is characterized by a general slowing of behavior and lowered activity. Patients with abulia show little spontaneous motor or speech activity and may at times fail to respond for minutes or at all to questions or commands. If they occur at all, the responses

are slow and apathetic. Akinetic mutism is an extreme form of abulia, in which patients appear to be awake and may attend to their surroundings but demonstrate no spontaneous motor and verbal responses. These patients may respond intermittently to noxious stimuli and may be doubly incontinent. All of these signs are related to supplementary motor area damage and can be seen with lesions anywhere in the ascending dopaminergic pathways. In these settings, primitive reflexes such as sucking and rooting may also emerge, but if the motor cortex is unaffected, the remainder of the examination may be unremarkable.

Anxiety and Obsessive-Compulsive Disorder Syndromes

Anxiety is an extremely common occurrence that affects everyone at some time and is characterized by an unpleasant and unjustified sense of fear that is usually associated with autonomic symptoms including hypervigilance, palpitations, sweating, lightheadedness, hyperventilation, diarrhea, and urinary frequency as well as fatigue and insomnia. Anxiety is thought to be mediated through the limbic system, particularly the cingulate gyrus and the septal-hippocampal pathway, as well as the frontal and temporal cortex. The term anxiety disorder is used to denote significant distress and dysfunction resulting from anxiety, including panic attacks and anxiety with specific phobias. Chronic, moderately severe anxiety tends to run in families and may be associated with other anxiety disorders or depression. The differential diagnosis of anxiety states includes other psychiatric conditions such as anxious depression as well as schizophrenia, which may present as a panic attack with disordered thinking. Uncomplicated anxiety may be a common problem in patients who abuse alcohol and hypnotic-sedatives, amphetamines, and caffeine. Other medical conditions that may be associated with anxiety include hypoglycemia, hyperthyroidism, and pheochromocytoma. As an organic disorder, anxiety is not intrinsically part of any neurological disease, although it is commonly seen with Gilles de la Tourette's syndrome, Parkinson's disease, and various headache syndromes.

Patients with obsessive-compulsive disorders have intruding unwanted thoughts that are distressful and recurrent ideas, images, and impulses that cannot be pushed out of consciousness. The patient may ruminate on these thoughts endlessly, impairing his or her ability to function. Most of these individuals develop rituals and compulsions that are performed to ward off an unwanted occurrence or to fulfill an obsession. Anxiety may be associated with the obsessions, and the performance of certain rituals may temporarily relieve this anxiety. The cause of this condition is unknown, but abnormalities in CNS serotonergic neurons have been implicated. Various studies and reports suggest that the frontotemporal lobes, cingulum, and basal ganglia may play a role in the generation of this behavior. Obsessive-compulsive disorder occurs in approximately 2 percent of the population and is more common in first-degree relatives of afflicted patients. Typically, this disorder begins in the third decade of life and is usually chronic with few remissions. This abnormal behavior may occur in the presence of depression or may be associated with certain neurological disorders including postencephalitic parkinsonism and Gilles de la Tourette's syndrome.

Impulse Dyscontrol and Aggression Syndromes

The impulse dyscontrol and aggression syndrome consists of an inability to resist an impulse to perform a harmful act; the impulse is accompanied by a buildup of tension needing to be released, and is followed by a feeling of satisfaction or relief when the act is committed. This in turn is followed by either relief, remorse, or a sense of justification for the act. Impulse dyscontrol and aggression can occur in neurologically normal individuals, but this behavior becomes pathological when carrying out the impulse consistently harms the subject or others. These behaviors may occur in patients with psychiatric disorders and global or localized brain dysfunction.

A number of other neuropsychiatric conditions may be associated with aggression. In patients with psychotic disorders, such as those mentioned earlier, aggressiveness may be a component. This type of behavior may also be seen with manic episodes and usually arises from delusional beliefs. A primary psychiatric disorder known as intermittent explosive disorder is characterized by discrete episodes of unrestrained violence that result in serious assaultive acts or destruction of property. The degree of aggressiveness is grossly out of proportion to any precipitating psychosocial stressors, occurs in a person with a clear consciousness, and is not accounted for by another mental disorder or the direct effects of a substance or any medical or neurological condition. Although the etiology of this disorder is unknown, investigations have suggested that disordered limbic system function with decreases in serotonergic transmission may play an important role.

Aggression may occur in patients with other medical or neurological conditions, producing global brain dysfunction. With a reduced level of consciousness and altered sleep-wake cycles, patients with delirium (due to electrolyte derangements, infection, drugs, or postsurgical or postictal conditions) may experience transitory ill-formed delusions and misperceptions leading to aggression. Encephalitis secondary to herpes simplex virus can become manifest with aggressiveness and may be associated with memory difficulties, irritability, distractibility, apathy, and restlessness. Childhood attention-deficit disorder, although it becomes manifest generally with attentional impairment, may be associated with destructive behavior when it is severe. Self-mutilation in association with aggression is a prominent feature of both the Lesch-Nyhan and the Prader-Willi syndromes, and may be seen in any condition that causes mental retardation. Finally, aggression in the context of a general personality change may be seen in patients with global neurodegenerative disorders such as Alzheimer's disease and Huntington's disease. When more

prominent frontal lobe involvement is present, as occurs in the frontal lobe dementias, explosive outbursts of rage may be seen.

Focal frontal lobe dysfunction in the presence of head

injury, tumors, or stroke may lead to disinhibited behavior and a need to do things on the spur of the moment. Disinhibited behaviors accompanied by a lack of restraint of antisocial impulses but without aggression can occur in patients with orbitofrontal damage. Aggressive impulses in the form of rage in response to trivial irritations may arise in patients with dorsolateral prefrontal damage. Limbic system dysfunction, particularly with involvement of the ventromedial hypothalamus or amygdala, in which the affective significance of stimuli may be altered, may also be associated with rage and violent behavior. This condition typically occurs in patients with amnesia, hyperphagia, and other evidence of hypothalamic dysfunction and is usually associated with neoplastic invasion. Occasionally, impulsive behavior, aggressiveness, or just inappropriate behavior is ascribed to seizures of temporal lobe onset, but complex behaviors involving directed interactions with other individuals is rarely of convulsive origin.

Altered Sexuality Syndromes

Altered sexuality may take many forms. The loss of libido is the most common form and can present as inhibited excitement or orgasm. Hypoactive sexual desire may be due to a number of psychiatric, medical, and neurological disorders. Typically, the cause is functional and the condition occurs in the presence of anxiety or depression. Hyposexuality associated with hypergraphia, hyper-religiosity, irritability, and elation comprise the main features of the Gastaut-Geschwind syndrome. This syndrome has been described as an interictal syndrome in patients with epilepsy of temporal lobe origin. These patients may also demonstrate "viscosity," which refers to a stickiness of thought processes and an interpersonal adhesiveness, and circumstantiality, which is manifest as a difficulty in terminating conversations.

A vigorous sexual drive can be a normal variant of human sexuality, but when it interferes with normal activities of living or is pursued at inappropriate times and with unwilling partners, it is considered pathological. Historically, hypersexuality was described as part of the Kluver-Bucy syndrome in association with loss of anxiety, diminished aggression, hypermetamorphosis, visual agnosia, and hyperorality. This syndrome is rare in humans but has occurred as a result of encephalitis. ^[21] Lesions of the hypothalamus are the most likely to create sexual disinterest, but medial temporal lobe damage may produce the same result. Frontal lobe lesions often create disinhibited behavior that may or may not be associated with a change in libido. Hypersexuality may also occur in individuals with Parkinson's disease or other parkinsonian patients treated with dopaminergic agents including levodopa, dopamine agonists, and amantadine.

[PreviousNext](#)

GENERAL MANAGEMENT GOALS

Affective Disorder Syndromes

When secondary causes have been sufficiently evaluated, treatment of depression can be initiated. Treatment may include psychological therapies (supportive psychotherapy and behavior therapy) as well as pharmacological agents. Nearly 80 percent of patients with major and most chronic minor depressions respond to drug therapy, including tricyclic antidepressants, specific serotonin reuptake inhibitors, and MAO inhibitors. Electroconvulsive therapy may be necessary if medications fail or their use is not tolerated, if immediate therapy is indicated, or in some patients with psychotic depressions.

When manic symptoms are mild (hypomania), the patient may be followed as an outpatient with home supervision by family members. These patients may benefit by a short course of an antipsychotic drug. If they are manic, patients require hospitalization and may require acute antipsychotic therapy in combination with a benzodiazepine. These medications should be tapered and discontinued when the initial phase of the manic episode has subsided and the effects of more definitive therapy using lithium carbonate, carbamazepine, or valproic acid have been established. Third-line therapies include clonazepam, clonidine, clozapine, and verapamil.

Psychotic Syndromes

Antipsychotics (neuroleptics) can be used in patients with acute psychoses while a specific etiology is being sought ([Table 3-4](#)). Although some of these drugs are sedating, they have more specific effects on the thought and mood disorder. Many different agents are available including the phenothiazines, thioxanthenes, dibenzoxazepines, and butyrophenones. The acutely psychotic patient who is a danger to himself or others may be treated parenterally with intramuscular haloperidol (5 mg every hour over 4 hours) or chlorpromazine. In addition, oral doses of haloperidol (10 to 15 mg/day) or chlorpromazine (300 to 400 mg/day) or the equivalent should be started.

TABLE 3-4 -- COMMON ANTIPSYCHOTIC DRUGS AND DOSES

Generic (Trade) Names	Dosage Form and Range	
	Oral	Parenteral (IM)
PHENOTHIAZINES		
Chlorpromazine (Thorazine)	200-800 mg/day	25-50 mg/dose
Fluphenazine (Prolixin) Hydrochloride	2-20 mg/day	None
Enanthate/decanoate	None	1.25-2.5 mg every 1-4 weeks
Trifluoperazine hydrochloride	5-20 mg/day	1-20 mg/dose
THIOXANTHENES		
Thiothixene hydrochloride (Navane)	5-30 mg/day	2-4 mg/dose
BUTYROPHENONE		
Haloperidol (Haldol) Hydrochloride	2-20 mg/day	2-5 mg/dose
Decanoate	None	25-250 mg every 2-4 weeks
HETEROCYCLICS		
Clozapine (Clozaril)	6.25-900 mg/day	None
Risperidone (Risperdal)	2-8 mg/day	None
Olanzapine (Zyprexa)	10-15 mg/day	None

Newer agents including clozapine, risperidone, and olanzapine may also be used.

Anxiety and Obsessive-Compulsive Disorder Syndromes

In patients with chronic mild or moderately severe anxiety, benzodiazepines, used sparingly for a few weeks to several months, can be helpful. When chronic treatment is necessary, buspirone, tricyclic antidepressants, and MAO inhibitors may be utilized in selected patients, particularly those with concomitant depression. Beta-blockers may also be useful in certain cases. Referral to a neuropsychologist or psychotherapist for training in self-reliance and relaxation techniques including biofeedback, meditation, and self-hypnosis should also be considered. The treatment of obsessive compulsive disorders should involve both pharmacological and psychological measures. Medications can significantly reduce the symptoms in over 50 percent of patients. Clomipramine is generally considered the drug of first choice, but other drugs with serotonergic properties such as fluoxetine, paroxetine, and clonazepam can be used.

Impulse Dyscontrol and Aggression Syndromes

Aggressiveness is a common management issue for clinicians of various specialties and may be a primary reason for referral. While aggression is not a specific diagnosis and its etiology should be sought, many of these conditions are not directly treatable, and symptomatic therapy is indicated. A wide assortment of medications in various pharmacological classes have been studied for patients with aggression, primarily in open-label fashion, and none have been found uniformly helpful. In practice, the neuroleptics are the most widely used agents (see [Table 3-2](#)). Benzodiazepines are useful for short-term control of aggression, but long-term treatment with these agents should be avoided because of the possibility of paradoxical disinhibition and tolerance necessitating dose escalation. Lithium has been shown to be helpful in the reduction of "psychotic excitement," not only in manic patients but also in those with aggression related to other conditions. Similarly, carbamazepine has been used to stabilize mood and may aid in the treatment of aggressive behaviors. Other agents that may be useful, alone or in combination, include the beta-blockers, clonidine, buspirone, and the serotonin-reuptake inhibitors (fluoxetine, paroxetine). A new class of drugs, termed the serenics, was specifically developed for the treatment of destructive behaviors in humans. However, one such agent, eltopazine hydrochloride, failed to show any significant effect when it was studied in patients with either Gilles de la Tourette's syndrome or epilepsy with aggressive behaviors.

HISTORY AND DEFINITIONS

Apraxia is a term that is applied to a diverse set of syndromes. However, this discussion will focus predominantly on limb apraxia. This term is defined as an inability to correctly perform learned skilled movements with the arms in the absence of primary, sensory, or motor impairments. To be classified as an apraxia, a patient's inability to perform learned movements cannot be caused by weakness, ataxia, seizures, or the superimposition of involuntary movements such as tremor, dystonia, chorea, ballismus, athetosis, or myoclonus. Patients with severe cognitive, memory, motivational, and attention disorders may also have difficulty in performing skilled acts without being apraxic. Whereas the presence of these disorders does not preclude the presence of apraxia, before apraxia is diagnosed the clinician should be certain that these behavioral disorders do not fully account for the patient's inability to perform skilled acts.

There are several types of limb apraxia that are defined by both the nature of the errors made by patients and the means by which these errors are elicited on the neurological examination ([Table 4-1](#)). Liepmann was the first to systematically study limb apraxia around the turn of the century. His thorough and insightful description of an Imperial Counselor who had suffered a stroke and demonstrated "mixed aphasia and post-stroke dementia" provided the fundamental basis for models of apraxia. Liepmann discussed three types of apraxia: melokinetic (or limb-kinetic), ideomotor, and ideational. Limb-kinetic apraxia has since been considered an elemental motor disorder rather than a disorder of learned skilled movements and will not be further discussed in this chapter. Since Liepmann's initial descriptions, three other forms of apraxia, designated disassociation apraxia, conduction apraxia, and conceptual apraxia, have also been described and are included here.

CLINICAL HISTORY

While some patients complain of a loss of ability to perform skilled movements, most do not recognize their disability or complain about it. The activities to be inquired about include the use of common bathroom tools such as toothbrushes, razors, combs, and brushes. Furthermore, the clinician should ask whether the patient can prepare his or her own meals and use typical kitchen utensils including forks, knives, spoons, and other ancillary household equipment. Because the apraxia associated with hemispheric injury such as strokes and trauma is often associated with a hemiparesis, patients with these disorders who attempt to perform skilled acts with the nonpreferred arm during daily activities state that they are impaired. Although patients may attribute the difficulty to a premorbid clumsiness of the nonpreferred arm, this potential error in interpretation of the clinical history should not be committed by the physician.

Patients with hemispheric strokes may be anosognosic for the apraxia and state that they are able to use their nonpreferred hand correctly although they are clearly apraxic.^{1,2} Additionally, many caretakers of chronically impaired individuals may find it easier to anticipate the patient's needs and perform mechanical tasks for them rather than await failures. It is, therefore, important to ask the caregiver about the presence of any impaired skills in the patient's activities of daily living. Since apraxia is most commonly seen in patients with strokes or Alzheimer's disease, special attention should be paid to obtaining the important elements of a history of praxis when the patient interview suggests these neurological disorders. Apraxia may, however, be seen in patients with many other diseases of the central nervous system including trauma and can be the presenting sign in those with corticobasal ganglionic degeneration.

ANATOMY OF PRAXIS

Much of what we know about the anatomical basis of praxis (the ability to perform voluntary skilled movements) comes from the observations of patients with discrete cerebral lesions who have lost these abilities. To perform learned skilled movements, several types of knowledge are required. One must know how to move the limb through space (spatial trajectory) and how fast to move it. To successfully interact with the environment, a conceptual knowledge of praxis is also needed, such as what action is associated with a tool.

Liepmann and Maas^[1] were the first to attempt to localize where this movement spatial temporal knowledge is stored. They described a patient with a right hemiparesis who was unable to correctly pantomime to command with his left arm. This patient had lesions of both the pons and the corpus callosum. Because this patient had a right hemiparesis, his right hand could not be tested. Since the work of Broca, it has been known that the left hemisphere in right-handed individuals is dominant for language. Liepmann and Maas could have attributed their patient's inability to pantomime with his left arm to a disconnection between the language and motor areas (i.e., the left hemisphere that mediates comprehension of the verbal command could not influence the right hemisphere's motor areas, which are responsible for controlling the left arm). However, this patient also could not imitate gestures or correctly use actual tools or objects. Therefore, a language-motor disconnection could not account for these findings. Liepmann and Maas posited that the left hemisphere of right-handed individuals contains movement formulas and that the callosal lesion in this patient disconnected these movement formulas from the right hemisphere's motor areas.

Geschwind and Kaplan^[2] and Gazzaniga and co-workers^[3] also found that their patients with callosal disconnection could not correctly pantomime to command with their left arm, but unlike Liepmann and Maas' patient, their patients could imitate and correctly use actual tools and objects with the left hand. The preserved ability to imitate and use actual tools and objects suggests that the inability to gesture to command, in these patients with callosal lesions, was induced by a language-motor disconnection rather than by a movement formula motor disconnection. In addition, a disconnection between movement formula and motor areas should produce spatial and temporal errors, but many of the errors made by Liepmann and Maas' patient appeared to be content errors.

Watson and Heilman,^[4] however, described a patient with an infarction limited to the body of the corpus callosum. This patient had no weakness in her right hand and performed all tasks flawlessly with her right hand. Yet, as Liepmann might have predicted, this patient could not correctly pantomime to command, imitate, or use actual tools with her left hand. Immediately after this patient's cerebral infarction, she made content errors, but subsequently she made primarily spatial and temporal errors. Her performance indicated that not only language but also movement representations were stored in her left hemisphere, and her callosal lesion disconnected these representations from the right hemisphere. In Watson and Heilman's patient there appeared to be two types of representations that were stored in the left hemisphere: spatial-temporal movement representations (also called visual kinesthetic engrams) and conceptual knowledge about the relationship between tools and the actions required to use these tools.

Heilman and colleagues^[5] and Rothi and associates^[6] proposed that the movement representations (visual kinesthetic movement engrams), first posited by Liepmann, were stored in the left parietal lobe of right-handed individuals, and that destruction of the left parietal lobe should induce not only a production deficit (apraxia) but also a gesture comprehension-discrimination disorder. Apraxia induced by lesions of the premotor cortex, the pathways that connect premotor areas to motor areas, and the pathways that connect the parietal lobe with the premotor areas, may also cause production deficits. In these situations, patients make spatial and temporal errors, but, unlike parietal lesions, these lesions do not induce gesture comprehension and discrimination disorders. When patients with anterior and posterior lesions were tested, it was found that while both groups of patients were apraxic, the patients with a damaged parietal lobe had comprehension and discrimination disturbances, but those without parietal lesions did not.

As discussed fully in [Chapter 15](#), the final common pathway that allows the muscles to move joints involves motor nerves that originate from the spinal cord. These spinal motor nerves are activated by corticospinal neurons, and the corticospinal tract is influenced by the premotor areas. In addition to direct connections with the spinal cord, the premotor area projects to the primary motor cortex. For each specific skilled movement, there is a set of spatial loci that must be traversed in a specific temporal pattern. It is proposed that movement formulas represented

in the inferior parietal lobe are stored in a three-dimensional supramodal code. For the corticospinal neurons to properly activate the motor nerves, the stored spatial temporal knowledge has to be transformed into a motor program.

The medial premotor cortex including the supplementary motor area (SMA) appears to play an important role in mediating skilled movements. Whereas electrical stimulation of the primary motor cortex induces simple movements, SMA stimulation induces complex movements that may include the entire forelimb. SMA receives projections from parietal neurons and projects to motor neurons. SMA neurons discharge before neurons in the primary motor cortex. Studies of cerebral blood flow, an indicator of cerebral metabolism and synaptic activity, have revealed that single repetitive movements increase activation of the contralateral primary motor cortex, but complex movements increase flow in the contralateral motor cortex and bilaterally in the SMA. When subjects remain still and think about making complex movements, blood flow is increased to the SMA but not to the primary motor cortex. Watson and colleagues^[7] reported several patients with left-sided medial frontal lesions that included the SMA who made spatial and temporal errors when they attempted to perform learned skilled movements.

The convexity premotor cortex also receives projections from the parietal lobes as well as from the medial premotor cortex, and, like the medial premotor cortex, the convexity premotor cortex also projects to the primary motor area. Many skilled movements require that multiple joints be moved simultaneously. For example, when using a knife to cut a slice of bread, on the forward thrust, the shoulder must be flexed and adducted while the elbow is extended. On the backward thrust, the arm must be extended at the shoulder while the shoulder is abducted and the forearm is extended at the elbow. Lesions in the convexity premotor cortex impair multiple joint coordination. Unlike patients with parietal lesions, patients with convexity and medial premotor lesions could both comprehend and discriminate between well-performed and incorrectly performed pantomimes, demonstrating that their spatial-temporal movement representations were intact but could not be implemented.

It has been suggested that apraxia might be due to deep subcortical lesions including lesions of the basal ganglia or thalamus. A recent analysis by Pramstaller and Marsden^[8] reviewed 82 cases of "subcortical" apraxias that were studied by either neuroimaging modalities or neuropathological means. They concluded that isolated damage to the basal ganglia (putamen, caudate, and globus pallidus) does not induce apraxia. However, they noted that small lesions of the thalamus can sometimes cause apraxia, yet the exact role of the thalamus in higher order motor control and apraxia remains to be determined.

NEUROLOGICAL EXAMINATION OF PRAXIS

Directed Neurological Examination

Because the diagnosis of apraxia is in part a diagnosis of exclusion, the clinician must perform a general neurological examination to determine whether the abnormal motor performance can be completely accounted for by nonapraxic motor, sensory, or cognitive disorders. Although the presence of elemental motor defects does not prohibit or preclude praxis testing, the examiner must interpret the results of praxis testing in light of the knowledge gained from the neurological examination.

When possible, both the right and left arms and hands should be tested. When one arm is weak or has another motor disorder that would interfere with testing, the nonparetic limb should be tested. Testing of praxis involves selectively varying input as well as varying task demands. If possible, the same items should be used for all subtests. First, patients should be requested to pantomime to verbal command (e.g., "Show me how you would use a bread knife to cut a slice of bread"). Both transitive gestures (i.e., using a tool and instrument) and intransitive gestures (i.e., communicative gestures such as waving good-bye) should be tested. The clinician should instruct the patient not to use the body part as the tool but instead pantomime the use of the tool. In addition, patients should be asked to imitate the examiner performing both meaningful and meaningless gestures. Independent of the results of the pantomime-to-command and imitation tests, patients should also be allowed to see and hold actual tools or objects and to demonstrate how to use the tool or object while they are seeing and holding these implements. In addition to having patients pantomime to verbal command, the examiner may also want to show them pictures of tools or objects for pantomime. The examiner should also allow patients to view real tools or the objects that tools work on (e.g., nails) and, without allowing them to hold the tool or object, ask them to pantomime the action associated with the tool or object. It may be valuable to see whether the patient can name or recognize transitive and intransitive pantomimes made by the examiner and can discriminate between well and poorly performed pantomimes. Patients should also be asked to perform a task that requires several sequential motor acts (e.g., making a sandwich). Lastly, the examiner may want to determine whether the patient can match tools with the objects on which they operate (e.g., given a partially driven nail, will he select a hammer?) and whether a patient can develop tools to solve mechanical problems.

The types of errors made by patients with apraxia often define the nature of the praxis defect. Therefore, it is important to categorize errors, which can be done using a scoring system that classifies praxis errors into either content or production errors. Content errors include semantically related productions (pantomiming playing a trumpet rather than a trombone) and unrelated responses (e.g., making hammering movements rather than those associated with a trombone). Production errors include assuming the wrong posture, moving the incorrect joints, improperly coordinating multijoint movements, assuming an incorrect orientation, and making timing errors (Table 4-2). Each gesture produced by the patient may contain one or more praxis errors (see Rothi and colleagues¹⁰ and Poizner and associates¹¹).

Associated Neurological Findings

Since the diagnosis of apraxia is one of exclusion, a thorough neurological examination is indicated to rule out

TABLE 4-2 -- TYPES OF PRODUCTION AND CONTENT ERRORS SEEN IN PATIENTS WITH APRAXIA

Error Type	Description	Example
PRODUCTION ERRORS		
Spatial		
Postural	Use a body part as tool	Pantomiming the use of scissors, patients use fingers as blades
Orientation	Fail to orient forelimbs to an imaginary target	Pantomiming cutting a piece of paper in half with scissors, patients orient scissors laterally or not in consistent plane
Movement	Incorrect joint movement	Pantomiming the use of a screwdriver, patients rotate the arm at the shoulder and fix the elbow
Timing	Increased latency and incorrect speed	Absence of smooth sinusoidal speeds of movement when cutting with a knife
CONTENT ERRORS		
Tool-object action knowledge	Lack of knowledge of the type of actions associated with tools, utensils, or objects	When pantomiming or using a screwdriver, the patient pantomimes a hammering movement or uses a screwdriver as a hammer
Tool-object association knowledge	Lack of knowledge of the association of a specific tool with a specific object	When shown a partially driven nail, the patient may select a screwdriver instead of a hammer from an array of tools
Mechanical knowledge	Lack of knowledge of overall mechanics of the use of tools	When attempting to drive a nail with no hammer available, the patient selects a screwdriver rather than a heavier tool (pliers)

abnormalities of skilled motor movements that result from abnormalities of attention, language, primary visual disturbances, muscle weakness, ataxia, or disorders of primary sensory function (touch, proprioception). If any of these are present, the diagnosis of apraxia may be difficult to substantiate.

Cerebral. Since patients with apraxia commonly have other neurobehavioral dysfunction, a thorough neuropsychological examination is indicated, including an evaluation of directed attention and language function. Patients with left-sided parietal lesions of the supramarginal and angular gyri may have dyscalculia, finger agnosia, left-right disorientation, and agraphia (Gerstmann's syndrome). Additionally, patients may have alexia, aphasia, and constructional apraxia. Neglect for right-sided stimuli may occur but is uncommon. Patients with degenerative causes of apraxia, such as Alzheimer's disease, may also demonstrate memory loss, aphasia, and agnosia. Individuals with corticobasal ganglionic degeneration may demonstrate frontal-subcortical dysfunction as well.

Cranial Nerves. Since patients with apraxia may have associated visual abnormalities due to involvement of the visual radiations in the parietal lobes, a bedside evaluation of the visual fields should be completed. Patients may demonstrate homonymous hemianopias or quadrantanopias. Visual pursuit and optokinetic nystagmus should be checked using a hand-held strip at the bedside because ipsilateral tracking abnormalities may be seen in patients with parietal lobe lesions. Occasionally, patients with apraxia related to more frontal lesions may demonstrate a conjugate gaze deviation.

Motor/Reflexes/Cerebellar/Gait. Patients with frontal lobe lesions associated with apraxia may have contralateral hemiparesis due to involvement of the motor cortex. Crural weakness without involvement of the arm and face suggests involvement of the medial frontal lobe; when acute, this suggests infarction in the territory of the anterior cerebral artery. These patients may also show evidence of callosal disconnection (see later discussion). Brachial-facial weakness suggests involvement of the distribution of the middle cerebral artery. Evaluation of tone and evaluation for the presence of abnormalities of movement is also important. Patients with apraxia as part of corticobasal ganglionic degeneration may have rigidity, bradykinesia, and tremor or myoclonus.

Sensory. Cortical sensory loss including impaired two-point discrimination, agraphesthesia, and astereognosis indicates involvement of the parietal cortex and can occur in patients with apraxia due to vascular causes as well as in those with corticobasal ganglionic degeneration.

Autonomic Nervous System. Disturbances of the autonomic nervous system generally do not occur in patients with apraxia.

Neurovascular. The patient's neck should be auscultated for the presence of vascular bruits because the presence of significant bilateral bruits is a risk factor for stroke that can cause apraxia in association with other neurological findings.

EVALUATION GUIDELINES

Abnormalities of praxis are assessed by clinical history and the bedside neurological examination. Complementary investigations, such as neuroimaging, electrophysiology, fluid and tissue analysis, and neuropsychological testing can contribute to the etiological diagnosis.

Neuroimaging. Neuroimaging can be very useful in localizing and identifying the various disorders that present with praxis abnormalities. While the clinical history and examination are most helpful in distinguishing apraxia due to an acute process, such as stroke, from a more chronic process such as the degenerative disorders, magnetic resonance imaging (MRI) and computed tomography (CT) are useful in differentiating the causes of stroke (hemorrhage, ischemia) and in ruling out central nervous system malignancies. Additionally, these imaging studies (particularly MRI) may show the areas of cortical atrophy in patients with degenerative disorders. Unilateral, predominantly parietal, atrophy suggests corticobasal ganglionic degeneration, whereas bilateral temporoparietal atrophy is associated with Alzheimer's disease. Single-photon emission computed tomography (SPECT) may be useful in demonstrating

decreased cortical activity when obvious atrophy is not observed. Photon-emission tomography (PET), utilizing oxygen metabolism and 18F-dopa uptake, can demonstrate asymmetrical hypometabolism in the posterior frontal, inferior parietal, and lateral temporal cortex, striatum, and thalamus in patients with corticobasal ganglionic degeneration, whereas patients with Alzheimer's disease generally show hypometabolism of the parietotemporal and frontal association area, which may be asymmetrical or symmetrical, but striatal metabolism is preserved.

Electrophysiology. Electroencephalography is one measure of cortical function, and the finding of asymmetrical or symmetrical slowing may aid in the localization of pathology in patients with apraxia. Electromyography and nerve conduction studies are generally of little use in the evaluation of patients with apraxia.

Cerebrospinal Fluid and Tissue Analysis. Cerebrospinal fluid (CSF) analysis is generally not helpful in differentiating the causes of apraxia, demonstrating at most nonspecific findings in patients with stroke or degenerative disorders. Brain biopsy, while potentially diagnostic in patients with apraxia associated with Alzheimer's disease or corticobasal ganglionic degeneration, is indicated only in atypical cases or when the history and examination suggest other potentially treatable etiologies.

Neuropsychological Tests. In addition to bedside testing of praxis function, additional neuropsychological tests may be useful in differentiating early degenerative disorders such as Alzheimer's disease, corticobasal ganglionic degeneration, or Pick's disease (see [Chapter 33](#)).

CLINICAL SYNDROMES (see Table 4-3)

Ideomotor Apraxia

Ideomotor apraxia (IMA) is characterized by an impairment in the selection, sequencing, and spatial orientation

TABLE 4-3 -- SELECTED ETIOLOGIES ASSOCIATED WITH DISORDERS OF PRAXIS

Etiological Category	Selected Specific Etiologies	Chapter
HEREDITODEGENERATIVE DISORDERS		
Degenerative dementias	Alzheimer's disease Pick's disease Corticobasal ganglionic degeneration	33
Movement disorders	Goribobasal ganglionic degeneration	34
NEUROVASCULAR DISORDERS	Ischemic/hemorrhagic infarction Arteriovenous malformation	45
NEOPLASTIC DISORDERS		
Primary neurological tumors	Astrocytoma/glioblastoma/oligodendroglioma/meningioma	46
Metastatic neoplasms and paraneoplastic syndromes	Metastatic disease	47
TRAUMATIC DISORDERS	Blunt or penetrating CNS trauma	51

of movements involved in gestures, including emblems and pantomimes. Two forms of ideomotor apraxia can be identified. A posterior form can be induced by left parietal cortex (angular or supramarginal gyrus) lesions, while an anterior form can occur following lesions anterior to the supramarginal gyrus that disconnect the visual kinesthetic motor engrams from the premotor and motor areas. Patients with posterior IMA have difficulty performing in response to command and imitation and do not discriminate well between poorly and well-performed acts. Patients with the anterior type of IMA also perform poorly to command or imitation but can comprehend and discriminate pantomimes (see Table 4-1).

When performing skilled acts, patients with IMA make primarily *spatial and temporal production errors* (see Table 4-2). Spatial errors can be divided into postural (or internal configuration), spatial orientation, and spatial movement subtypes. *Postural errors* are seen in patients with apraxia when they are asked to pantomime a skilled motor task and use a body part as a tool rather than acting as if they were using the particular implement.^[12] For example, when certain patients with IMA are asked to pantomime the use of a pair of scissors, they may use their fingers for the blades. Although many normal subjects can make similar errors, it is important to instruct the patient specifically not to use a body part as a tool. Unlike normal subjects, patients with IMA continue to use their body parts as tools despite these instructions.^[13]

Also unlike normal subjects, who, when asked to use a tool, orient that tool to an imaginary target of the tool's action, patients with IMA often fail to orient their forelimbs to the imaginary target. These are errors of *spatial orientation*. As an example, when asked to pantomime cutting a piece of paper with scissors, rather than keeping the scissors oriented in the sagittal plane, IMA patients may either orient the scissors laterally,^[10] or they may not maintain any consistent plane.

When patients with IMA attempt to make a learned skilled movement, they often make the correct core movement (e.g., twisting, pounding, cutting), but their limb moves through space incorrectly.^{[10], [11]} These *spatial movement errors* are caused by incorrect joint movements. Apraxic patients often stabilize a joint that they should be moving and move joints that should not be moving. For example, when pantomiming the use of a screwdriver, the patient with IMA may rotate his arm at the shoulder and fix his elbow. Shoulder rotation moves the hand in arcs when the hand should be rotating on a fixed axis. When multiple joint movements must be coordinated, the patient with apraxia may be unable to coordinate these actions to achieve the desired spatial trajectory. For example, when asked to pantomime slicing bread with a knife, both the shoulder and elbow joints must be alternately flexed and extended. However, when the shoulder flexes, the elbow should extend. When the joint movements are not well coordinated, patients may make primarily chopping or stabbing movements.

Patients with IMA may also make *timing errors*, including long delays before initiating a movement and brief multiple stops (stuttering movements), especially when changing direction.^[13] In addition, when normal subjects make a curved movement, they reduce the speed of the

movement, and when they move in a straight line, they increase the speed. Patients with IMA, however, do not demonstrate a smooth sinusoidal hand speed when performing cyclical movements such as cutting with a knife.

Conduction Apraxia

Patients with conduction apraxia show a greater impairment when imitating movements than when pantomiming to command. Because this constellation of signs was similar to those of the conduction aphasic who repeats poorly, Ochipa and colleagues termed this disorder conduction apraxia.^[14] Patients with conduction apraxia can comprehend examiners' pantomimes and gestures but cannot perform the movements themselves. We, therefore, believe that patients' visual systems can access the movement representations (praxicons) and that these activated movement representations can activate semantics. It is possible that decoding a gesture requires accessing different movement representations than does programming an action. Therefore, according to Rothi and her co-workers, there may be two different stores of movement representations, an input praxicon and an output praxicon.^[15] In the verbal domain a disconnection of the hypothetical input and output lexicons induces conduction aphasia, and in the praxis domain, a disconnection between the input and output praxicons could induce conduction apraxia. Whereas the lesions that induce conduction aphasia are usually in the supramarginal gyrus or Wernicke's area, the lesions that induce conduction apraxia are unknown.

Disassociation Apraxia

Patients with verbal disassociation apraxia cannot gesture normally to command but perform well with imitation and actual tools and objects. Heilman^[16] described patients who, when asked to pantomime to command, looked at their hand but would not perform any recognizable action. Unlike the patients with ideomotor and conduction apraxia described previously, their ability to imitate motions and use objects was flawless. De Renzi and colleagues^[17] also reported such patients as well as others who had a similar defect in other modalities. Others have reported patients with a disassociation apraxia of only the left hand following a callosal lesion.^{[3], [4]} Whereas language in these patients was mediated by the left hemisphere, we posit that movement representations may have been bilaterally represented. Therefore, their callosal abnormalities induced a disassociation apraxia of only the left hand because the verbal command could not get access to the right hemisphere movement representations. Although the patient with callosal disassociation apraxia is not able to correctly carry out skilled learned movements of the left arm on command, these patients can imitate and use actual tools and objects with the left hand because these tasks do not require verbal mediation, and the movement representations stored in the right hemisphere can be activated by visual input.

Right-handed patients in whom both language and movement formulas are represented in the left hemisphere may show a combination of disassociation and ideomotor apraxia in the presence of callosal lesions.^[3] When asked to pantomime with their left hands, patients may look at them and perform no recognizable movement (disassociation apraxia), but when imitating or using actual tools and objects, they may make the same spatial and temporal errors seen in patients with ideomotor apraxia.

Left-handed individuals may demonstrate an ideomotor apraxia without aphasia from a right hemisphere lesion. These left-handed individuals are apraxic because their movement representations were stored in the right hemisphere and were destroyed by the lesion.^{[18], [19]} These left-handed persons are not aphasic because language is mediated by the left hemisphere (as is the case in the majority of left-handed people). If these left-handed individuals had a callosal lesion, they might

have demonstrated a disassociation apraxia of the left arm and an ideomotor apraxia of the right arm.

The disassociation apraxia described by Heilman^[16] from left hemispheric lesions was incorrectly termed "ideational apraxia." These patients and those of De Renzi and associates^[17] probably had an intrahemispheric language-movement formula, visual-movement formula, or somesthetic-movement formula disassociation. The locations of the lesions that cause these intrahemispheric disassociation apraxia are not known.

Ideational Apraxia

Patients with ideational apraxia are unable to carry out an ideational plan or a series of acts in the proper sequence.^[20],^[21] When performing a task that requires a series of acts, these patients have difficulty in sequencing the acts properly. For example, when writing and sending a letter, the patient with ideational apraxia may seal the envelope before inserting the letter. Unfortunately, the use of the term ideational apraxia has been confusing, since it has been used erroneously to label other disorders,^[22],^[23] including those involving dissociation apraxias^[16] and conceptual apraxias. Many patients who demonstrate ideational apraxia have bilateral frontal and parietal dysfunction such as that seen with degenerative dementias including Pick's disease.

Conceptual Apraxia

Whereas patients with ideomotor apraxia make production errors (e.g., spatial and temporal errors), patients with conceptual apraxia make *content and tool selection errors*. These patients may not recall the type of actions associated with specific tools, utensils, or objects (*tool-object action knowledge*) and therefore make content errors.^[24],^[25] For example, when asked to demonstrate the use of a screwdriver, either pantomiming or using the tool, the patient who has lost tool-object action knowledge may pantomime a hammering movement or use the screwdriver as if it were a hammer. Although this type of error may occur in the presence of an object agnosia, Ochipa and colleagues^[25] reported a patient who could name tools and therefore was not agnostic but often used them inappropriately.

5

Patients with conceptual apraxia may be unable to recall which specific tool is associated with a specific object (*tool-object association knowledge*). For example, when shown a partially driven nail, they may select a screwdriver rather than a hammer from an array of tools. This conceptual defect may also be found in the verbal domain such that when an actual tool is shown to a patient, he or she may be able to name it (e.g., hammer), but when he is asked to name or point to a tool when its function is described, he cannot. These patients may also be unable to describe the functions of tools.

Patients with conceptual apraxia may also have impaired *mechanical knowledge*. For example, if they are attempting to drive a nail into a piece of wood and there is no hammer available, they may select a screwdriver rather than a wrench or pliers (which are hard, heavy, and good for pounding).^[26] Mechanical knowledge is also important for tool development, and patients with conceptual apraxia may also be unable to correctly develop tools from available materials. Conceptual apraxia is perhaps most commonly seen in the degenerative dementia of the Alzheimer type,^[26] but is also seen with hemispheric dysfunction.^[27]

GENERAL MANAGEMENT GOALS

The performance of learned motor tasks involves the ability to complete many of the activities of daily living including personal hygiene and meal preparation. As a result, the presence of apraxic deficits can result in the loss of independence for many patients. While physical rehabilitation may improve other associated neurological deficits following head trauma or stroke, the presence of apraxia can make occupational rehabilitation difficult because the patient will have difficulty in performing these skilled tasks. Although there is significant interest in cognitive rehabilitation, little is presently known about the rehabilitation of patients with apraxia. The clinician must thus inform the patient and caregivers that the apraxic patient should avoid participating in activities in which he or she may injure himself or others. Occupational therapy and counseling may be useful for the patient and caregiver to teach various compensatory strategies. There is no pharmacological therapy that has been shown to be useful in treating apraxia.

HISTORY AND DEFINITIONS

Types of Memory

Memory in health and disease has been the focus of medical studies throughout history. In the first century, Pliny the Elder described a man who fell off a roof and afterward could not remember his mother, neighbors, and friends. Galen (130-200) placed emphasis on the ventricles as the anatomical key to mental processing, a view advocated by Nemesius of Syria, Posidonius of Byzantium, and several other early religious leaders whose views influenced medical thought. The perceived role of the ventricles declined during the Renaissance, and Thomas Willis entertained the idea that the cerebellum and brain stem controlled memory. Later, such figures as David Harley (1705-1757) and Charles Bonnet viewed memory in terms of vibration waves that oscillated in the brain. Scientific measurement of memory began in the late 1800s with Ebbinghaus' monograph and turned the study of memory away from philosophers and toward experimentalists. Studies of dementia, brain atrophy and memory decline, and trauma in relation to amnesia were conducted by several neurological luminaries including Samuel Wilks, Jean Esquirol, and Alois Alzheimer. Linkage of memory with emotional elements was presented by James Papez, whose anatomical studies form much of the basis of modern knowledge of memory circuitry.

Memory is the recording, retention, and retrieval of knowledge. It accounts for all knowledge gained from experience--facts that are known, events that are remembered, and skills that are gained and applied. Memory is not a unitary faculty but rather an ensemble of various forms of learning that differ in their uses, their operating characteristics, and the neural networks that mediate their processing. A *memory system* may be defined as a particular neural network that mediates a specific form of mnemonic processing. Neurological or psychiatric diseases result in characteristic mnemonic deficits that reflect which memory systems are injured by a particular disease.

In regard to memory, several distinctions should be made between aspects of memory that are useful from the clinical perspective and those that are useful from the neuroscience perspective. One such distinction is between *declarative* and *nondeclarative* forms of memory.^[1] Declarative memory corresponds to the everyday sense of memory and is responsible for the learning and remembrance of new events, facts, and materials. Thus, it encompasses both episodic memories (remembrance of personal experiences that took place at a particular place and time) and semantic memories (knowledge of generic information, such as the meaning of a word).^[2] It is the form of memory people use to recollect facts and events consciously and intentionally, and is therefore also referred to as *explicit* memory.

Nondeclarative memory refers to the many forms of memory that are not retrieved explicitly or intentionally but reflexively or incidentally. Remembering how to swim or ride a bicycle belong in this category. Nondeclarative forms of memory do not depend on the psychological processes or brain regions that are vital for declarative memory. These forms of memory guide current behavior on the basis of past experiences unrelated to any conscious awareness of those experiences, and therefore are referred to as *implicit* memory. Implicit forms of memory include perceptual, motor, and cognitive *skill learning* (sometimes referred to as procedural memory), which is the increased

accuracy, speed, or skill acquired for a given task during multiple training sessions in the absence of conscious awareness; classic and other sorts of *conditioning*, in which repeated pairing of an unconditioned stimulus such as a tone with an unconditioned response such as salivation at the sight of food, leads to a conditioned response (salivation) when the tone is presented in the absence of the evoking stimulus (food); and *repetition priming*, which is the facilitated processing of a stimulus, such as a word or picture, due to prior exposure to that stimulus.

Temporal properties also distinguish one form of memory from another. *Immediate memory* refers to the recall of information without delay, either immediately after presentation or after uninterrupted rehearsal. Immediate memory is characterized by sharply limited capacities for how much and how long information can be remembered. For example, most people can remember no more than seven random digits and only as long as they rehearse the digits. Immediate memory often has perceptual characteristics. For example, errors in immediate memory for words are more likely to reflect word sounds than word meanings. *Working memory* is a multicomponent psychological system that mediates the temporary processing and storage of internal representations that guide and control action. Information is held in working memory only as long as it is useful for solving a problem at hand.

Long-term memory refers to permanent and large stores of episodic and semantic memories. Long-term memories are not, however, passively stored records of experience. Rather, they are constantly used to interpret new experiences. That ongoing use can alter the original memory (retrograde interference) and yield inaccurate memories (false or distorted memories). Long-term memory is often organized by meaning (semantics) or gist rather than by perceptual characteristics of experience. For example, people remember the content of a sentence they have read far better than the specific order of words or the font in which the sentence was seen. Similarly, people remember a set of related words (e.g., fruits) better than a set of unrelated words. It is common, however, to believe falsely that a particular fruit was in the set of words when it was not actually presented.

The relation between short-term and long-term memory is often misunderstood, in part because of various meanings of the term short-term memory. Sometimes the term short-term memory is used to refer to attention. An individual who cannot repeat back even a single digit or word is better described as having a deficit in attention than a deficit in any sort of memory. A second use of short-term memory is to refer to a memory mechanism that supports remembrance of information after a delay of seconds or minutes and without rehearsal. There is, however, no evidence of any anatomical memory system that has a temporal span between immediate and long-term. There is, instead, constant and rapid loss of long-term memory for most events and facts. Therefore, memory of information after a brief delay of seconds or minutes will be superior to memory after a longer delay, but this difference reflects the dynamics of long-term memory and not the existence of any particular short-term memory store. It is often thought that information must go through short-term memory in order to reach long-term memory. This is correct if short-term memory refers to attention because people do not remember that which they do not notice. Surprisingly, this notion is incorrect if short-term memory refers to immediate memory. Patients with severe immediate memory deficits show minimal long-term memory deficits. This finding indicates that information from the environment enters immediate-memory and long-term memory stores in parallel rather than serially.

There is also a relation between working and long-term memory that is apparent on strategic memory tasks. Strategic memory tasks require manipulation of long-term memories rather than the mere retrieval of those memories. The mere retrieval of memories, for example, is sufficient to support performance on a recognition test in which an individual is asked to differentiate items that were seen earlier from those that were not. In contrast, an individual must initiate and use a strategy when asked to recall what items were seen or in what order the items were seen. For these strategic memory tasks, individuals must use a plan to "work with" long-term memories in order to solve a memory problem.

Cognition and Memory

Cognition refers to the mental processes of knowing, including high-level perception, language, and reasoning. Cognitive processes may be dichotomized as crystallized or fluid.^[3] Crystallized processes involve the application of well-established knowledge and well-practiced routines, such as vocabulary knowledge. Fluid processes are invoked when a problem must be solved with a novel, flexible strategy, such as reasoning. Fluid processes are far more dependent on working memory capacity than crystallized processes are. Some factors influence cognitive functions in a global fashion. Education, for example, typically augments many cognitive abilities. There is, however, considerable evidence that various forms of cognition reflect psychologically and neurally distinct processes. For example, spatial and verbal cognition depend mostly on processes that are psychologically distinct and mediated by different brain regions.

Cognition has multiple relations with memory. Impaired cognition in a particular knowledge domain is usually correlated with both declarative and nondeclarative memory impairments in that domain. A patient with aphasia, for example, is likely to have impaired declarative and nondeclarative memory for words. Declarative memory, however, can be greatly impaired without affecting cognition except insofar as cognition depends on the acquisition of new declarative memories. Thus, individuals who cannot form new declarative memories can perform very well on many demanding tests of cognition. The same individuals, however, can fail relatively undemanding tests of cognition if they involve the explicit learning of new information. Specific impairments in working memory can lead to broad difficulties in cognition because reduced working memory capacity limits the expression or use of acquired information in situations that require fluid thinking.

Disorders of Memory

A disorder of declarative memory is defined as *amnesia*. A pure amnesia refers to a relatively circumscribed disorder of declarative memory that cannot be accounted for

by nonmnemonic deficits such as attention, perception, language, or motivation. *Anterograde amnesia* refers to the inability to acquire new declarative memories. *Retrograde amnesia* refers to the loss of memories acquired prior to the onset of the amnesia. Retrograde amnesias are described as flat when they extend back uniformly through an individual's life. More often, however, retrograde amnesias are temporally graded, being most severe or limited to a time period preceding the onset of the amnesia, and less severe or absent for more remote experiences.^[1] The gradient may reflect the time when the memory was acquired or the strength of the original memory. Depending on the size and location of lesions, amnesias can vary considerably in anterograde and retrograde scope and severity.

Dementia may be defined as a chronic and substantial decline in two or more areas of cognition. In addition to memory impairment, at least one of the following must occur: aphasia, agnosia, or a disturbance of executive function (see [Chapter 33](#)). The cognitive deficits must reflect a decline from the person's former function and must be sufficiently severe to cause impairment in occupational or social activities of daily living. Dementia differs from delirium because it is neither acute in onset nor a diffuse confusional state that affects all realms of function. It differs from amnesia in that dementia is not circumscribed to a declarative memory disorder. Dementia, however, can greatly affect memory ability in primary and secondary ways. Dementia can include a primary memory disability when declarative memory is one of the areas of decline. Indeed, many definitions of Alzheimer's disease, the most common dementing disorder, require that declarative memory be one of the areas of decline. Dementias can also affect memory ability in a secondary way when the multiple cognitive deficits impede memory performance. A dementia featuring a severe attentional disorder, for example, impedes many aspects of memory performance. For similar reasons, mental retardation, confusional states, inattention, or motivational difficulties such as depression all have broad and substantial secondary effects on memory performance.

Memory is also affected by nondisease influences such as aging. Older people in their sixties and seventies typically perform less well on standard measures of memory than younger people in their twenties and thirties.^[2] This decline is sometimes referred to as *age-associated memory impairment*. Age-associated changes in the absence of overt disease, however, vary considerably for different kinds of cognition and memory. They are more severe for fluid than for crystallized aspects of cognition; indeed, crystallized cognition is often minimally affected. Working memory capacity appears to decline constantly across the life span; therefore, aging affects strategic memory far more than nonstrategic declarative memory performance. Semantic memory appears to be affected only in very old age. There are few, if any, age-associated changes in some forms of nondeclarative memory, such as repetition priming,^[3] and there are severe declines in other forms of nondeclarative memory, such as conditioning.^[4] Longitudinal studies provide evidence that age-associated memory impairment is accounted for partly by individuals who are in a preclinical form of Alzheimer's disease. It is unclear at present whether age-associated memory impairments reflect only preclinical forms of age-related diseases or whether age-related reductions in memory occur that are independent of disease processes.

CLINICAL HISTORY

Patients with memory deficits are, by definition, limited in their ability to provide information about their history, and this limitation is especially salient for patients who may be demented. Therefore, obtaining a clinical history from a patient complaining of memory disorders usually requires considerable cooperation from the patient's family or caregivers. In many cases, they are the ones who can most accurately recite the patient's problems. This fact introduces a challenge to the interpersonal skills of the examining physician because the patient must retain a feeling of central importance during the interview even though much information about the patient must come from these collateral sources.

The physician, after introductions, can elicit a general history that may be directed if the patient begins to go off-track. As the patient begins to tell the history of the present illness, the physician should be appraising the patient for a general view of affect and cognitive function, and for salient aspects of the patient's personality, educational background, and state of health. Information about the temporal onset and progression of memory impairment is useful in focusing the differential diagnosis. An acute onset of decline to a chronic level of memory dysfunction suggests a stroke or anoxic episode. An abrupt onset with a stepwise progression raises a suspicion of a vascular-based memory problem such as multi-infarct dementia. An insidious, slowly progressive, chronic decline shifts attention to the possibility of alcohol-related dementia or Alzheimer's disease. A more rapid progression of memory dysfunction over weeks to months may point to a depression-related memory loss or, especially if seizures are present also, to primary or metastatic tumors or encephalitis.

Family history should include the age and state of health or age at death and cause of death of at least the siblings, parents, grandparents, aunts, and uncles. Neurological disease in any relatives or the possibility of consanguinity should be pursued as a lead to uncovering a genetic etiology.

Occupational and intellectual achievements of the past should be elicited. A discordance between poor language or judgment relative to superior occupational and intellectual achievements in the past suggests causes that are not consonant with more pure amnesias. Further, high levels of premorbid functioning may mask the severity of current problems because such individuals can effectively compensate for memory loss. Paradoxically, individuals with high levels of premorbid functioning may be most sensitive to and concerned about memory disturbances, and they may interpret such age-associated disturbances as harbingers of Alzheimer's disease.

The past and current medical history should be thorough because memory disorders have a wide range of primary and secondary causes. Information about alcohol, drug, and dietary habits should be obtained. Substantial alcohol consumption, which should be quantified, may lead to

memory dysfunction through Wernicke-Korsakoff psychosis or hepatorenal encephalopathy. A detailed drug history should be obtained because many medications directly or indirectly (e.g., via lethargy) reduce memory performance. Commonly used prescription and nonprescription drugs that may interfere with memory and cognition include analgesic, antihypertensive, anticholinergic, psychotropic, and sedative medications.

A history of surgery, trauma, or head injury should be pursued for the possibility of cerebral anoxia or direct trauma to the brain structures. Onset and progression of seizures and headaches should be clarified to direct suspicions of tumors, aneurysms, encephalitis, or epilepsy. A cancer history should raise a suspicion of metastases to the brain or paraneoplastic disorders, and known hypertension, stroke, or transient ischemic attacks point to a vascular cause of a memory disorder.

A history of depression is particularly notable because memory loss is often seen during depressive episodes, in which anxiety, guilt, and delusions are also present. For this reason, it is useful to assess the mood of the patient and make note of any insomnia or fatigue. A primary memory disorder, however, can affect a patient's mood, sleep, work, family relations, and daily activities. Personality changes, usually reported by the family, should be pursued to determine whether they are an incidental finding, a consequence of the memory dysfunction, or a clue to the underlying etiology, such as depression or frontal lobe tumors.

Finally, social and legal issues may have to be considered, especially when the findings are inconsistent across time or do not agree with the signs of an organic disorder. Stressful family situations may color the complaints of the patient or family. Legal motivations are salient in cases of insurance claims or conservatorships.

ANATOMY OF MEMORY (Table 5-1)

Papez Circuit

It is well recognized that the ability to recall and engender memories is intimately linked to the emotional makeup of such memories. Furthermore, several clinical conditions show combined deficits in these domains, suggesting a direct anatomical or physiological interaction of functions. In 1937, the neuroanatomist Papez published a study describing an anatomical circuit that involved a number of central nervous system nuclei and pathways that are important in aspects of memory and emotion. Familiarity with this Papez circuit allows clinicians to think systematically about the overall anatomical foundation of memory and to analyze which elements are involved in different aspects of memory function. The concept of a circuit is particularly important in dealing with memory, since lesions anywhere along the pathway may interrupt memory function, although the coloration of the deficit may be particularly influenced by the specific nuclei or path that is damaged (Fig. 5-1 (Figure Not Available)).

The circuit is schematically diagrammed in Figure 5-1 (Figure Not Available) A, and the anatomical nuclei and pathways are identified in the sagittal brain section shown in Figure 5-1 (Figure Not Available) B. The pathway is circular and provides continual reintegration of information. The two prominent cortical areas are the cingulate cortex and the hippocampus of the temporal lobe. Diffuse cortical impulses travel into the hippocampus, traverse the midline fornix pathway to the mammillary bodies of the hypothalamus, and continue to the anterior and dorsal thalamus. From these regions, information projects to the midline cingulate cortex, which finally projects diffusely to cortical regions.

Anatomy of Declarative Memory

A broad convergence of human and animal research indicates that declarative memory depends on an interaction between domain-specific neocortical regions and domain-independent medial-temporal, diencephalic, and basal forebrain regions. ^[9] Long-term memories are thought to be stored in the neocortex, the neocortical location reflecting the content of the memory. Thus, knowledge about the visual appearance of a tool may be stored separately,

TABLE 5-1 -- CLINICO-ANATOMICAL CORRELATIONS OF MEMORY DISORDERS

Anatomic Site of Damage	Memory Finding	Other Neurological and Medical Findings
Frontal lobe	Lateralized deficits in working memory. Right spatial defects, left verbal defects, impaired recall with spared recognition	Personality change Perseveration Chorea, dystonia Bradykinesia, tremor, rigidity
Basal forebrain	Domain-independent declarative memory deficits	
Ventromedial cortex	Frontal lobe-type declarative memory deficits	Upper visual field defects
Hippocampus and parahippocampal cortex	Bilateral lesions yield global amnesia, unilateral lesions show lateralization of deficits--left: verbal deficits; right: spatial deficits	Myoclonus Depressed level of consciousness Cortical blindness Autonomations
Fornix	Global amnesia	
Mammillary bodies	Declarative memory deficits	Confabulation, ataxia, nystagmus, signs of alcohol withdrawal
Dorsal and medial dorsal nucleus thalamus	Declarative memory deficits	Confabulation
Anterior thalamus	Declarative memory deficits	
Lateral temporal cortex	Deficits in autobiographical memory	

Figure 5-1 (Figure Not Available) Papez circuit that integrates cortical and subcortical structures involved in memory or emo (From Goetz CG, Wilson RS: Behavioral Neurology. In Weiner WJ and Goetz CG [eds]: Neurology for the Non-Neurologist. Philadelphia, J.B. Lippincott, 1994, pp 184-194.)

perhaps near the visual neocortex, from knowledge about its use, which may be stored in areas that include the premotor areas. ^[9] Memory of an event or fact, therefore, may be widely distributed in the neocortex with specific perceptual, conceptual, and emotional features of an event stored in specialized neocortical regions. The hippocampal complex has reciprocal connections with higher-order association cortices, and it is hypothesized that the hippocampal complex somehow binds or relates multiple features about an event or fact across physically disparate neocortical regions. Over time, the features somehow become consolidated and no longer require the hippocampal complex for binding. It is thought that temporally limited retrograde amnesia reflects the disruption of consolidation processes.

Damage to a neocortical region results in both the loss of previously acquired memory, or knowledge, stored in that area and an inability to acquire new memories involving that kind of knowledge. For example, patients with left temporal lesions lose specific knowledge about the names of animals, tools, or people, depending on the location of the lesion. ^[9] Thus, neocortical damage is thought to result in domain-specific memory deficits in which the loss of old memories and the inability to gain new memories reflect the kind of knowledge represented in that neocortical region.

In contrast, damage to medial temporal lobe, diencephalic, and basal forebrain regions yield widespread, or domain-independent, declarative memory deficits. Global amnesia can arise from damage to any one of these regions, even if the other regions remain intact. Bilateral damage to these regions can yield a global amnesia that affects all domains of declarative memory. Unilateral left- or right-sided lesions typically result in material-specific memory dysfunctions for, respectively, verbal or nonverbal information. An important exception to this rule occurs in patients with longstanding unilateral injury, such as that seen sometimes in epilepsy. In such cases, the relatively spared contralateral brain region may become critical for verbal and nonverbal memory functions.

The medial-temporal region includes a number of interconnected but anatomically distinct structures: the amygdala, the hippocampal region that includes the cornu ammonis (CA) fields, dentate gyrus, and subiculum; the entorhinal cortex; the perirhinal cortex; and the parahippocampal cortex. Research with animals and humans indicates that these structures all have their own specialized roles in memory. It is now thought that the amygdala is not critical for most aspects of declarative memory. Rather, the amygdala appears to play a specific role in the emotional modulation of memories; its role in fear conditioning is especially well documented. ^[10] Focal damage to the CA1 region of the hippocampus is sufficient to result in a clinically substantial declarative memory deficit. ^[11] More widespread damage to the entorhinal, perirhinal, and parahippocampal regions results in increasingly devastating memory deficits. ^[11] In addition, the fornix constitutes the major subcortical output pathway of the hippocampal region. Damage to the fornix can produce global amnesia. ^[12] The specific mnemonic roles of medial temporal lobe regions critical for declarative memory ability have not yet been characterized in humans.

Diencephalic regions linked to declarative memory include the dorsomedial and anterior nuclei of the thalamus, the mammillary bodies, the mammillothalamic fiber tract connecting the medial hippocampal complex to the anterior thalamic nuclei, and the ventroamygdalofugal fiber tract connecting the amygdala to the dorsomedial nuclei. The precise roles of these structures are not well specified, in part because damage tends to co-occur in multiple structures. For example, the mammillary bodies and dorsomedial nuclei are both greatly affected in alcoholic Korsakoff's amnesia. Acute thalamic lesions producing amnesia often injure both the dorsomedial nucleus and the surrounding mammillothalamic and ventroamygdalofugal tracts. The preponderance of the evidence favors a critical role for the dorsomedial nucleus of the thalamus and, perhaps, the surrounding fibers of the mammillothalamic tract. ^[13] The importance of the mammillary bodies is less certain. Lesions there sometimes appear to account for declarative memory deficits in patients ^[14] but do not produce the long-lasting memory impairments seen in monkeys that have sustained medial-temporal or dorsomedial thalamic lesions. Declarative memory failure after diencephalic lesions appears to be quite similar to that seen after

medial-temporal lesions, although additional nonmnemonic deficits may result from diencephalic lesions.

The basal forebrain is composed of midline structures

including the septal nuclei, diagonal band of Broca, and substantia innominata. These regions provide the largest input of acetylcholine, the neurotransmitter most directly implicated as critical for declarative memory, to the hippocampus and many neocortical areas. The basal forebrain also supplies to the cerebral cortex other neurotransmitters that contribute to the modulation of memory, including dopamine, norepinephrine, and serotonin. An extensive lesion to the basal forebrain yields a severe declarative memory impairment.^[15] Partial damage to this and adjacent ventromedial frontal cortex often occurs after ruptures of anterior communicating artery aneurysms, which often lead to mild but persistent anterograde amnesia.^[16]

There is increasing evidence of a correlation between the severity of anterograde amnesia and the extent of retrograde amnesia. Further, the severity of both anterograde and retrograde amnesia appear to correlate with the extent of medial-temporal injury.^[11] Some patients with mild anterograde amnesias, however, show a surprising loss of personal memories concerning major life events or family members.^[17] These patients typically have sustained damage to the more lateral temporal neocortex, which may store long-term autobiographical memory representations. These patients fail to exhibit the temporally graded retrograde amnesia characteristic of patients with lesions restricted to medial-temporal areas.

Anatomy of Nondeclarative Memory

Whereas declarative memory depends on the integrity of a limited number of brain regions, nondeclarative memory encompasses all other forms of memory mediated by all other brain regions. In this sense, nondeclarative memory may be described as more diffuse in its neural representation. Each specific form of nondeclarative memory, however, is closely linked to specific brain structures and regions.

Immediate memory stores appear to be located in posterior neocortical regions, the location reflecting the modality (auditory or visual) and material (verbal or nonverbal) of the briefly retained information. For immediate auditory memory, left and right temporal-parietal cortices, respectively, mediate auditory verbal and nonverbal material. For immediate visual memory, left and right occipitoparietal cortices, respectively, mediate immediate verbal and nonverbal material. Thus, a reduced ability to immediately recall aurally presented digit strings occurs in patients with left temporal-parietal lesions.

Working memory processes that support selective aspects of declarative memory have been linked to the dorsolateral frontal cortex and to basal ganglia and cerebellar areas that are directly or indirectly linked to the dorsolateral frontal cortex. The prevailing view is that there are discrete dorsolateral frontal areas that direct the rehearsal of the immediate memory stores. Thus, keeping a spatial location in mind may involve a right-frontal area that directs the maintenance of that information in a right parietal area, whereas keeping a word in mind may involve a left-frontal area that directs the maintenance of that information in a left temporal or parietal area.^[18] Specific basal ganglia and cerebellar areas appear to support the working memory capacity of particular frontal regions.

Implicit memory processes appear to depend on the same brain regions that mediate performance in any given domain. By this view, implicit memory reflects adaptive plasticity within neural systems that occurs in the course of the support by those systems of particular forms of behavior. Thus, motor-skill learning has been linked to pyramidal, extrapyramidal, and cerebellar motor systems.^[19] Interestingly, perceptual and cognitive skill learning has also been linked to the same action systems, with some evidence indicating that they may reflect adjacent but separable frontostriatal and frontocerebellar circuits. Perceptual repetition priming has been linked to modality-specific neocortices (e.g., visual priming with visual cortex)^[20] and conceptual repetition priming has been linked to polymodal linguistic neocortical regions in the left frontal and left temporoparietal areas.^[21]

Classic conditioning has been well characterized as being dependent on the dentate and interpositus nuclei of the cerebellum in animals, and such conditioning depends on the same cerebellar structures in humans.^[22] More complicated conditioning paradigms appear to require, in addition, medial-temporal regions.^[23]

Memory-Related Anatomical Changes

Memories are presumably formed by experience-induced changes in the operating characteristics of single cells, local circuits, and large-scale systems. Little is known directly about how these changes occur in the human brain. A great deal is known about some memory-related phenomena at cellular levels in *in vitro* and invertebrate models, such as the marine snail *Aplysia*. These findings offer suggestions about the cellular bases of human memories.

Aplysia withdraw their gills when stimulated with a brief jet of seawater. Repeated stimulation, however, leads to habituation such that the gills are no longer withdrawn. Habituation has been linked to decreasing presynaptic transmitter release. In other conditions, repeated stimulation can lead to sensitization. For example, a strong noxious stimulation, such as an electrical shock, can intensify a subsequent withdrawal response to a touch. Sensitization involves an increase of transmitter release from a facilitating interneuron.^[24]

Long-term, but not short-term, memory processes require messenger RNA and protein synthesis.^[25] These findings indicate that there are genes and proteins that guide long-term memories that are not invoked in short-term memories. These long-term changes may involve structural changes in presynaptic neurons. Long-term habituation may involve a pruning of presynaptic terminals, whereas sensitization may involve a proliferation of presynaptic terminals.^[26] A strong candidate for a cellular basis of mammalian learning is long-term potentiation (LTP). A neuron becomes potentiated (i.e., increasingly responsive to new input of the same type) for minutes, days, or weeks when it is bombarded with brief but rapid series of stimulations. The fact that simultaneous stimulation of different synapses,

or cooperativity, is required for LTP makes it a promising mechanism for associative learning at the level of a single cell. Cooperativity and other sources of evidence indicate that the postsynaptic neuron triggers LTP. LTP-induced changes in postsynaptic neurons are known to increase the concentration of calcium in dendrites, which activates a cascade of protein phosphorylation leading to changes in synaptic properties. LTP has been extensively studied in hippocampal synapses, in which NMDA glutamate receptors are of critical importance for the establishment, but not the maintenance, of LTP. There is evidence of similar mechanisms in the amygdala, cerebellum, and cerebral cortex. LTP in different brain regions exhibits different rates of development and stability, suggesting the involvement of multiple cellular mechanisms.

Memory-Related Chemical Changes

The specific roles of different neurotransmitters in memory are just beginning to be appreciated. The cholinergic system appears to be critical for the acquisition of long-term declarative memories. In healthy subjects, cholinergic antagonists such as scopolamine impair declarative memory performance, whereas agonists such as physostigmine facilitate such performance.^[27] Some nondeclarative forms of memory, however, are not affected by scopolamine. Cholinergic function decreases somewhat with age and greatly in patients with Alzheimer's disease,^[28] and these changes may contribute importantly to corresponding reductions in declarative memory ability.

The catecholamines appear to have an important role in working memory. Dopaminergic function is decreased in patients with Parkinson's disease, who have reduced working memory capacity. There is some evidence that dopamine agonists can improve working memory capacity in patients with Parkinson's disease^[29] and in healthy subjects.^[30]

EXAMINATION OF MEMORY

Directed Neurological Examination

The first goal of the neurological examination of memory is to ascertain that memory impairment is not secondary either to a specific perceptual, motor, or cognitive disability or to a broad impairment of mental status. This goal can be accomplished by performing a mental status assessment and brief bedside tests of orientation, receptive and expressive language, and visual constructional abilities. Confusional states can be evaluated both informally, while the patient tells his or her history, by noting confusion or incoherence in thinking, anxiety level, and inconsistencies and inaccuracies about dates and symptoms, and formally by asking about the present day, date, place, and year. Further memory assessment should be undertaken only if a patient's level and content of consciousness and attention are determined to be unimpaired. One widely used standardized mental status test is the mini mental status examination (MMSE).^[31]

The second goal of the directed neurological examination is to characterize the nature of a primary memory problem by the use of brief tests of immediate, long-term, and remote memory. Tests of immediate memory require the patient to repeat exactly a series of random digits; normal adults can repeat 5 to 7 digits. Such tests assess the ability to attend to events adequately and to encode information. Immediate memory is relatively spared in patients with even the most severe amnesias and moderate dementias. Failure to immediately repeat 5 digits in the order presented suggests a problem in attention or orientation. The rare exceptions include patients with specific immediate memory deficits who may be differentiated from inattentive patients by virtue of their intact immediate memory in another modality (e.g., when shown 5 digits visually).

Tests of long-term memory (often referred to as short-term memory in standard neurological usage) require the patient to remember and later recall (e.g., after 3 minutes) three items of information (e.g., words or objects). It is useful to warn the patient that memory will be tested for the information and to have the patient immediately repeat the words or name the objects to rule out attentional, perceptual, and linguistic bases for any later memory failure. It is important that the delay between the study and the test be filled with activity such as counting before the patient is asked to recall the words or objects. Otherwise, a patient may quietly rehearse the words, and the test no longer measures long-term memory. In patients with expressive aphasia, demands on speech production may be bypassed by having the patient select the test object from a set of objects. Such tests assess the ability to learn new material and evaluate the possibility of anterograde amnesia.

Tests of remote memory used to evaluate the possibility of retrograde amnesia (often referred to as long-term memory in standard neurological usage) require patients to recall past personal, geographical, or historical facts (e.g., the names of the last six presidents).

Additional Neurological Findings

Cerebral. The presence of accompanying cortical signs other than memory loss helps to localize the anatomical basis of an amnesic syndrome. Accompanying dyspraxia, aphasia, or agnosia indicates that the cortex is involved in the pathological process. An assessment of affect is also important, since depression can produce a picture of seeming dementia (pseudodementia). Emotional lability or poor voluntary control over emotional expression (pseudobulbar affect) can occur in patients with conditions that affect both cortices or with progressive supranuclear palsy.

Cranial Nerves. In the context of compromised cognition, cranial nerve abnormalities are valuable in elucidating the underlying location and cause. Increased intracranial pressure is suggested by papilledema and sixth nerve paresis, and progressive supranuclear palsy often produces distinctive defects in volitional conjugate vertical gaze. A variety of extraocular muscle pareses and nystagmus may accompany Wernicke-Korsakoff syndrome, and visual field defects of a homonymous hemianopia pattern suggest the presence of deep lesions of the white matter pathways, which are seen in patients with thalamic and temporal lobe disorders. Multiple cranial nerve deficits are seen in patients with chronic meningitis.

Motor/Reflexes/Cerebellar/Gait. Chorea and dystonia suggest the possibility of Huntington's disease. Bradykinesia, tremor, rigidity, and postural reflex impairment are seen in Parkinson's disease, and myoclonus typifies postanoxia syndromes and spongiform encephalopathies, among other conditions. Primitive reflexes like snout, plantar extension, and palmomental reflexes, such as rooting responses, suggest the presence of bilateral cortical, subcortical, or brain stem disease. Ataxia and other cerebellar signs may occur in patients with Wernicke-Korsakoff syndrome. Asymmetrical reflexes and mixed areas of weakness (for example, a slight facial paresis on one side and a mild weakness of a leg or arm on the other side) suggest multiple strokes, often subcortical in location.

Sensory. Primary sensory function is difficult to test in patients with memory or cognitive impairment because they are often inattentive and inconsistent in their responses. If primary sensation is normal and a deficit in higher cortical sensory processing is present, such as astereognosis, extinction, or neglect, a cortical disorder should be suspected. Preferential vibration and position sensory loss in combination with memory problems may suggest vitamin B₁₂ deficiency, whereas severe, painful crises and loss of pin and temperature sensation are more typical of syphilitic illness.

Autonomic Nervous System. In patients with diffuse sympathetic hyperactivity that can occur in the presence of hypothalamic lesions, bilaterally dilated pupils can occur, along with cardiac dysrhythmias and blood pressure instability.

Neurovascular. In the context of possible strokes, the neck vessels should be examined, and evidence of orthostatic hypotension should be sought.

Associated Medical Findings

Impaired memory and cognitive functioning are characteristic of drug intoxication or withdrawal as well as of several systemic diseases such as vitamin deficiencies, endocrine disorders, chronic infections, and carcinomas. A general physical examination, therefore, is necessary to identify the precipitating cause. Typically, in disorders of memory such as dementia and amnesic syndromes, the patient does not appear to be acutely ill unless a systemic disorder is also present.

The general physical examination may reveal reversible memory disturbances, the most common causes of which are intracranial masses, normal pressure hydrocephalus, thyroid dysfunction, and vitamin B₁₂ deficiency. Examination of the patient's general appearance, vital signs, skin and mucous membranes, head, neck, chest, and abdomen should reveal clinical signs that will aid in the differential diagnoses of dementia and amnesic syndromes. Fever, tachycardia, hypertension or hypotension, sweating, hypothermia, and impaired level of consciousness should suggest a systemic disease, anticholinergic intoxication, or withdrawal from ethanol or sedative drugs rather than an isolated memory disorder. Jaundice suggests hepatic disease; glossitis, intestinal problems, and yellowish skin suggest a vitamin B₁₂ deficiency; hot, dry skin is often characteristic of anticholinergic drug intoxication. Hypothermia, hypotension, bradycardia, coarse dry skin, brittle hair, and subcutaneous edema are characteristic of hypothyroidism. Recent trauma to the head may be evidenced by scalp lacerations or contusions and pain. Positive Kernig's and Brudzinski's signs are found in cases of meningitis and subarachnoid hemorrhage.

EVALUATION GUIDELINES ([Table 5-2](#))

Neuroimaging. Neuroimaging techniques provide valuable information in the assessment of extent of structural and functional brain abnormalities in a patient. These data can be used to target further assessment of a patient's memory complaint. Gross structural abnormalities are often adequately revealed by computed tomography (CT), but more refined volumetric assessment of the deep cortical structures such as the hippocampal formation and amygdala are better visualized by magnetic resonance imaging (MRI). Lesions that can be detected include space-occupying masses like tumors or abscesses and diffuse or focal degenerative illnesses involving the cortex and subcortical regions. Whereas diffuse atrophy typifies Alzheimer's disease, prominent frontal or parietal lobe atrophy is characteristic of Pick's disease. Contrast infusion studies highlight the abnormalities seen in vascular disorders and hence may help in leading the clinician to the proper etiological diagnosis.

Other functional neuroimaging techniques, such as positron emission tomography (PET) and single-photon emission computed tomography (SPECT), assess global metabolic patterns and are useful in assessing the diffuse neuronal loss that occurs in degenerative diseases. For instance, in patients with dementias marked by memory loss, such as Alzheimer's disease, hypometabolism occurs primarily bilaterally in the temporal-parietal regions with relative sparing of the posterior cortices.^[32] In contrast, in dementias marked by relative sparing of memory, such as Pick's disease, hypometabolism occurs primarily in the bilateral frontal cortices.^[33] These techniques, plus, more recently, functional MRI, offer great potential for clinical application in the diagnosis and assessment of memory disorders. In their current state of development, however, they remain predominantly research tools because their specificity and sensitivity to specific diseases of memory are not yet sufficient for diagnostic purposes. They may, however, be useful when a patient's pattern of memory loss and sparing is difficult to comprehend and structural

imaging reveals no lesions. In these cases, atypical functioning of a particular brain region may provide useful information.

Electrophysiology. EEG is used routinely to detect the gross locus and nature of seizure activity in patients with epilepsy, although an abnormal EEG may result from any number of conditions including tumors, abscesses, and subdural hematomas. Memory problems are mainly associated with medial temporal-lobe epilepsy, and the nature of memory deficits varies with the epileptogenic hemisphere. EEG data are of limited value in indexing a memory deficit because often other areas of the epileptogenic hemisphere or the nonepileptogenic hemisphere may appropriate the memory functions normally subserved by the epileptic tissue. Consequently, the patient may present with very mild or no memory deficits. EEG data are valuable in the diagnosis of sleep disorders that can result in memory problems. In many dementing processes, the EEG shows a diffuse and nonspecific slowing that may be most predominant in the temporal regions. Distinctive processes like periodic 1- to 2-cycle per second slow wave triphasic spike activity or a burst suppression pattern may suggest dementing illnesses such as spongiform encephalopathies.

Fluid and Tissue Analysis. Memory impairment may occur secondarily to conditions such as drug and alcohol intoxication or withdrawal and to systemic diseases such as vitamin deficiencies, endocrine disorders (specifically thyroid disease), chronic infections, or carcinomas. These are often treatable conditions diagnosed by analysis of tissue (by biopsy) or fluids (by tests of blood and urine). When a treatable condition is found, further evaluation of memory need not be performed unless the memory impairment persists or becomes worse after the underlying disease has been treated. Some tests, such as the sedimentation rate, are nonspecific but lead the investigator toward other tests that may properly document a condition such as vasculitis or cerebritis. Choice of the biopsy site depends on the diagnosis being actively entertained—for example, amyloidosis is often diagnosed by rectal biopsy, while temporal arteritis is diagnosed by examination of the temporal artery itself. In patients with memory problems in whom management or treatment depends directly on a specific diagnosis, a brain biopsy should be considered. Instances include primary cerebral vasculitis, spongiform encephalopathies, tumors that require specific treatment, or likely infections, abscesses, or cysts.

Genetic testing is a new and growing potential source of evaluative information. In some cases (e.g., Huntington's disease), it is part of a standard diagnosis, but in other cases it is optional. In patients with Alzheimer's disease, atypical early-onset cases may be screened for specific mutations on chromosomes 1, 14, and 21. More typical cases of Alzheimer's disease have been linked to apolipoprotein E4 alleles, but this linkage is probabilistic.^[34] Because such genetic testing cannot definitively determine the diagnosis of Alzheimer's diseases, drawbacks to such screening are salient. One drawback is that the appropriate diagnosis of dementia or Alzheimer's disease could be overly influenced by genetic information. A second drawback concerns the complex and controversial ethical issues involved in deciding whether this information should be available to the patient, family members, or insurers when the information does not define a disease. For these reasons, it is reasonable to suggest that apolipoprotein E testing is not yet appropriate for clinical use.

Cerebrospinal Fluid. Once a space-occupying lesion has been excluded, CSF may be obtained for analysis of treatable causes of memory problems. Infection, in the form of a chronic meningitis, is suggested by the presence of white blood cells; and in patients with tertiary syphilis, inflammatory cells and positive serological tests (CSF, venereal disease research laboratories test [VDRL]) are diagnostic.

Neuropsychological Tests. One of the most important goals of neuropsychological testing is to determine whether the patient has a "pure" memory deficit or whether the deficit is due to a defect in some general cognitive function. Thus, neuropsychological testing should be comprehensive enough to identify the patient's strengths as well as weaknesses. The most widely used standard battery of tests of anterograde memory is the Wechsler Memory Scale (WMS)--Revised,^[35] which includes a variety of subtests that assess verbal and nonverbal immediate and delayed memory and attention span. The battery yields five indices (verbal, visual, general memory, attention-concentration, and delayed recall). The criteria for a diagnosis of amnesia is considered a normal attention-concentration score but an impaired delayed recall score. Although the test is widely used, a major limitation is that it does not discriminate well between moderate and severe forms of amnesia. The WMS-R measures free recall and cued recall but not recognition memory, and therefore, both moderately and severely impaired patients often perform at the same low level. Further, it may not discriminate well between different types of memory disorders, such as that following frontal lobe lesions, which results in a selective memory impairment on recall tests, and that following temporal lobe lesions, which results in a global memory impairment on both recall and recognition tests.

A memory battery that does incorporate both recall and recognition measures is the California Verbal Learning Test (CVLT).^[36] A strength of the CVLT is that it assesses the processes driving subjects' performance such as organizing strategies and sources of interference. Assessment of visuospatial memory, however, is not included. A widely used test of visuospatial memory is the Rey-Osterrieth Complex Figure Test,^[37] which includes assessment of copying and of immediate and delayed recall. It is laborious to score but allows assessment of the perceptual strategies patients use or fail to use. Patients with left-hemisphere lesions often cannot remember internal details, whereas those with right-hemisphere lesions often cannot remember the general configuration.

Retrograde amnesia is more difficult to assess because it is culturally, geographically, and temporally specific to an individual. Further, it is difficult to ascertain what a person knew years ago. There are a few standardized tests in this area, including the Boston Retrograde Amnesia Battery (BRAB),^[38] which assesses the extent of the temporal gradient of a person's retrograde amnesia by incorporating pictures of famous people at different ages; a temporal gradient will be revealed if the amnesic patient recognizes the person at a young but not older age. These instruments are useful for documenting major losses of knowledge but

have limited value in assessing subtle or very temporally limited (e.g., days, weeks, or months) retrograde amnesias.

Memory disorders are sometimes simulated by patients, particularly when amnesia would result in financial or legal gain. In such cases, neuropsychological testing can be helpful in distinguishing real from feigned memory loss. Often patients feigning amnesia mimic psychogenic amnesia, as shown in movies and on television, and report a total retrograde amnesia without any anterograde amnesia. Such a condition has not been documented in patients with verifiable lesions, although it may occur legitimately in a psychiatric form. It is worthwhile to note that psychogenic retrograde amnesias are highly selective in terms of what is forgotten. Patients may forget their identity and personal history, but they often remember public events. This is exactly the opposite of lesion-induced retrograde amnesia in which patients remember their identity and forget personal and public experiences on the basis of temporal factors. One approach to distinguishing real from feigned anterograde memory loss is to administer easy multiple-choice recognition tests in which pseudoamnesic patients may perform less well than chance if they systematically avoid selecting the correct response. Another approach is the use of implicit memory tests that yield normal results in amnesic patients. Malingering subjects often perform poorly on these tests. Unaware of the findings that amnesic patients perform at normal levels, malingering subjects purposefully avoid using information presented earlier (Colorado Malingering Tests).¹³⁹

CLINICAL SYNDROMES OF MEMORY DYSFUNCTION (Table 5-3)

Dementia

Dementia refers to the loss of multiple acquired cognitive and emotional abilities sufficient to interfere with daily activities. It is defined by a behavioral syndrome and not by etiology or lesion location. Its onset is often insidious and its course is often progressive. Dementia is an age-associated syndrome that has a prevalence of 1 percent at age 60 and doubles every 5 years, becoming 30 to 50 percent by age 85.^[40] More than 50 diseases may produce dementia, but Alzheimer's disease is thought to account for

TABLE 5-3 -- SELECTED ETIOLOGIES ASSOCIATED WITH MEMORY DISORDERS

Etiological Category	Specific Etiologies	Chapter
STRUCTURAL DISORDERS		
Developmental disorders	Compensated hydrocephalus	28
HEREDITARY AND DEGENERATIVE DISORDERS		
Chromosomal abnormalities and neurocutaneous disorders	Consanguinity	32
Degenerative dementias	Alzheimer's disease, Pick's disease	33
Movement disorders	Parkinson's disease, Huntington's disease	34
ACQUIRED METABOLIC AND NUTRITIONAL DISORDERS		
Endogenous metabolic disorders	Hepatic encephalopathy, hypothyroidism, anoxia	38
Exogenous acquired metabolic disorders:	Anticholinergic intoxication	39
Toxins and illicit drugs	Lead intoxication	
Nutritional deficiencies and syndromes associated with alcoholism	Korsakoff's psychosis Alcoholic withdrawal	40
INFECTIOUS DISORDERS		
Viral infections	Herpes simplex encephalitis	41
Nonviral infections	Bacterial encephalitis Cerebral abscess, bacterial meningitis	42
Transmissible spongiform encephalopathies	Creutzfeldt-Jakob disease	43
HIV and AIDS	AIDS dementia complex	44
NEUROVASCULAR DISORDERS	Multi-infarct dementia Posterior cerebral artery occlusion	45
NEOPLASTIC DISORDERS		
Primary neurological tumors	Primary tumor (especially those involving the medial temporal lobe, fornix, or thalamus)	46
Metastatic neoplasms and paraneoplastic syndromes	Metastatic melanoma, paraneoplastic syndrome	47
DEMYELINATING DISORDERS		
Demyelinating disorders of the central nervous system	Multiple sclerosis, subcortical arteriosclerotic encephalopathy (Binswanger's disease)	48
TRAUMATIC DISORDERS	Traumatic head injury	51
EPILEPSY	Medial temporal lobe epilepsy	52
SLEEP DISORDERS	Insomnia, sleep apnea	54
DRUG-INDUCED AND IATROGENIC NEUROLOGICAL DISORDERS	Surgical lobectomy to treat medial temporal lobe epilepsy Electroconvulsive treatment Medications: analgesic, antihypertensive, anticholinergic, psychotropic, sedative	55

about 70 percent of dementia cases.^[41] The second main cause is multi-infarct or vascular dementia; it may account for 10 to 20 percent of dementias. Other causes of dementia, including treatable causes, are rare. Although they account for relatively smaller percentages of dementias, some neurological diseases inevitably (e.g., Huntington's disease) or frequently (e.g., Parkinson's disease) result in dementia. For diseases that are age associated, such as Parkinson's disease, it is difficult to know whether dementia reflects that disease per se or co-morbid Alzheimer's disease.

Dementia, unlike pure amnesia, has a virtually unlimited range of specific presentations that depend on which particular abilities are compromised. Disabilities may occur in memory, language, spatial perception, and cognition, attention, high-level motor control, emotion, and motivation. The breadth and diversity of presentation require the exclusion of other bases for widespread cognitive failure, including diminished arousal or wakefulness or an acute confusional state (e.g., drug intoxication). More circumscribed deficits, such as an aphasia or amnesia, must also be excluded. As discussed later for amnesia, focal damage to mental abilities like language or memory may appear superficially as a widespread disorder of cognition. For example, an aphasic individual could appear to fail in many areas of thought if he or she cannot adequately understand or respond to questions.

In patients with Alzheimer's disease, an impairment of declarative memory is typically the first sign. This is often manifested as forgetfulness in daily tasks, with appointments missed and possessions misplaced. The gradual progression of declarative memory failure is often noted when an individual fails to accomplish a habitual task, such as maintaining a checkbook, following a recipe, or following a route home. It may be noticed better by family members than by the patient, who is losing the very memory and other intellectual abilities needed to discern a decline in mental performance.

Two factors may obscure the declarative memory deficit. First, a mild degree of declarative memory difficulty is common in aging. Second, well-established knowledge and habits may continue to guide behavior and mask a declarative memory deficit for recent experiences and novel information. Remote memories appear intact relative to recent memories, but careful testing usually reveals a temporally extensive retrograde amnesia.^[42]

A second cortical dementing illness is Pick's disease or lobar cerebral atrophy.^[43] The clinical picture is similar to that seen with Alzheimer's disease, although neuroimaging studies may reveal a preferential atrophic process in the frontal or parietal lobes. In some cases, the memory problems and dementia occur in the context of deficits that suggest the preferential lobar involvement: personality changes, aphasia, and disinhibition typify Pick's disease patients with frontal lobe involvement, and apraxias are the prominent feature in those with parietal lesions.^[44] In many patients with Pick's disease, however, the deficits appear to be more global, and the patients are not specifically separable clinically from subjects with Alzheimer's disease.

In the later stages of Alzheimer's disease, the cognitive deficits become more pronounced and pervasive.^[45] The language deficit is severe in all aspects of production and comprehension. Patients lose their arithmetic skills. Spatial disorientation extends to simple everyday tasks such as dress. Patients forget how to use common objects and tools. Florid psychiatric symptoms occur, including delusions and visual hallucinations.^[46] Parkinsonian motor signs become more apparent and lead to

problems in locomotion. Finally, the patient lies in bed and must be fed and bathed. This progression occurs over a course of 5 or more years and often consists of alternating precipitous declines and plateaus of little apparent change. ^[47]

Cortical Versus Subcortical Dementing Syndromes

A distinction has been noted between the cortical dementia typically seen in Alzheimer's or Pick's disease and the subcortical dementia typified by Huntington's and Parkinson's disease but noted also in progressive supranuclear palsy, multiple sclerosis, Wilson's disease, and human immunodeficiency virus (HIV) infection. ^[48] Dementia seen in diseases with primarily subcortical neuropathology feature slowed movement (bradykinesia) and thought (bradyphrenia), disproportionate problems in the efficient use of memory, poor planning, judgment, and reasoning, and often affective changes.

The distinction is not absolute because most of these diseases are not limited to either cortical or subcortical regions, and therefore many patients exhibit elements of both kinds of dementia. Most of the differences between cortical and subcortical dementia are matters of degree and proportion rather than strict dichotomies. These characteristic differences in the patterns of dementias may be more distinct in the early, mild stages; the distinctions are less clear in later stages.

When measured formally, impairments in speed of mental processing, working memory, reasoning, and strategic memory (e.g., recall) are evident in nondemented patients with striatal diseases, including patients with early Parkinson's disease. ^[49] These deficits are highly intercorrelated, suggesting that they reflect a family of interacting memory processes mediated by frontostriatal neural circuits. In nondemented patients, these deficits may be circumscribed, and the patients perform normally on tests of immediate memory, semantic memory, nonstrategic declarative memory (recognition), and language. When dementia develops in a patient with a subcortical disease, problems in speed of mental processing, working memory, reasoning, and strategic memory then become disproportionately severe relative to other problems in language or memory. The disproportionate deficit in strategic memory may be contrasted with the more proportionate and global declarative memory deficits (e.g., recall and recognition) seen in persons with Alzheimer's disease or amnesia. In addition, demented patients with Parkinson's or Huntington's disease often have deficits in procedural forms of memory, motoric and nonmotoric, that remain intact in patients with Alzheimer's disease and amnesia. Thus, disproportionate impairments in speed of mental processing, working memory, reasoning, strategic memory, and procedural memory may reflect disproportionate damage to the frontostriatal regions in diseases that initially affect those brain regions.

Amnesia

Amnesia refers to a relatively circumscribed deficit in declarative memory that cannot be accounted for by impairments in attention, language, motivation, reasoning, or other nonmnemonic abilities. It is defined by a behavioral syndrome and not by etiology or lesion location. The severity of the deficit can vary considerably, but at a minimum it interferes with daily activities and quality of life. The purity of the deficit also varies because many patients have some degree of other cognitive difficulties as well. To the extent that those difficulties are mild and do not account for the memory deficit, a patient may be classified as amnesic. Otherwise, a patient may be better classified as demented, with memory being one of multiple deficits. The amnesia is described as global if it extends to both verbal and nonverbal information. The amnesic patient performs well on tests of attention, reasoning, and general information as long as the tests do not make demands on declarative memory.

Patients with pure amnesia have a pervasive impairment on tests of declarative memory. The anterograde amnesia extends to memory for all sorts of materials and events in all modalities. It is apparent in both easy and difficult tests of memory. The severity of amnesia varies considerably, however, so that a mildly amnesic patient could perform well on easy tests of memory. Because judgment is preserved in amnesic patients, they are usually aware of having a memory problem. They may, however, underestimate the severity of the problem because they are aware only of memory difficulties at the present moment and cannot remember the sorts of memory failures they experienced earlier.

Amnesic patients perform normally on tests of immediate memory, classic conditioning, skill learning (motoric, perceptual, and cognitive), and perceptual and conceptual repetition priming. ^[5] Declarative memory, however, is often invoked by tests that are not ostensibly memory tests. Many complex tests of cognition require some degree of declarative memory, if only to remember the instructions for the test. Other tests confound anterograde amnesia with general knowledge. For example, a patient who became amnesic in 1985 would not know the current president of the United States and other sorts of widely known information about events since 1985. For the same reason, a purely amnesic patient could even fail to answer some questions used to probe orientation, such as where the patient is at present. The amnesic patient would not remember the name or address of a hospital or medical building and would not know the day, month, or year because all of these facts are learned via declarative memory. For these reasons, intelligent amnesic patients may earn a poor score on a standard dementia rating scale. Pure amnesia is quite rare, so routine application of assessment measures may be misleading.

Amnesia by definition features an anterograde amnesia, and a retrograde loss of memories is frequently but variably present. The retrograde amnesia is typically temporally graded, with more recent memories being most vulnerable to amnesia and remote memories most likely to be spared. In general, the severity of anterograde and retrograde amnesias are correlated. If a lesion extends laterally from medial temporal lobe areas, it may injure temporal lobe regions that normally represent autobiographical knowledge. Such a lesion would exacerbate the retrograde amnesia and lead to a more extensive loss of acquired memories, even important ones from remote time periods.

Amnesic syndromes can occur in isolation or can be accompanied by other neurological signs. In patients with the Wernicke-Korsakoff syndrome (see [Chapter 40](#)), which is often associated with thiamine deficiency but also with head trauma, epilepsy, and anoxia, amnesia may develop in the context of ataxia and extraocular muscle pareses. An overall confusional state may be seen early in such cases, but the enduring learning and memory deficit is the most distinctive mental aberration of this syndrome. In such cases, the anatomical lesion should be sought in the diencephalon, medial temporal lobes, mamillary bodies, and connecting pathways of these regions regardless of etiology.

Pseudodementia

The term pseudodementia refers generically to treatable disorders that mimic dementia. The most common is depression. Depression and dementia can both lead to reduced motivation, impaired concentration, and mental slowing. Consequently, both diseases can lead to widespread cognitive and memory dysfunctions. Formal testing has shown that purely depressed patients perform better on declarative memory tests than genuinely demented patients, but this difference may be difficult to determine in particular patients. Because depression, with or without the co-occurrence of dementia, is treatable, it should be considered in any diagnostic evaluation. Some instruments, such as the Geriatric Depression Scale, may be useful in diagnosing depression in elderly individuals.

Transient Global Amnesia

Transient global amnesia is a relatively rare syndrome characterized by a sudden onset of severe anterograde amnesia and confusion that often includes repetitive questioning. Patients are often disoriented in regard to time and place but usually not personal identity. The confusion may simply reflect a response to the amnesia (e.g., if an amnesic patient asks what is wrong with his or her memory or what the date is, he will forget any answer provided within moments). The absence of such overt confusion and repetitive questioning in chronic amnesia patients may reflect an eventual accommodation of the patient to the amnesic state. Transient global amnesia typically lasts for hours, although its duration may range from minutes to days. Retrograde amnesia is also common, although its severity varies much more than that of anterograde amnesia. Retrograde amnesia is usually extensive and is temporally graded. As the anterograde amnesia gradually resolves, the temporal extent of the retrograde amnesia appears to shrink. After recovery, the patient retains an amnesia for the period of the transient global amnesia and often for a few hours preceding it. ^[50] Transient global amnesia is often associated with atherosclerotic disease, especially ischemia

in the posterior circulation, but seizure activity and migraine attacks have also been posited as a mechanism in some cases. In patients with this syndrome, an EEG may show abnormalities, although in most cases the findings are nonspecific. Attacks recur in less than 25 percent of patients, and fewer than 5 percent have more than three. The frequency of seizures or subsequent strokes is no different from that in a comparable age-matched population. No special treatment is indicated for these unusual cases of transient but traumatic memory impairment.

GENERAL MANAGEMENT GOALS

The first goal is to diagnose any treatable memory problems. These include cases in which the problem is secondary to a treatable illness, such as depression or a systemic disease. Memory problems arising from medications may be treated by discontinuing any unneeded medications or considering alternative medications for needed treatments.

For untreatable causes of memory disorders, the main goal is to establish a framework for the care of patients who are or will be unable to take care of themselves. Informing the patient involves judgment about what information is useful to the patient. On the one hand, it is desirable to have the patient feel that he or she is at the center of the management goals. On the other hand, patients with severe memory disorders remember little of what is told to them, and discussions may produce distress for the patient with no benefit.

A primary consideration is the safety and security of the patient. Patients with dementia or pure amnesia have a limited ability to take care of themselves. Patients should be protected, therefore, from taking actions that may cause injury to themselves and others and for which they can no longer be held responsible. If a patient is still working, a plan for retirement should be initiated. A plan for the daily supervision of the patient should be developed that takes into account the present mental status of the patient and the resources of the family. It is usually advantageous, when possible, for the patient to sustain habits of daily activities in a familiar environment because these habits rely on abilities that are the last to decline. Supervision of the patient must be considered in terms of medical care, diet, medications, and daily activities. A common and difficult problem is determining when certain activities, particularly driving, become potentially dangerous. Legal issues, such as conservatorships, often arise at some stage of the disease. The nature of these issues varies a great deal between patients with chronic amnesia, in which the patient's judgment may remain intact, and those with dementia, in which judgment typically declines considerably. In both cases, however, patients cannot be responsible for or take care of themselves. For those with progressive diseases, however, hospitalization is inevitable.

Information given to family members is critical in several respects. First, they have to understand what the patients can and cannot do for themselves. This is important not only for practical reasons but also because uninformed family members may misinterpret the actions of a memory-impaired patient as reflecting poor motivation or judgment. Therefore, family members must have as clear a picture as possible about the patient's abilities and disabilities.

Important information includes whether the memory impairment is chronic and whether it is likely to improve or become worse. It is useful for family members to understand whether the memory disorder is global or limited. It is also important for them to understand how pervasive a declarative memory disorder can be because few people appreciate how memory constantly supports the activities of daily living, including the taking of medications, preparing or eating meals, paying bills, and so on. Often, patients and family members are surprised by the contrast between anterograde amnesia and relative preservation of memory for remote periods. The severity and purity of the memory disorder dictate whether the patient can provide some degree of compensation in daily life. For example, patients with mild or moderate amnesias and without other major cognitive deficits can use notes or computers, especially small portable computers, to keep a useful record of goals and appointments. Even in these cases, however, frequent supervision is needed because important information may be ignored. Patients with severe amnesia or substantial additional cognitive deficits often cannot use such external memory devices effectively because they cannot even remember to use the devices.

It is also helpful to remind family members that memory-disordered patients retain many of their intellectual and emotional capacities and therefore need to have an active, regular schedule. Even patients with substantial memory or cognitive problems can slowly adapt to a regular, well-structured schedule. It is good to maintain a relatively normal sleep-wake cycle that ensures a good rest at night. This may require efforts to keep the patient awake during the day. Medications may be required to sustain a healthy sleep-wake cycle. Conversely, unexpected events can be exceptionally distressing to patients who cannot cope with novel circumstances.

In many respects, the diagnosis of dementia or chronic amnesia is as devastating to family members as to the patients. Family members face a long and difficult personal path in terms of emotional, financial, and often legal issues. This burden falls on the very shoulders of those who must now take exceptional responsibility for the care of their spouse, parent, or sibling. It is not uncommon for them to have strong feelings of denial, guilt, or blame. These feelings may not only affect the family members but also compromise the supervision of the patient. It is important to monitor the mental health of family members and to encourage the use of appropriate resources, including social services and support groups.

Finally, medical care for the memory-disordered patient must be maintained. For example, a number of diseases that lead to memory disorders also lead to seizures that must be treated. Medical supervision is challenging because amnesic patients are often unable to provide any useful history, and demented patients may be unable to answer even simple questions about their present condition.

HISTORY AND DEFINITIONS

A wide variety of language disorders has been noted for many centuries before the more recent interest in aphasia study. The formal delineation of aphasia as presently recognized dates from 1861. In the early nineteenth century, similarly to other brain functions, language was considered to be subserved by a specific area in the brain. Opponents of this localization approach considered mental function to be a product of the entire brain working as a unit. In 1861, Paul Broca presented to the French Society of Anthropology a case of a patient who became speechless and then died. Postmortem studies revealed a large frontal lesion supporting the localization viewpoint. After this case, multiple clinicopathological studies were reported, confirming Broca's finding and lateralizing language function to the left hemisphere. In 1874, Karl Wernicke distinguished two types of aphasia, motor and sensory, which were clinically and anatomopathologically separable. He also postulated the existence of a conduction aphasia based on a theoretical diagram linking the sensory and motor components of language. Technological advancements, including neuroimaging techniques and more standardized aphasia batteries, have helped considerably in assessing patients with language disorders and in elucidating the intricate subsystems subserving language function.

Speech is the ability to vocalize by coordinating the muscles controlling the vocal apparatus. It is the mechanical aspect of oral communication. Speech disorders are termed dysarthria, a disturbance in articulation, or dysphonia, a disturbance in vocalization or phonation. Patients with dysarthria or dysphonia retain their language ability despite their speech disturbance.

Language is the cognitive aspect of symbolic communication.

It is the ability to converse, comprehend, repeat, read, and write. Language ability depends on central processing for either comprehension or formulation for expression the sounds and symbols of propositional communication. Language disorders are termed aphasias, and involve language disturbances in comprehension, production, or both.

This chapter reviews clinical syndromes of both speech and language disorders. An overview of anatomy and physiology of speech and language is a first step toward understanding the pathophysiology underlying these disorders. Examination of speech and language disorders is emphasized and forms the basis for diagnosis, lesion localization, and treatment.

CLINICAL HISTORY

Clinical history is critical for speech and language assessment. Information from relatives, friends, or witnesses is often necessary owing to the patient's decreased ability to communicate. History taking should include the following components.

Temporal development of symptoms provides valuable information on the underlying pathophysiological process. An acute impairment of speech output indicates a possible underlying vascular, infectious, inflammatory, or traumatic pathology. A chronic and progressive course of symptoms is more suspicious for a degenerative or neoplastic process.

Description of the symptom is important in characterizing and differentiating speech and language disorders. Difficulty in articulation or vocalization implies a speech disorder, whereas the inability to find words, comprehend, read, or write is indicative of a language disorder. Differentiation of speech and language disorders has important localizing value for the underlying pathology within the nervous system and helps distinguish among different etiological processes.

Associated features should be sought. The presence of other neurological symptoms may help in localization of the pathological process or in discovering the etiology of the disorder. For example, a patient who complains of progressive headaches, decreased level of consciousness, and weakness in the right upper extremity associated with language difficulties most likely has a left frontal expanding, neoplastic lesion.

Handedness should always be assessed. The left hemisphere is the dominant hemisphere for language for almost all right-handed adults and for many left-handed adults. This information has crucial significance for localization of the underlying disturbance.

Associated intercurrent or past medical illnesses are important clues to the underlying etiology of speech and language disorders. Vascular risk factors such as hypertension, diabetes, or evidence of atherosclerotic disease, including previous strokes or myocardial infarctions and smoking, should be assessed. A history of infection, trauma, alcohol or drug abuse, and malignancy may also be important.

Past psychiatric history should be reviewed. Psychiatric conditions such as schizophrenia, bipolar illness and conversion disorders may present with speech and language symptoms closely mimicking a neurological syndrome.

Other important components of clinical history include *developmental and educational background, and family history*. It is crucial to know the patient's previous language abilities including reading, writing, and the presence of a known developmental delay. This information may help distinguish a developmental disorder from an acquired disorder.

ANATOMY OF SPEECH AND LANGUAGE

Anatomy of Speech (Normal Phonation and Articulation)

Normal speech involves a highly coordinated sequence of contractions of the respiratory musculature, larynx, pharynx, tongue, and lips. These muscles are innervated by the facial, vagal, hypoglossal (reviewed in [Chapters 11](#), [13](#), and [14](#)), and phrenic nerves. The nuclei of these nerves are controlled by the motor cortices through the corticobulbar tracts. Coordination of the movements of the articulatory structures requires simultaneous and coordinated activation of these cranial nerves, not only by direct cortical motor activation but also by indirect involvement of the basal ganglia and cerebellum. The basal ganglia and the cerebellum are also important participants in producing the prosodic aspects of speech, including pitch or frequency, stress or the differential emphasis placed on syllables, and rhythm or timing.

Thus, pathology affecting speech could be located at several sites within the motor systems. Speech is impaired when any of the following structures are damaged or dysfunctional: motor cortex and its outflow tracts, cerebellum, basal ganglia, brain stem, peripheral portions of cranial nerves controlling the speech apparatus, and target speech musculature, including facial muscles, pharynx, palate, tongue, vocal cords, diaphragm, and intercostal muscles.

Anatomy of Language

OVERVIEW

Language processes are lateralized to the left hemisphere. This has been determined through anatomoclinical correlation in patients with language disturbances and associated brain pathology. It has also been demonstrated by electrical stimulation and seizure activity in the left hemisphere, as well as injection of sodium amytal in the left internal carotid, all causing language disturbances and speech arrest. Increased cerebral blood flow to the left hemisphere during language processing also confirms this lateralized brain function. In addition, there are anatomical differences between the left and right hemispheres. The planum temporale, the region on the superior surface of the temporal lobe posterior to Heschl's gyrus and extending to the posterior end of the sylvian fissure, is slightly larger on the left which is consistent with Wernicke's area. ^[1] Computerized

tomography (CT) has shown the left occipital lobe to be longer than the right.

Approximately 90 percent of the general population are right-handed. ^[2] They prefer using their right hand for most motor activities, especially skillful tasks. Approximately 99 percent of right-handed individuals have language functions in the left hemisphere. There is a tendency for left-handed and ambidextrous individuals to have varying degrees of bilateral representation of language and visuospatial functions. ^[3] Left-handers are more likely to become aphasic because of the bilateral representation, but their aphasia tends to be milder and more brief than that of right-handers. ^[4] Specific cortical areas in the left hemisphere subserve distinct language functions. For example, the production or comprehension of a word requires serial and parallel processing of information through cortical and possibly subcortical circuits (Fig. 6-1 (Figure Not Available)).

SPEECH COMPREHENSION AND PRODUCTION

Speech comprehension and production are complex processes. Words first reach the peripheral auditory apparatus, which transforms the mechanical input from the tympanic membrane into electrical impulses that travel to the brain stem cochlear nucleus, then to the medial geniculate nucleus of the thalamus via the trapezoid body and lateral lemniscus, finally reaching the primary auditory cortex (Heschl's gyrus) in the superior temporal gyrus. The auditory language content undergoes preliminary decoding in the auditory association cortex, Wernicke's area (Brodmann's area 22) located in the posterior third of the left superior temporal gyrus (see Fig. 6-1 (Figure Not Available)). The sounds undergo further processing in the heteromodal association cortex, the angular gyrus, to provide the semantics (the meaning) and relate it to other incoming words, other sensory modalities, and past experiences. If the words are to be repeated, the auditory information is transmitted forward to Broca's area without necessarily passing through the angular gyrus. This information travels from Wernicke's area to the motor association cortex, Broca's area (Brodmann's area 44, 45 located in the posterior part of the inferior left frontal convolution), through the arcuate fasciculus, a band of white matter deep to the supramarginal gyrus connecting both language areas. Broca's area initiates a motor plan that is transmitted to the primary

Figure 6-1 (Figure Not Available) Primary language areas of the brain (From Mayeux R: Disorders of language: The aphasias. In Kandel ER, Schwartz JH (eds): Principles of Neural Science, 3rd ed. New York, Elsevier, 1991.)

motor cortex (Brodmann's area 4) to pronounce the words. The motor cortex, in coordination with the supplementary motor area, basal ganglia, and cerebellum, sends corticobulbar fibers to implement speech sounds. ([Figure 6-2](#) illustrates the four principal areas involved in comprehension of spoken language.)

READING AND WRITING

Reading depends on visual stimuli (written words) reaching the primary visual cortex (Brodmann's area 17). The visual stimuli are then transmitted from the primary visual cortex, where they are decoded, to the visual association cortex, or unimodal association cortex, to be processed into words. The words are further processed in the heteromodal association cortex, the angular gyrus, for semantic meaning and integration with other sensory modalities and passed experiences. If the words are to be read aloud, then the information is transmitted forward from the visual association cortex to Broca's area through the arcuate fasciculus, without necessarily passing through the angular gyrus. From Broca's area they are spoken using the same circuits as described earlier. A clinically pertinent fact is that visual information from the right visual cortex must travel through the posterior part of the corpus callosum to be further processed and read in the language regions of the left hemisphere.

Writing requires the transfer of language information possibly to the motor association cortex superior to Broca's area and then to motor neurons in the primary motor cortex (Brodmann's area 4), projecting to the arm and hand. Writing to dictation involves the transfer of auditory information from Wernicke's area to the anterior motor areas; copying written material involves transfer of information from visual association cortex to the anterior motor areas for execution. Visuospatial input is also important in the orientation of written language.

Figure 6-2 Artist's rendition of the four areas involved in comprehension of spoken language. R = receptive area (Heschl's gyrus); P = perceptive area (auditory association cortex); SE = semantic interpretation area (angular gyrus); SY = syntactical interpretation area (Broca's area) (From Benson DF, Ardila A: Aphasia: A Clinical Perspective. New York, Oxford University Press, 1996.)

Anatomy of the Affective Elements of Speech and Language

The right hemisphere has a dominant role in processing the emotional prosodic aspects of communication. ^[5] Expression of emotional intonation in speech, facial expressions, and use of gestures are functions of the right frontal opercular area or its corrections (the right hemisphere's equivalent of Broca's area). ^[6] The ability to perceive the affective content of language is also considered to be a function of the right hemisphere.

Other Left Hemisphere Cortical and Subcortical Structures

In addition to the known left hemisphere cortical functions in language processing, other structures, including the insula, striatum, thalamus, and subcortical white matter, are involved in language function. The striatum is involved in speech output and prosody; the thalamus is important for cortical arousal and language comprehension. The subcortical white matter interconnects language areas.

EXAMINATION OF SPEECH AND LANGUAGE

Directed Neurological Examination

Speech. The examination of speech includes the assessment of speech volume, rate, articulation, prosody, and initiation.^{[7], [8]} Each component of speech can be affected differently in various disorders. The examiner should assess speech through spontaneous conversation or by having the patient read a standardized passage to elicit a wide range of sounds including labials, linguals, dentals, and gutturals.

Speech volume may be increased with auditory perceptual problems. Reduced volume (hypophonia) is seen in extrapyramidal motor disorders and in peripheral disorders such as vocal cord paresis.

The *rate of speech* may be increased in Parkinson's disease, in which patients speak rapidly, and in patients with Wernicke's aphasia, who have pressured speech. In general, nonfluent aphasics speak slowly.

Articulation defect is a sign of motor impairment. Dysarthric speech often results in stereotyped speech errors, that is, repeating the same errors when trying to produce certain sounds. This helps distinguish dysarthric speech from paraphasic speech, in which substituted letters occur in a variable pattern.

Prosody evaluation includes assessment of the inflection, prosodic matching of sentence structure (declarative sentence, questions, boundaries between clauses), assessment of affective intent, and assessment of pragmatic intent (humor, declarative, sarcastic, defensive). Speech inflection and prosodic matching of sentence structure are mediated by the left hemisphere, whereas affective intent is mediated by right hemisphere and basal ganglia functions.

Timing of speech initiation is related to supplementary

motor area function and its outflow.^{[9], [10]} Patients with severe latencies do not speak at all (mutism).

Laryngeal phonation, or breathiness, and resonance, or nasality, are two other qualities of speech that aid in localization.

Language. The six main parts of the language examination can be performed at the patient's bedside. These parts include (1) expressive speech, (2) comprehension of spoken language, (3) repetition, (4) naming, (5) reading, and (6) writing.^{[11], [12], [13]} The examiner can classify most aphasic syndromes after evaluating spontaneous speech, repetition, and comprehension ([Fig. 6-3](#)).

Expressive Speech. The evaluation of aphasia traditionally begins by observing the spontaneous or conversational speech of the patient. Aphasic verbal output is either nonfluent or fluent. Normal English output is 100 to 150 words per minute.^[14] Nonfluent aphasic output is sparse (under 50 words per minute), produced with considerable effort, poorly articulated, of short phrase length (often only a single word), and dysprosodic (abnormal rhythm), and features a preferential use of substantive meaningful words with a relative absence of functor words (prepositions, articles, adverbs). Fluent aphasic output is the opposite, featuring many words, easily produced, with normal phrase length and prosodic quality but often omitting semantically significant words. Fluent aphasia, when severe, may sound empty and devoid of content. In addition, paraphasic errors (substitution of phrases or words) are often abundant in fluent aphasic output. Nonfluent aphasic output is associated with pathology involving the anterior left hemisphere,^{[15], [16]} and fluent aphasia results from pathology posterior to the fissure of Rolando.

Comprehension of Spoken Language. Comprehension can be assessed in many ways^[17]; four examples of clinical evaluations of comprehension include (1) *conversation*--engaging the patient in ordinary conversation probes the patient's ability to understand questions and commands; (2) *commands*--a series of single or multistep commands, such as asking the patient to pick up a piece of paper, fold it in two, and place it on a bedside stand; (3) *yes and no answers*--require only elementary motor function and can be used to assess various comprehension levels (for example, are the lights on in this room?); and (4) *pointing*--requires a limited motor response (patients can be asked to point to the window, the door, and the ceiling; the patients are asked to point to these places in a specific sequence, and more difficult tasks also can be given [e.g., point to the source of illumination in this room]).

Despite all of these methods, comprehension remains difficult to assess. Patients may derive significant meaning from nonverbal cues (e.g., tone of voice, facial or arm gesture) and may lead the clinician to underestimate the comprehension deficit. Apraxia and other motor disorders may cause a failure to perform, leading to an overestimation of the deficits. Perseverative answers may further complicate comprehension assessment.

Repetition. The examiner tests repetition by requesting that the patient repeat digits, words, and sentences. A phrase like "no ifs, ands, or buts" poses special difficulty.^[12] Aphasics with impaired repetition have pathology that involves the perisylvian region. In contrast, a strong, often mandatory tendency to repeat (echolalia) suggests an extrasylvian locus of pathology, often involving the vascular borderzone areas.

Figure 6-3 Algorithm for demonstration of aphasia syndromes.

Naming. Disturbances in confrontational naming are the least specific language abnormalities. Naming is disturbed in most aphasic patients. Testing should evaluate the patient's ability to name objects (both high and low frequency), body parts, colors, and geometrical figures. If the patient fails, the examiner provides a phonemic cue (such as pronouncing the initial phoneme of the word) or a semantic cue (such as "You write with a _____."). Anomia is generally not a reliable localizing abnormality.^[18]

Reading. The examination tests both reading aloud and reading for comprehension.

Writing. Writing is nearly always disturbed in aphasic patients. Writing provides a further sample of expressive language and permits evaluation of spelling, syntax, visuospatial layout, and mechanics. The examiner assesses writing to dictation and to command (e.g., describe your job), as well as copying.

Additional Neurological Findings

Cerebral. Many portions of the cerebral examination are of considerable value in helping localize lesions associated with speech and language disorders.

When speech alterations are due to bilateral involvement of corticobulbar tracts, a special type of affect is observed in which the patient experiences emotional incontinence (spasmodic crying and laughing). This is part of the pseudobulbar syndrome, which is described in the next section. These patients typically also have evidence of psychomotor slowing.

Language disturbances can be associated with other types of cognitive dysfunction, such as impaired memory, abstraction, visuospatial function, and praxis, as well as changes in personality (decreased inhibition), irritability, apathy, and agitation, which may indicate the presence of widespread dysfunction such as that encountered in degenerative dementing diseases. Evaluation for apraxia (which is defined as failure to carry out a maneuver on command, excluding any primary motor, sensory, or comprehension disorder) is important because ideomotor and buccofacial apraxia are often associated with nonfluent aphasias and conduction aphasia.

Cranial Nerves. Speech disorders could be associated with lower motor neuron pathology including abnormalities of the neuromuscular junction. Therefore, it is important to search for any weakness, atrophy, and fasciculation in the facial musculature, the tongue, and the palate. Also, the cranial nerves must be assessed. Ptosis, ophthalmoplegia, and fatigability should be observed and tested. The gag reflex should be examined because it may be depressed in dysarthria of the lower

motor neuron type and increased in dysarthria of the upper motor neuron type. A masked or inexpressive face and decreased blinking may be clues to the presence of an extrapyramidal cause of dysarthria.

Right homonymous hemianopia or quadrantanopia is helpful in localizing the site of pathology associated with language disorders. Anterior aphasias have little or no involvement of the visual fields compared with more posterior aphasic syndromes. The cranial nerves should also be assessed for the presence of a central type of facial muscle weakness on the right side. Occasionally, patients with acute onset of anterior aphasia have a conjugate gaze deviation to the left (see [Chapter 1](#)).

Motor/Reflex Cerebellar/Gait. Speech abnormalities in the presence of a significant spastic paralysis involving the entire side of the body suggest a deep-lying lesion involving the contralateral internal capsule. This type of lesion typically gives rise to spastic speech. When weakness is bilateral or unilateral but is associated with cranial nerve deficits on the opposite side, a brain stem lesion is suspected. Dysarthria associated with this type of insult is either flaccid or spastic, depending on the involvement of either the motor nuclei controlling the speech apparatus or their supranuclear pathways. Bradykinesia, rigidity, resting tremor, chorea, and dystonia are all signs suggestive of extrapyramidal disease and are usually associated with hypokinetic or hyperkinetic dysarthrias. Upper motor neuron signs including spasticity and hyper-reflexia should be sought as well as lower motor neuron signs including atrophy, fasciculation, and hyporeflexia and areflexia. These signs are helpful in distinguishing lesions producing spastic dysarthria from those causing flaccid dysarthria. Cerebellar findings include ataxia, dysmetria on finger-to-nose and heel-to-shin testing as well as gaze-evoked nystagmus, dysmetric saccades, and rebound nystagmus. These findings are often associated with ataxic dysarthria.

Weakness involving only one limb with or without facial weakness is most suggestive of cortical pathology. Brachiofacial involvement suggests infarction of the territory of the middle cerebral artery and is usually associated with perisylvian aphasias; crural weakness without involvement of the arm and face suggests infarction in the territory of the anterior cerebral artery and is usually associated with transcortical motor aphasia. Greater weakness of proximal musculature in contrast to distal musculature is suggestive of involvement in the border zone vascular areas and can be associated with extrasylvian aphasias (transcortical aphasias). Testing for ideomotor apraxia is helpful to localize pathology further within the left hemisphere. Language disturbances are not usually associated with cerebellar disease.

Sensory. Intact perception of light touch and proprioception with impaired sensation of pain and temperature occurring in an alternate pattern affecting one side of the face and the opposite side of the body helps localize pathology to the lateral brain stem. This type of lesion could also affect lower cranial nerves such as cranial nerves IX and X and create a flaccid dysarthria.

Cortical sensory loss (astereognosia, impaired two-point discrimination, agraphesthesia) indicates involvement of the parietal cortex and can be associated with more posterior aphasia-producing lesions. Pseudothalamic pain that begins months after the onset of the sensory abnormality is seen after lesions affecting the white matter just deep to the supramarginal gyrus and can be associated with conduction aphasia. ^[11]

Neurovascular. The presence of significant bilateral vascular bruits on neurovascular examination is an important risk factor for stroke. Stroke patients could present with spastic dysarthria or pseudobulbar palsy secondary to single or multiple cerebral infarcts, respectively.

As for speech disorders, abnormal neurovascular examination suggests the presence of cerebrovascular disease. Multiple language disturbances and syndromes are caused by strokes. Transcortical aphasia occurs following watershed zone infarction in patients with severe carotid stenosis during a hypotensive episode.

EVALUATION GUIDELINES ([Table 6-1](#))

Speech and language disturbances are assessed by clinical history, bedside speech and language assessment, and neurological examination. Complementary investigations, such as neuroimaging, electrophysiology, fluid and tissue analysis, neuropsychological testing and other tests help confirm the clinical diagnosis.

Neuroimaging. Several techniques are extremely helpful for localizing and identifying various types of pathologies underlying a speech or language disturbance, or both. With the advent of CT and magnetic resonance imaging (MRI), the improved visualization of subcortical structures have implicated these regions in a growing number of speech and language disorders. Investigators have used positron emission tomography (PET) and single photon emission computed tomography (SPECT) to investigate aphasia and the anatomy of language. The studies have largely confirmed lesion-derived conclusions about the anatomy of language described earlier.^[19]

Electrophysiology. Electroencephalography (EEG) measures one parameter of brain function and can help in the localization of pathology. Repetitive magnetic stimulation has been used to localize lesions within the language dominant hemisphere.^[20] Electromyography (EMG) and nerve conduction studies could assist in the diagnosis of peripheral causes of speech disorders, including motor neuron disease, and disorders of the neuromuscular junction.

Cerebrospinal Fluid. Lumbar puncture, blood and urine analysis, as well as more invasive procedures such as brain biopsy may be performed to confirm a diagnosis and help in the treatment of the underlying pathology, particularly in patients with inflammatory or infectious disorders.

Neuropsychological Tests. Numerous tests provide valuable information about cognitive function, particularly in patients suspected of having a degenerative disease underlying their language disturbance. Severe aphasia makes it impossible to perform meaningful neuropsychological assessment.

Other Tests. Of additional value, laryngoscopy (direct and indirect) and diaphragmatic fluoroscopy can be helpful in the diagnosis of peripheral causes of speech disorders.

[PreviousNext](#)

CLINICAL SYNDROMES

A discussion of speech disorders, including dysphonias, dysarthrias, and speech-related disorders is followed by a discussion of language disorders, including aphasia, alexias, and agraphias, and language-related disorders. [Tables 6-2](#) and [6-3](#) outline the classification of speech and language disorders. This classification is meant to help in localizing various clinical syndromes according to current information regarding anatomoclinical correlations. Some entities could be classified in several subcategories, but they have been categorized under the most probable anatomical localization. Future research will help refine the classification. Three major speech disturbances are recognized: dysphonias, dysarthrias, and other speech-related disturbances. ^[21]

Dysphonia

Dysphonia is the inability to vocalize (loss of voice) due to a disorder of the larynx or its innervation. Dysphonic patients have a breathy sound resulting from abnormal apposition of the vocal cords.

VOCAL CORD DYSFUNCTION OR PARALYSIS

Laryngitis is the most common cause of decreased voice volume, but laryngeal hypophonia may be based on other causes such as damage to the superior laryngeal nerve, nodules or polyps of the larynx or vocal cords, or carcinoma involving the larynx. Muscle paralysis or fatigability can produce hypophonia, which is produced after excessive speaking. When a patient presents with variable hypophonia and/or dysarthria, a disorder of the neuromuscular junction should be sought. Dysphonia should lead to an investigation of laryngeal disease, either primary or secondary to an abnormality of innervation.

SPASMODIC DYSPHONIA

Spasmodic dysphonia is a segmental dystonia and is usually nonprogressive. This unusual syndrome occurs in middle aged or elderly individuals. Spasmodic dysphonia involves dystonic spasms of the laryngeal muscles. In the most common form, the adductor type, the voice will be strained, high-pitched, and commonly punctuated by repetitive brief interruptions of speech. Singing, whispering, or changing the voice's pitch may sometimes help lessen the spasms. Less commonly, the voice has a whispering, breathy quality, due to abduction spasms of the vocal cords.

Dysarthria

Dysarthria is the inability to form or produce understandable speech due to lack of motor control over peripheral

TABLE 6-1 -- USEFUL STUDIES IN THE EVALUATION OF SPEECH AND LANGUAGE DISORDERS

Disorder	Neuroimaging	Electrophysiology	Fluid and Tissue Analysis	Neuropsychology Tests	Other Tests
DYSPHONIA					
Muscle paralysis or fatigability	Mass lesion compressing the tenth cranial nerve, or on the vocal cords	Abnormal decrement of CMAP with repetitive stimulation in myasthenia gravis. Single-fiber EMG showing jitter in NMJ defects	Carcinoma of the vocal cords, carcinomatous meningitis	Normal language and cognitive function	Vocal cord pathology visualized by direct or indirect laryngoscopy
DYSARTHRIA					
Spastic dysarthria	Multiple subcortical white matter disease	Prolonged sensory and visual evoked potentials in multiple sclerosis	Oligoclonal bands in CSF in multiple sclerosis	Pseudobulbar affect, psychomotor slowing, retrieval memory deficit	
Flaccid dysarthria	Brain stem lesion, atrophy, or normal	Fibrillation, fasciculation and neurogenic recruitment on EMG testing, prolonged latencies	Increased protein in CSF with Guillain-Barre syndrome, carcinomatous meningitis	Normal language and cognitive function	
Ataxia dysarthria	Atrophy of cerebellum, stroke or cerebellar tumor	Decreased CMAP, SNAP in axonal polyneuropathy secondary to alcohol. CMAP potentiation with Eaton-Lambert syndrome	Increased CSF protein, anti-Purkinje cell antibodies, vitamin E deficiency	Normal language	Prolonged latencies of evoked potentials in multiple sclerosis
Extrapyramidal dysarthria	Stroke in basal ganglia atrophy of the caudate			Mild cognitive decline, psychomotor slowing	
APHASIA					
Perisylvian aphasia	Stroke, tumor, abscess in pensylvian area	Slowing over the frontoparieto-temporal region on EEG	Increased cholesterol, anticardiolipid antibodies	Decreased verbal memory	Holter and echocardiogram to rule out embolic causes of stroke, chest x-ray study
Extrasylvian aphasia (transcortical)	Stroke in border zone vascular territory	Slowing over the left hemisphere on EEG			Doppler study of the carotids to rule out occlusion
Subcortical	Stroke in striatocapsular region or thalamus			Psychomotor slowing and possible decreased verbal memory	
Nonlocalizing (anomic)	Generalized atrophy or left hemisphere lesion	Slowing over the temporal lobes over the left hemisphere on EEG	Plaques and tangles or spongiform changes on brain biopsy	Prominent cognitive deficits visuospatial, praxis, memory	Apolipoprotein E
OTHER DISORDERS					
Alexia without agraphia	(L) Occipital infarct involving the splenum of the corpus callosum	EEG slowing over the (L) occipital cortex			
Alexia with agraphia	Generalized atrophy or focal infarct in left parietotemporal junction	(L) Centrottemporal slowing on EEG		Associated Gerstmann's syndrome plus anomia constitutes the angular gyrus syndrome	
Reiterative speech	Border zone vascular infarct or generalized atrophy	(L) hemisphere slowing on EEG	Plaques and tangles or spongiform changes on brain biopsy	Multiple cognitive deficits when there is underlying degenerative disorder	

Delirium	Usually normal or generalized atrophy	Abnormal chemistry panel, urine culture, positive hemoculture, abnormal liver or renal function		Multiple cognitive deficits
Psychiatric disease	Normal	Normal	Normal	Bizarre thought content, flight of ideas, grandiosity, word salad

CMAP, Compound muscle action potential; CSF, cerebrospinal fluid EEG, electroencephalogram; EMG, electromyogram; NMJ, neuromuscular junction; SNAP, sensory nerve action potential.

speech organs. Defects in articulation may be subdivided into several types: flaccid, spastic, ataxic, hypo/hyperkinetic, and mixed.

FLACCID DYSARTHRIA

Flaccid dysarthria is also called lower motor neuron dysarthria or bulbar paralysis. This is due to disease affecting motor neurons in the medulla and lower pons or their intramedullary or peripheral extensions. Speech becomes slurred and progressively less distinct. There is special difficulty in the enunciation of vibrative letters such as "R"; lingual and labial consonants may become impossible with advancing paralysis. Speech has a nasal quality with bilateral paralysis of the palate as may be seen with diphtheria and poliomyelitis and in progressive bulbar palsy. The voice may have a raspy quality because of vocal cord paralysis. Facial diplegia as in Guillain-Barre(c) syndrome affects the

lips and impairs enunciation of labial consonants (B, M, P). Neurological examination may reveal atrophy and fasciculations of the tongue and weakness of the palate and the facial muscles. When a history of variable dysarthria or dysphonia, with prominent fatigability is elicited, a neuromuscular junction disorder such as myasthenia gravis may be present.

SPASTIC DYSARTHRIA

Spastic dysarthria is also called upper motor neuron dysarthria. It is a motor speech problem characterized by a harsh, low-pitched, slow, monotonous verbal output that sounds strained or strangled. This is the speech that characterizes pseudobulbar palsy (bilateral involvement of corticobulbar tracts) and, to a lesser degree, may

be present following significant unilateral upper motor neuron disturbance. Spastic dysarthria may occur with nonfluent aphasia, particularly Broca's aphasia.

MUTISM

Mutism is the total loss of speech and is discussed here because the underlying pathology most often involves the upper motor neurons. Several diseases and various sites of pathology can produce mutism. Peripheral disorders such as laryngitis or vocal cord paralysis occasionally can cause a mute state. Patients with aphemia (described later), global aphasia, transcortical motor aphasia, and aphasia with subcortical lesions frequently present with initial mutism. Persistent mutism is associated with bihemispheric involvement, particularly of the frontal lobes.^[22],^[23] Tissue destruction or dysfunction affecting the upper brain stem or the frontal septal area bilaterally, or both, can interfere with the initiation of both behavior and verbal output. When it is severe, this state is called akinetic mutism.^[24] Mutism can also be of psychogenic origin.

ATAXIC DYSARTHRIA

Ataxic dysarthria is manifested by slowness of speech, altered rhythm, irregular breakdowns, and improper stress, producing an uneven, jumpy, and unpredictable output. Coordination of speech and of respiration is disturbed. There may not be enough breath to utter certain words or syllables, and others are expressed with greater strength than intended (explosive speech). This speech disorder is most commonly encountered with acute and chronic cerebellar disease.

Scanning speech is part of Charcot's triad (ataxia, nystagmus, scanning speech), which is historically considered to be pathognomonic for multiple sclerosis, but it is more common with head injuries. Scanning speech is characterized as a slow, deliberate, segmented, and monotonous output, presented as individual words or major segments of words. The output retains both grammatical and semantic competence, and articulation remains relatively normal. It is the prosodic quality, particularly of the rhythm and inflection, that are disrupted. The major pathology underlying

this disorder is located at the level of the decussation of the brachium conjunctivum in the mesencephalon affecting crossed efferent cerebellar pathways and motor fibers in the cerebral peduncles, which lie in close proximity.^[25] Although scanning speech is easily misinterpreted as a nonfluent aphasia, careful evaluation reveals that there is no true language impairment.

HYPOKINETIC AND HYPERKINETIC DYSARTHRIA

Extrapyramidal disease is often associated with either hypokinetic or hyperkinetic dysarthria. Hypokinetic dysarthria occurs in Parkinson's disease and other rigid types of extrapyramidal disorders. This speech abnormality is characterized by rapid utterances, slurring of words, and decrescendo volume at the ends of sentences. The voice is low pitched and monotonous, lacking both inflection and volume (hypokinetic and hypophonic). In advanced states only whispering is possible.

Two varieties of speech disorders can be classified as hyperkinetic. The first, *choreiform dysarthria*, features prolonged phoneme and sentence segments, intermixed with silences and showing variable, often improper, stress (phoneme inflections). This gives speech a bursting quality. This speech output occurs in choreiform disorders such as Huntington's disease and in myoclonic disorders. The second type, *dystonic dysarthria*, produces a slower speaking rate, with prolongation of the individual phonemes and segments and with abnormal, unexpected appearances of stress or of silence. Dystonic dysarthria occurs in dystonia musculorum deformans. Spastic dysphonia is one type of dystonic dysarthria.

MIXED DYSARTHRIAS

In clinical practice, a mixed dysarthria syndrome that has characteristics of several types of motor speech disorders is commonly seen. Several classic neurological disorders, such as multiple sclerosis, Wilson's disease, and advanced amyotrophic lateral sclerosis, produce several variations of dysarthria concurrently including spastic, flaccid, ataxic, and hypokinetic and hyperkinetic dysarthrias.

Speech-Related Disorders

Miscellaneous speech-related disturbances not classified as dysarthrias or dysphonias include phonic tics, vocalizations, coprolalia, and reiterative speech disorders.

PHONIC TICS AND VOCALIZATIONS

Phonic tics are either simple or complex vocal tics. Simple vocal tics are similar in character to motor tics and are expressed as inarticulate noises and sounds (throat clearing, grunts, coughs, shouts, snorts, word accentuation). Complex vocal tics include articulate words, phrases, or sentences such as echolalia (involuntary repetition of the last sound, word, phrase, or sentence of another person) or coprolalia (involuntary utterance of socially unacceptable or obscene words, phrases, or sentences). Phonic tics, including various involuntary vocalizations and coprolalia, occur most often in Gilles de la Tourette syndrome. Degenerative diseases of the nervous system (e.g., neuroacanthocytosis, Huntington's disease), as well as use of neuroleptic medication and acquired brain injuries, have also been associated with tic disorder.

REITERATIVE SPEECH DISTURBANCES

Echolalia. This syndrome is a nearly mandatory tendency to repeat what has just been said by the examiner. Fully developed echolalia encompasses entire phrases and sentences. The echoed phrase may be the only output the patient can offer. In other cases, the echoed phrase may be followed by a run of jargon output, with the patient apparently unaware of what he or she is saying.^[11] Most patients with echolalia show the completion phenomenon; thus, if started on a phrase that is not completed (red, white, and _____), the correct word is supplied by the patient automatically. Echolalia is most often encountered in patients with transcortical aphasias, notably transcortical sensory and mixed transcortical aphasias. Echolalia is also encountered in many degenerative brain diseases.^[26],^[27]

Palilalia. This rare speech disorder is characterized by involuntary repetition of words and phrases during verbal output. In most instances, palilalia and aphasia are separate disorders, but palilalia has been reported with both anterior and posterior aphasias. Basal ganglia involvement has been suggested as the cause of some cases of palilalia. Palilalia can be seen in untreated schizophrenic patients, in paramedian thalamic damage, in the later stages of degenerative brain diseases such as Alzheimer's disease,^[26],^[27] and during electrical stimulation of left hemisphere sites.

Stutter. Many patients have a tendency to repeatedly iterate an uttered sound. It is common particularly among developing males. Stutter can appear following brain damage in an individual who had not stuttered previously.^[28]

The co-occurrence of acquired stutter and aphasia has been reported. The most common stutter is developmental stuttering, which is characterized by the involuntary repetition of the first syllable of a word. Initiation of the word is followed either by a machine gun-like repetition (stutter) or the presentation of the syllable followed by a prolonged silence (stammer). Both situations are accompanied by physical and emotional discomfort (stress). The patient with a newly acquired stutter produces repetitions and prolongations that are not restricted to the initial syllable. The patient does not exhibit evidence of anxiety associated with the difficult performance. Studies suggest that acquired stutter most often occurs with bilateral brain dysfunction. No focal neuroanatomical site or sites have been associated with acquired stuttering.

Logoclonia. In this condition, there is the tendency for a patient to repeat the final syllable of a word, and often indicates bilateral brain dysfunction. Logoclonia is reported in later stages of dementia.^[27]

Aphasias

Language disorders affect the ability to comprehend and express spoken or written language, or both. Aphasias are the most classic syndromes and are presented here; disorders of written language, including alexias and agraphias as well as other related language disorders, are discussed in the next section.

The clinical characteristics of aphasia syndromes are summarized in [Table 6-4](#).

PERISYLVIAN SYNDROMES

Perisylvian syndromes include classic aphasic syndromes occurring with lesions along the sylvian fissure. They include Broca's, Wernicke's, and conduction aphasia syndromes. Subtypes of Broca's and Wernicke's aphasia are described ([Fig. 6-4](#)).

Broca's Aphasia. In 1861 Paul Broca described an aphasic syndrome and correlated it with underlying pathology.^[29] Broca's aphasia has since been called by several names. For instance, the same findings have been called expressive aphasia, anterior aphasia, and motor aphasia. The term Broca's aphasia is still the most universally recognized for this syndrome, and a specified anatomical localization has been widely accepted.

Verbal output in Broca's aphasia, which is assessed through conversational speech, is markedly reduced, often to fewer than 10 words per minute. The central feature of Broca's aphasia is a nonfluent verbal output^[30]; it is sparse, poorly articulated, and produced with considerable effort. The quality of speech is markedly dysprosodic, lacking melody and rhythm. Sentences are very short, and most responses by a nonfluent aphasic are limited to single word sentences or telegraphic speech.^[11] Even though very few words are produced by the nonfluent aphasic, the output often conveys significant information and may be well inflected.

Figure 6-4 Lateral view of the left hemisphere indicating presylvian area (central clear region), and extrasylvian areas or border zone area (cross-hatched region). TMA = region where a lesion may result in transcortical motor aphasia; TSA = region where a lesion may result in transcortical sensory aphasia.

There is near absence of syntactical words (prepositions, articles, adverbs). The words produced are usually nouns, action verbs, or descriptive adjectives. This alteration of normal grammatical sentence structure is called agrammatism.^[31]

Other language characteristics are less dramatic. The comprehension of spoken language is always significantly better than verbal output. Most patients with Broca's aphasia have some degree of comprehension defect; most often it is a difficulty understanding syntactical structures. The disturbance involves abnormal comprehension of the same terms that the patients omit from their verbal expressions, and they have difficulty with relational words such as up and down, and inside and outside. Repetition of spoken language is abnormal. Confrontation naming is invariably poor. Patients often accept prompting well and improve in pronunciation or initiating articulation. This finding is characteristic of Broca's aphasia, even though it can be found in other types of aphasia. Reading out loud is very difficult for Broca's aphasia patients. Reading comprehension can also be somewhat disturbed, but it is comparatively well preserved. Writing is abnormal, affecting both writing to command or copying written material. The letters are oversized, and multiple misspellings are common.

Neurological examination shows some degree of right-sided weakness in the majority of patients (over 80 percent) with a variable degree of severity. The weakness usually has a brachiofacial distribution. Hyperactive reflexes are frequently present on the involved side. Ideomotor apraxia, an inability to carry out on command a task that can be done spontaneously, frequently involves the nonpathological left hand of patients with Broca's aphasia.^[11]

Sensory loss is not consistent. If a severe hemisensory loss is present at the onset but clears rapidly, a unilateral inattention syndrome is suggested rather than a true sensory defect.^[32] Often, a conjugate ocular deviation to the left will be present initially. A visual field defect is uncommon and, if it is present, suggests more posterior neuroanatomical involvement.

The site of pathology in Broca's aphasia has been localized to the left posteroinferior frontal lobe, Brodmann's area 44, or simply Broca's area. Patients with the classic syndrome of Broca's aphasia often have associated deep-extending pathology involving the insula, basal ganglia, and periventricular white matter ([Fig. 6-5](#)).^[13],^[19],^[33],^[34] Various types of pathology, including trauma, tumor, infection, abscess, and others, can produce Broca's aphasia. The most common cause is cerebral vascular disease. Occlusion of one or several tributaries of the middle cerebral artery feeding the inferior frontal region is the most common cause of Broca's aphasia.

Broca's aphasia that rapidly improves is associated with

Figure 6-5 MRI of the brain showing a large, deep infarct involving Broca's area, the internal capsule and the basal gan (From Damasio H, Damasio AR: *Lesion Analysis in Neuropsychology*. New York, Oxford University Press, 1989.)

lesions involving the frontal operculum but not extending deeply. These patients have a different clinical picture, and the condition has been called Little Broca's aphasia or aphemias.^[13]

Wernicke's Aphasia. In 1874, Karl Wernicke described a language impairment that was characterized by fluent verbal output and impaired comprehension. Essentially identical aphasia syndromes have also been called sensory aphasia or receptive aphasia.

Verbal output in Wernicke's aphasia is either normal or increased (over 200 words per minute).^[14] Speech production demands little or no effort, and articulation is normal. Sentences are of normal length with normal prosody. However, sentences are devoid of meaningful words, so that almost no information is conveyed, an output that can be called empty speech; paraphasia is common.^[11] Paraphasia may be literal when a syllable is substituted within a word (phonemic substitution) or semantic (also termed verbal paraphasia) when a word is substituted. Words can also be substituted by meaningless, nonsense words (neologisms). "Jargon aphasia" is a severe form of Wernicke's aphasia with rapid verbal output, abundant paraphasic substitutions, and incomprehensible verbalization. When patients have

an increased output and speak incessantly, this is called logorrhea or pressured speech, an aphasic output nearly diagnostic of Wernicke's aphasia.

Comprehension of spoken language is disturbed in Wernicke's aphasia. The severity of the comprehension deficit is variable. Patients can sometimes understand a few words and even short sentences. Comprehension ability may decrease with testing, a phenomenon called fatigue or jamming. Two varieties of comprehension defect are described.^[35] In one variety, the ability to comprehend spoken language is considerably worse than the ability to comprehend written language (the patient is predominantly word deaf), whereas in the other the opposite is true (the patient is predominantly word blind). Classic Wernicke's aphasia features a combination of the two.^[17]

Other aspects of language are disturbed. Repetition of spoken language is invariably abnormal. Naming is often abnormal, and grossly paraphasic responses can be produced during confrontational naming. Reading out loud as well as reading comprehension are abnormal. Writing is also abnormal in Wernicke's aphasia. The output consists of well-formed letters combined in a meaningless manner. Correctly produced words may be scattered among the unintelligible combinations.

Neurological examination is often unrevealing. Some degree of cortical sensory loss may be present. A superior quadrantanopia suggesting involvement of the temporal radiation of the geniculocalcarine tract is often the only neurological deficit associated with Wernicke's aphasia. The absence of associated neurological deficits may lead to the erroneous diagnosis of psychosis or schizophrenia, particularly in younger patients, or dementia in older patients.

The pathology in most cases of Wernicke's aphasia is localized in the auditory association cortex of the posterosuperior portion of the first temporal gyrus of the left temporal lobe. When word deafness is predominant over word blindness, pathology tends to be deeper in the first temporal gyrus, involving Heschl's gyrus or its connections. Predominance of word blindness suggests greater involvement of the contiguous parietal cortex (primarily the angular gyrus). Pure word deafness is discussed in the next section. A variety of pathological entities are known to produce Wernicke's aphasia, including vascular events and tumors or abscesses of the temporal lobe.

The outcome and recovery of Wernicke's aphasia is less favorable than Broca's aphasia. With improvement, some ability to recognize spoken words appears. With continued improvement the patient may be able to understand auditory material if it is presented slowly.^[36] Recovery may be delayed by associated behavioral problems; most of the patients, however, are unaware of their deficit, making rehabilitation efforts difficult, and paranoid ideation common.^[11]

Conduction Aphasia. Conduction aphasia occurs in up to 15 percent of admissions of patients with aphasia in some reports.^[35],^[37] The defining feature of conduction aphasia is the repetition difficulty. Unlike Broca's aphasia, verbal output in conduction aphasia is fluent and paraphasic, but the amount of output is less than Wernicke's aphasia. Articulation is excellent, and comprehension of spoken language is intact. In contrast, the repetition of numbers or the naming of colors may be contaminated with verbal paraphasias. Confrontational naming is also disturbed mainly because of paraphasic contamination. Reading out loud rapidly breaks down into a severely paraphasic output; in contrast, reading silently for comprehension is intact. The ability to write is invariably disturbed to some extent. Most often, words and letters are substituted or misspelled or misplaced. Often, conduction aphasia is not diagnosed at the onset but develops in the recovery phase from Wernicke's aphasia. With further improvement, patients remain anomic.

The neurological examination often shows no abnormalities, but variable motor or sensory findings and ideomotor apraxia may be present, particularly with lesions above the sylvian fissure. A pseudothalamic pain syndrome may develop in the recovery phase. Visual fields may show variable deficits reflecting involvement of different sites neighboring the locus of pathology underlying conduction aphasia.^[11]

The site of pathology in conduction aphasia involves the left hemisphere arcuate fasciculus, most often deep to the supramarginal gyrus. This may produce a separation of the sensory and motor language areas, as originally suggested by Wernicke.^[38],^[39] Cases with features of conduction aphasia have been described with lesions outside this area, notably in the left supramarginal gyrus and left temporal gyrus.^[35],^[37] The most common cause of conduction aphasia is occlusion of a portion of the angular branch of the middle cerebral artery.

Global Aphasia. In global aphasia, all language functions are seriously impaired. The verbal output is always limited but not to a state of mutism. Single words or syllables can sometimes be produced, and occasionally, verbal output is limited to strings of a single syllable.^[11] Comprehension is often better than verbal output but is also seriously disturbed. Repetition, naming, reading, and writing are all compromised. Neurological examination often shows hemiplegia, visual field loss, and sensory abnormalities. In some patients, the condition evolves from global aphasia to the other aphasia syndromes. Patients

who do not make a rapid recovery soon after onset have a poor prognosis. The pathology may involve a large part of the left hemisphere, often in the distribution of the middle cerebral artery. Rare cases are reported, however, with a global aphasia but few associated neurological deficits. In those cases, small, strategically placed lesions involve Broca's and Wernicke's areas simultaneously.^[40] Strokes are probably the most common cause, but a tumor, trauma, an infection, a gunshot wound, and other causes can all lead to severe global aphasia.

EXTRASylvian AphasiaS

In extrasylvian aphasiaS, pathology is localized outside the regions immediately bordering the sylvian fissure (see [Fig. 6-4](#)). There are four recognized aphasic syndromes in this category. Transcortical motor, transcortical sensory, mixed transcortical aphasiaS, and supplementary motor area aphasia are discussed.

Transcortical Motor Aphasia. Transcortical motor aphasia resembles Broca's aphasia, but the patients are able to repeat. The term transcortical aphasia was suggested by Wernicke in 1881 and Lichtheim in 1885. It was also termed anterior isolation syndrome by Benson and Geschwind.^[41] Verbal output is described as nonfluent and dysarthric, as in Broca's aphasia. But patients with transcortical motor aphasia have a stronger tendency to stutter, and output is often agrammatic and is produced with considerable effort. Comprehension of spoken language is normal. Sometimes the presence of associated apraxia might falsely suggest that the patient does not comprehend when asked to point to room objects or carry out commands. Repetition is usually good to excellent. Confrontational naming is often disturbed, and prompting with contextual cues or phonemic cues helps these patients considerably. Reading out loud produces poorly articulated speech. Comprehension of written language is intact and usually better than in patients with Broca's aphasia. Writing ability is always defective. It is often clumsily written with large letters, poor spelling, and agrammatical output. Most often, transcortical motor aphasia is seen in the recovery phase from Broca's aphasia. Patients with transcortical motor aphasia usually have variable recovery.

Neurological examination usually reveals right hemiplegia. Apraxia is very common, and conjugate ocular deviation is occasionally seen. Sensory loss and visual field loss do not occur.

Transcortical motor aphasia is not a frequent entity. Cases occur with lesions in the anterior watershed area or with occlusion of the left anterior cerebral artery. In some cases, pathology is located in the left frontal or prefrontal regions of the dominant hemisphere anterior or superior to Broca's area.^[19] It is suggested that transcortical motor aphasia is the result of a separation of the pathways that connect the supplementary motor area with Broca's area.^[42] Other patients have lesions of the left medial frontal region.

A variant of transcortical motor aphasia has been termed *supplementary motor area aphasia*. This syndrome is basically identical to transcortical motor aphasia but is produced by damage to the dominant hemisphere medial frontal structures notably the cingulate cortex and supplementary motor area. Following initial mutism, patients with this disturbance develop a slow hypophonic output that improves considerably with repetition. In comparison with transcortical motor aphasia, patients with supplementary motor area aphasia have a characteristic neurological disturbance with weakness of the right lower extremity and shoulder but relatively normal strength in the arm and face. A similar pattern of sensory disturbance may or may not be present.^[9] This syndrome is not common and occurs most often after occlusion of the dominant hemisphere anterior cerebral artery.

Transcortical Sensory Aphasia. Transcortical sensory aphasia is a distinct entity that features fluent output that is often contaminated by considerable paraphasia, including both neologistic and semantic substitutions. Comprehension of spoken language is severely disturbed. In striking contrast, repetition is intact. The patient is often echolalic, repeating most of the examiner's utterances with apparent unawareness of what is said. Naming is disturbed. Reading out loud may be preserved but is usually contaminated with paraphasic errors. Reading comprehension is defective. Writing is also abnormal.

Sensory abnormalities usually of the cortical type are found as well as a visual field defect. Occasionally, patients with transcortical sensory aphasia have a normal

neurological examination and are misdiagnosed as schizophrenics.

The pathology underlying this syndrome is often located in the parietal and temporal areas, posterior to the perisylvian region. Occlusion of the left internal carotid with a subsequent posterior border zone infarction frequently underlies transcortical sensory aphasia. Tumors in the parieto-temporo-occipital junction area, as well as trauma, intracerebral hematoma,^[43] and degenerative disorders such as Alzheimer's disease^[44] are other reported causes.

Transcortical sensory aphasia may also follow the resolution of Wernicke's aphasia. The prognosis is usually guarded.

Mixed transcortical aphasia. Mixed transcortical aphasia, or isolation aphasia, is equivalent to global aphasia with preserved repetition.^[45] Patients with this syndrome do not speak unless spoken to and their verbal output is almost entirely limited to what has been offered by the examiner, a true echolalia.^[41] Patients may also embellish the output in the form of the completion phenomenon. Thus, if told the beginning of a common phrase, the patient may not only repeat what has been said but continue the phrase to completion. Comprehension of spoken language is severely disturbed. The ability to repeat, although well preserved compared with all other language features, remains limited and is often below normal. The number of words in a sentence that can be repeated is often limited to three or four. Naming, reading out loud, reading for comprehension, and writing are severely compromised. When a response is elicited, it is often contaminated with paraphasias. Neurological examination reveals variable motor, sensory, and visual field deficits.

The pathology underlying mixed transcortical aphasia is most often located in both the anterior and posterior vascular border zone cortical areas of the left hemisphere. Although border zone pathology is rare in its pure form, individuals with acute left internal carotid occlusion or the residuals of severe cerebral edema or prolonged hypoxia may show the mixed transcortical language pattern. The

course of this syndrome is often stable but unimproving. The syndrome has also been seen with unusual frequency in Creutzfeldt-Jakob disease.

SUBCORTICAL APHASIA

With the advent of brain imaging, language disorders that previously were difficult to characterize were found to have pathology affecting subcortical structures, particularly the basal ganglia and the thalamus.^[46] Considerable variation is seen in the clinical picture depending on the specific subcortical structures involved, but several general characteristics help define the entity. First, there is typically an acute onset with mutism, recovering slowly to a hypophonic, slow, and poorly articulated output. In addition, other language features vary depending on the site of subcortical pathology.

There are several potential localizations for subcortical aphasia. Left thalamic lesions most commonly secondary to hypertensive hemorrhage have a Wernicke-like fluent aphasia, with paraphasic output but with comparatively good comprehension and repetition.^[41] Causes of thalamic aphasia include hemorrhage and ischemic infarctions. Left striatal lesions often produce dysarthria, nonfluent paraphasic speech, and relatively mild comprehension deficits, as well as preserved repetition. These findings resemble the transcortical motor aphasia except for the presence of paraphasias and dysarthria. More posterior lesions occasionally produce a Wernicke-like aphasia. Even small lesions in the posterior internal capsule and adjacent putamen occasionally produce mild, mixed aphasic syndromes, but they usually manifest dysarthria.

Research focusing on subcortical aphasias is an evolving field of knowledge, and new clinical syndromes with more precise anatomical localization are being described. There is a high likelihood of recovery from subcortical aphasia, and this transient nature can be accepted as a diagnostic characteristic.^[47] If, however, the causative lesion also involves language cortex, which is a common situation, recovery will be incomplete.^[47] It has been suggested from PET studies that lesions in the basal ganglia affect language functions indirectly via decreased activation of the language cortex.^[48] The presentation of a difficult-to-classify aphasic syndrome, in the presence of dysarthria and right hemiparesis, should lead to suspicion of a subcortical lesion.

NONLOCALIZING APHASIC SYNDROMES

Anomic Aphasia. Anomic aphasia is also known as amnesic aphasia and nominal aphasia. Anomia is a very frequent finding in aphasia to the extent that it is considered imprudent to suggest a diagnosis of aphasia in its absence.^[11] Anomic aphasia refers to those aphasic syndromes in which the principal deficit is in confrontational naming. Although spontaneous speech is fluent and easily produced, there is an emptiness, which results from a lack of substantive words, with substitution of many nonspecific words that often fail to communicate an idea satisfactorily. This vague output is called empty speech. Most often, excessive word-finding pauses typify the anomic output. If the description demands a substantive word that cannot be produced, another description may be tried. This rapidly produces a circuitous output called circumlocution.

Other language aspects are more intact. Comprehension is relatively well preserved. Reading and writing may be entirely normal but not infrequently there is abnormality in both. When anomia occurs by itself, it may result from pathology almost anywhere in the left hemisphere area and can even be seen in some cases of right hemisphere lesions.^[11], ^[17] There is a fairly common syndrome in which anomic aphasia is associated with alexia plus the Gerstmann's syndrome (agraphia, right-left disorientation, acalculia, and finger agnosia). In this syndrome, the pathology is localized in the left angular gyrus.^[11], ^[12] Anomia is often the residual of more severe aphasic syndromes and remains the complaint of many well-recovered aphasics. Anomia is also seen in degenerative disorders such as Alzheimer's disease.

Alexias and Agraphias

ALEXIA WITHOUT AGRAPHIA

Alexia without agraphia was first described by Dejerine in 1892 in a patient who suddenly lost the ability to read but had no other language disturbance. The only neurological finding of significance was a right homonymous hemianopia. Although the patient was unable to read except for some individual letters, he could write adequately. In patients with this syndrome, the patient can write but cannot read his or her own written output. If the letters of a word are read aloud, the patient can often put them together so that the word can be deciphered. The patient often has verbal alexia, which refers to an inability to read words (also called word blindness) but not literal alexia (letter blindness), retaining the ability to read letters. The patient with alexia without agraphia can recognize individual letters when they are drawn in the palm or palpated from embossed blocks. Patients with this syndrome do not lose the ability to see verbal stimuli, but visual information has lost access to the language area. Patients with this disorder also have greater difficulty in copying written material than in producing words to dictation. They can spell words out loud without difficulty. Many patients have disturbed color naming as well as a mild degree of anomia. Some have difficulty in reading numbers and others suffer from true acalculia.

The causative lesion is nearly always a stroke in the territory of the left posterior cerebral artery, with infarction of the medial occipital lobe, the medial temporal lobe, and the splenium of the corpus callosum. Dejerine suggested a disconnection between the intact right visual cortex and the left hemisphere areas mediating language, particularly the angular gyrus. Geschwind repopularized this disconnection theory.^[49]

As a separate but closely related entity, Greenblatt^[50] has described a syndrome that he named subangular alexia. Patients with this disorder have alexia without agraphia and without hemianopia. The structural pathology in these cases involves the white matter deep in the dominant parietal cortex, undercutting the angular gyrus.

ALEXIA WITH AGRAPHIA

In 1891, Dejerine also described a syndrome of alexia with agraphia in a patient who suffered a cerebral vascular accident. The ability to read both letters and words is impaired, and there is equal difficulty in comprehension of numbers and musical notation. Cues are of little help. Thus, tracing the letter with the finger does not aid in identification, and the patient with this type of alexia cannot decipher a word when it is spelled aloud for him. The writing disturbance is usually of equal severity. The ability to copy written material is far better than the ability to produce it on command. This syndrome may be considered an acquired illiteracy, in which a

previously educated patient is rendered unable to read and write.

This disorder often overlaps with Wernicke's aphasia. In those cases, the patients often have a paraphasic output, impaired naming, and repetition, as well as disturbed written comprehension (word blindness) more than auditory comprehension (word deafness). Associated findings include right hemianopia or superior quadrantanopia, elements of Gerstmann's syndrome, and right-sided sensory loss. Most often, there is partial recovery, permitting only limited reading comprehension.

The most common locus of pathology in this syndrome is situated in the parietotemporal junction of the dominant hemisphere, particularly in the angular gyrus.

The association of alexia with agraphia in Gerstmann's syndrome and anomia has been called the angular gyrus syndrome, and the combined disorder almost invariably indicates a left hemisphere inferior parietal location of the causative pathology.

FRONTAL ALEXIA

A number of features of frontal alexia are sufficiently distinctive to allow differentiation from the other varieties of alexia. Most patients with the disorder can read, both aloud and for comprehension, but only isolated words from a given sentence are uttered; the recognized words are almost exclusively substantives. If relational words such as adjectives and prepositional phrases are the determining language structures, the patient may completely misinterpret the sentence. Nonfluent aphasia is often associated with frontal alexia. The site of pathology in frontal alexia involves the same locus as Broca's aphasia.

Other types of alexias have been described, including hemialexia following posterior corpus callosum section, unilateral paralexia, a manifestation of unilateral inattention, and other variants.

AGRAPHIA

Agraphia may be defined as a loss or impairment of the ability to produce written language, caused by brain dysfunction. Almost without exception, every individual with aphasia shows at least some degree of agraphia, and tests of writing ability can be used as a screening device to detect the presence of aphasia. Caution is necessary, however, because agraphia accompanies many disturbances other than aphasia. Abnormalities of constructional skills, visuospatial discrimination, and disturbances of motor skills, such as ataxia, rigidity, spasticity, chorea, myoclonus, and tremor, cause major alterations in the quality of graphic output.

Three variations of agraphia are outlined. *Left frontal (anterior) agraphia* is seen in patients with Broca's aphasia, and their written output parallels their verbal output. Words and letters are large and messy with poor spelling, and sentences are devoid of grammatical words (agrammatism). *Left parietotemporal (posterior) agraphia* is seen in patients with posterior aphasias, and written output parallels their spoken output. Literal and verbal paraphasias as well as empty writing are present. *Visuospatial agraphia* is most commonly associated with posterior right hemisphere defects causing constructional disturbance. The script is well formed but there is a tendency for the written line to slant upward and for the left margin to be larger and increasing in size with subsequent lines.

Language-Related Disorders

APHEMIA

Aphemia was the term originally used by Broca to describe all language disturbances, but he later accepted the term aphasia promoted by Trousseau (1864). Bastian (1887) used aphemia to denote a specific syndrome described here; others have termed the same language abnormality pure motor aphasia, cortical anarthria, or apraxia of speech.

The patient presents acutely with mutism but is able to communicate using written language. When verbalization returns, the output is hypophonic, slow, and poorly articulated so as to be almost incomprehensible. Comprehension of spoken language is intact. Although both repetition and naming are severely disturbed because they demand vocalization, patients can comprehend written language and are able to write without difficulty. Primary laryngeal pathology should be ruled out.

Neurological examination reveals a transient right hemiplegia or hemiparesis without other neurological signs except for an often associated buccofacial apraxia. Patients have difficulty performing on command acts such as whistling, sucking, blowing, and winking. In contrast, they have no trouble performing limb activities such as imitating the use of a comb or a toothbrush, waving goodbye, and saluting.

In aphemia, the communication disturbance involves verbal output and is a speech problem rather than an impairment of language. There is often an overlap, however, between aphemia and the anterior aphasia syndromes. An aphemia-like state appears in some patients who have recovered from Broca's aphasia. Some investigators have even considered aphemia to be a minor subtype of Broca's aphasia, also called little Broca's aphasia.

However, aphemia differs from true Broca's aphasia because of the absence of agrammatism in the spoken and written output. Most often, aphemia improves to useful language output, but a dysprosodic speech quality remains, producing a so-called foreign accent syndrome, a disorder of rhythm, inflection, and articulation, suggesting that the patient is not a native speaker of the language. The pathology is located in or immediately inferior to Broca's area in the dominant hemisphere (see Fig. 6-5).

TABLE 6-5 -- CLINICO-ANATOMICAL CORRELATIONS OF SPEECH AND LANGUAGE DISORDERS

Anatomical Site of Damage	Speech or Language Syndrome	Other Neurological and Medical Findings	Common Etiologies	Comments
(L) Posterior inferior frontal lobe	Broca's aphasia	Brachiofacial weakness	Stroke, trauma, tumor, infection	Initial (L) conjugate gaze deviation
(L) Posterior superior temporal gyrus	Wernicke's aphasia	Visual field deficit	Stroke, temporal lobe abscess	
(L) Posterior sylvian region	Conduction aphasia	Cortical sensory deficit pseudothalamic pain	Stroke	Associated ideomotor apraxia
(L) Sylvian region	Global aphasia	Hemianopia, hemiplegia	Stroke, tumor, trauma, infection	
(L) Dorsolateral frontal cortex	Transcortical motor aphasia	Buccofacial apraxia, hemiparesis is occasional	Anterior border zone vascular infarction	
(L) Temporoparieto-occipital junction	Transcortical sensory aphasia	Cortical sensory deficit Visual field deficit	Posterior border zone vascular infarction Degenerative disease	Echolalia is common
(L) Hemisphere, vascular border zone areas	Mixed transcortical aphasia	Variable motor, sensory, and visual field deficits	Border zone infarctions, anoxia, carbon monoxide poisoning	Echolalia very common
(L) Thalamus, striatum white matter	Subcortical aphasia	Hemiplegia/sensory loss	Stroke, ischemic and hemorrhagic	No visual field or cortical sensory loss
Unilateral or bilateral corticobulbar tracts	Spastic dysarthria	Unilateral or bilateral hyperreflexia or spasticity	Stroke, demyelinating and degenerative disease	

Cerebellum	Ataxic dysarthria	Dysmetria, nystagmus ataxia	Stroke, degenerative, toxic disorder; tumor	
Lower motor neuron brain stem or peripheral nerves	Flaccid dysarthria	Atrophy, fasciculation, decreased gag	Motor neuron disease, stroke, carcinomatous meningitis	Risk of aspiration pneumonia
Basal ganglia	Hypokinetic/hyperkinetic dysarthria	Parkinsonism, dystonia, chorea	Degenerative disease, Parkinson's disease, Huntington's disease, stroke	
Vocal cords or their innervation	Dysphonia	Fatiguability, ptosis	Laryngitis, vocal cord paralysis, myasthenia	May be a sign of laryngeal carcinoma

PURE WORD DEAFNESS

Pure word deafness is a rare prelanguage syndrome in which only reception of spoken language is involved. Individuals with pure word deafness do not understand spoken language and cannot repeat. However, they are able to hear and identify adequately nonverbal sounds such as a whistle, a telephone ring, and a dog bark. Their reading is intact, and they often carry with them a writing tablet for others to use. [17]

There are two known loci of pathology. Some patients have a single lesion deep in the dominant superior temporal region affecting the primary auditory cortex or the pathways to it from the medial geniculate nucleus. More commonly, there is bilateral pathology involving the mid-portion of the superior temporal gyrus of both hemispheres. Wernicke's area (left auditory association cortex) is not involved.

Some cases of pure word deafness have associated paraphasic output and mild written language comprehension deficits. These cases should be classified as Wernicke's aphasia with predominant word deafness and relatively less word blindness (reading comprehension).

Pure word deafness is not a disturbance of language ability. Delivery of the auditory signal to the area mediating language interpretation is defective, which is a sensory transmission problem rather than a language disturbance. Pure word deafness resembles deafness more than aphasia. It has also been called auditory verbal agnosia. [52] Although pure word deafness is rare in isolation, it may be associated with posterior aphasic disorders.

DELIRIUM

Delirium with fluctuating consciousness and disturbed thought content is associated with variable language difficulties with or without structural brain pathology. Patients often have impaired attention and do poorly on tasks such as digit span and mental control. Language disturbances can be the presenting feature of delirium, particularly in patients with decreased attention and concentration. Associated features may include agitation, hallucinations, confusion, and myoclonus.

PSYCHIATRIC DISORDERS

Psychiatric disorders can occasionally mimic classic language syndromes. Schizophrenics often present with verbal output described as word salad, containing bizarre words and sentences. Written output parallels the content of verbal output. These patients have no other language disturbances and are usually readily distinguished from Wernicke's or other posterior aphasias. Manic patients often present with logorrheic output, pressured speech, and grandiose content; but no other language disturbances are

encountered that distinguish them from other classic aphasia syndromes.

RIGHT HEMISPHERE DISORDERS

Right hemisphere disorders can affect language function, most commonly in left-handed individuals. Rarely, right-handed patients become aphasic after strokes in the right hemisphere, a phenomenon called crossed aphasia in dextrals. Even in right-handed people with typical left hemisphere dominance for language, subtle alterations in language function occur after right hemisphere damage. The right hemisphere has a dominant role for expressing emotion including emotional prosodic aspects of communication. [9] Amelodia (also called affective motor aprosodia) is a disturbance characterized by loss of melody, prosody, or emotional intonation in verbal output. [53] There is a flat monotonous verbal output, inability to produce a melody when singing (expressive amusia), decreased facial expression, and sparse use of gestures. The result is a seemingly emotionless response, which is easily misinterpreted as depression. The neuropathology involves the right frontal opercular area and its connections, which is the right hemisphere equivalent of Broca's area. In addition, receptive amusia and other disorders of music appreciation are related disturbances predominantly associated with right hemisphere lesions.

Tables 6-5 and 6-6 summarize clinico-anatomical correlations

TABLE 6-6 -- SELECTED ETIOLOGIES OF SPEECH AND LANGUAGE DISORDERS

Etiological Category	Selected Specific Etiologies	Chapter
STRUCTURAL DISORDERS		
Developmental	Arnold-Chiari malformations	28
HEREDITARY AND DEGENERATIVE DISORDERS		
Storage diseases: Lipidoses, glycogen disorders and leukoencephalopathies	Adrenoleueodystrophy, Krabbe's disease, metachromatic leucodystrophy	30
The degenerative dementias	Alzheimer's disease, fronto-temporal degeneration, Parkinson's disease, Huntington's disease	33
Movement disorders	Hallervorden-Spatz disease, Wilson's disease, progressive supranuclear palsy, Parkinson's disease, multiple system atrophy, Huntington's disease	34
Ataxias	Friedreich's ataxia, abetalipoproteinemia	35
Degenerative motor, sensory, and autonomic disorders	Amyotrophic lateral sclerosis	36
Inherited muscle, neuromuscular, and neuronal disorders	Myopathies	37
ACQUIRED METABOLIC AND NUTRITIONAL DISORDERS		
Endogenous metabolic disorders	Hypothyroidism	38
Exogenous acquired metabolic disorders of the nervous system: Toxins and illicit drugs	Cocaine	39
Nutritional deficiencies and syndromes associated with alcoholism	Alcoholic cerebellar degeneration Vitamin E deficiency	40
INFECTIOUS DISORDERS		
Viral infections	Herpetic encephalitis	41
Nonviral infections	Toxoplasmosis or bacterial abscess of the temporal lobe	42

Transmissible spongiform encephalopathies	Creutzfeldt-Jakob disease, Gerstmann-Straussler syndrome	43
HIV and AIDS	Lymphoma, toxoplasmosis, AIDS dementia complex	44
NEUROVASCULAR DISORDERS	Vascular dementia, embolic, thrombotic, and hemorrhagic stroke	45
NEOPLASTIC DISORDERS		
Primary neurological tumors	Glioblastoma, meningioma, astrocytoma	46
Metastatic neoplasms and paraneoplastic syndromes	Metastasis from lung, breast, melanoma, paraneoplastic cerebellar degeneration	47
DEMYELINATING DISORDERS		
Demyelinating disorders of the central nervous system	Multiple sclerosis, progressive multifocal leucoencephalopathy	48
Demyelinating disorders of the peripheral nervous system	Guillain-Barre syndrome	49
AUTOIMMUNE AND INFLAMMATORY DISORDERS	Myasthenia gravis	50
TRAUMATIC DISORDERS	Contusion, subdural hematoma	51
EPILEPSY	Frontal lobe epilepsy	52
HEADACHE AND FACIAL PAIN	Migraine with aura	53
SLEEP DISORDERS	Hypoxemia and hypotension with sleep apnea	54
DRUG-INDUCED AND IATROGENIC NEUROLOGICAL DISORDERS	Anterior cerebral infarction following aneurysm clipping	55
AIDS, Acquired immunodeficiency syndrome; HIV, human immunodeficiency virus.		

and major etiological categories of speech and language disorders.

GENERAL MANAGEMENT GOALS

Language and speech are so basic for human existence that their loss is often catastrophic. Most patients lose their ability to communicate in a sudden and unexpected way. In addition to the loss of language itself, patients may lose their employment, social position, recreational opportunities, and many other stabilizing factors of personal existence.^[13] The prognosis of any speech and language disorder depends on many factors, including etiology, lesion site, severity, profile of aphasic deficits, age at onset, individual (crossed aphasics), or group characteristics (left-handedness).

Most clinicians agree that speech therapy may be helpful and begin treatment as soon as possible, but delays in treatment are not detrimental and are warranted until the patient is neurologically stable.^[54] Therapy should be goal driven, not simply to maximize or optimize language function. The therapist should identify limiting factors, establish treatment plans for the treatable factors, and specify both the expected outcome and specific duration of treatment.

Treatment should also include addressing complications of speech and language disorders. Depression is associated with left hemisphere injury, particularly in the deep frontal regions, and is associated with Broca's aphasia, global aphasia, or subcortical aphasia with anterior extension.^[55],^[56] Treatment of depression includes support and encouragement, concentration on domains in which the patient succeeds, and antidepressant medication. Paranoid and agitated behavior is occasionally observed in patients with posterior aphasic syndromes, particularly those with Wernicke's aphasia and pure word deafness^[57]; management consists of antipsychotic drugs in a low dose. Finally, patients with associated bulbar or pseudobulbar palsy are at increased risk for aspiration and secondary lung infection and should be monitored closely and considered for percutaneous gastric feeding tube.

Patients with aphasia are often assumed to be incompetent because of their reduced communication ability; the inability to communicate, however, through verbal or written language does not preclude aphasic patients from nonverbal communication, thinking, and expressing opinions. Even severe aphasic patients can live semi-independently and develop new interests and goals.

DEFINITIONS

Cranial nerve I (CN I) constitutes the primary receptor cells for the sense of smell. This nerve monitors the intake of airborne agents into the human respiratory system and largely determines, along with the sense of taste, the flavor and palatability of foods and beverages. In addition to purveying esthetic pleasures, CN I warns of spoiled foods, leaking natural gas, polluted air, and smoke, and mediates elements of basic communication (e.g., mother-infant interactions). Of particular interest to the neurologist is the fact that alterations in the ability to smell are among the first, if not the first, signs of Alzheimer's disease and idiopathic Parkinson's disease.

Olfactory dysfunction can affect a patient's safety, nutritional status, and quality of life. Among 750 consecutive patients presenting to the University of Pennsylvania Smell and Taste Center with mainly olfactory problems, 68 percent experienced an altered quality of life, 46 percent reported changes in appetite or body weight, and 56 percent noted adverse influences on daily living or psychological well-being. [1] Many anosmics report increased use of sugar and seasonings to compensate for their olfactory disorder, a situation detrimental to persons with diabetes and salt-sensitive hypertension. In experimental settings, older persons with diminished smell function ingest foods that younger persons find distasteful, implying that such individuals are at considerable risk for food poisoning. It is well documented that a disproportionate number of elderly persons die from accidental gas poisoning, which is due, in large part, to their decreased ability to smell.

Most patients presenting with decreased "taste" function actually have decreased smell function. The perception of decreased ability to "taste" during deglutition is usually due to a loss of flavor sensations derived from retronasal stimulation of the olfactory receptors rather than to a loss of taste bud-mediated sensations per se. Thus, such flavors as coffee, chocolate, vanilla, strawberry, pizza, licorice, steak sauce, root beer, and cola disappear when CN I is markedly damaged, leaving intact only sweet, sour, salty, bitter, and umami (monosodium glutamate-like) sensations. Whole-mouth taste function is much more resilient to pathological or trauma-related alterations than is olfactory function, in large part because the taste buds have redundant innervation from several cranial nerves (i.e., CN VII, IX, and X).

The nomenclature for olfactory dysfunction is straightforward. *Anosmia* refers to a loss of ability to smell, whereas *hyposmia* or *microsmia* refers to diminished ability to smell. *Dysosmia* is distorted or perverted smell perception, such as when a rose smells more like garbage than a rose (*parosmia*, *cacosmia*) or when a medicine-like smell is present in the absence of odor stimulation following head trauma (*phantosmia*). *General* or *total anosmia* implies inability to smell all odorants on both sides of the nose. *Partial anosmia* implies an inability to smell certain odorants. In some cases, partial anosmia is indicative of a decreased sensitivity to a broad spectrum of odorants (*general hyposmia*), with the decrement exceeding the absolute threshold for only some odorants. *Specific anosmia*, the inability to smell one or a few odorants in the presence of an otherwise normal sense of smell, is rarely a reason for medical consultation. *Hyperosmia* is a rare condition of abnormally acute smell function. This occurs, for example, in some epileptic patients prior to the onset of ictal activity.

Olfactory dysfunction can be either *bilateral* or *unilateral*

(sometimes termed *binasal* or *uninasa*). Thus, if a person has anosmia on the left side of the nose but not the right, the condition is described as unilateral left anosmia. Anosmia that is present on both sides of the nose is termed bilateral anosmia, or, as noted previously, total anosmia.

Occasionally, complaints of dysosmia reflect foul odors that are produced either within the nasal cavity (e.g., as a result of infections within the nose) or within the body proper (e.g., as a result of altered metabolism). In the latter case, bad odors may come from saliva, exhaled breath, skin secretions, or urine. Although the basis of a number of such problems has nothing to do with alterations in any element of the olfactory pathway, the term dysosmia is still appropriate for describing the complaint but not the clinical syndrome. Examples are trimethylaminuria (fish odor syndrome), in which a metabolic defect results in excretion of fishlike smelling amines, and cat's odor syndrome, a childhood neurological disorder associated with a defect in the enzyme beta-methyl-crotonyl-CoA carboxylase.

CLINICAL HISTORY

A patient's description of the nature and onset of the chemosensory problem is an essential element of the clinical history, as is an historical assessment of the patient's general health, including endocrinological state, hospital admissions, surgical interventions, radiological treatments, and medications received for other conditions. The use of thyroid agents and drugs that affect cell turnover (e.g., chemotherapeutic drugs) may be of etiological significance. Retarded or delayed puberty in association with anosmia (with or without midline craniofacial abnormalities, deafness, and renal anomalies) suggests the possibility of Kallmann's syndrome. Importantly, associated events such as viral or bacterial respiratory infections, head trauma, exposure to toxic fumes, systemic diseases, and signs of early parkinsonism or central tumors are critical for arriving at an etiological diagnosis, which is possible in the majority of cases. Information related to exposure to environmental chemicals and signs of seizure activity (e.g., automatisms, occurrence of blackouts, déjà vu, etc.) should be sought, particularly in patients in whom heightened sensitivity is a symptom. Attention to the possibility of renal disease as well as liver disease is crucial, given reports of alterations of olfactory function in patients with cirrhosis of the liver, acute viral hepatitis, or renal dysfunction. Decreased olfactory function has been observed in some persons with human immunodeficiency virus (HIV) infection.

In patients complaining of anosmia or hyposmia, it is useful to ask whether smell function is diminished or completely lost, localized to the right or left nostril, or both, and whether the dysfunction is for all odorants or only a few. Patients with loss due to nasal sinus disease are more likely to experience a gradual loss of function than those who have loss due to a prior upper respiratory infection or to head trauma. Some patients report temporary recovery of function in circumstances in which nasal patency is increased, such as on warm days or during exercise, showering, or treatment with corticosteroids; this implies a problem with intranasal airway blockage (as in allergic rhinitis) rather than a sensorineural problem.

The smoking history should be explored in light of evidence that the ability to smell decreases as a function of cumulative smoking dose and that cessation of smoking can result in improvement in olfactory function over time. A history of allergy should be sought, as should a history of current or past nasal or paranasal sinus infections. Inquiry should be made about nasal or paranasal sinus operations or other treatments such as the use of topical intranasal medications. Importantly, the association of nasal obstruction, headache, facial pain, postnasal discharge, purulent or clear rhinorrhea, ear symptoms, and throat symptoms should be sought with specific questioning. The order in which the symptoms appeared and regressed is at times helpful. The duration of the problem is important in relation to the possibility of spontaneous recovery, which is generally assumed to be unlikely after 6 months if damage to the olfactory epithelium has occurred.

The patient should be asked about olfactory distortions and whether they seem to be bilateral or are confined to one or the other nasal chamber. In various stages of olfactory epithelial degeneration or regeneration, a dysosmia--usually foul--is often present that may or may not require an inhaled stimulus for elicitation. Dysosmias are sometimes associated with certain mental disorders, including epilepsy, psychosis, schizophrenia, and depression-related syndromes such as the olfactory reference syndrome. In some cases, aura-like dysosmic phenomena may occur without any evidence of seizure activity. Fortunately, most olfactory perversions are temporary, although long-standing cases have been reported.

Exploring a patient's complaint of taste loss is essential because it usually reflects an olfactory disorder. It is useful to have the patient differentiate between the loss of perception of flavors of food or beverages and the loss of perception of sweet, sour, bitter, and salty stimuli. The physician can ask whether the patient is able to perceive saltiness in potato chips, sourness in lemonade, or sweetness in sugar on cereal to arrive at this differentiation. A patient with anosmia may be able to taste the sweetness of an apple or a pear but is unable to distinguish between their flavors.

ANATOMY OF CRANIAL NERVE I ([Table 7-1](#))

Sensory Receptors and Primary Neurons

Cranial nerve I is the collection of approximately 6 million bipolar receptor cells whose cell bodies, dendrites, and initial axon segments are located within the olfactory neuroepithelium and whose axons project through the cribriform plate of the ethmoid bone to the anterior cranial fossa (Fig. 7-1 (Figure Not Available)). The olfactory neuroepithelium is a pseudostratified columnar epithelium supported by a highly vascularized lamina propria and is situated on the cribriform plate as well as on segments of the superior septum and both the superior and middle turbinates. Each bipolar receptor cell sends 3 to 50 cilia (which lack dynein arms and commonly have a 9 + 2 microtubule arrangement) from its dendritic knob into the overlying mucus. The cilia, which can radiate across the epithelial surface for over 30 µm, contain the receptor sites where odorants bind and

TABLE 7-1 -- CLINICO-ANATOMICAL CORRELATION OF DISORDERS OF THE OLFACTORY NERVE

Anatomic Site of Damage	Typical CN I Finding	Other Neurological and Medical Findings	Common Etiologies
Sensory receptors and primary neuron	Hyposmia or anosmia Dysosmia Can be unilateral	With trauma, rare nasal leaks of CSF	Head trauma Upper respiratory infections Nasal or sinus disease Toxic exposure
Secondary neurons	Hyposmia or anosmia	Foster Kennedy syndrome	Meningioma
Olfactory bulb cells	Dysosmia	Disinhibition, change in personality	Neurodegenerative diseases (Alzheimer's disease, Parkinson's disease, Huntington's disease)
Anterior olfactory nucleus	Can be unilateral	Gait dyspraxia, disinhibition, change in personality	
Medial and lateral striae			Frontal lobe tumors Pituitary tumors Aneurysms
Medial dorsal nucleus of thalamus	Decreased odor identification Normal or increased odor thresholds*	Signs of Wernicke-Korsakoff syndrome: ataxia, extraocular paresis, nystagmus, memory problems including confabulations	Wernicke-Korsakoff syndrome Infarctions
Primary and secondary olfactory cortex	Decreased odor identification Normal or increased odor thresholds*	Lip smacking, automatisms during seizures Dementia, memory loss Tremor, bradykinesia Chorea, dementia Contralateral weakness, aphasia, homonymous quadrant visual field defects	Epilepsy Neurodegenerative disorders Alzheimer's disease Parkinson's disease Huntington's disease Tumors or infarcts

* Because of bilateral cortical and subcortical representation of olfactory function, unilateral lesions at this level generally do not cause clinically meaningful olfactory dysfunction.

provide a relatively large area for such binding. Assuming 6 million bipolar receptor cells, each containing 20 cilia 30 µm long and with an average diameter of 0.5 µm, the surface area of the cilia proves to be nearly 9 square inches.

In addition to bipolar receptor cells, the olfactory epithelium contains several other major cell types (see Fig. 7-1 (Figure Not Available)). The sustentacular or supporting cells, whose apical ends have microvilli that extend into the olfactory mucus, span the distance from the epithelial surface to the basal laminae and function to (1) mechanically isolate the bipolar receptor cells from one another, (2) secrete mucopolysaccharides, (3) transport molecules across the epithelium, and (4) detoxify and degrade odorants. Some of the basal cells, located near the basement membrane, serve as precursors for the generation of other cell types within the neuroepithelium. The duct cells of Bowman's glands line passages through which most of the olfactory mucus is secreted, whereas the microvillar cells, located at the surface of the epithelium, send tufts of microvilli into the nasal mucus. The function of these flask-shaped cells is unknown. However, they number about 600,000 in humans and have an axon-like process that extends to the olfactory bulb.

The constituent bipolar neurons of CN I are unique in three respects. First, their apical processes are more or less directly exposed to the external environment. Second, unlike nearly all other neuronal cells, they have the propensity to regenerate from basal cells after being damaged; indeed, some of these cells die and replenish themselves at regular intervals, although others are more long-lived. Third, each of these cells serves as both a receptor cell and as a first-order neuron, projecting an axon directly from the nasal cavity into the brain without an intervening synapse. Unlike the other major cell types of the epithelium, these cells have relatively little xenobiotic-metabolizing capacity and are a primary route of invasion into the central nervous system of toxic agents and viruses. Indeed, it is believed that the majority of neurovirulent viruses first enter the CNS through this pathway.

Within the lamina propria, the unmyelinated and unbranched axons of the olfactory receptor cells coalesce into bundles of approximately 200 axons, each surrounded by ensheathing or Schwann cell mesoaxons. Axons within these bundles are in direct contact with one another and may interact metabolically and electrically. These bundles in turn combine with other bundles to form the olfactory fila, which traverse the cribriform plate of the ethmoid bone through 50 or so foramina. The fila, on exiting from the cribriform plate, form a dense layer of axons on the surface of the olfactory bulb. From here, the receptor cell axons branch and synapse with second-order neurons within the glomeruli of the bulb.

Secondary Sensory Neurons: Olfactory Bulb and Projections

The olfactory bulbs are complex ovoid structures located on the ventral surface of each frontal lobe dorsal to the cribriform plate. Each bulb is composed of a number of types of cells, including neurons, afferent and efferent nerve fibers, microglia, astrocytes, and blood vessels, all surrounded by a thin layer of pia-arachnoid cells. The cellular elements of the bulb are arranged in six concentric layers: the olfactory nerve layer (ONL), the glomerular layer (GL), the external plexiform layer (EPL), the mitral cell layer (MCL), the internal plexiform layer (IPL), and the granule cell layer (GCL). The GCL is the largest of these layers, making up about half the volume of the entire bulb. The anterior olfactory nucleus (AON) lies within the

Figure 7-1 (Figure Not Available) Low-power electron micrograph (x1000) of a longitudinal section through a biopsy of human olfactory mucosa taken from the nasal septum. Four cell types are indicated: ciliated olfactory receptor cells (c), microvillar cells (m), supporting cells (s), and basal cells (b). The arrows point to ciliated olfactory knobs of bipolar receptor cells; d indicates degenerating cells; bs, the base of supporting cells; lp the lamina propria; n, a nerve bundle; and bg, a Bowman. (From Moran DT, Rowley JC III, Jafek BW et al: The fine structure of the olfactory mucosa in man. J Neurocytol 1982; 11:721-746.)

core of the olfactory bulb and extends through the olfactory tract to the rostral part of the olfactory peduncle near the anterior perforated substance. This structure, which is considered to be an element of the primary olfactory cortex, contains pyramidal cells whose dendrites receive synapses from mitral and tufted cells as well as from the contralateral AON (via the anterior commissure [AC]) and numerous central brain structures. The axons of its pyramidal cells project to ipsilateral bulb

neurons (mainly granule cells) as well as to the contralateral AON, bulb, or rostral olfactory cortex via the AC. Although termed a nucleus, the AON has a cortical structure with subdivisions based on cellular architecture and connectational patterns. ^[11]

The first synapse of a CN I bipolar neuron occurs in the olfactory bulb's *glomerulus*, a defining feature of both vertebrate and invertebrate olfactory systems ([Fig. 7-2](#)). The olfactory bulb of nonelderly humans has thousands of these 50- to 200- μm structures, arranged in single or double layers within the GL. With age, the number and integrity of the glomeruli greatly decrease, so that they are nearly absent in persons over the age of 80 years. ^[12] The development and maintenance of the glomeruli depend on trophic influences exerted by the receptor cells. Synapses between axons of the olfactory receptor cells and dendrites of second-order neurons occur within these structures. A given receptor cell projects to only one glomerulus, and a given glomerulus appears to receive most of its input from a restricted region of the epithelium.

The main afferent second-order neurons are termed mitral and tufted cells (see [Fig. 7-2](#)). The apical dendrites of these cells are influenced not only by the olfactory nerve terminals, but also by interneurons and centrifugal fibers, most of which are GABAergic or dopaminergic. ^[11]

Central Connections

The olfactory tract, which contains both afferent and efferent fibers, is relatively flat posteriorly and becomes the olfactory trigone just rostral to the anterior perforated substance (so named because of the many small holes for blood vessels found throughout this region). At the edges of the trigone, the tract divides into the medial and lateral olfactory striae.

The axons of the mitral and tufted cells arise from the caudolateral part of the olfactory bulb and form the olfactory tract at the surface of the olfactory peduncle. According to Price, ^[12] the consensus of studies performed during the last two decades is that there is no medial olfactory tract in mammals. Thus, all mitral and tufted cell axons leave the olfactory bulb via the lateral olfactory tract to synapse on structures collectively termed the primary olfactory cortex. These structures are (1) the anterior olfactory nucleus, (2) the olfactory tubercle (poorly developed in humans), (3) the piriform cortex, (4) the anterior cortical nucleus of the amygdala, (5) the periamygdaloid complex, and (6) the rostral entorhinal cortex. ^[12] The components of the olfactory cortex have rich (and reciprocal) relations with a number of higher brain structures. For example, the entorhinal cortex supplies afferent fibers along the entire length of the hippocampus, including the dentate gyrus. Indeed, because of these connections, the olfactory system has the most direct access of all sensory systems to the hippocampus. ^[11] It is generally believed that the olfactory system is unique among sensory systems in sending fibers directly to cortical regions without synapsing in the thalamus. Extensive interactions occur between the cells comprising the superficial and deeper laminae of each component of the olfactory cortex as well as among the components themselves. ^[11]

In humans, it appears that most of the projections of the mitral and tufted cells extend to the more rostral elements of the primary olfactory cortex. It is presently believed that specific sites within the bulb do not preferentially communicate with specific sites within the primary olfactory cortex; i.e., no obvious point-to-point topography exists. ^[11] Thus, small areas of the bulb can project to large areas of the olfactory cortex and vice versa. ^[12] Among the brain regions that exhibit reciprocal connections with the olfactory cortex are the orbitofrontal cortex, the dorsomedial and submedial thalamic nuclei, the lateral hypothalamus,

Figure 7-2 Diagram of major layers and types of olfactory bulb neurons in the mammalian olfactory bulb, as based upon Golgi stained material. Main layers are indicated on left as follows: ONL, olfactory nerve layer; GL, glomerular layer; EPL, external plexiform layer; MBL, mitral body layer; IPL, internal plexiform layer; GRL, granule cell layer; ON, olfactory nerves; PGb, periglomerular cells with biglomerular dendrites; PGm, periglomerular cell with monoglomerular dendrites; SAe, short-axon cell with extraglomerular dendrites; M, mitral cell; M/Td, displaced mitral or deep tufted cell; Tm, middle tufted cell; Ts, superficial tufted cell; Gm, granule cell with cell body in mitral cell layer; Gd, granule cell with cell body in deep layers; SAC, short-axon cell of Cajal; SAg, short-axon cell of Golgi; C, centrifugal fibers; AON, fibers from the anterior olfactory nucleus; AC, fibers from anterior commissure; LOT, lateral olfactory tract (From Shepherd GM: *Synaptic organization of the mammalian olfactory bulb*. *Physiol Rev* 1972; 52:864-917. Used with permission.)

the amygdala, and the hippocampus. ^[12] A major pathway from the olfactory cortex to the orbitofrontal cortex is via the mediodorsal nucleus of the thalamus.

Neurochemical Olfactory Transduction Processes

Peripheral olfactory transduction occurs in several stages: first, odorants move from the air phase of the nasal cavity into the aqueous phase of the olfactory mucus; second, odorants (most of which are hydrophobic) diffuse or are transported through this aqueous phase to the proteinaceous olfactory receptors; third, odorants bind to the receptors; fourth, action potentials are generated within the receptor neurons as a result of such binding; and fifth, integration of information occurs at higher levels, such as within the glomeruli of the olfactory bulb. Although some odorants stimulate nerve endings from CN V and perhaps other cranial nerves distributed in the nasal mucosa, nasal pharynx, or oral cavity, these involve primarily somatosensory sensations of the "common chemical sense," such as warmth or coolness, pungency, and irritation.

There is evidence that small water-soluble proteins, termed odorant-binding proteins, assist the movement of some hydrophobic lipid-soluble molecules through the mucus to the receptor proteins of the olfactory cilia. ^[13] Such assistance may be selective, and at least some of these proteins may serve to inactivate odorant molecules or filter the number of such molecules reaching the receptors. For example, some odor-induced signals appear to be rapidly abolished by detoxification or biotransformation enzymes within the mucus. ^[14]

After reaching the cilia, odorants bind to receptor sites located on their surface. Different models of ligand-receptor interactions have been proposed, although little is known about the specific nature of the odorant-receptor interactions. There is evidence, however, that G-proteins play an important role in olfactory transduction. G-proteins have been identified in olfactory receptor cells, ^[15] and adenylate cyclase, an enzyme that is usually coupled to a G-protein, is highly active in olfactory cilia. ^[16] The activity of this enzyme in cilia is increased in the presence of guanosine triphosphate (GTP) by a number of odorant ligands. ^[17] Interestingly, a positive correlation exists between an odorant's ability to activate adenylate cyclase activity in a frog ciliary preparation and both its perceived odor intensity to humans and the magnitude of the electro-olfactogram (EOG), a summated neural response produced in frog epithelia. This implies that a functional relation exists between the amount of adenylate cyclase activated and the intensity of odor perception. ^[18]

Recent studies indicate that there is marked genetic diversity in olfactory receptors. Buck and Axel, ^[19] in a pioneering study, identified a large multigene family that appears to code for odorant receptor proteins with seven transmembrane domains on rat olfactory sensory neurons. Subsequent studies have identified homologous gene families in a range of vertebrate forms, including humans. ^[20] As noted in a recent review by Sullivan and colleagues, ^[21] current estimates place the size of the olfactory receptor gene family in mammals at 500 to 1000 genes. This suggests

that the basis of the ability of mammals to smell thousands of odorants derives from a wide range of ligand specificities.

It has long been known, mainly from single cell electrophysiological recordings, that individual olfactory receptor cells respond to a wide variety of odorants, leading earlier workers to label olfactory receptor cells "generalists." However, on closer scrutiny, it has become evident that such cells do not respond exactly to the same sets of stimuli, which allows for the possibility of cross-neuron coding. Recent research, incorporating gene probes from in situ hybridization studies, has provided three new pieces of information about the distribution of receptors on olfactory receptor cells and the relationship of such cells to higher-order structures. ^[22] First, most rodent olfactory receptor genes are expressed in only about 0.1 percent of the population of olfactory sensory neurons, in accordance with the hypothesis that each sensory neuron expresses only one or at most a few receptor genes. Second, neurons expressing the same gene do not clump together within the olfactory epithelium but seem to be randomly distributed within the epithelium in "spatial zones," across which different sets of olfactory receptor genes are expressed. ^[22] For example, in the mouse four such zones, formed as a series of strips extending along the anterior-posterior axis of the nasal cavity, have been identified. Neurons that recognize the same odors (i.e., express the same olfactory receptor genes) are more or less confined to the same zone. Third, axons of neurons that express the same odorant receptor tend to converge on a small number of glomeruli within the olfactory bulb, suggesting that each glomerulus may be dedicated to only one or a very small number of receptor types, receiving input from only receptor cells expressing that receptor type. As noted by Sullivan and colleagues, ^[21] "a stereotyped and highly organized map of sensory information exists in the bulb, in which information provided by different ORs (odorant receptors) is mapped into discrete sites. As a single odorant can activate many glomeruli and a single glomerulus responds to many odorants, this map may well be a map of individual structural determinants, or epitopes, each shared by many odorants and recognized by different ORs."

A number of odorants produce a dose-related increase in intracellular cyclical adenosine 3

,5
-monophosphate (cAMP) in olfactory receptor cells,^[17] thereby triggering the opening of cAMP-gated cation channels.^[23] There is a suggestion that a seemingly small set of other odorants increases the formation of intraciliary inositol-1,4,5-triphosphate (IP₃), which in turn directly gates plasma membrane Ca²⁺ channels that produce cell depolarization.^[24] Stimuli with similar odor qualities, however, do not all activate the same second messenger but induce the formation of either cAMP or IP₃.^[25]

EXAMINATION OF CRANIAL NERVE I

Directed Neurological Examination

Essential components of the directed physical examination include a neurological evaluation emphasizing the cranial nerves and orbital contents (to direct attention to lesions of the skull base) as well as a general evaluation of the ears, upper respiratory tract, and head and neck. Although much can be gained by evaluating the nose using anterior rhinoscopy, nasal endoscopy allows a more thorough assessment. With this procedure, the rhinologist can often directly visualize the olfactory neuroepithelium and establish whether airflow access to the epithelium is blocked. In the nasal examination, the nasal mucosa is evaluated for color, surface texture, swelling, inflammation, exudate, ulceration, epithelial metaplasia, erosion, and atrophy. Discovery of purulent rhinorrhea, especially its site of origin, is considered significant; if it is present throughout the nasal cavity, rhinitis is suggested. If rhinorrhea is present in the middle meatus, maxillary or anterior ethmoid sinusitis is possible, whereas if the frontal recess is involved, frontal sinusitis is implicated. Finally, if rhinorrhea originates from the superior meatus or sphenoidal recess, posterior ethmoid or sphenoid sinusitis is likely. The presence of polyps, masses, adhesions of the turbinates to the septum, and marked septal deviations all have the potential to decrease airflow to the olfactory epithelium. Allergy is suggested if the mucous membrane is pale, usually as a result of edema within the lamina propria. Chronic or acute exposure to environmental or industrial pollutants is suggested by metaplasia within the epithelium as well as by swelling, inflammation, exudate, erosion, or ulceration. Atrophy of the lamina propria is suggested by unusual spaciousness, dryness, and crusting, as seen in atrophic rhinitis or rhinitis medicamentosa.

Quantitative testing of olfactory function is essential to (1) establish the validity of a patient's complaint, (2) characterize the specific nature of the problem, (3) reliably monitor changes in function over time, including those resulting from medical interventions or treatments, (4) detect malingering, and (5) establish compensation for permanent disability. It should be noted that some patients who present with complaints of anosmia or hyposmia actually have normal function relative to their peers. Others can be unaware of their deficits. For example, approximately 90 percent of patients with idiopathic Parkinson's disease have a demonstrable olfactory loss, yet less than 15 percent are aware of the problem until they are tested objectively.

Historically, a popular means of assessing the ability to smell has been to ask a patient to sniff a few small vials containing odorants such as coffee or cinnamon and then report whether or not an odor is perceived. Unfortunately, this procedure is akin to testing vision by shining an intense light into the eye and asking whether or not it can be seen. This problem is not corrected by asking the patient to attempt to identify an odor, since, without cues, even normal subjects have difficulty in identifying some odors. Although most olfactory disorders can be detected by administering a wide variety of nominally distinct olfactory tests, including tests of odor detection, discrimination, identification, and memory, interpretation of the findings of such tests must be done conservatively. All such tests are influenced by damage to the olfactory membrane, making it dangerous to assume, in any given case, that poor performance on a specific type of test (e.g., odor memory) has anything to do with damage to the neural circuits underlying the name of the test (e.g., odor memory circuits). The

fact that the reliability (and hence sensitivity) of a number of such tests is low or unknown adds further difficulty to attempts to establish differential function.

Since assessment of olfactory function often has both medical and legal consequences, accuracy in olfactory testing is essential. Anosmia or hyposmia is a common consequence of head injury and is frequently the only residual neurological impairment of a fall or motor vehicle accident. In the United States, disability compensation is provided under the 1963 amendment to the Workman's Compensation Law when a diminution of future earning power is apparent, and the Veterans Administration awards a 10 percent whole body disability for total anosmia. The *Guides to the Evaluation of Permanent Impairment* published by the American Medical Association provide another authoritative basis for disability compensation.^[26] However, this document equates total anosmia and total ageusia (a condition that exists rarely, if ever) with a 3 percent impairment of the whole person, a figure that is far below the amount given in most legal settlements for anosmia alone and that many view as insufficient. In Great Britain, disability benefits for anosmia resulting from an injury are available under the National Insurance Act as well under private accident insurance policies. Occupation must be taken into account in disability issues because loss or decreased smell function is quite a different matter for persons in some occupations (e.g., chefs, plumbers, wine tasters, municipal gas workers) than in others (e.g., sanitation workers).

Five practical clinical quantitative tests of olfactory function of known reliability are now commercially available. The most widely used of these tests is the University of Pennsylvania Smell Identification Test (UPSIT), also known as the Smell Identification Test (Sensonics, Inc., Haddonfield, NJ).^[27],^[28] The UPSIT, which can be self-administered in 10 to 15 minutes by most patients in the waiting room and scored in less than a minute by nonmedical personnel, consists of four booklets containing 10 odorants apiece. The stimuli are embedded in 10- to 50- μ m diameter microencapsulated crystals located on "scratch and sniff" strips near the bottom of each page. Above each strip is a multiple choice question with four response alternatives. The patient is required to choose an answer, even if none seems appropriate or no odor is perceived (i.e., the test is forced-choice). This helps to encourage the patient to carefully sample each stimulus and provides a means of detecting malingering; since chance performance is 10 out of 40, very low scores reflect avoidance, and hence recognition, of the correct answer. Norms based on the administration of this test to nearly 4000 people are provided, and an individual's percentile rank is established relative to persons of the same age and gender.^[28] This test makes it possible to classify an individual's function, on an absolute basis, into one of six categories: normosmia, mild microsmia, moderate microsmia, severe microsmia, anosmia, and probable malingering. The reliability of this test is high (test-retest Pearson $r_s > 0.90$).

The four other commercially available olfactory tests are the three-item forced-choice microencapsulated Pocket Smell Test (which is only a brief screening test), the 12-item Cross-Cultural Smell Identification Test (CC-SIT),^[29] the five-odorant T&T olfactometer threshold test,^[30] and a squeeze bottle odor threshold test kit.^[31] With the exception of the Pocket Smell Test, the test-retest reliability coefficients of these tests are around 0.70. Norms that take into account both age and gender are available only for the UPSIT and CC-SIT, although the small number of items in the latter test allows neither differentiation between degrees of olfactory loss nor a means for determining malingering.

Although most cases of olfactory dysfunction are bilateral, in some instances unilateral testing is needed. To accurately assess olfaction unilaterally, the naris contralateral to the tested side should be occluded to prevent or minimize crossing of inhaled or exhaled air at the rear of the nasopharynx to the opposite side (so-called retronasal stimulation). An easy way of doing this is to seal the contralateral naris using a piece of Microfoam tape (3M Corporation, Minneapolis, MN) cut to fit its borders. The patient is instructed to sniff the stimulus normally and to exhale through the mouth.

Associated Neurological Findings

Cerebral. The neurologist should be alert to signs of dementia (e.g., inattention, memory dysfunction, apathy, disorientation) in patients presenting with olfactory dysfunction, since decreased ability to smell is among the first signs of Alzheimer's disease and is also seen in some patients with Huntington's chorea, multi-infarct dementia, and Pick's disease. Evidence of fainting spells or blackouts, disorientation, seizure activity, and mood change should be sought because both increases and decreases in olfactory function are found in patients with temporal lobe epilepsy. Olfactory loss, along with short-term memory problems and associated confabulation, may help to define vitamin B₁ deficiency and the Wernicke-Korsakoff syndrome. Cognitive alterations (e.g., mental slowing, confusion, depression, and hallucinations) may also signal the presence of pernicious anemia.

Cranial Nerves. Optic disk examination and documentation of increased intraocular or intracranial pressure (papilledema) should be obtained because tumors in the olfactory groove or sphenoid ridge (e.g., meningiomas) can cause the Foster Kennedy syndrome, which is composed of three clinical hallmarks--ipsilateral anosmia or hyposmia, ipsilateral optic atrophy, and contralateral papilledema. Although rare, visual disturbances are caused by some forms of sinusitis, which can also alter chemosensation. For example, optic neuropathy has been reported secondary to cocaine-induced osteolytic sinusitis.^[32] Altered visual contrast sensitivity, color perception, and perception of the visual vertical may provide additional information about a more diffuse chemosensory disorder. Hearing problems may reflect viral or bacterial infections in the middle ear that alter taste function in the anterior tongue via chorda tympani nerve (CN VII) damage or inflammation, as well as more general nasal sinus infections that also influence olfaction. Specifically, patients with Korsakoff's syndrome have deficits not only in memory and olfactory function but also in color discrimination and several measures of auditory perception, including dichotic listening tasks. Pupillary reaction to light is also sluggish in patients with this syndrome,

and horizontal nystagmus and ophthalmoplegia, usually involving the bilateral lateral recti in isolation or with other extraocular muscle palsies, are also commonly present.

Applying small drops of sweet, sour, bitter, and salty tasting stimuli (with water rinses between applications) to the fungiform papillae on the front of the tongue (which are innervated by the chorda tympani division of CN VII) and on the circumvallate papillae at the rear of the tongue (CN IX) can be useful in identifying regional deficits and damage to specific nerves involved in taste perception. Iatrogenic factors, such as tonsillectomy, can damage CN IX fibers and produce taste distortions, whereas alterations in CN VII function (i.e., the chorda tympani nerve) can be caused by middle ear infections. Local factors (e.g., dryness, inflammation, edema, atrophy, abnormal surface texture, leukoplakia, erythroplasia, exudate, erosion, and ulceration) can influence taste function through a variety of means (e.g., gastric reflux), as can poor oral health and the use of smokeless tobacco.^[33]

Motor/Reflexes/Cerebellar/Gait. Attention to ataxia, apraxia for orolingual movements, oculomotor abnormalities, coordination problems, gait disturbances, tremor, bradykinesia, and rigidity is critical, since alterations in the ability to smell are present in some patients with Huntington's chorea and multiple sclerosis, and in approximately 90 percent of patients with early-stage Parkinson's disease. In Korsakoff's syndrome, ataxia of the trunk but not of the limbs is frequently present, as are signs of acute alcohol withdrawal (e.g., tremor, delirium, and tachycardia).

Sensory. Decreased position, vibratory, temperature, and pain appreciation occurs in several neuropathies associated with hyposmia. These include diabetes, the neuropathy of renal and hepatic failures, and a large variety of toxic neuropathies. In patients with pernicious anemia, the large myelinated central fibers carrying position and vibration senses are preferentially affected. In the context of hepatitis, the acquired immune deficiency syndrome (AIDS), and other virus-related illnesses, hyposmia can occur along with an ascending polyneuropathy of the Guillain-Barre type. In seizure patients with uncal or temporal lobe foci that induce dysosmic auras, altered sensations in a hemibody distribution can occur as part of the seizure or as a postictal transient sequela.

Associated Medical Findings

Evidence of a fever or stiff neck may help to determine the presence of an ongoing infection, including very serious disorders such as meningitis, which can be associated with chemosensory dysfunction. Flamboyant signs or inconsistencies in the examination may signal psychogenic factors or a propensity for malingering. Signs of diabetes should be sought, since both olfactory and gustatory dysfunction may be altered in this disorder.

EVALUATION GUIDELINES

Neuroimaging. The sensitivity of computed tomography (CT) to soft tissue disease and bony changes makes it ideal for the investigation of the sinonasal cavities. All of the nasal cavity, paranasal sinuses, hard palate, anterior skull base, orbits, and nasopharynx should be scanned and, if central causes of olfactory dysfunction are suspected, the brain as well. Coronal scans are particularly valuable for the assessment of the paranasal anatomy, namely, the anterior nasoethmoid (ostiomeatal) region (i.e., the maxillary sinus ostium, infundibulum, uncinate process, and middle meatus). To better identify vascular lesions, tumors, abscess cavities, and meningeal or parameningeal processes, intravenous contrast enhancement is frequently employed. Presently, high-resolution CT appears to be the most useful and cost-effective screening tool for the assessment of sinonasal tract inflammatory disorders.

Magnetic resonance imaging (MRI) is superior to CT in the discrimination of soft tissue but is less sensitive than CT to bony cortical abnormalities or landmarks. Thus, MRI is the technique of choice for the evaluation of the olfactory bulbs, olfactory tracts, and intracranial causes of olfactory dysfunction because they can be visualized rather clearly on coronal scans. MRI is also the method of choice for the evaluation of skull base invasion by sinonasal tumors. Gadolinium-enhanced scans are particularly valuable in detecting dural or leptomeningeal involvement at the skull base. The paramagnetic contrast agent gadolinium-DTPA has been widely used to enhance the margins of sinonasal tumors and to distinguish solidly enhancing tumors from rim-enhancing inflammatory processes.^[34]

Electrophysiology. Outpatient testing for EEG activity in individuals with dysosmia may be enhanced by using electrodes placed in the nasopharyngeal region or over the lower temporal areas. Inpatient EEG monitoring is indicated if epileptic-like olfactory events occur frequently but cannot be discerned by outpatient testing procedures.

Although odor-evoked potentials can now be measured accurately in most patients, the stimulus presentation equipment is complex and is at present very expensive (more than \$100,000); thus, such testing is available in very few clinics. The major technical problem is that trains of well-defined odorant pulses, with steep-onset gradients, must be imbedded in a humidified airstream that is flowed through the nose in a manner that does not evoke somatosensory afferents. To date, only late near-field potentials have been recorded using this technique. When available, evoked potential olfactometry is useful in detecting malingering as well as for providing information about olfactory function that does not depend on verbal or other overt responses of the patient.

Fluid and Tissue Analysis. In patients in whom a clear cause is not found, a complete blood count (CBC) may be indicated to better define whether infective, nutritional, or hematopoietic processes are involved. A nonspecific indication of an autoimmune or inflammatory process can be obtained from the erythrocyte sedimentation rate. Although frank zinc deficiency has the potential to alter olfactory function, there is no evidence that zinc treatment of persons without stark zinc deficiency influences any olfactory disorder. Indeed, a double-blind clinical trial using a cross-over design in which zinc was compared to placebo showed no advantage of zinc over placebo in the treatment of hyposmia or hypogeusia.^[35] Since vitamin B₁ deficiency is clearly implicated in the Wernicke-Korsakoff syndrome, determination of the erythrocyte thiamine level is indicated in patients with a significant history of suspected or documented

chronic alcohol abuse. Early reports that vitamin A therapy may be of value in some cases did not include controls, making the efficacy of this therapy enigmatic.

Neuropsychological Tests. Given the close association between olfactory loss and several forms of dementia, including Alzheimer's disease and multi-infarct dementia, neuropsychological testing may be indicated to better identify the presence of dementia (for details of the tests listed below, see reference 36). The mini-mental state examination is a widely used brief screening instrument for dementia and can be used alone or as a component of examination protocols such as the Consortium to Establish a Registry for Alzheimer's Disease (CERAD) battery. More extensive assessment of dementia can be obtained using either the Mattis Dementia Rating Scale, the Blessed Dementia Scale, the Boston Naming Test, or the logical memory and visual reproduction subtests of the Wechsler Memory Scale--Revised (WMS-R). The WMS-R and the California Verbal Learning Test have proved useful in patients in whom schizophrenia is suspected.

Malingering can be detected or is strongly suspected when a person scores below chance level on the UPSIT. Further verification of malingering can be obtained by administering neuropsychological tests specifically designed for this purpose. Among those that are widely used are Rey's memory test (RMT), also known as Rey's 3 x 5 test and the Rey 15-item memory test. The rationale behind this test is that malingerers typically fail at a memory task that all but the most retarded or severely brain-damaged persons perform easily. Another widely used test, the Portland digit recognition test, incorporates, like the UPSIT, a forced-choice procedure to ascertain whether test performance falls below that expected on the basis of chance. Unfortunately, this test takes nearly an hour to administer and provides no other neuropsychological information. Abbreviated versions of this test, however, are available.

Other Tests. To document changes in cellular aspects of the olfactory neuroepithelium, olfactory biopsies can be performed. In this procedure, a small amount of olfactory neuroepithelial tissue is stripped from the nasal septum by the rhinologist using small forceps or a specialized instrument and subsequently analyzed histologically.^{[37], [38]} This procedure must be performed by a surgeon who is experienced in the technique, and multiple biopsies are usually needed, given the considerable metaplasia of respiratory-like epithelium in the region of the olfactory neuroepithelium.

CLINICAL SYNDROMES (Table 7-2)

Anosmia and Hyposmia

Loss or decreased olfactory function is estimated to be present in approximately 1 percent of the American population under the age of 60 and in more than half of the population over that age.^[39] The causes of loss or decreased olfactory function are variable, and simply establishing the presence of olfactory loss per se provides little insight into the cause. Nearly two thirds of patients with chronic anosmia or hyposmia (i.e., those that are presumably permanent) are due to prior upper respiratory infections, head trauma, and nasal and paranasal sinus disease, and most reflect damage to the olfactory neuroepithelium.^[4] Other causes include iatrogenic interventions (e.g., septoplasty, rhinoplasty, turbinectomy, radiation therapy), intranasal neoplasms (e.g., papillomas, hemangiomas, and ameloblastomas), intracranial tumors or lesions (e.g., Foster Kennedy syndrome, olfactory groove meningiomas, frontal lobe gliomas), epilepsy, psychiatric disorders, exposure to environmental chemicals, hypothyroidism, renal disease, and kidney disease. According to Finelli and Mair,^[40] the single most egregious error of neurologists in dealing with olfactory disturbances is the failure to recognize the symptom of anosmia as the principal or sole feature of an olfactory groove meningioma. Five to 10 percent of head trauma patients have olfactory dysfunction, and the majority of these have anosmia.^[41] Of particular interest to the neurologist is the observation that olfactory dysfunction may be the first sign of Alzheimer's disease and idiopathic Parkinson's disease.^[39] Patients with intractable epilepsy who are candidates for temporal lobe resection have a hyposmic condition prior to surgery. In most of these cases the hyposmia is bilateral, although asymmetry in function can be present, the greatest decrement being observed on the side of the focal damage. Interestingly, after surgical removal of diseased tissue in the right hemisphere, some measures of olfactory function improve significantly on the left side of the nose.

In most patients with congenital anosmia, MRI reveals a lack of or marked hypoplasia of the olfactory bulbs and stalks bilaterally. For example, in a study of 25 patients with congenital anosmia from the University of Pennsylvania Smell and Taste Center, MRI revealed an absence or hypoplasia of olfactory bulbs and tracts in all instances.^[42] Verification of a physical cause of this disability proved to be quite therapeutic for some of these individuals.

Dysosmia

Dysosmia (disordered smell perception) presents as either a distortion in the perceived quality of an odor (*parosmia*, *cacosmia*) or as the presence of a strange odor in the absence of actual odor stimulation (*phantosmia* or *olfactory hallucinations*). Most dysosmias reflect dynamic elements associated with degeneration (or, more rarely, regeneration) of the olfactory epithelium and remit over time. However, it is common for patients with anosmia to report that prior to the onset of anosmia they experienced a period of weeks or months when dysosmia was present. Extremely debilitating chronic dysosmias have been reported that have required surgical intervention, such as ablation of portions of the olfactory epithelium^[43] or removal of the olfactory bulbs.^[44] Most such cases present unilaterally. More commonly, dysosmias are part of the sequelae of events that occur after the olfactory nerve fibers have been partially damaged by upper respiratory infections, head trauma, nasal sinus disease, or other disorders. In the majority of these cases, marked smell loss does not accompany the dysosmic condition, implying that it requires a relatively intact sensory system for expression.

TABLE 7-2 -- SELECTED ETIOLOGIES ASSOCIATED WITH DISORDERS OF CRANIAL NERVE I

Etiological Category	Selected Specific Etiologies	Chapter
STRUCTURAL DISORDERS		
Developmental	Kallmann's syndrome	28
Degenerative and compressive	Schizophrenia	
	Usher's syndrome	29
HEREDITARY AND DEGENERATIVE DISORDERS		
Amino/organic acidopathies, mitochondrial enzyme defects and other metabolic errors	Trimethylaminuria	31
Chromosomal abnormalities and neurocutaneous disorders	Down's syndrome	32
Degenerative dementias	Alzheimer's disease	33
	Pick's disease	
Movement disorders	Idiopathic Parkinson's disease	34
	Huntington's disease	
Degenerative motor, sensory, and autonomic disorders	Amyotrophic lateral sclerosis	36
ACQUIRED METABOLIC AND NUTRITIONAL DISORDERS		
Endogenous metabolic disorders	Diabetes	38
	Hypothyroidism	
	Kidney disease	
	Liver disease	
Exogenous acquired metabolic disorders of the nervous system: Toxins and illicit drugs	Toxic chemical exposure	39
Nutritional deficiencies and syndromes associated with alcoholism	Wernicke-Korsakoff syndrome	40
	Cirrhosis	
INFECTIOUS DISORDERS		
Viral infections	Upper respiratory viral infection	41
	Acute viral hepatitis	
	Acute poliomyelitis (CNs XI, XII)	
Nonviral infections	Bacterial meningitis	43
	Neurosyphilis (CN XII)	
	Pneumonia	
HIV and AIDS	Human immunodeficiency virus (HIV)	44
NEUROVASCULAR DISORDERS	Stroke	45
NEOPLASTIC DISORDERS		
Primary neurological tumors	Foster Kennedy syndrome	46
Metastatic neoplasms and paraneoplastic syndromes	Metastatic carcinoma	47
DEMYELINATING DISORDERS		
Demyelinating disorders of the central nervous system	Multiple sclerosis	48
AUTOIMMUNE AND INFLAMMATORY DISORDERS	Allergies	50
TRAUMATIC DISORDERS	Head trauma	51
EPILEPSY	Temporal lobe epilepsy	52

In rare instances, dysosmias reflect aura-like processes that are suggestive of central brain tumors or lesions, particularly lesions of the temporal lobe. In some cases, aura-like dysosmias can be chronic or occur regularly without producing any evidence or any clear sign of seizure activity (although, as noted earlier in this chapter, inpatient EEGs may be needed to detect infrequent partial seizure episodes). A few psychiatric syndromes, like olfactory reference syndrome, are also associated with dysosmic episodes, as are metabolic disturbances such as trimethylaminuria.

Hyperosmia

Hyperosmia (heightened smell function) is a relatively rare condition, usually of idiopathic origin, in which quantitative olfactory testing reveals heightened performance (e.g., UPSIT scores of 40 and detection threshold values that are several orders of magnitude below those of normal subjects). Although untreated adrenal cortical insufficiency is reportedly accompanied by hyperosmia,^[45] this work has not been replicated, and animal studies have showed no evidence of heightened odor detection performance following adrenalectomy.^[46] Indeed, adrenalectomy reduces rather than enhances peripheral nerve responses to a number of types of sensory stimuli, including tastants.^[47] There have been suggestions of hyperosmia in patients with syndromes such as multiple chemical sensitivity, but the limited data available fail to support this notion.^[48] Hyperosmia occurs in some patients with epilepsy during the interictal period, although, as noted earlier, patients with long-term epilepsy

100

and intractable seizure activity, such as candidates for temporal lobe resection, typically are hyposmic.

Dissociated Olfactory Function Syndromes

Some types of olfactory tests (e.g., tests of odor identification and discrimination) may be altered by central brain lesions that have little or no influence on other types of olfactory tests (e.g., odor detection thresholds). Thus, a dissociation between elements of the olfactory perceptual process may occur. For example, H.M., the only patient on record to have undergone bilateral temporal lobe resection, is said to perform normally on tests of odor detection, suprathreshold intensity discrimination, and adaptation, but abnormally on tests of odor quality discrimination and identification.^[49] In one study, resection of left temporal lobes, right or left frontal lobes, and the right frontotemporal region significantly depressed scores on the UPSIT but not on a detection threshold test.^[50] As noted earlier, however, care must be taken in the interpretation of such test results, given the fact that many olfactory tests, most notably some olfactory threshold tests, are relatively unreliable and thus insensitive to subtle alterations in smell function.

GENERAL MANAGEMENT GOALS

Patients with complaints of olfactory dysfunction, regardless of etiology or anatomical localization, should receive careful sensory and neurological testing to ensure accurate categorization of both their sensory problem and, ideally, its physiological basis. In patients in whom anosmia or hyposmia is caused by airway blockage, treatment to relieve the edema or physical obstruction can be undertaken with optimism. Examples of treatments that have restored such function include allergic management, topical and systemic corticosteroid therapies, antibiotic therapy, and various surgical interventions. In cases in which tumors are the cause of the problem, their removal with the goal in mind of maintaining the integrity of the olfactory pathways can sometimes restore olfactory function. For patients with dysosmia, a careful review and systematic cessation of drugs that are potentially associated with the dysfunction may be fruitful in some instances, although this process can take several months, depending on the mode of action of the drugs involved and the number of medications being taken by the patient. In rare cases of long-term chronic dysosmia severe enough to produce depression, weight loss, or nausea because of the perversion of food flavor, surgical intervention may be indicated. If the dysosmia is unilateral (detected by blocking the flow of air to one side of the nose or by anesthetizing the olfactory membrane unilaterally), unilateral surgical intervention may correct the problem while sparing olfactory function on the contralateral side. Of the surgical approaches, intranasal ablation or stripping of tissue from the olfactory epithelium on the affected side is more conservative and less invasive than removing the olfactory bulb or tract through a craniotomy. Should the dysosmia reappear after such surgery, additional intranasal ablations may be performed.

Treatment of patients with anosmia due to sensorineural problems is challenging. Although there are a few advocates of zinc and vitamin therapies, sound empirical evidence of their efficacy is lacking. In patients in whom olfactory loss has been present for a long period of time and can be attributed to neural damage within the olfactory neuroepithelium, prognosis is poor, and no treatment is possible. Nevertheless, simply providing such patients with accurate information about their disorder, establishing objectively the degree and nature of the deficit, and ruling out the possibility of a serious disorder as the cause of the problem can diminish anxiety and may be very therapeutic. Because half of elderly persons with permanent olfactory loss are at or above the fiftieth percentile of their norm group, these individuals can be informed that while their olfactory function is below what it used to be, they still are outperforming most of their peers. This knowledge is extremely therapeutic and helps them place the natural age-related loss of olfactory function in a broader perspective.

HISTORY AND DEFINITIONS

The afferent visual pathways encompass structures responsible for perceiving, relaying, and processing visual information: the eyes, optic nerves (cranial nerve II), chiasm, tracts, lateral geniculate nuclei, optic radiations, and striate cortex. In general, the visual abnormalities caused by lesions anterior to and including the chiasm cause acuity (clarity) loss, color deficits, and visual field defects (abnormal central or peripheral vision). From a neuro-ophthalmical standpoint, patients with unilateral retrochiasmal disturbances present primarily with visual field defects without acuity abnormalities. Higher order processing, which is instrumental for interpreting visual images, occurs in extrastriate association cortex. Abnormalities in these areas cause, for instance, deficits in object recognition, color perception, and visual attention (neglect of visual stimuli in left or right hemifields).

This chapter reviews the neuroanatomical features of these structures and provides a systematic approach to the evaluation of clinical syndromes involving cranial nerve II, other parts of the afferent visual pathway, and higher cortical visual areas.

[PreviousNext](#)

CLINICAL HISTORY

Common complaints encountered with visual loss include so-called negative phenomena such as blurry vision or gray vision. Patients with higher cortical disorders often have nonspecific complaints such as "I'm having trouble seeing" or "difficulty focusing." Patients with lesions of the afferent visual pathway may also complain of positive phenomena, such as flashing or colored lights (phosphenes or photopsias), jagged lines, or formed visual hallucinations (illusions of something that is not there). The level of visual image complexity does specify localization (see later).

The temporal profile of the visual loss suggests possible diagnoses, and its monocular or binocular nature helps in localization. As a general rule, acute or subacute visual deficits result from ischemic or inflammatory conditions or may be caused by a vitreous hemorrhage or retinal detachment. Chronic or progressive visual loss, in turn, may result from a compressive, infiltrative, or degenerative process. Cataracts, refractive error, open-angle glaucoma, and retinal disorders such as age-related macular degeneration or diabetic retinopathy also need to be considered when visual symptoms are insidious.

If a patient complains of monocular visual loss, a process

in one eye or in the optic nerve should be considered. Painful monocular visual loss is characteristic of an inflammatory or demyelinating optic neuropathy. With binocular visual loss, a lesion of both eyes or optic nerves, or of the chiasm, tract, radiations, or occipital lobe should be investigated. Associated neurological deficits, such as motor or sensory abnormalities, also assist in localization and often indicate a hemispheric abnormality. Medical conditions should always be investigated in the review of systems. Hypertension and diabetes, for instance, predispose the patient to vascular disease, and a history of coronary artery disease should alert the examiner to the possibility of carotid artery insufficiency as well. Visual loss accompanied by endocrine symptoms, such as those consistent with hypopituitarism (e.g., amenorrhea, decreased libido, impotence) or pituitary hypersecretion (e.g., galactorrhea, acromegaly), suggests a chiasmal disorder.

[Previous](#)[Next](#)

ANATOMY OF CRANIAL NERVE II AND AFFERENT VISUAL PATHWAYS [Table 8-1](#))

Overview

Retinal ganglion cell axons carry visual information to the brain via the optic nerve, chiasm, and tract. A small portion subserves the pupillary light reflex by leaving the optic tract to reach the mesencephalon. Other axons synapse in the lateral geniculate body, which in turn sends projections via the optic radiations to reach striate cortex in the occipital lobe. Visual information undergoes higher order processing in occipitotemporal, temporal, occipitoparietal, and parietal lobes.

Eyes

The eyes are the primary sensory organs of the visual system. Before reaching the retina, light travels through the ocular media, consisting of the cornea, anterior chamber, lens, and vitreous. The size of the pupil, like the aperture of a camera, regulates the amount of light reaching the retina. The cornea and lens focus light rays to produce a clear image on the retina, and the ciliary muscle changes the lens shape to adjust for objects at different distances (accommodation). ^[1]

Retina

Retinal processing of visual information occurs before its transmission through the optic nerve and remainder of the afferent visual pathway. The cone and rod photoreceptors

TABLE 8-1 -- CLINICOANATOMICAL CORRELATION OF DISORDERS OF CRANIAL NERVE II AND AFFERENT VISUAL PATHWAYS

Anatomical Location	Visual Phenomena	Other Neurological and Medical Findings	Possible Etiologies
Retina	Transient monocular visual loss	Hollenhorst's plaque	Carotid disease, giant cell arteritis, migraine, vasospasm, cardiac emboli
	Acute monocular visual loss	Cherry-red spot, box-carring	Central retinal artery occlusion
	Subacute monocular visual loss	Retinal hemorrhage, cotton wool spots, dilated retinal veins	Central retinal vein occlusion
	Subacute monocular visual loss	Vitreous opacification	Vitreous hemorrhage
	Impaired visual acuity	Metamorphopsia	Central serous chorioretinopathy, macular degeneration
Optic nerve	Ipsilateral visual loss (decreased acuity decreased color vision, central scotoma, altitudinal field defect)	Optic atrophy, optic disc swelling	Optic neuritis, ischemic optic neuropathy, compressive lesions
Optic chiasm	Bitemporal hemianopsia, decreased acuity and color vision	Optic atrophy	Pituitary adenoma, craniopharyngioma, optic glioma, meningioma, aneurysm
Optic tract	Contralateral incongruous homonymous hemianopia	Contralateral relative afferent pupillary defect, "bowtie" optic atrophy	Pituitary adenoma, craniopharyngioma, aneurysm
Optic radiations	Contralateral homonymous hemianopia	Preserved visual acuity, intact pupillary response, decreased OKN to side of lesion, sensory loss, hemiparesis	MCA stroke, temporal or parietal mass lesion
Occipital lobe	Contralateral congruous homonymous hemianopia (with or without macular sparing), quadrantic field defect, homonymous hemianopic central scotoma, cortical blindness (if bilateral)	Usually isolated deficits	PCA stroke, migraine, Alzheimer's, hypertensive encephalopathy
Association cortex	Cerebral hemiachromatopsia		Lingual and fusiform gyri lesion
	Alexia without agraphia		Left occipital lobe and splenium of corpus callosum lesion
	Visual agnosia, prosopagnosia		Bilateral medial occipitotemporal lesions
	Defective motion perception		Lateral occipitotemporal lesion (Brodmann area 39)
	Left hemifield visual neglect	Auditory and tactile neglect in left hemifield	Right parietal lesion
	Balint's syndrome (optic ataxia, simultagnosia, ocular apraxia) Palinopsia		Bilateral occipito-parietal lesions Temporo-occipital lesion

OKN, optokinetic nystagmus; MCA, middle cerebral artery; PCA, posterior cerebral artery

first convert light (photons) to neuronal signals. The cones are located primarily in the middle of the retina, or *macula*, which is dedicated to central vision. The center of the macula, called the *fovea centralis*, is composed exclusively of cones. The rods occupy the retinal periphery. They subserves peripheral vision and are more useful in dim situations. Cones function best in bright light and are more important for color vision. Three types of cone photoreceptors are found, and each has a characteristic absorption spectra and responds best to blue, green, or red light. The perceived color of an object is based upon the extent to which each of the three classes of cone photoreceptors is stimulated. ^[2]

The pigment molecules rhodopsin (in rods) and cone opsin (in cones) both contain 11- *cis*-retinal and are situated in the membrane of the outer segment of the photoreceptors. Light causes 11- *cis*-retinal to change to *trans*-retinal, and this process causes a conformational change in rhodopsin and cone opsin. The activated pigments stimulate transducin, which then activates cyclic guanosine monophosphate phosphodiesterase (cGMP), which causes the breakdown of cGMP to 5'-GMP. Sodium channels, which are normally open in the dark, are then forced to close, resulting in hyperpolarization of the cell. ^[3] Photoreceptor signals are communicated to bipolar cells, then to the retinal ganglion cells, and these messages are modified by amacrine cells and horizontal cells ([Fig. 8-1](#)).^[4]

The nasal retina receives visual information from the temporal field, and the temporal retina receives visual information from the nasal field. The superior and inferior halves of the retina have a similar crossed relationship with respect to lower and upper fields of vision. This type of parceling of visual information continues throughout the afferent visual pathway.

The majority of the blood supply of the eye travels via the ophthalmic artery, which is the first major intradural branch of the internal carotid artery, although there are external carotid anastomoses. The first major branch of the ophthalmic artery, the central retinal artery, pierces the dura of the optic nerve just behind the globe and travels within the nerve (Fig. 8-2 (Figure Not Available)). The central retinal artery then emerges at the disc surface where it typically branches into superior and inferior branches, each of which in turn divides into nasal and temporal branches to supply the four quadrants of the inner two thirds of the retina. The ophthalmic artery also gives rise to the long and short posterior ciliary arteries. The long posterior ciliary arteries pierce the sclera lateral to the optic nerve to supply the ciliary body and iris. The short posterior ciliary arteries enter the sclera near the optic nerve to supply the prelaminar portion of the optic nerve and outer one third of the retina. In some individuals, a cilioretinal artery, supplied by the choroidal circulation, may be seen at the temporal edge of the disc. The cilioretinal artery can provide

an alternate blood

Figure 8-1 The three nuclear layers of the retina contain five major classes of cells: photoreceptors (rods and cones), bipolar cells, horizontal cells, amacrine cells, and ganglion cells. Photoreceptors, bipolar, and horizontal cells make synaptic connections with each other in the outer plexiform layer. The bipolar, amacrine, and ganglion cells make contact in the inner plexiform layer. Information flows vertically from photoreceptors to bipolar cells to ganglion cells and is modified by horizontal cells in the outer plexiform layer and amacrine cells in the inner plexiform layer. Output of visual information from the retina transported through the retinal ganglion cell axons. (From Tessier-Lavigne M: *The retina and phototransduction*. In Kandel ER, Schwartz JH, Jessell TM [eds]: *Principles of neural science*. East Norwalk, CT, Appleton & Lange, 1991, p 409.)

Figure 8-2 (Figure Not Available) The blood supply of the optic nerve head is derived primarily from the arteriolar anastomotic circle of Zinn-Haller, which is supplied by the posterior ciliary arteries, the pial arteriole plexus, and the peripapillary (Redrawn from Hayreh SS: *The central artery of the retina*. *Br J Ophthalmol* 1963; 47:655.)

supply to the papillomacular and macular regions in the event of a central retinal artery occlusion. ^[1]

Optic Nerve

The optic nerve has four major portions: intraocular, intraorbital, intracanalicular, and intracranial. The intraocular portion, the optic disc, consists of the unmyelinated retinal ganglion cell axons and astrocytes and is situated 3 to 4 mm nasal to the fovea. As the nerve exits the globe, it traverses the lamina cribrosa, which is a trabeculated meshwork of collagenous tissue. Just posterior to this, the optic nerve increases in diameter as it becomes myelinated by oligodendrocytes. At this point, the optic nerve is also invested with pia, arachnoid, and dura. The arachnoid extends to the sclera of the globe and contains cerebrospinal fluid (CSF) that is contiguous with that of the central nervous system (CNS). The dural covering fuses with the sclera around the optic nerve and more posteriorly blends into the periosteum of the optic canal. ^[1]

The intraorbital segment of the optic nerve is approximately 5 mm longer than the distance from the orbital apex to the posterior aspect of the globe. Within the orbital apex, the optic nerve is encased by the annulus of Zinn, which consists of the connective tissue origins of the superior, medial, lateral, and inferior rectus muscles. The nerve then passes through the optic foramen into the bony optic canal, which lies posteromedially in the sphenoid bone. The paired optic nerves course medially and rise at an angle of 45 degrees toward the chiasm. Intracranially, the optic nerves lie inferior to frontal lobes (gyrus recti) and anterior cerebral and anterior communicating arteries. ^[1]

The blood supply of the optic disc is derived from the arteriolar anastomotic circle of Zinn-Haller, which is supplied by the posterior ciliary arteries, the pial arteriole plexus, and the peripapillary choroid (see Fig. 8-2 (Figure Not Available)). Perforating branches of the ophthalmic artery supply the intraorbital segment of the optic nerve. The intracanalicular and intracranial portions of the optic nerve are supplied by a neurovascular network derived from the ophthalmic artery, internal carotid, anterior cerebral, and anterior communicating arteries. The central retinal artery does not directly supply the optic nerve. ^[1], ^[2]

Optic Chiasm

The optic nerves join at the optic chiasm, which lies in the suprasellar region, superior to the diaphragma sella, inferior to the third ventricle and hypothalamus, and just anterior to the infundibular stalk. The chiasm tilts forward at an angle of 45 degrees and most commonly lies directly above the pituitary fossa, although occasionally it may be prefixed or postfixed in position relative to the sella. Within the chiasm, fibers from the nasal retina cross, and the most ventral axons from the inferior nasal retina bend temporarily through the contralateral optic nerve (Wilbrand's knee), whereas the fibers from temporal retina remain ipsilateral (Fig. 8-3 (Figure Not Available)). The existence of Wilbrand's knee has come into question. ^[1] The ratio of crossed to uncrossed fibers is 53 to 47 percent, respectively. The fibers transmitting visual information from the superior retina remain superior in the chiasm, whereas those from the inferior retina remain situated inferiorly. The papillomacular bundles lie superiorly and posteriorly within the chiasm. ^[1], ^[2]

Most of the fibers traveling through the optic chiasm are destined for the optic tracts and lateral geniculate bodies. Retinal projections may also exist from the posterior chiasm to the hypothalamus, specifically the suprachiasmatic nucleus or the supraoptic nucleus. ^[1] This pathway is thought to mediate the visual input responsible for diurnal variations of neuroendocrine systems. The chiasm's neuroanatomical locale in relation to surrounding vascular structures is important, given the potential aneurysms and subsequent visual field defects that they may produce. The carotid arteries ascend lateral to the optic chiasm, and the precommunicating segments of the anterior cerebral arteries lie superior to the chiasm. ^[1]

Figure 8-3 (Figure Not Available) Optic chiasm: correlation of lesion site and field defect. (From Liu GT: *Disorders of the eyes and eyelids*. In Samuels MA, Feske S [eds]: *The office practice of neurology*. New York, Churchill-Livingstone, 1996, p 46. Adapted from Hoyt WF, Luis O: *The primate chiasm*. *Arch Ophthalmol* 1963; 70:69-85. Copyright© 1963, American Medical Association.)

The chiasm derives its blood supply from an inferior and superior anastomotic group of vessels. ^[1] The inferior group is made up of the superior hypophyseal arteries, which derive their blood supply from the internal carotid, posterior communicating, and posterior cerebral arteries. The superior group of vessels consists of precommunicating branches of the anterior cerebral arteries. ^[1]

Optic Tract and Lateral Geniculate Body

The afferent visual fibers exit the chiasm posteriorly and diverge to form the left and right optic tracts, each of which is made up of ipsilateral temporal fibers and contralateral nasal fibers. The optic tracts sweep around and above the infundibulum, below the third ventricle, and superomedially to the uncus gyri. They then turn posterolaterally to the interpeduncular cistern, just ventral to the rostral midbrain and cerebral peduncles.

Most of the fibers synapse within the ipsilateral lateral geniculate nucleus; however, a few axons depart from the optic tract to complete the afferent limb of the pupillary light reflex. These fibers pass ventral to the medial geniculate nucleus; then they continue through the brachium of the superior colliculi before reaching the pretectal nuclei, where they synapse (Fig. 8-4 (Figure Not Available)). In turn, these nuclei connect bilaterally to the Edinger-Westphal nuclei in the oculomotor complex. Parasympathetic pupillary fibers leave the brain stem within the third nerve, then synapse in the

Figure 8-4 (Figure Not Available) Pupillary light reflex-parasympathetic pathway. Light entering one (straight black arrow, bottom right) stimulates the retinal photoreceptors (RET), resulting in excitation of ganglion cells, whose axons travel within the optic nerve (ON), partially decussate in the chiasm (CHI), then leave the optic tract (OT) (before the lateral geniculate nucleus [LGN]) and pass through the brachium of the superior colliculus (SC) before synapsing at the mesencephalic pretectal nucleus (PTN). This structure connects bilaterally within the oculomotor nuclear complex at the Edinger-Westphal (E-W) nuclei, which issues parasympathetic fibers that travel within the third nerve (inferior division) and terminate at the ciliary ganglion (CG) in the orbit. Postsynaptic cells innervate the pupillary sphincter, resulting in miosis. Note light in one eye causes bilateral pupillary constriction. (From Liu GT: *Disorders of the eyes and eyelids*. In Samuels MA, Feske S [eds]: *The Office Practice of Neurology*. New York, Churchill-Livingstone, 1996, p 61. Adapted from Siamovits TL, Glaser JS: *The pupils and accommodation*. In Glaser JS [ed]: *Neuro-ophthalmology*, 2nd ed. Philadelphia, J.B. Lippincott, 1990, p 460.)

ciliary ganglion in the orbit. Postganglionic fibers mediate pupillary constriction. Details regarding the Edinger-Westphal nuclei in oculomotor complex are contained in the chapter on cranial nerves III, IV, and VI (see [Chapter 9](#)).

The lateral geniculate nucleus (LGN), which is situated within the lateral recess of the choroidal fissure, above the ambient cistern, is considered part of the thalamus. Coronally, the LGN has six neuronal layers, and the input into each is monocular and retinotopically organized. Visual information from the ipsilateral eye synapses within laminae 2, 3, and 5, whereas that from the contralateral eye synapses within laminae 1, 4, and 6. Layers one and two contain large neurons (magnocellular LGN layers), whereas layers three through six contain smaller neurons (parvocellular LGN layers). Studies suggest the existence of at least two types of retinal ganglion cells (M and P, respectively) that project preferentially to each group, and that each layer may have distinct projections within the striate cortex as well.

The blood supply of the optic tract is variable but typically comes from an anastomotic network made up of the anterior thalamic perforators (from the posterior cerebral artery) and the anterior choroidal artery (from the internal carotid artery). The LGN also has a rich anastomotic blood supply made up of the anterior and posterior choroidal arteries. The lateral wedge of the LGN is supplied by the anterior choroidal artery, the medial wedge by the posterior choroidal artery, and the middle wedge (hilum) by both vascular supplies. In about 50 percent of cases, small portions of the LGN receive blood from other small posterior cerebral artery

(PCA) branches. Ischemic lesions to the posterior portion of the optic tract and the LGN are considered rare because of their rich anastomotic blood supply. ^[1], ^[2]

Optic Radiations

The optic radiations (geniculocalcarine fibers) exit dorsally from the LGN, then spread into two major bundles. The group of fibers containing contralateral superior quadrant visual information (inferior fascicle) curves in an anteroinferior direction into the anterior pole of the temporal lobe, forming Meyer's loop. The superior fascicle lies deep within the parietal lobe and subserves visual information from the contralateral inferior quadrant. The temporal and parietal fascicles project in a retinotopic fashion to the lower and upper banks of calcarine cortex, respectively.

The temporal portion of the optic radiations receives its blood supply from the anterior choroidal artery and other middle cerebral artery (MCA) branches within the sylvian fissure, including the lenticulostriate and inferior temporo-occipital artery. The distal branches of the MCA, including the angular and posterior temporal arteries, supply the more superiorly situated parietal fascicles. The most posterior portions of the optic radiations, just before their entry into the occipital lobe, are supplied by the superior temporo-occipital sylvian artery branch of the MCA and the anterior temporal and calcarine arteries of the posterior cerebral artery (PCA). ^[3], ^[4]

Striate Cortex

Brodmann area 17 (or V1, primary, calcarine, or striate cortex) is the end organ of the afferent visual system and is situated in the occipital lobe. The upper bank of striate cortex lies superior to the calcarine fissure, and the lower bank lies below the fissure. Other boundaries of striate cortex include the splenium of the corpus callosum anteriorly, interhemispheric fissure medially, and occipital pole posteriorly. Laterally, some striate cortex may be visible on the posterolateral outer surface of the occipital lobes.

Neuronal input arrives in a retinotopic fashion from fibers of the LGN and synapses within striate cortex, which is divided into six layers. The thick, light-colored layer IV is visible to the naked eye and has been termed the *striae*

of Gennari. The parvocellular neurons synapse within the layer IVB, whereas the magnocellular cells synapse within layers II and III. ^[5] Fibers from the medial aspect of the LGN, carrying information from superior retina, project to the upper bank of the calcarine cortex, whereas those from the lateral aspect, carrying information from the inferior retina, project to the lower bank. The inferior visual fields are thus represented within the upper bank, and the superior visual fields are represented within the lower bank. Left and right visual fields are represented within right and left occipital lobes, respectively. Macular projections synapse in the occipital pole and occupy about one half the entire surface area of striate cortex. The occipital tip is devoted to foveal vision.

The majority of the blood supply to striate cortex derives from branches of the PCA: the calcarine artery, mostly, with lesser contributions from the posterior temporal and parieto-occipital arteries. In most cases, small penetrating branches from the calcarine artery supply both the upper and lower banks of calcarine cortex. In up to one third of cases, one major branch to each bank may be seen. At the occipital pole, there is an anastomosis between PCA vessels and the superior temporo-occipital sylvian artery from the MCA. This dual blood supply to the area responsible for central vision is one vascular explanation for macular sparing in the setting of PCA occlusion.

Visual Association Areas

Extrastriate areas V2 and V3 surround V1 above and below the calcarine sulcus. Isolated and clinically apparent lesions of V2 and V3 are unusual, but a combined lesion of V2 and V3 restricted to upper or lower bank typically causes a homonymous quadrantic visual field defect. ^[6]

Higher cortical processing of visual information occurs in visual association areas, which are divided anatomically and functionally into ventral and dorsal pathways. In general, the ventral stream (occipitotemporal) is more concerned with object recognition ("what") and represents the continuation of the parvocellular pathway. ^[7] Area V4, which is situated in the lingual and fusiform gyri, is responsible for color perception within the contralateral hemifield. ^[8] Bilateral mesial occipitotemporal regions are necessary for object and facial recognition. ^[9] ^[10] ^[11] In contrast, the dorsal stream carries out functions related to spatial orientation ^[12] (the "where" pathway) and is the extension of the magnocellular pathway. The parietal lobe is devoted to directed attention. Evidence suggests that Brodmann area 39, within the lateral occipitotemporal region, is analogous to monkey area MT and is important for motion perception.

EXAMINATION OF CRANIAL NERVE II AND AFFERENT VISUAL PATHWAYS

Directed Neurological Examination

VISUAL ACUITY

Visual acuity is a measurement of the individual's capacity for visual discrimination of fine details of high contrast. ^[17] Best corrected visual acuity should be tested for each eye. ^[1] Distance vision is assessed with a standard Snellen chart and near vision with a hand-held card. If the patient does not bring corrective lenses for the examination, a pinhole can correct most refractive errors.

Acuity is most often recorded as, for example, 20/40, in which the numerator refers to the distance (in feet) from which the patient sees the letters and the denominator the distance from which a patient with normal vision sees the same letters. Visual acuity with the near card is often recorded using the standard Jaeger notation (J1, J3, etc). If a patient is unable to read the largest Snellen letters (20/200 or 20/400), the acuity should be characterized by the ability to count fingers (CF) (and at what distance), detect hand motions (HM), or have light perception (LP). An eye that is blind has no light perception (NLP). Contrast sensitivity testing with sine-wave gratings is a useful adjunct in the evaluation of visual acuity. In younger preverbal patients, assessment of fixing and following in most instances is sufficient. When more accurate visual acuities are required, preferential looking tests (Teller's acuities) may be used. ^[18] These tests are based upon the principle that a child would rather look at objects with a pattern stimulus (alternating black and white lines of specific widths) than at a homogeneous field. The smallest pattern that the child seems to prefer is an indicator of best visual acuity.

Visual acuity can be altered by macular, optic nerve, or chiasmal lesions. Disturbances that are posterior to the chiasm (retrochiasmal, that is, tract, optic radiations, and occipital lobe) can affect visual acuity only if they are bilateral.

COLOR PERCEPTION

Color vision can be tested with standard pseudoisochromatic Ishihara or Hardy-Rand-Ritter plates, both of which contain numbers or geometrical shapes that the patient is asked to identify among different colored dots. ^[2] Qualitative inter-eye differences in color perception can be tested by comparing a red bottle top, for example, with each eye. A patient with monocular "red desaturation" may state that with the affected eye the red bottle top appeared washed out, pink, or orange.

Color vision can be altered by macular, optic nerve, or chiasmal lesions. Retrochiasmal disturbances can produce abnormal color vision in the defective visual field. A lesion of the lingual and fusiform gyri can cause defective color vision in the contralateral hemifield.

VISUAL FIELD TESTING

Testing the patient's visual fields can be accomplished at the bedside by finger confrontation methods in all four quadrants of each eye by asking the patient to "count my fingers" or "tell me when you first see my finger wiggling." In a patient who is aphasic, uncooperative, intubated, sedated, or very young, responses such as finger mimicry, pointing to targets presented, visual tracking, or reflex blink to visual threat allow for a gross assessment of visual field integrity. Color or subjective hand comparison is a useful

adjunct to elicit defects respecting the vertical or horizontal meridians. ^[1] To test central or macular vision, an Amsler grid (similar to a piece of graph paper with a central fixation point) can be viewed by the patient. Patients may perceive abnormal areas on the grid that may correspond with visual field deficits.

Accurate documentation of visual fields requires kinetic testing with a tangent screen, Goldmann's perimeter, or automated threshold perimeter. The Goldmann's kinetic technique is useful when evaluating patients with significant neurological impairment, because it is shorter and involves interaction with the examiner. Threshold computerized perimetry of the central 30 degrees of vision is a more sensitive and reproducible test for patients with optic neuropathies and chiasmal disturbances. When visual fields are recorded, they are presented so that the right field is to the right and the left field to the left. The blind spot, corresponding to the optic nerve, is located approximately 15 degrees temporal to fixation and is recorded as an area without vision. ^[1]

The visual field can be altered by lesions anywhere in the afferent visual pathway, and the specific patterns in relationship to neuroanatomical structures are discussed in more detail later.

HIGHER CORTICAL VISUAL FUNCTION

It is often difficult to separate a dense left hemianopia from dense neglect in a patient with a large right parietal lesion. In instances when the deficits are more subtle, the examiner can screen for visual inattention by presenting visual stimuli, such as a fingers, separately in each hemifield, then together on both sides of midline (double simultaneous visual stimulation). People with subtle visual inattention but intact fields see the stimulus when presented separately but not when shown simultaneously. Other bedside tests include letter cancellation, in which the patient is asked to find a specific letter or shape within a random array. Patients with left visual neglect may find the specified letter only when it appears on the right side of the page. When patients with left neglect are asked to bisect lines drawn randomly on a page, they may tend to "bisect" the lines to the right of their center.

In patients suspected of agnosias, informal tests of visual recognition can be performed at the bedside using common objects such as a pen, cup, or book. An inability to recognize faces (prosopagnosia) or interpret complex scenes (asimultagnosia) can be tested with magazine or newspaper photos and advertisements. Standardized facial and object recognition tasks are available during more formal neuropsychological testing.

PUPILLARY EXAMINATION

The size of each pupil can be measured in light and dark using the pupil scale found on most near-acuity cards. Pupillary light reactivity is tested with a bright light, such as a halogen transilluminator, while the patient fixes on a distant object (to avoid accommodation). While the light is shining in one eye, the ipsilateral pupillary light reflex, termed the *direct response*, and the contralateral, termed the *consensual response*, should be noted. Transient fluctuations in pupillary diameter are normal and are called *hippus*. The swinging flashlight test involves alternating a bright light equally at each eye to compare each pupil's reactivity to light. Because light from one eye will reach both Edinger-Westphal nuclei (see Fig. 8-4 (Figure Not Available)), normally both pupils react briskly when light is shined into just one eye, and the amount of constriction is the same regardless of which eye is stimulated.

If one eye has reduced vision owing to an optic neuropathy or large retinal process, light directed into that eye produces a relatively weaker pupillary response in both eyes (relative afferent pupillary defect [RAPD]) (see Fig. 8-5). ^[1] Asymmetrical chiasmal disturbances may lead to an RAPD in the eye with worse acuity or greater field loss. Optic tract lesions can be associated with an RAPD in the contralateral eye, owing to interruption of the crossing nasal fibers, which outnumber the uncrossed temporal fibers. Because afferent pupillary fibers leave the afferent visual pathway before the geniculate, geniculocalcarine disorders are not associated with pupillary abnormalities.

FUNDUSCOPIC EXAMINATION

The posterior pole of the eye can be viewed with a direct ophthalmoscope through an undilated pupil. Any

Figure 8-5 A, Normal swinging flashlight test, in which light directed in either eye elicits the same amount of pupillary constriction. Swinging flashlight test revealing a left relative afferent pupillary defect (L RAPD) in the hypothetical setting of visual loss in the left eye due to an optic neuropathy. Pupillary sizes are equal at rest in ambient lighting (b-1). Light stimulation of the good right eye results in brisk bilateral pupillary constriction (b-2). Light stimulation of the defective left eye produces comparatively weaker pupillary constriction, and both pupils dilate (b-3).

Figure 8-6 (Figure Not Available) Photograph(left) of a normal left fundus. The corresponding illustration(right) identifies important structures.(From Liu GT: Disorders of the eyes and eyelids. In Samuels MA, Feske S [eds]: The Office Practice of Neurology. New York, Churchill-Livingstone, 1996, p 41.)

media opacity due to corneal exposure, cataract, or vitritis, for instance, can create a hazy view. Posteriorly, the optic disc, retinal vasculature, macula, and peripapillary retina should be carefully examined (Fig. 8-6 (Figure Not Available)). Important details of the optic disc that should be noted include its color and contour and cup-to-disc ratio. The retinal vasculature should be evaluated in detail, with particular attention to the caliber of arteries and veins, branching patterns, and, when suspected, possible emboli. The macula, best observed by asking the patient to look at the direct ophthalmoscope's light, is examined for evidence of degeneration, lipid deposition, detachment, edema, or change in pigment color. Thorough evaluation of the retinal periphery requires a pharmacologically dilated pupil and indirect ophthalmoscopy.

Optic disc swelling suggests an optic neuropathy or papilledema. Chronic optic nerve processes lead to disc atrophy. Macular disturbances are associated with central field loss and decrease in visual acuity. If large enough, other retinal abnormalities can also cause corresponding field loss. For instance, retinitis pigmentosa beginning peripherally causes field constriction, whereas inferior branch retinal artery occlusion is associated with a superior altitudinal field defect.

ANCILLARY OPHTHALMOLOGICAL TECHNIQUES

The evaluation of patients with disorders of the afferent visual pathways often is enhanced by consultation with an ophthalmologist or neuro-ophthalmologist, who has ancillary ophthalmological equipment available. The most common cause of blurry vision is refractive error, and an ophthalmologist is the individual best to make the required measurements. Applanation tonometry is a necessary screen for glaucoma. An exophthalmometer helps measure anterior protrusion of the eye, and it is indispensable when following proptosis, for example, in a patient with thyroid orbitopathy.

Slit lamp examination (biomicroscopy) uses what essentially is a horizontally mounted microscope and a special light source to visualize directly the cornea, anterior chamber, iris, vitreous, and posterior pole of the fundus (disc and macula, primarily). Indirect ophthalmoscopy, using a 20-diopter lens, allows more complete visualization of the posterior pole and peripheral retina. Both techniques follow pharmacological dilation of the pupil (usually 2.5 percent phenylephrine and 1 percent tropicamide topically), and each permits a stereoscopic view of the fundus, which is especially important when evaluating disc swelling, disc contour, cup-to-disc ratio, and macular edema. In addition, both slit lamp biomicroscopy and indirect ophthalmoscopy employ very bright light sources, allowing greater visualization of structures in the back of the eye when there is a media opacity such as a cataract.

Associated Neurological Findings

Cerebral. Hemianopias that result from lesions of the optic radiations are often associated with other "cortically-based" neurological findings. Temporal lobe lesions may be accompanied by personality changes, complex partial seizures, memory deficits, fluent aphasia (if the dominant side is involved), or Kluver-Bucy syndrome (hypersexuality, placidity, hyperorality, visual and auditory agnosia, and apathy) with involvement of the anterior temporal lobes bilaterally. Conduction aphasia, Gerstmann's syndrome (finger agnosia, agraphia, acalculia, and right-left disorientation), and tactile agnosia, all suggest a dominant parietal lobe process. Left-sided neglect, topographic memory loss, constructional and dressing apraxias, in association with a left hemianopia, suggest a nondominant parietal lesion. More parieto-occipital or occipitally-based visual disturbances such as in Balint's syndrome or cortical blindness may accompany dementia in Creutzfeldt-Jakob disease, progressive multifocal leukoencephalopathy, or Alzheimer's disease.

Cranial Nerves. Lesions causing visual loss and ocular motility deficits frequently exhibit characteristic recognizable

symptom complexes. For instance, orbital apex disturbances cause an optic neuropathy and third, fourth, and sixth cranial nerve dysfunction, as well as cranial nerve V1 distribution sensory loss, and oculosympathetic paresis. Suprasellar masses may compress the optic chiasm, and if large enough, can extend laterally to involve cranial nerves III, IV, VI, V1, and V2 within the cavernous sinus. In rare instances, seesaw nystagmus occurs in association with sellar lesions with bitemporal hemianopias. In this unique motility disturbance, one eye elevates and intorts while the other depresses and extorts, then the process reverses and repeats. Deep parietal lobe lesions can produce a homonymous hemianopia and poor tracking of objects moving toward the lesion. This effect results from involvement of the optic radiations and adjacent descending corticobulbar fibers from the parieto-occipitotemporal pursuit area.

In contrast, normal optokinetic responses can be expected in a hemianopia due to a lesion solely within the occipital lobe. Bilateral parietal lesions may cause abnormal initiation of voluntary eye movements, despite normal reflex saccades and pursuit (ocular motor apraxia), as seen in Balint's syndrome (see later). Hemianopias related to occipital lobe infarction may be associated with brain stem ocular motor dysfunction, if the etiology is vertebrobasilar occlusion. Patients with a hemianopia or neglect may have a gaze preference away from the visual deficit.

Patients with cerebellar disease and acquired nystagmus, particularly pendular, may complain of oscillopsia, the illusion of motion, and may suffer a reduction in visual acuity. Conversely, patients with bilateral visual loss involving the anterior visual pathways, especially if congenital or acquired in childhood, may develop nystagmus with vertical and horizontal components.^[19] Patients with severe visual loss of any type may also display a "searching" nystagmus in their attempt to localize objects without adequate visual feedback.

Patients with multiple sclerosis presenting with optic neuritis may have nystagmus or a unilateral or bilateral internuclear ophthalmoplegia, indicating previous white matter involvement in the posterior fossa.

Motor/Reflexes/Cerebellar/Gait. Hemispheric lesions may produce a homonymous field defect and ipsilateral hemiparesis when the optic radiations and motor strip or descending motor fibers are disrupted. A proximal posterior cerebral artery occlusion causes a similar clinical picture by leading to infarction of the cerebral peduncle in the midbrain and of the occipital lobe. Signs of cerebellar dysfunction such as nystagmus, truncal or appendicular ataxia, dysmetria, intention tremor, dysidiadochokinesia, or scanning speech together with a congruous homonymous hemianopia suggest vertebrobasilar occlusion. Patients with multiple sclerosis presenting with optic neuritis may have cerebellar signs indicating previous white matter involvement. Any process affecting both the afferent visual pathways and corticospinal tracts can cause visual loss and hyperreflexia. For instance, large hemispheric lesions can be expected to result in contralateral hemianopia and hyperreflexia. Conditions affecting central myelin (e.g., multiple sclerosis or acute disseminated encephalomyelitis) can cause optic or chiasmal neuropathy as well as spasticity and hyperreflexia. In central and peripheral dysmyelinating syndromes, there may be visual loss and hyporeflexia.

Sensory. A homonymous field defect in combination with ipsilateral sensory loss, astereognosis, decreased two-point discrimination, or graphesthesia suggests a parietal lesion. A process within the nondominant (usually right) parietal lobe can also produce a contralateral neglect syndrome or hemianopia, accompanied by contralateral sensory inattention. Pain, hemianesthesia, or choreoathetoid movements and an ipsilateral homonymous field deficit imply co-involvement of the thalamus and optic radiations.

Autonomic Nervous System. Autonomic system dysfunction, primarily because of pupillary and lacrimal disturbances, may lead to visual complaints. For instance, patients with pathological mydriasis due to parasympathetic dysfunction can suffer from photophobia or refractive error. The latter results from exposing spherical aberrations in the lens and cornea. Tonic pupils (Adie's pupils, for instance) are associated with accommodative insufficiency, and patients may complain of difficulty reading. Lacrimation abnormalities cause dry corneas, resulting in hazy views with irritative symptoms that are responsive to topical lubrication. Horner's syndrome (oculosympathetic dysfunction), by itself, should not cause visual abnormalities.

Neurovascular. Amaurosis fugax due to carotid stenosis may be associated with a carotid bruit, although that finding is notoriously unreliable. Cranial or ocular bruits may indicate an intracranial arteriovenous malformation or a carotid-cavernous fistula. In some instances of visual loss due to anterior ischemic optic neuropathy, underlying giant cell arteritis is suggested by tender, cord-like temporal arteries.

Associated Medical Findings

A thorough but directed general examination of all patients can often provide important clues to neuro-ophthalmical diagnoses. It is impossible to list all the abnormalities one may find; however, some examples are reviewed.

Proptosis or periorbital fullness suggests an orbital process such as Graves' disease, orbital meningioma, or orbital pseudotumor. The patient's general appearance may suggest an underlying chromosomal, endocrinological, or metabolic disorder. For instance, the disfiguring frontal bossing and enlargement of the mandible and hands are characteristic of acromegaly associated with a growth hormone-secreting pituitary adenoma. The heart rate, blood pressure, and carotid and cardiac examinations are important in any patient with a possible ischemic event. Patients with pseudotumor cerebri tend to be young females with obesity or a history of recent weight gain. Skin lesions such as erythema migrans (Lyme disease) or malar rash (systemic lupus erythematosus), and abnormal discolorations, such as cafe(c)-au-lait spots and axillary freckling (neurofibromatosis), or hypopigmented ash-leaf spots (tuberous sclerosis) also may be helpful in guiding the evaluation of patients with visual disturbances.

EVALUATION GUIDELINES (Table 8-2)

Neuroimaging. Most patients with suspected optic neuropathies should undergo neuroimaging to exclude a compressive

TABLE 8-2 -- USEFUL STUDIES IN THE EVALUATION OF DISORDERS OF CRANIAL NERVE II AND AFFERENT VISUAL PATHWAYS

Syndrome	Neuroimaging	Electrophysiology	Fluid and Tissue Analysis	Neuropsychological Tests	Other Tests
Retina	MRA: carotid occlusion, stenosis, or dissection	Abnormal electroretinogram if photoreceptors are affected	Elevated ESR in giant cell arteritis	N/A	Vascular occlusion or leakage on fluorescein angiography Thromboembolic source on cardiac echography or carotid ultrasound
Optic nerve	MRI with gadolinium and fat saturation, coronal views: optic nerve enlargement or enhancement, or compressive mass lesion	Visual evoked potentials: decreased amplitude or increased latency	Elevated ESR in giant cell arteritis. CSF pleocytosis if inflammatory	N/A	N/A
Optic chiasm	MRI with gadolinium, thin coronal and sagittal cuts through sella: chiasmal enlargement or enhancement, or sellar compressive mass	N/A	CSF pleocytosis if inflammatory, endocrine studies showing evidence of hypopituitarism or hormone hypersecretion	N/A	N/A
Optic tract	MRI: compressive mass	N/A	N/A	N/A	N/A
Lateral geniculate body	MRI: infarction	N/A	N/A	N/A	N/A
Optic radiations	MRI: infarction or tumor MRA: carotid or MCA occlusion	N/A	N/A	Deficits in spatial ability and attention	Thromboembolic source on cardiac echography or carotid ultrasound
Occipital lobe	MRI: infarction or tumor MRA: posterior circulation occlusion	N/A	N/A	N/A	Thromboembolic source on cardiac echography
Higher cortical areas	MRI: infarction or tumor	N/A	N/A	Deficits in color perception or object or face recognition	Thromboembolic source on cardiac echography
Visual hallucinations	MRI: infarction or tumor	Epileptiform discharges on EEG if hallucinations are due to seizures	N/A	N/A	N/A
Other positive visual phenomena	MRI: infarction or tumor	Epileptiform discharges if positive phenomena are due to seizures	N/A	N/A	N/A

MRA, magnetic resonance angiography; MRI, magnetic resonance imaging; ESR, erythrocyte sedimentation rate; EEG, electroencephalogram; CSF, cerebrospinal fluid; N/A, not applicable.

or inflammatory process. The major exceptions are typical optic neuritis (although magnetic resonance imaging [MRI] scan may be appropriate to determine the prognosis for developing subsequent multiple sclerosis) or classic anterior ischemic optic neuropathy. Transient visual loss in the setting of migraine does not require neuroimaging when the historical features are characteristic and results of the neurological examination are normal. All patients with chiasmal and retrochiasmal patterns of visual loss should undergo imaging examination.

In general, MRI, with and without gadolinium, is the preferred technique for the evaluation of patients with suspected lesions of the afferent visual pathway. ^[20], ^[21] In addition to the usual brain studies, some special instances require further neuroimaging. For instance, when an optic nerve process is suspected, MRI of the orbits with fat

saturation and coronal views should be obtained. The chiasm is best imaged with additional thin cuts, coronal and sagittal, through the sellar area. Vascular disturbances, whether occlusive or aneurysmal, require MRI-angiography, and then in some instances, formal angiography. Computerized tomography (CT) is helpful when fractures, bony erosion, or calcification is suspected, as in meningiomas or craniopharyngiomas.

Some experimental functional neuroimaging techniques may be helpful in cases when MRI or CT evaluation is inconclusive. Using positron emission tomography (PET) or single-proton emission computed tomography (SPECT) techniques, hypoperfusion in visual association areas may be demonstrated in patients with visual agnosias, achromatopsia, and deficits in motion perception, for example. ^[22] Functional MRI can highlight areas of cortical activation by detecting small changes in local blood flow. Functional MRI technique may be more helpful for localization of normally functioning areas of brain.

Amaurosis fugax, central retinal artery occlusion, and ischemia in the middle and anterior cerebral artery distributions necessitate Doppler examination or MRI-angiography of the carotids. Echocardiography should be performed when a cardiac embolus or patent foramen ovale is suspected.

Electrophysiology. Other diagnostic tests used in combination with the clinical examination include electrophysiologic testing such as an electroretinogram (ERG) or visual evoked potential (VEP). ERGs measure rod and cone photoreceptor function and help to distinguish the retinal degenerations and dystrophies. VEPs measure the cortical activity in response to flashes of light or checkerboard stimuli and if abnormal suggest a lesion of the afferent visual pathway. VEPs, when the result is normal, are particularly helpful in excluding organic lesions when functional visual loss is suspected. In addition, they can detect clinically silent lesions in the afferent visual pathway of patients with multiple sclerosis. VEPs should never take the place of the clinical examination and field testing, however, in the diagnosis or follow-up of patients with optic neuropathies or chiasmal disturbances. When cardiac source emboli are suspected, arrhythmias should be excluded by telemetry or Holter monitoring.

Fluid and Tissue Analyses. Blood studies are indicated when specific pathological processes are suspected. Vascular events may require evaluation of the erythrocyte sedimentation rate (ESR), rapid plasmin reagin (RPR), antinuclear antibody (ANA), and coagulation indices such as prothrombin time, partial thromboplastin time (PT and PTT), and platelet count. The ESR is especially important in transient or permanent visual loss in the elderly to rule out giant cell arteritis. In young individuals without an obvious risk factor for stroke, protein C, protein S, antithrombin III, antiphospholipid antibody, and anticardiolipin antibody levels should be obtained. A toxicology screen is necessary if drug use is suspected. Most intracranial mass lesions require either at least brain biopsy if a primary neoplasm is suspected, or a metastatic evaluation if multiple metastases are more likely. In many cases of demyelinating disease, other autoimmune, inflammatory,

and infectious disorders should be excluded by evaluating the ANA titer result, angiotensin converting enzyme (ACE) level, Lyme disease titer, and ESR, for instance.

When visual loss due to a sellar process is suspected, pituitary and hypothalamic function should be evaluated. The basic outpatient endocrinological panel should include serum prolactin, growth hormone (GH) (after a 75-g oral glucose load), insulin-like growth factor-I, adrenocorticotrophic hormone (ACTH), cortisol (serum morning sample or 24-hour urine free cortisol), thyroid-stimulating hormone (TSH), T3, T4, luteinizing hormone (LH), follicle-stimulating hormone (FSH), estradiol, and testosterone level. Low values, and even normal ones in some instances, are consistent with hypopituitarism. High values imply pituitary hypersecretion by a pituitary adenoma.

Cerebrospinal Fluid. In some instances, CSF examination may aid in establishing the cause of visual loss. Inflammatory and infectious processes require CSF analysis (cell count, protein, glucose, Gram's stain, and culture [bacterial, fungal, and viral when indicated]) when suspected. Carcinomatous or lymphomatous meningitis may require CSF cytology testing, including flow cytometry if available.

When pseudotumor cerebri is suspected in an individual with papilledema and normal neuroimaging results, a lumbar puncture (LP) is necessary to rule out meningitis, for example, and to document the CSF opening pressure. The lumbar puncture should be performed with the patient relaxed in a lateral decubitus position, with the head and spine at the same level and the neck and knees slightly flexed. To establish the diagnosis of pseudotumor cerebri, the CSF opening pressure should exceed 250 mm H₂O, which is the upper limit of normal for most obese and nonobese people.^[23] Approximately 20 to 30 ml of CSF can be removed, although the optimal amount has not been studied. In suspected cases with a normal CSF opening pressure, monitoring for 1 hour with an epidural transducer or subarachnoid bolt may be considered,^[24] but such a procedure is rarely done in clinical practice. The cell count and glucose levels should be normal, and the protein level normal or low.^[25]

LPs are not necessary in the evaluation of patients with typical isolated optic neuritis, because they rarely change the diagnosis and do not add to information garnered from an MRI in predicting the future development of multiple sclerosis.^[26] The protein and glucose levels are usually normal, and only one third of patients have a pleocytosis that is between 6 to 27 white blood cells (WBC)/mm³ and rarely ever higher. Myelin basic protein can be detected in about one fifth of patients and IgG synthesis in about two fifths. Oligoclonal banding occurs in approximately half of these patients and is associated with the future development of clinically definite multiple sclerosis. Oligoclonal banding usually occurs in the presence of white matter lesions on MRI, however, which has been found to be highly correlated with the future evolution of multiple sclerosis. Therefore, oligoclonal banding adds little to the prognosis when neuroimaging, which is less invasive, has already been performed.^[26]

Neuropsychological Testing. Neuropsychological assessment of higher cognitive functions can be used as an adjunct to the neuro-ophthalmic examination. By combining the disciplines of neurology and cognitive psychology, it is possible to analyze systematically the subcomponents

14

of complex cognitive abilities or "information processing." The general functions that may be analyzed in detail include attention, speech and language, memory (short- and long-term, verbal and visual), visuospatial and perceptual functions (neglect, construction, praxia, and agnosia), and specific thought processes that include calculations, abstractions, judgment, and problem solving.^[27]

Other Tests. Color stereo disc photographs aid frequently in the management of patients with optic disc swelling and pseudopapilledema due to disc drusen, for instance. Fluorescein angiography highlights the choroidal and retinal vasculature and involves intravenous injection of an aqueous fluorescein solution. Funduscopic pictures are taken before injection and at specific intervals after injection. This method detects vascular occlusion, abnormal retinal pigmentation or hemorrhages, and disturbances of the retinal pigmented epithelium. Truly swollen discs leak fluorescein, whereas, in general, discs with pseudopapilledema do not.

CLINICAL SYNDROMES ([Table 8-3](#))

Retina

Retina-related visual loss is usually painless and, in the acute setting, is almost always associated with some abnormality

TABLE 8-3 -- SELECTED ETIOLOGIES ASSOCIATED WITH DISORDERS OF CRANIAL NERVE II AND AFFERENT VISUAL PATHWAYS

Etiological Category	Specific Etiologies	Chapter
STRUCTURAL DISORDERS		
Developmental structural disorders	Septo-optic dysplasia	28
HEREDITODEGENERATIVE DISORDERS		
Storage diseases: lipidoses, glycogen disorders, and leukoencephalopathies	Adrenoleukodystrophy, Niemann-Pick disease, mucopolysaccharidoses	30
Amino/organic acidopathies, mitochondrial enzyme defects and other metabolic errors	Cystinosis, Leber's hereditary optic neuropathy	31
Chromosomal abnormalities and neurocutaneous disorders	Optic pathway glioma in neurofibromatosis type-1	32
Degenerative dementias	Alzheimer's disease	33
Ataxias	Spinocerebellar degenerations	35
ACQUIRED METABOLIC AND NUTRITIONAL DISORDERS		
Endogenous metabolic disorders	Diabetes	38
Exogenous acquired metabolic disorders of the nervous system, toxins and illicit drugs	Methanol	39
Nutritional deficiencies and syndromes associated with alcoholism	Nutritional amblyopia, B ₁₂ deficiency	40
INFECTIOUS DISORDERS		
Nonviral infections	Bacterial meningitis	42
	Lyme meningitis	
	Tuberculous meningitis	
Transmissible spongiform encephalopathy	Creutzfeldt-Jakob disease	43
HIV and AIDS	Progressive multifocal leukoencephalopathy	44
NEUROVASCULAR DISORDERS		
	Central retinal artery occlusion	45
	Ophthalmic artery occlusion	
	Occipital or parietal lobe infarction	
NEOPLASTIC DISORDERS		
Primary neurological tumors	Optic pathway glioma	46
	Optic nerve meningioma	
	Craniopharyngioma	
DEMYELINATING DISORDERS		
Demyelinating disorders of the CNS	Optic neuritis/multiple sclerosis/Devic's	48
AUTOIMMUNE AND INFLAMMATORY DISORDERS		
	Giant cell arteritis	50
	Sarcoidosis	
	Systemic lupus erythematosus	
TRAUMATIC DISORDERS	Traumatic optic neuropathy	51
HEADACHE AND FACIAL PAIN	Migraine	53
SLEEP DISORDERS	Narcolepsy	54
DRUG-INDUCED AND IATROGENIC NEUROLOGICAL DISORDERS	Functional visual loss	55
	Drugs	
	Radiation	

on funduscopic examination. Peripheral retinal disorders cause peripheral visual loss. Macular lesions tend to affect central vision and visual acuity. Symptoms of retinal degenerations include slowly progressive visual loss and poor night vision. Clues to underlying neurological disease may be provided by associated vascular, metabolic, hereditary, and degenerative retinal disorders.

Patients with transient monocular visual loss (amaurosis fugax) sometimes describe a descending "gray shade" that resolves after a few seconds or minutes. [28] A yellow cholesterol (Hollenhorst's) plaque may be seen at retinal vascular bifurcations, indicating an embolus from an atheromatous internal carotid artery or aortic arch. Emboli originating from calcific cardiac valves can produce similar symptoms but appear funduscopically as intra-arterial white plaques. Other causes of transient monocular visual loss include giant cell arteritis, retinal migraine, and vasospasm.

If the vascular obstruction persists, a completed central or branch retinal artery occlusion results. Typically the funduscopic examination reveals a normal optic disc, vessel attenuation, segmentation of the blood column ("box-carring" of arterial blood flow), retinal edema (pale and opaque), and a macular cherry-red spot. The latter results from the visible perfused choroid in the macular region, surrounded by opaque, infarcted ganglion cells, which are absent in the macula.

Painless monocular visual loss may also occur following a vitreous hemorrhage. Affected patients often report seeing large floaters in the affected eye, and blood within the vitreous impedes a complete fundus examination. These hemorrhages can result from neovascularization (e.g., diabetic) or acutely elevated intracranial pressure associated with a subarachnoid hemorrhage (Terson's syndrome).

Common causes of subacute monocular visual loss evolving over hours that involve the retina include retinal vein occlusions and retinal detachments. A patient with a central or branch retinal vein occlusion generally reports a painless loss of vision. Funduscopic examination reveals retinal hemorrhages; cotton wool spots; edema; and tortuous, dilated retinal veins. Peripheral visual loss may be reported, and decreased visual acuity suggests macular involvement or optic nerve ischemia. Retinal detachments are usually preceded by floaters and flashes of light (photopsias). If the macula becomes involved, the patient may experience acuity loss.

Central serous chorioretinopathy, which is characterized by elevation of the sensory retina with underlying serous fluid, affects the macula acutely. More insidious

macular processes include age-related macular degeneration (exudative and nonexudative) and hereditary disorders such as Stargardt's disease.

Metabolic and energy disorders of neurological importance often produce characteristic retinal abnormalities that can cause progressive visual loss. These findings also provide important diagnostic clues, however. For instance, the presence of a macular cherry-red spot may suggest Tay-Sachs disease or sialidosis. Pigmentary retinal changes are often observed in Hallervorden-Spatz disease, neuronal ceroid lipofuscinosis, abetalipoproteinemia, mucopolysaccharidosis, or Refsum disease. Macular "salt and pepper" pigmentary retinopathy can be seen in patients with mitochondrial disorders such as MELAS syndrome (mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes), Kearns-Sayre syndrome, and chronic progressive external ophthalmoplegia.

Optic Nerve

Decreases in visual acuity and color vision, unilateral visual field loss, and an afferent pupillary defect suggest an optic neuropathy. Commonly associated field defects include arcuate, central, altitudinal scotomas, and constriction. The funduscopic examination may reveal an optic disc that is normal, swollen, or pale, depending on the etiology and temporal profile of the optic neuropathy. A glaucomatous disc has a normal rim, normal overall color, and an enlarged cup. Optic disc swelling, which is characterized by hyperemia, nerve fiber layer edema, venous congestion, obscuration of retinal vessels, and peripapillary hemorrhages, is indicative of active processes such as raised intracranial pressure or optic nerve inflammation, ischemia, or infiltration. Retrobulbar optic neuropathies by definition have no disc swelling because the pathology occurs more proximally, away from the optic nerve head. Optic disc pallor suggests an atrophic process and is seen at least to some degree in all chronic optic neuropathies when the damage has been present for at least 4 weeks.

Although the most common optic neuropathy results from glaucoma (increased intraocular pressure), others associated with neurological disease include inflammatory, vascular, compressive, infectious, infiltrative, neoplastic, nutritional, toxic, congenital, and hereditary etiologies.

Patients with optic neuritis, which is an inflammatory optic neuropathy, present with acute monocular (usually) visual loss with pain exacerbated by eye movements. Two thirds of the cases are retrobulbar,^[29] and visual loss results from inflammatory demyelination of the optic nerve. Most cases resolve spontaneously,^[30] but some patients continue to notice a transient loss of vision in the previously afflicted eye (Uhthoff's symptom) during periods of elevated body temperature during exercise or showering.

Some vascular etiologies of optic nerve dysfunction include ischemic optic neuropathy (nonarteritic or arteritic, secondary to giant cell arteritis), blood loss, and hypotension. Nonarteritic anterior ischemic optic neuropathy is an idiopathic, ischemic insult of the optic nerve head.^[31] Acute, painless visual loss (decreased acuity and an altitudinal defect, usually) and optic disc swelling characterize this disorder. The prognosis for visual recovery is poor (in contrast to optic neuritis), and patients are typically older.^[32] Presumed risk factors include a crowded, cupless optic disc; diabetes; and hypertension. Arteritic anterior ischemic optic neuropathy is associated with more severe visual loss,^[32] and the disc swelling tends to be pallid.

The most common compressive lesions causing optic neuropathies are carotid-ophthalmic artery aneurysms and sellar masses (craniopharyngioma, meningioma, or pituitary adenoma/apoplexy). Primary neoplastic processes affecting the optic nerve include optic nerve gliomas (often associated with neurofibromatosis type 1), and optic nerve sheath meningiomas. Infiltrative processes (sarcoidosis, carcinomatous meningitis, leukemia, and lymphoma); nutritional

deficiencies (cobalamin and thiamine deficiency); infections (syphilis); trauma; toxin exposures (ethambutol, methanol, and isoniazid); and congenital disc abnormalities (disc hypoplasia, congenital disc elevation, and optic nerve head drusen) may all cause optic neuropathies. The cause of tobacco/alcohol amblyopia, which appears classically as disc pallor and cecentral scotomas, is unclear. The most common form of hereditary optic neuropathy is the maternally inherited Leber's hereditary optic neuropathy.^[33] Appearing in young males with severe, often sequential visual loss, this disorder is typically associated funduscopically with nonedematous disc elevation and peripapillary telangiectasias.

Pseudotumor cerebri (idiopathic intracranial hypertension) should be mentioned here because its major morbidity is visual loss related to optic nerve dysfunction. We dislike the term *benign intracranial hypertension* because the visual deficits can be severe and blinding. Patients should satisfy the following (modified Dandy's)^[34] criteria: (1) signs and symptoms due to elevated intracranial pressure; (2) a normal result on neurological examination except for an abducens palsy; (3) modern neuroimaging excluding a mass lesion or other cause of elevated intracranial pressure; and (4) normal CSF parameters, except an elevated opening pressure (greater than 250 mm H₂O). Patients are usually young obese females who may complain of headache, transient visual obscurations (seconds), pulsatile intracranial noises, or double vision. Almost uniformly, patients have papilledema; other causes of disc elevation, such as pseudopapilledema (optic nerve drusen or congenital nerve head elevation, for instance), should be excluded. Typically, visual acuity and color are preserved, but optic nerve-related visual field defects, which are best detected with computerized threshold perimetry, are present in over 90 percent of patients and include enlarged blind spots, generalized constriction, and inferior nasal field loss.^[4]

The combination of optic disc pallor and papilledema in the fellow eye is termed *Foster Kennedy's syndrome*. Classically, the culprit lesion is a subfrontal mass, typically a meningioma, which compresses the ipsilateral optic nerve, causing disc atrophy. If the lesion is large enough to cause elevated intracranial pressure, papilledema results in the contralateral eye, but the ipsilateral optic nerve cannot swell because it is atrophic. Bilateral optic nerve compression is another possible mechanism.^[35] Nontumor causes, resulting in the pseudo-Foster Kennedy syndrome, are actually more common. Examples include consecutive anterior ischemic optic neuropathy, characterized by new ischemic disc swelling in one eye accompanied by longstanding disc atrophy resulting from a previous event.

Optic Chiasm

A chiasmal process should be considered in patients with temporal field defects that respect the vertical meridian in either or both eyes, or in patients with visual loss of any type accompanied by an endocrinopathy. The most common field defect is a bitemporal hemianopsia, although the pattern of visual loss may vary depending both on the chiasm's position and the exact nature and location of the offending process (see Fig. 8-3 (Figure Not Available)). When a sellar mass is the cause, prefixed chiasms or more posteriorly situated lesions predispose to optic tract syndromes or central hemianopic scotomas. Postfixed chiasms or more anteriorly situated lesions are more likely to appear as an optic neuropathy or junctional scotoma with involvement of the ipsilateral optic nerve and Wilbrand's knee.

Patients with a bitemporal hemianopia are often without visual complaints unless visual acuity is abnormal, and such defects may not be apparent until the patient reads only the nasal half of the acuity chart. Some patients may complain of double vision because they may be unable to align the noncorresponding nasal fields of each eye (hemifield slide phenomenon). Asymmetrical lesions may produce an ipsilateral afferent pupillary defect, and color vision may be abnormal only in the defective field. Congenital or chronic processes may lead to optic atrophy, but rarely does a lesion compressing the optic chiasm lead to optic disc swelling without concomitant compression of the third ventricle. Rarely patients present with asymmetrical shimmering nystagmus, torticollis, and head bobbing (mimicking spasmus nutans) or seesaw nystagmus.

Chiasmal syndromes are most commonly caused by sellar and suprasellar compressive masses. Such lesions are suggested by historical evidence of pituitary or hypothalamic dysfunction, and the differential diagnosis depends largely on the age of the patient. In the pediatric population, chiasmal-hypothalamic gliomas^[36] and craniopharyngiomas^[37] are most likely, whereas in middle-age to elderly-age patients, pituitary adenomas,^[38] internal carotid aneurysms, craniopharyngiomas, and meningiomas should be considered. Compressive lesions usually produce insidious visual loss, and medical or surgical decompression may provide partial or complete visual recovery, especially in patients without evidence of optic atrophy. Rapid onset of visual loss and hypopituitarism suggests pituitary apoplexy.^[38],^[39] Rarely, chiasmal syndromes can be congenital as in septo-optic dysplasia (de Morsier's syndrome), characterized by hypoplasia of the optic nerves and chiasm, a hypoplastic or absent septum pellucidum, and pituitary ectopia.

Optic Tract/Lateral Geniculate Body

Complete lesions of both these structures cause dense contralateral homonymous hemianopias. Isolated syndromes involving these structures are rare. Incongruous homonymous hemianopias characterize partial optic tract and lateral geniculate body lesions (Fig. 8-7 (Figure Not Available)). A contralateral relative afferent pupillary defect can accompany an optic tract lesion; much rarer pupillary abnormalities include contralateral mydriasis (Behr's pupil), and a hemianopic pupillary reactivity (Wernicke's pupil). Because of presynaptic interruption, patients may have bilateral optic atrophy with ipsilateral temporal pallor and contralateral "bowtie" or "band" atrophy. Visual acuity is normal in isolated tract lesions. Sellar and parasellar masses, especially craniopharyngiomas and aneurysms, commonly compress

the optic tract.^[40] Isolated tract syndromes may also result from demyelination or rarely ischemia.

Although it is often difficult to distinguish clinically between

Figure 8-7 (Figure Not Available) Visual pathways: correlation of lesion site and field defect, view of underside of the brain. Homonymous refers to a defect present in both eyes with the same laterality, whereas hemianopia refers to visual loss respecting the vertical meridian. Congruous fields are symmetrical in both eyes. Note that lesions of upper or lower occipital banks produce quadrantic defects, whereas lesions within temporal and parietal lobes cause field defects, which tend not to respect the horizontal meridian. (From Liu GT: *Disorders of the eyes and eyelids*. In Samuels MA, Feske S [eds]: *The Office Practice of Neurology*. New York, Churchill-Livingstone, 1996, p 43. Adapted from Mason C, Kandel ER, Schwartz JH, Jessell T [eds]: *Principles of Neural Science*, 3rd ed. East Norwalk, CT, Appleton and Lange, 1991, p 437.)

lateral geniculate and tract syndromes, there are two unique exceptions owing to the geniculate's dual vascular supply. A congruous homonymous horizontal wedge-shaped sectoranopia results from lateral choroidal artery infarction, whereas upper and lower homonymous sectoranopias result from anterior choroidal artery occlusion.

Optic Radiations

An isolated lesion of Meyer's loop typically leads to a congruous or incongruous contralateral homonymous hemianopia denser superiorly (pie-in-the-sky defect), whereas lesions of the parietal lobe lead to defects more prominent inferiorly. In clinical practice, there is significant variation in these findings. Complete interruption of the optic radiations causes a dense homonymous hemianopia. Visual acuity is spared in unilateral lesions, but it can be impaired if bilateral lesions are present. Again, the pupillary responses are normal.

Occipital Lobe

Unilateral occipital lobe lesions, which are commonly due to vascular insults or primary and metastatic neoplastic lesions, cause a contralateral congruous homonymous hemianopia respecting the vertical meridian. Posterior cerebral artery infarction may produce a hemianopia with macular sparing (rather than macular splitting), and this feature is specific to occipital lobe-related hemianopias. Proposed mechanisms include the dual vascular supply of the occipital poles, bilateral representation of the maculae, and test artifact due to poor central fixation by the patient. Restricted lesions of the upper or lower banks of the calcarine cortex cause quadrantic field defects.

Bilateral upper or lower bank disturbances produce altitudinal hemianopias respecting the horizontal meridian. Homonymous hemianopic central scotomas are a telltale sign of a unilateral occipital lobe tip disturbance. Acuity is preserved with unilateral occipital lobe damage, but it can be impaired with bilateral geniculocalcarine lesions. Any level of visual acuity is possible with bilateral retrochiasmal lesions, but the acuities should be symmetrical unless there is superimposed anterior visual pathway disease.

Hemianopias that are stroke-related are often isolated, unless a proximal posterior cerebral artery occlusion leads to a third-nerve palsy, ataxia, or ipsilateral hemiparesis from mesencephalic involvement, and memory or personality changes from mesial-temporal or thalamic involvement. A patient with a unilateral hemianopia due to occipital lobe

infarction has a normal optokinetic response. In contrast, one with a hemianopia owing to an occipital lobe mass with edema extending into the parietal lobe may have an abnormal optokinetic response when the targets are drawn ipsilaterally to the lesion (Cogan's rule).

Cortical blindness, characterized by absent blink to threat and optokinetic responses, results from bilateral occipital lobe involvement. Clinically, patients with cortical blindness can be distinguished from those with pregeniculate lesions by the presence of intact pupillary light responses. Cortically blind patients may confabulate visual perceptions or deny their blindness (Anton's syndrome). Some of these patients have additional contributory cerebral lesions that alter recognition, memory, and behavior.

Unusual features observed following occipital lobe injury include unconscious vision in the blind hemifield (blindsight) and the recovery of motion perception (Riddoch's phenomenon). A "second," more primitive, retinal-tectal-pulvinal subcortical, extrastriate visual pathway has been proposed as a possible explanation. Polyopia (single objects appearing as several), palinopsia (persistence of visual images), and optic allesthesia (abnormal object orientation in space) are other unusual phenomena resulting from occipital, occipitoparietal, or occipitotemporal lesions.

Migrainous phenomena can involve the occipital lobes and manifest with transient hemianopic phenomena, with or without scintillations or phosphenes, followed by headache. Some patients experience only the visual prodrome without the headache (acephalgic migraine). In rare instances, a complicated migraine may lead to occipital lobe infarction and a fixed hemianopic defect.

In elderly patients, the differential diagnosis of occipital lobe dysfunction also includes Alzheimer's disease and hemorrhagic infarction due to amyloid angiopathy. Hypertensive encephalopathy or eclampsia can produce cortical blindness or transient hemianopias in patients of any age. Infectious causes include encephalitis, abscesses, progressive multifocal leukoencephalopathy, and Creutzfeldt-Jakob disease. In children, meningoencephalitis, adrenoleukodystrophy, and MELAS may be responsible for hemianopias. Ictal or postictal hemianopias are rare.

Higher Cortical Lesions

Patients with lesions of visual association areas may have visual field defects if striate cortex is involved, but their visual complaints frequently cannot be explained by field loss alone. Further investigation often allows more accurate characterization of their symptoms.

Inferior occipital lobe dysfunction, involving the lingual and fusiform gyri, results in a contralateral homonymous upper quadrantanopia and abnormal color vision in the contralateral hemifield (cerebral hemiachromatopsia). With left-sided lesions when the splenium of the corpus callosum or adjacent periventricular white matter is involved, alexia without agraphia (or pure alexia or "word blindness") may be observed. This represents a disconnection syndrome characterized by a right homonymous field defect and inability to retrieve lexical visual information processed in the intact right occipital lobe.

Visual agnosia (the inability to recognize visual objects), in the absence of significant afferent visual pathway disruption, suggests bilateral medial occipitotemporal lesions disrupting the inferior longitudinal fasciculus, which is a white matter tract connecting striate cortex with the visual association areas of the temporal lobe. Prosopagnosia, a visual agnosia specific for faces, results from similar lesions. Defective motion perception is observed with lesions of Brodmann area 39 or lateral occipitotemporal cortex.

Neglect or inattention to visual, tactile, or auditory stimuli in the left hemifield; dressing and constructional apraxia; and spatial disorientation suggest right hemispheric lesions. Neglect can occur without a hemianopia. Large parietal lesions frequently cause both, however, and in affected patients it may be difficult to separate dense visual neglect from field loss. The severity of neglect ranges from complete inattention to all stimuli in the left hemifield to subtle visual neglect of objects to the left only when stimuli are presented simultaneously on both sides of midline (double simultaneous stimulation).

Balint's syndrome is characterized by optic ataxia (a defect in reaching under visual guidance), simultanagnosia (an inability to recognize a whole picture despite the ability to perceive its parts), and ocular apraxia (a defect in voluntary eye movements). The symptom complex is caused by bilateral occipitoparietal lesions that are important for visual attention and foveal refixation. One or all elements may be present. Because the lesions commonly involve upper banks of occipital cortex, Balint's syndrome is commonly associated with inferior altitudinal field defects. Watershed infarctions are the usual cause.

Visual Hallucinations

These are visual images that the patient claims to see but that other observers do not. Visual hallucinations can be characterized as unformed (e.g., dots, flashes,

zig-zags) or formed (actual objects or people). They may occur in patients with damage to the afferent visual pathways, sensory deprivation, migraine, seizures, brain stem lesions, drug toxicity or abuse, and psychiatric illnesses. ^[41]

Patients with visual loss due to a lesion anywhere within the afferent visual pathways may complain of hallucinations (positive visual phenomena) within the defective field. ^[42] This clinical scenario has been termed Charles Bonnet's syndrome. The complexity of the visual phenomenon is nonlocalizing. Patients may find these visual images pleasant or disturbing and may be embarrassed to volunteer their occurrence to their physician. Physiologically, they may represent visual phenomena released by lack of inhibitory input. ^[43] This mechanism may also explain visual hallucinations associated with severe sensory deprivation in prisoners of war.

Migraine visual aura may include positive phenomena such as stars, sparks, flashes, simple geometrical forms, enlarging scintillating scotomas, and fortification spectra. ^[44] Typically, auras develop over more than 4 minutes, last less than 1 hour, and precede or rarely accompany or follow the headache. ^[45] Uncommonly the positive phenomena may persist in patients with or without "migrainous infarction." ^[46]

19

Epileptic visual hallucinations of occipital lobe origin may be very similar to migraine aura, and clinically the two disorders may be difficult to distinguish. ^[47] Secondary generalization, loss of consciousness, and ictal occipital discharges on electroencephalogram (EEG) may support a diagnosis of epilepsy, whereas transient visual loss, headache, and family history are more suggestive of migraine. Epileptiform discharges from other parts of the brain (the temporal lobe, for instance) may also produce positive visual phenomena. Other clinical features, however (autonomic, for example), are expected. As with release hallucinations, the complexity of the visual phenomena generally does not help localize the seizure focus.

Peduncular hallucinations, consisting of vivid and life-like visual images of concrete objects, are rare sequelae of ventral midbrain injury. The hallucinations are frequently accompanied by sleep and cognitive disturbances. One clinicopathological study ^[48] suggested that their expression requires bilateral destruction of the medial substantia nigra pars reticulata.

Illicit drug use (cocaine, lysergic acid diethylamide [LSD], marijuana), medications (digoxin, anticholinergics, and dopaminergics), and parasympatholytic eye drops (atropine) may also be responsible for visual hallucinations. A psychotic psychiatric disorder is suggested when complex visual hallucinations are accompanied by occasional auditory hallucinations. ^[49] Normal people may experience both formed and unformed visual images upon waking (hypnopompic) or upon going to sleep (hypnagogic). A number of degenerative neurological diseases (Parkinson's disease, progressive supranuclear palsy), in the setting of medication use (levodopa, dopamine agonists, monoamine oxidase [MAO] inhibitors, and anticholinergics) can make visual hallucinations a common clinical disorder. Other disorders such as diffuse Lewy body disease may have visual hallucinations as a primary symptom as well.

Other Positive Visual Phenomena

Phosphenes are flashes of light witnessed in patients with a blow to the eye, traction on the retina, optic nerve compression, or optic neuritis. ^[49] More complex positive visual phenomena include palinopsia (persistence of visual images), polyopia (multiple images), micropsia (shrunken images), macropsia (enlarged images), metamorphopsia (distortion of shape), and Alice-in-Wonderland syndrome (distortion of bodily image). All of these may occur during migraine aura. Metamorphopsia is a much more common complaint, however, among patients with macular disease and micropsia/macropsia among those with seizures. Palinopsia is more characteristically a symptom of occipitotemporal lobe damage.

Functional Visual Loss

Nonphysiological or functional visual loss can be either subconscious (hysteria) or deliberate and willful (malingering). Commonly encountered neuro-ophthalmic complaints include visual impairment or complete loss of vision, visual field defects such as constricted fields, and monocular diplopia. When confronted with a patient whose complaints and examination do not seem to correlate (subjective/ objective mismatch) or whose visual deficit is nonphysiological, there are several clinical tools that help determine whether these findings are nonorganic.

The following clinical tests, when abnormal, are useful in a patient with suspected nonphysiological visual loss: (1) lack of a normal linear improvement of Snellen visual acuity with decreasing distance or increasing letter size (for example, a patient who correctly identifies a 20/100 letter at 20 feet should equally identify a 20/50 letter at 10 feet); (2) presence of normal color vision and stereoacuity despite severely affected Snellen acuity; (3) normal menace or threat reflex, in which an approaching examiner's hand or bright light directed into the eye of interest causes a blink response; (4) presence of optokinetic nystagmus using an optokinetic nystagmus (OKN) strip; (5) presence of fixation of a patient's eyes on his or her reflected image during the "swinging mirror" test; (6) suggestive Schmidt-Rimpler test result, which involves having the patient hold up his or her hand while instructed to look at it, which is a test of proprioception more so than vision. A patient with functional visual loss often looks everywhere but directly at the hand. Next, the patient is asked to touch the two index fingertips together, which, in nonorganic instances, is performed improperly; and (7) normal EEG and psychogalvanic skin responses to light. With an intact afferent visual system, light shone into a normal eye causes a dampening of the posterior dominant alpha rhythm on EEG. The psychogalvanic skin reflex uses an electrode placed on the skin to measure the sympathetic response when a bright light is shone into the eye of interest. A normal response produces a deflection; no response is expected from the blind eye. ^[50] VEPs may also be helpful in this regard, although abnormal responses can be intentionally generated.

Monocular visual loss in the absence of a relative afferent pupillary defect suggests a nonorganic etiology. Tests that require binocularity (unknownst to the patient) can be extremely helpful in these cases. Perception of nine of nine stereo dots in the Titmus test requires 20/20 vision in both eyes. ^[51] During the Worth's four-dot test the patient views red and green lights through a red glass over the right eye and a green one over the left. The right eye will see the red dots, and the left eye will see the green ones. It is impossible for an individual with one blind eye to see red and green dots simultaneously. In another maneuver, a prism is placed over the suspect eye while the patient reads the Snellen chart. Reading continues uninterrupted if the eye is blind. If vision is really normal in that eye, the patient pauses while refixating. ^[52] Perhaps the best stratagem is to fog the good eye secretly with a +10.00 diopter lens, then ask the patient to read the Snellen chart with both eyes. Any line read correctly must have been seen by the reported blind eye.

"Tunnel vision" is a classic nonphysiological visual field defect, and the patient usually complains of decreased peripheral vision. ^[53] Tangent screen testing reveals a lack of physiological expansion of the patient's perceived visual fields when the target size and distance from the screen are doubled. A patient's complaint of monocular hemianopia that upon formal visual field testing is present while

20

testing the involved eye, absent while testing the unaffected eye, then present again when testing under binocular conditions is also nonphysiological. Although there are identifiable causes of monocular diplopia, such as disturbances of the ocular media and some occipital lobe lesions, most are also considered nonphysiological, especially when they do not resolve with a pinhole.

GENERAL MANAGEMENT GOALS

Some causes of visual loss, such as optic neuritis, tend to resolve spontaneously. Others due to compressive lesions and pituitary adenomas, for instance, have a good prognosis once the mass is removed surgically. Unfortunately, many of the vascular, hereditary, and degenerative causes of visual dysfunction have a poor prognosis for improvement.

Low vision aids may be helpful in some of these cases. In people with poor visual acuity, magnifiers can help them to read newspapers or other printed material. Closed circuit televisions, which enlarge written material without the distortion lenses may produce, are becoming popular for this purpose as well.

Patients with dense homonymous hemianopias can be offered prism therapy, but only a minority of them find it beneficial. A 30- to 45-diopter base-out Fresnel press-on prism is placed on the temporal half of an eyeglass ipsilateral to the hemianopia. This device projects images in the blind half of vision into the good half. The patients who like the prism therapy are those who use the prism to notice novel objects in their blind field; they then turn their head in that direction to use their good field to see the objects more clearly. Unfortunately, most individuals find this process too confusing and the result is suboptimal. It certainly does not improve their vision to the point at which they can drive. Base-out prism therapy should be attempted only in individuals who have normal mentation and in whom the hemianopia is isolated.

Experimental vestibular stimulation (by cold water, for instance) may have some efficacy in patients with visual neglect. We have no personal experience with this technique, however.

We have found that visual occupational therapy and rehabilitation is relatively unhelpful. Little proof exists that visual training after injury makes any difference in the speed or amount of visual recovery.

HISTORY AND DEFINITIONS

The third, fourth, and sixth cranial nerves and the muscles they innervate are involved in moving the eyes to allow inspection of visual objects. The act of positioning the image of an object on the retinal fovea, which is the locus of highest visual acuity and the psychological center of the visual field, is referred to as *fixation*. This is accomplished by activating combinations of extraocular muscles to achieve a specific angle of globe rotation in order to place the fovea in direct line with an image. *Fusion* denotes the primitive reflex action, organized within the central nervous system (CNS), in which the visual axes of the two eyes are made to converge on a single object of regard. This allows the same image in visual space to be focused simultaneously on the foveas of both eyes, and the image is perceived as a single object. The *visual axis* is an imaginary line connecting the fovea of the retina with the object of regard. It defines the direction of gaze and corresponds to the Y axis on [Figure 9-1](#). *Strabismus* is present when there is deviation or misalignment of the visual axes.

There are nine cardinal positions of gaze, subdivided into primary, secondary, and tertiary positions. The primary position is straight ahead, and eccentric gaze develops when the two eyes deviate away from primary gaze. Secondary positions include straight up, straight down, straight in toward the nose, and straight out toward the temple. Tertiary positions are those away from the primary position

12

Figure 9-1 The axes of rotation of the eye. The Y axis corresponds to the line of sight when the eye is in the primary position looking straight a (From Miller, NR: Walsh and Hoyt's Clinical Neuro-Ophthalmology, Vol 2, 4th ed. Baltimore, Williams & Wilkins, 1985.)

with combined simultaneous horizontal and vertical deviation. These tertiary positions include elevation in adduction, elevation in abduction, depression in adduction, and depression in abduction. Abduction refers to movement of the eye toward the temple in the horizontal plane about a vertical axis, and adduction is the movement of the eye toward the nose in the horizontal plane about a vertical axis (Z axis, [Figure 9-1](#)). Rotational movements relate to the eye's turning about an axis in the coronal or frontal plane of the globe. The axis may be vertical (horizontal rotation) or horizontal (vertical rotation) or oblique (oblique rotation) at any angle. *Torsional movements* relate to an eye turning in the frontal plane about an anteroposterior axis through the center of rotation of the globe. The direction of torsion is specified by the movement of the 12 o'clock meridian of the limbus or corneal margin. *Intorsion* is defined as rotation of the point inward toward the nose or midline, and *extorsion* refers to rotation outward toward the temple. The rotation of both eyes in the same direction and at the same speed is known as *conjugate gaze*. This keeps the relative position of the visual axes constant (nearly parallel for distant objects, convergent for near objects). These conjugate movements of the two eyes are termed *versions* to distinguish them from *vergence movements*, in which the visual axes do not remain parallel but either converge or diverge.

Phoria denotes a latent eye deviation or deviation of the visual axes not present under conditions of binocular viewing. A phoria becomes manifest (becomes a tropia) when the image of the object of regard is made different in the two eyes such that the fusion mechanism cannot operate or operates inefficiently. *Tropia* is defined as deviation that is present with both eyes viewing, and hence is the condition that underlies diplopia. *Diplopia*, or double vision, is defined as seeing two separate images of the same object in visual space, with one of the images displaced from the other. Binocular diplopia results from the misalignment of the visual axes (the two eyes are looking in slightly different directions). This type is present only when the patient is viewing the object of regard simultaneously with both eyes and disappears when either eye is covered. *Polyopia*, or seeing three or more simultaneous images of a single object in visual space is categorically not a feature of binocular diplopia in humans. It is usually caused by an optical aberration in the refractive media of the eye, but a cerebral form also exists and is usually from lesions in the occipital-parietal lobes.

There are three systems of *conjugate* eye movement, including smooth pursuit, saccades, and the vestibulo-ocular reflex (VOR) that deviate the eyes in unison. Smooth pursuit eye movements stabilize on the fovea images of small objects moving in visual space. Saccades redirect the line of gaze to an object of interest, placing its image on the fovea. The VOR compensates for head movement, stabilizing gaze in space.

CLINICAL HISTORY

Because cranial nerves III, IV, and VI innervate the extraocular muscles that move the eyes, the striated muscles that elevate the upper eyelids, and the iris sphincters that constrict the pupils, several symptoms develop when damage occurs. In general, dysfunction of these nerves causes different combinations of binocular double vision from misalignment of the visual axes. Damage to cranial nerve III causes *ptosis* from weakness of the levator palpebrae muscle, as well as pupil mydriasis or dilatation from paresis of the iris sphincter muscle.

Altered function in the supranuclear control of the ocular motor system leads to conjugate gaze palsy or paresis in which the visual axes remain parallel or appropriately convergent on the object of regard. In these settings, the patient does not experience diplopia, because the two eyes simultaneously fail to achieve full movement in one or several directions from primary gaze. In some cases of conjugate gaze paresis, the eyes fail to deviate fully into the defective direction, and in other cases, the deficit is more subtle, so that the eyes deviate fully but move more slowly than they should or with an interrupted course. These dynamic alterations are generally without subjective symptoms and must be observed during the course of examination. Even patients with complete lack of gaze in a particular direction often have no complaints but automatically turn their head to compensate for the loss of eye deviation. The major exception to this principle is loss of downgaze, which generally creates much difficulty for the patient even when walking on a flat surface and especially in negotiating stairs and other uneven terrain. This is particularly irksome when coupled with the involuntary head and neck retraction or extension that often accompanies progressive supranuclear palsy (PSP) (see [Chapter 34](#)). Falling backward is common in PSP patients, and this problem should also be asked about specifically. A key symptom of pathological underactivity in the vestibulo-ocular reflex is *oscillopsia*, which is an illusory sense of movement of the visual environment as the head moves. This is a direct consequence of foveal image slippage engendered specifically by head movement, and the illusion ceases when the head is immobile. Vertigo, another common symptom of vestibular disorders, is often present when the head is still, although it is usually aggravated by

head movement. Vertigo is a rotational illusion that is often accompanied by rhythmical oscillopsia as a consequence of nystagmus, in which case the rhythm is imposed by the regular fast phases of the nystagmus. The vertigo may be subjective, in which case patients feel as though they are rotating, or it may be objective, in which case they perceive that the environment is rotating.

The time course of the symptoms constitutes the best evidence for the etiology of the disorder and must be probed in detail. Diplopia is a markedly troublesome symptom, and it is either present or not, making its onset always acute. The angle of deviation between the eyes and the consequent distance between the two images may vary after onset, and this feature can be used to discern whether the course is stationary, progressive, or remitting. Symptoms from compressive cranial nerve lesions secondary to tumors and from degenerative conditions generally have a progressive course, whereas inflammatory diseases such as orbital inflammatory pseudotumor or Tolosa-Hunt syndrome (orbital and cavernous sinus inflammation, respectively) (see [Chapter 53](#)) often run either a course of remissions and exacerbations or a progressive course. Ischemic causes tend to produce a stationary or, more commonly, a remitting course.

Both ischemic and inflammatory disorders of cranial nerves III, IV, or VI tend to be associated with pain in the ipsilateral eye or orbit, sometimes with wide radiation to the brow, frontal, and temporal regions and downward into the cheek and even to the mandible. Malignant neoplasms may involve the cranial nerves III, IV, and VI anywhere along their courses, and pain can accompany the other features, especially when there is meningeal, bony, or dural infiltration. As with inflammatory diseases, the pain is usually centered on the ipsilateral orbit but may radiate widely. Not infrequently, intraorbital lesions, even malignant ones, can involve the cranial nerves without pain, possibly because they do not stretch or invade pain-sensitive structures, including muscle and particularly dura and periosteum. Absence of pain, therefore, should not in itself engender a false sense of security that the lesion causing the cranial neuropathy is benign.

A detailed characterization of the direction and circumstances of image separation is important in establishing which muscle or muscles, and hence, which cranial nerve or nerves, are involved. Horizontal diplopia arises from disorders affecting either the lateral rectus or medial rectus muscles. If the paretic muscle is one or both lateral rectus pair, the visual axes will be convergent (esotropia), and if the involved muscle is one or both medial recti, the visual axes will be divergent (exotropia). It is important to note that at minimal angles of binocular divergence, the patient often describes the visual experience as a blur rather than doubling of images. It is important to ask any patient with blurred vision if it clears on covering *either* eye, which will be the case for blur that is a result of minimal angle binocular diplopia. Blurring can be misconstrued for diminished acuity, but acuity is a function of cranial nerve II. Patients often cannot tell from the diplopia whether they have convergent or divergent eyes, because either condition produces horizontal image separation. Asking the patient when he or she covers the right eye whether the right or left image disappears can be helpful. If the eyes are exodeviated (divergent), the image to the left disappears. If the eyes are esodeviated (convergent), the image to the right disappears. A convenient way to remember the directions is to consider that *crossed* (X) diplopia results from *ex*odeviation (divergent visual axes, medial rectus weakness) and *homonymous*, or same side, diplopia results from *eso*deviation (convergent visual axes, lateral rectus weakness). The terms *crossed* and *homonymous* refer to the relation between the side of the eye covered and the relative position of the image that disappears--on the same (*homonymous*) or opposite (*crossed*) side. This same principle underlies diplopia testing and is considered in the examination section.

The visual axes are nearly parallel for viewing very distant objects. As the object of regard is brought progressively closer to the viewing subject, the person's visual axes must become more convergent to keep the images on both retinal foveas. Convergence is, therefore, a normal voluntary action in which the medial recti of both eyes are simultaneously activated and the resulting esodeviation is appropriate for near viewing. Because of this, patients with lateral rectus (sixth cranial nerve) dysfunction and esotropia have diplopia only for relatively distant objects. All objects in near space can be fused by adding normal convergence to the esotropia that results from the muscle weakness. On the other hand, patients with exotropia do not have single vision at any distance. The presence or absence of fusion and single vision at some near point can be used to discern esotropia from exotropia.

Vertical image separation implies dysfunction of a vertically acting muscle in one or both eyes. These include the superior rectus and oblique and the inferior rectus and oblique muscles on either side. The details of image separation for vertical muscle imbalance must usually await examination using diplopia testing, but the patient may be able to supply some useful hints by way of history. Patients with a third cranial nerve dysfunction usually have mixed horizontal and vertical diplopia (oblique image separation) because several vertical muscles and the horizontally acting medial rectus muscle are commonly involved together. Also, these patients usually have some degree of upper eyelid ptosis, which is noticed by the patient on looking in the mirror. As ptosis becomes more severe, there is first restriction of the upper visual field and then loss of all vision when the pupil is completely covered. Asking the patient about upper field loss and total vision loss can help plot the time course of the ptosis. The most common neural cause of *isolated* vertical diplopia is fourth cranial nerve dysfunction. The weak muscle is the superior oblique, which turns the eye down (depression) and does so most efficiently in adduction (horizontal deviation toward the nose). The image separation is widest in downgaze and looking to the side opposite the lesion, which brings the involved eye into adduction. If the patient can say that the vertical diplopia is wider looking down and widest looking down and to the left, then right superior oblique muscle weakness is most likely and vice versa. The diplopia is isolated in fourth cranial nerve palsy because the nerve does not innervate any muscles other than the superior oblique and, in that respect, differs from third cranial nerve palsy, with its multiplicity of simultaneously involved muscles.

Patients with fourth cranial nerve palsy often have torsional imbalance with excyclodeviation of the involved eye. Most patients automatically compensate by tilting and turning the head to minimize and sometimes eliminate diplopia. The resulting head position--tucked down, turned away, and tilted away--is characteristic and usually has been noticed as peculiar by others if not by the patient himself or herself. Patients often avoid diplopia altogether by using the compensatory head position. It can be useful to ask when people started saying things about the patient's head position, if it is unclear when the fourth nerve palsy really started. Also, it is useful to review family photographs from the patient's childhood and infancy. Head tilt in a childhood photo is good evidence of congenital fourth cranial nerve palsy--a common condition that may present with the onset of diplopia later in life.

Oculomotor dysfunction may occur in the setting of any systemic disorder. One of the most common diseases to affect ocular motility is thyroid orbitopathy. The past history is particularly important because thyroid function studies are commonly normal when the patients present with orbital findings. A history of fatigue, weight change, skin alterations, heat intolerance, and other constitutional symptoms is thus important to elicit. A large contingent of patients who present with cranial mononeuropathies have a presumed ischemic etiology based on putative small vessel occlusive disease. These can usually present in persons older than 60 years of age, and many have other arteriosclerotic risk factors such as systemic hypertension or diabetes mellitus. A history of these disorders should be elicited by the interviewer. A full inquiry about multisystem signs and symptoms is essential to identify collagen vascular diseases such as periarteritis nodosa or systemic lupus erythematosus, which may be complicated by ischemic cranial mononeuropathy. Orbital inflammatory pseudotumor or Tolosa-Hunt syndrome may be caused by sarcoidosis, and the history should be probed for any of its many systemic manifestations including skin, muscle, joint, pulmonary, hepatic, or renal involvement. Myasthenia gravis frequently presents with ptosis and weakness of various extraocular muscles and may closely mimic cranial nerve lesions. This neuromuscular

disorder (see [Chapter 50](#)) has the remarkable capacity to look like a pupil-sparing third cranial nerve palsy or, in a more limited case, internuclear ophthalmoplegia (INO) from a lesion along the medial longitudinal fasciculus (MLF) in the brain stem. ¹³ Myasthenia most frequently runs a remitting, exacerbating course with involvement of axial and appendicular muscle groups. It is important, therefore, to ask about past or concurrent weakness in the limbs, trouble swallowing, weak phonation, and trouble breathing. Finally, a full family history and review of all medications is necessary. Many commonly prescribed general medical and neurological drugs can be associated with diplopia (carbamazepine, phenytoin), particularly at toxic levels.

ANATOMY OF CRANIAL NERVES III, IV, AND VI (Table 9-1)

Extraocular Muscles

Figure 9-2 represents a schematic diagram of the orbits viewed from above, with the eyes looking to the right. The superior rectus and superior oblique muscles are shown with their insertions on the top of the globes--the superior rectus muscle elevates the globe and the superior oblique muscle depresses the globe. The inferior rectus and oblique muscles insert at homologous sites on the bottom of the globe, and the horizontal vectors of pull are the same, except the inferior rectus muscle depresses the globe while the inferior oblique muscle elevates it. The adducted position of the left eye places the superior oblique in a position to depress the eye as a primary and direct action (see also Figure 9-2 B and Table 9-2). The abducted position of the right eye puts the right superior rectus in position to elevate the right eye as a primary and direct action. The direction of pull of the left superior rectus muscle on the adducted left eye puts it in position to intort the eye as a primary and direct action (incyclodeviation or intorsion, rotation of the 12 o'clock meridian toward the nose or midline about the Z axis [see Fig. 9-1]). Similarly, the direction of pull of the right superior oblique muscle on the abducted right eye puts it in position to intort the right eye as its primary and direct action. More generally, the oblique muscles act as the pure depressor and elevator of the eye when it is in adduction, and the rectus muscles act as the pure depressor and elevator of the eye when it is in abduction. Conversely, the primary torsional action is carried out by the rectus muscles when the eye is in adduction and by the oblique muscles when the eye is in abduction. When the eyes are in primary position, the oblique and the rectus muscles both perform a mixture of vertical and torsional action. The action of the medial and lateral rectus muscles is simple relative to the vertical muscles. The medial rectus muscle adducts and the lateral rectus muscle abducts the eye.

The importance of these relationships lies in the fact that the binocular relative deviation is largest when the patient attempts to look into the direction of pull of the defective muscle. By determining the angles of deviation between the visual axes in all the cardinal positions of gaze, the weak muscle can be identified as the one that serves the cardinal position with the largest deviation.

Oculomotor Nerve (Cranial Nerve III)

The third cranial nerve innervates the medial rectus, superior rectus, inferior rectus, and inferior oblique muscles, along with the pupillary sphincter and the levator palpebrae that elevates the upper eyelid.

The third nerve originates in a rostrocaudally elongated group of subnuclei clustered in the midbrain, just rostral to the level of the fourth cranial nerve nucleus. The architecture of this nuclear group has been the subject of intensive study over the years. The most widely accepted anatomical scheme is that of Warwick¹² and is represented in Figure 9-3 (Figure Not Available). Warwick suspected that there is a subnucleus for each muscle and that these structures are in rostrocaudally elongated columns of cells. Axons from the more dorsally situated subnuclei pass through the middle and inferior columns of cells on their way to the point of exit from the ventral aspect of the midbrain near the cerebral peduncles. The nuclei for the inferior rectus, inferior

TABLE 9-1 -- CLINICOANATOMICAL CORRELATION OF DISORDERS OF CRANIAL NERVES III, IV, AND VI

Anatomical Structure	Ocular Findings	Etiologies
CRANIAL NERVE III		
Nuclear	Bilateral ptosis and upgaze limitation; ipsilateral impairment of elevation, depression, adduction, and pupillary paralysis	Ischemia, central demyelinating disorders, neoplasm, inflammatory or infectious (abscess) lesions
Fascicular	Ipsilateral limitation of ocular elevation, depression, adduction; ptosis; pupillary paralysis	Ischemia, central demyelinating disorders, neoplasm, and inflammatory or infectious (abscess) lesions
Subarachnoid	Ipsilateral limitation of ocular elevation, depression, adduction; ptosis; pupillary paralysis	Meningeal neoplastic infectious, and inflammatory infiltrative disorders; aneurysm of the posterior communicating artery-internal carotid junction
Cavernous	Ipsilateral limitation of ocular elevation, depression, and adduction; ptosis; pupillary paralysis	Pituitary adenoma with lateral expansion, inflammatory (Tolosa-Hunt syndrome) and infection (aspergillosis), meningioma, giant carotid siphon aneurysm, pseudoaneurysm, carotid and dural branch to cavernous sinus fistulae, cavernous sinus thrombosis
Orbital	Ipsilateral limitation of ocular elevation, depression, and adduction; ptosis; pupillary paralysis	Orbital inflammatory pseudotumor, primary tumors (hemangioma, meningioma), metastatic tumors
CRANIAL NERVE IV		
Nuclear	Failure of the ipsilateral eye to depress fully in adduction, excyclodeviation, ipsilateral hyperdeviation (greatest in adduction and depression)	Ischemia, central demyelinating disorders, neoplasm inflammatory or infectious (abscess) lesions
Fascicular	Failure of the ipsilateral eye to depress fully in adduction; excyclodeviation (torsion); ipsilateral hyperdeviation greatest in adduction and depression	Ischemia, central demyelinating disorders, neoplasm, inflammatory or infectious (abscess) lesions
Subarachnoid	Failure of the both eyes to depress fully in adduction; excyclodeviation (torsion); ipsilateral hyperdeviation greatest in adduction and depression and inflammatory or infectious (abscess) lesions	Head trauma (downward/backward displacement of the brain stem with impaction of both cranial nerves IV) Ischemia, central demyelinating disorders, neoplasm, and inflammatory or infectious (abscess) lesions
Cavernous	Failure of the ipsilateral eye to depress fully in adduction; excyclodeviation (torsion); ipsilateral hyperdeviation greatest in adduction and depression	Pituitary adenoma with lateral expansion, inflammatory (Tolosa-Hunt syndrome) and infectious (aspergillosis) lesions, meningioma, giant carotid siphon aneurysm, pseudoaneurysm, carotid and dural branch to cavernous sinus fistulae, cavernous sinus thrombosis
Orbital	Failure of the ipsilateral eye to depress fully in adduction; excyclodeviation (torsion); ipsilateral hyperdeviation greatest in adduction and depression	Orbital inflammatory pseudotumor, primary tumors (hemangioma, meningioma), metastatic tumors (lymphoma)
CRANIAL NERVE VI		
Nuclear	Conjugate gaze palsy ipsilateral to the lesion, plus OE failure of ipsilateral eye to abduct fully and esotropia	Ischemia, central demyelinating disorders, neoplasm, inflammatory or infectious (abscess) lesions
Fascicular	Failure of ipsilateral eye to abduct; esotropia greatest in gaze toward the lesion side	Ischemia, central demyelinating disorders, neoplasm, inflammatory or infectious (abscess) lesions
Subarachnoid	Failure of ipsilateral eye to abduct; esotropia greatest in gaze toward the affected side	Meningeal neoplastic, infectious, and inflammatory disorders; false-localizing cranial nerve VI palsy with elevated intracranial pressure
Cavernous	Failure of ipsilateral eye to abduct; esotropia greatest in gaze toward the lesion side	Pituitary adenoma with lateral expansion, inflammatory (Tolosa-Hunt syndrome) and infectious (aspergillosis) disorders, meningioma, giant carotid siphon aneurysm, pseudoaneurysm, carotid and dural branch to cavernous sinus fistulae, cavernous sinus thrombosis
Orbital	Failure of ipsilateral eye to abduct; esotropia greatest in gaze toward the affected side	Orbital inflammatory pseudotumor, primary tumors (hemangioma, meningioma), metastatic tumors (lymphoma)

SUPRANUCLEAR CONTROL

Cortical	Long latency, hypometric contralateral saccades, increased frequency square wave jerks; low-gain 'slow' ipsilateral smooth pursuit with catch-up (forward) saccades	Degenerative diseases, benign and malignant primary and metastatic neoplasms, focal infectious or inflammatory lesions, ischemic and hemorrhagic stroke
PPRF	Slow saccades, low-gain smooth pursuit with catch-up saccades, and conjugate gaze palsy all horizontal and ipsilateral	Benign and malignant primary and metastatic neoplasms, focal infectious or inflammatory lesions, ischemic and hemorrhagic stroke involving dorsal medial pons
Cerebellum	Gaze-evoked nystagmus with fast phases ipsilateral, macro-square wave jerks saccadic dysmetria, saccadic oscillations, macrosaccadic oscillations	Cerebellar degenerative diseases, benign and malignant primary and metastatic neoplasms, focal infectious or inflammatory lesions, ischemic and hemorrhagic stroke
Vestibular system	Vestibular (constant velocity slow-phase) nystagmus in plane of affected semicircular canal for peripheral lesions, pure upbeat for central lesions	Cerebellar degenerative diseases (flocculus and nodulus), benign and malignant primary and metastatic neoplasms, focal infectious or inflammatory lesions, ischemic and hemorrhagic stroke

SUPRANUCLEAR CONTROL

MLF	Failure of ipsilateral eye to adduct during versions (conjugate gaze) to the side opposite the lesion; dissociated sustained or transient nystagmus of the abducting eye with fast phases away from lesion side	Multiple sclerosis, benign and malignant primary and metastatic neoplasms, focal infectious or inflammatory lesions, ischemic and hemorrhagic stroke
Gaze-holding system	Gaze-evoked nystagmus with fast phases ipsilateral	Cerebellar degenerative diseases (flocculus and nodulus), benign and malignant primary and metastatic neoplasms, focal infectious or inflammatory lesions, ischemic and hemorrhagic stroke

MLF, Medial longitudinal fasciculus, PPRF, parabrachial pontine reticular formation

oblique, and medial rectus muscles send axons only to the ipsilateral third cranial nerve. The caudal central subnucleus for the levator palpebrae is a midline structure and sends axons to both nerves. The Edinger-Westphal nucleus is also an unpaired midline nucleus situated rostral to the caudal central nucleus. Cells within this nucleus synapse in the ciliary ganglion in the inferior orbit. From this structure, postganglionic parasympathetic fibers innervate the pupillary sphincter muscle and the ciliary muscle that controls accommodation of the crystalline lens. Finally, the superior rectus subnucleus sends axons only to the contralateral third nerve trunk. These anatomical details lead to clinical rules by which one can determine whether a lesion is in the third nerve nucleus or in the fascicular portion, which is more distal. Fascicular cranial nerve III involvement by intramedullary lesions can also be distinguished from extramedullary lesions by concomitant involvement of either the red nucleus (Claude's syndrome), cerebral peduncle (Weber's syndrome), or both (Benedikt's syndrome) (see [Chapter 22](#)).

Within the subarachnoid space, the nerve trunk is fed by branches of the posterior cerebral artery, superior cerebellar artery, and branches of the meningeophyseal trunk. In the cavernous sinus, cranial nerve III runs superior to cranial nerve IV in the deep layer of the lateral wall of the cavernous sinus ([Fig. 9-4](#)). Cranial nerve III enters the orbit inferior to the fourth cranial nerve. Within the common tendon sheath of the extraocular muscles, the annulus of Zinn, cranial nerve III then divides into the superior and inferior rami ([Fig. 9-5](#)). The actual point of division varies among individuals and can occur within the cavernous sinus. The superior ramus of cranial nerve III innervates the superior rectus and levator palpebrae muscles, while the inferior ramus innervates the medial and

TABLE 9-2 -- PRIMARY ACTIONS OF THE EXTRAOCULAR MUSCLES

Muscle	Action	Optimum Position
Medial rectus	Adduction	
Lateral rectus	Abduction	
Superior rectus	Elevation	In abduction
Inferior rectus	Depression	In abduction
Superior oblique	Depression	In adduction
Inferior oblique	Elevation	In adduction

inferior rectus muscles, inferior oblique muscle, and ciliary ganglion.

Sympathetic Innervation of the Pupil

In opposition to the pupillary constriction produced by cranial nerve III, the sympathetic system dilates the pupil. The dilator system functions by a reflex arc similar to the sphincter system. The afferent arm, however, is much less circumscribed than the light reflex. Afferent stimulation along pain and temperature pathways from the spinal cord generally causes pupillary dilatation that is abrupt in onset and lasts 20 to 60 seconds. More sustained dilatation often attends mental states involving fear, anxiety, or surprise. Because the sympathetic afferent pathways are anatomically ill defined, especially at rostral levels of the CNS, this discussion focuses on the efferent sympathetic pathways. Anatomical reports have shown sympathetic fiber degeneration in the upper brain stem after experimental lesions in the hypothalamus. These studies document widely dispersed fiber tracts in the upper midbrain and diencephalon but none in the pons or medulla. The descending system is most likely a polysynaptic one, despite the clinical use of "the central neuron" in the chain leading to the iris dilator. Clinical studies have documented that dorsolateral lesions throughout the brain stem often produce ocular sympathetic dysfunction ipsilaterally, whereas medial and ventral lesions do not. This is the basis for the widely accepted view that the polysynaptic central ocular sympathetic system is dorsolaterally disposed in the brain stem.

This pathway continues into the spinal cord to the C8 through T2 segmental levels, where the central fibers synapse with cells in the intermediolateral gray horns. This zone between C8 and T2 is commonly known as the *cilio-spinal center of Budge and Waller*. The central pathways through the cervical spinal cord are located very superficially (near the pia) in the lateral columns. The preganglionic cells from the cilio-spinal center send axons to the *paravertebral sympathetic ganglion chain* by way of the C8-T2 ventral roots. These preganglionic fibers travel upward in the sympathetic chain through the *stellate* (combined upper thoracic and lower cervical ganglion) and the *middle cervical* ganglions. They synapse with postganglionic cells in the *superior cervical ganglion*, which is usually

Figure 9-2 A, Axial section of the orbits viewed from above. The eyes are shown in conjugate right gaze, which places the right eye in the abducted position and the left eye in the adducted position. The superior oblique muscle is shown with its tendon passing through the trochlea or pulley on the anterior medial orbital rim. The rectus muscles are the primary elevators and depressors when the eye is in abduction, and the obliques perform this function with the eye in adduction. A diagram showing the position of maximum action of the extraocular muscles of the two eyes as viewed from in front of the patient. MR, medial rectus; LR, lateral rectus; SR, superior rectus, IR, inferior rectus; IO, inferior oblique; SO, superior oblique.

Figure 9-3 (Figure Not Available) A cross section through the midbrain showing the third cranial nerve nuclear complex. The subnuclei extend in rostrocaudally oriented columns, as depicted in this three-dimensional representation modeled on Warwick's schemata. The letters superimposed on each nuclear group indicate the muscle innervated as follows: LP, levator palpebrae; SR, superior rectus; IR, inferior rectus; IO, inferior oblique; MR, medial rectus. A right nuclear third nerve lesion is illustrated. Open triangles and dotted lines indicate lesioned neurons and their axons. Filled triangles and solid lines denote normal neurons and their axons. All of the outflow to the right third nerve is lesioned. Crossed outflow from the right SR and LP subnuclei gives rise to paresis of contralateral eye elevation and ptosis. The left ptosis is partial because there is still ipsilateral (uncrossed) outflow from left LP subnucleus to the left LP. The crossed pathway from left LP subnucleus to right LP is affected at the axonal level as the fibers course through the damaged right third nerve complex (transition of solid lines to dotted); thus right ptosis is complete. The contralateral elevator palsy and ptosis thus distinguish nuclear nerve palsy from fascicular palsy, in which the findings are limited to the ipsilateral eye (From Goodwin JA: *Eye signs in neurologic diagnosis*. In Weiner WJ, Goetz CG: *Neurology for the Non-Neurologist*, 3rd ed. Philadelphia, J.B. Lippincott, 1994, pp 298-348.)

Figure 9-4 Diagram of the cavernous sinus. Oculomotor (III), trochlear (IV) and ophthalmic division of the trigeminal and abducens cranial (VI) nerves are indicated (From Miller NR: *Walsh and Hoyt's Clinical Neuro-Ophthalmology*, Vol 2, 4th ed. Baltimore, Williams

found high in the neck, often under the angle of the mandible. This means that the common lesions that cause ocular sympathetic palsy (Horner's syndrome) interfere with preganglionic fibers as they course through the upper thorax and neck. Virtually all lesions producing postganglionic sympathetic dysfunction are intracranial and intraorbital, because the superior cervical ganglion is so near the base of the skull. The postganglionic axons at first travel in the adventitia of the carotid artery and those supplying vascular and sweat gland structures in the lower face travel with external carotid branches. The ocular sympathetics and those serving vasomotor and sudomotor function for the forehead travel with the internal carotid into the middle cranial fossa. A contingent of ocular sympathetic fibers takes a side path through the otic ganglion in the middle ear. This apparently explains the occasional occurrence of Horner's syndrome with middle ear infections. The main ocular sympathetic pathway, however, follows the carotid artery through its *siphon* region and then joins the *first division (ophthalmic) of the trigeminal nerve*, which carries it into the orbit. A sympathetic contingent passes through the parasympathetic ciliary ganglion, constituting the so-called sympathetic root of the ganglion, but no sympathetic synapses occur there. In the orbit, the ocular sympathetics innervate the iris dilator muscles together with small smooth muscles in the lids (Muller's muscle), which contribute to upper lid elevation and lower lid depression.

Trochlear Nerve (Cranial Nerve IV)

Cranial nerve IV is unique in that it exits from the brain stem dorsally and crosses to the other side before encircling the brain stem on the way to the cavernous sinus. This anatomy renders it particularly susceptible to trauma in which forces are brought to bear on the dorsal midbrain. This situation usually occurs in the setting of very severe head trauma in which the brain stem is forced downward and angulated backward by a sudden shift of supratentorial structures. The course of cranial nerve IV in the subarachnoid space is relatively protected from compressing lesions by the adjacent free edge of the tentorium. Within the

Figure 9-5 View of the posterior orbit showing the origins of the extraocular muscles and their relationships to the optic and ocular motor ne(Reproduced with permission from Miller NR: Walsh and Hoyt's Clinical Neuro-Ophthalmology, Vol 2, 4th ed. Baltimore, Williams & Wilkins, 1985.)

138

cavernous sinus, cranial nerve IV can be found in the deep layer of the lateral wall inferior to cranial nerve III (see [Fig. 9-4](#)). Cranial nerve IV enters the orbit through the superior orbital fissure superior to cranial nerve III but outside the annulus of Zinn (see [Fig. 9-5](#)). It lies in the superior orbit, crosses over the superior rectus muscle, and innervates the superior oblique muscle. 

Abducens Nerve (Cranial Nerve VI)

The abducens nucleus is medial and dorsal at the pontomedullary junction, separated from the floor of the fourth ventricle by the genu of the facial nerve. Within the abducens nucleus, lateral rectus motor neurons intermix with internuclear neurons, sending their axons across to the opposite MLF and then to the contralateral third cranial nerve. Axons of the sixth cranial nerve course almost directly ventral and exit from the pons near the midline. The axons emerge in the horizontal sulcus between the pons and medulla, lateral to the bundles of the corticospinal tract. The sixth cranial nerve ascends underneath the pons in the prepontine cistern and enters Dorello's canal beneath Gruber's (petroclinoid) ligament. Within the cavernous sinus, the nerve is situated between the carotid artery medially and the ophthalmic branch of the fifth cranial nerve. The large cells of the abducens nucleus innervate the lateral rectus muscle, while a small cell population innervates the contralateral medial rectus subnucleus of the oculomotor complex (third cranial nerve) via the MLF.

SUPRANUCLEAR CONTROL OF EYE MOVEMENTS

As with other motor anatomical systems, conjugate gaze has lower motor nuclei and an upper motor neuron control system.

The upper motor neuron supranuclear control resides bilaterally in the cerebral cortex and cerebellum, and the control networks that produce conjugate gaze functions are the saccade, pursuit, and vestibulo-ocular systems, each with a specific anatomical arrangement in the cerebral hemispheres, brain stem, and cerebellum. All of the supranuclear systems are concerned with *conjugate* eye movements, and destructive lesions in these systems cause conjugate deviation in the direction of the unopposed antagonist muscles. Dysconjugate eye movements indicate a disorder at or below (peripheral to) the third, fourth, and sixth cranial nerve nuclei or in the pathways joining these nuclei.

Anatomy of the Saccade System

Three important cortical areas are involved with saccade generation and include the frontal eye fields (FEF), the supplementary eye fields (SEF), and the parietal eye fields (PEF). Other zones of the association cortex that play a secondary, but important role in saccade generation are the prefrontal cortex (PFC) and posterior parietal cortex. The interrelationships of these structures are complex and are summarized with a clinical emphasis (Fig. 9-6 (Figure Not Available)).^[9] The FEF is located in the lateral part of the precentral sulcus at the posterior end of the middle frontal gyrus. It is primarily involved with intentional conjugate visual exploration to the contralateral visual space and is active in the disengagement from fixation that must precede each refixation saccade. The FEF receives input from the PFC, which functions in prediction, spatial memory, and inhibition of saccades; the SEF, wherein reside motor programs; and the PEF, which is specialized to integrate spatial vectors and facilitate reflexive visual exploration.^[9],^[10] FEF output is directed to the superior colliculus (SC) and saccade generators (burst neurons) in the brain stem reticular formation.^[11],^[12]

The SEF is in the anterior part of the supplementary motor area in the posteromedial part of the superior frontal gyrus.^[13],^[14] It receives input from the PFC and from the posterior hemisphere,^[9] and it projects to the FEF,^[10] the SC, and the brain stem reticular formation.^[15] The SEF functions to coordinate visual with other sensory and motor inputs to maintain eye position in space, despite head and body movement during and between successive saccades.^[16],^[19] The PEF is situated in the superior part of the angular gyrus and supramarginal gyrus within areas 39 and 40 of Brodmann.^[20],^[21] Lesions of this area result in increased latency of reflexive, visually guided saccades^[22] to the contralateral visual space, and this area has also been shown to be involved with disengagement from fixation as well as the triggering of reflexive visually guided saccades. The PEF seems more important in the reflexive exploration of the visual environment, while the FEF is more active with intentional (internally generated or willed) exploration.

The descending saccadic pathways most likely mimic those described in lower order primates. In these animals, the frontal lobes project to the SC, which is then projected to the saccade generators in the pons (paramedian pontine reticular formation [PPRF]) for horizontal saccades and the midbrain for vertical saccades (see later). There are two parallel systems for the FEF and SEF. A subcortical circuit has also been demonstrated from the frontal cortex to the caudate nucleus and projects to the substantia nigra (pars reticularis) that sends inhibitory output to the SC, suppressing unnecessary saccades.

In a clinical example, a patient with an acute unilateral right-sided cerebral infarction resulting in left-sided limb weakness may maintain his or her eyes and head turned to the right. This patient's gaze may be brought to near the midposition, but attempts at saccades with the left gaze field are not possible. The doll's head maneuver does, however, bring the eyes past the midline to the left. In contrast, a patient with an acute unilateral right-sided pontine infarct will have left-sided limb weakness also, but gaze preference will be to the left with impaired rightward horizontal saccades. The doll's head maneuver will not bring the eyes past the midline.

Anatomy of the Pursuit System

In contrast to the saccadic control, the conjugate pursuit system of each hemisphere controls binocular eye movements

Figure 9-6 (Figure Not Available) Hypothetical cortical pathways involved in saccade control. The cortical relays of saccade pathways are represented by arrowheads. FEF, frontal eye field; H, hippocampal formation; OC, occipital cortex; PEF, parietal eye field; PFC, prefrontal cortex (i.e., area 46 of Brodmann); PPC, posterior parietal cortex; SC and RF, superior colliculus and reticular formation; SEF, supplementary eye field; SPI, superior parietal lobule; T, thalamus; VC, vestibular nucleus (From Pierrot-Deseilligny C, Rivaud S, Gaymard B, et al: Cortical control of saccades. *Ann Neurol* 37:557-567, 1995.)

to the *ipsilateral* visual space.^[23] Occipital visual areas (Brodmann 18 and 19) provide input on spatial vectors to the middle temporal (MT) and medial superior temporal (MST) cortices. These areas are of primary importance in generating smooth conjugate pursuit eye movements.^[24],^[25] Efferents from MT and MST travel to the FEF, posterior parietal cortex, and brain stem reticular formation. Brain stem connections undergo a double decussation, resulting in each hemisphere's controlling ipsilateral smooth pursuit eye movements.^[26],^[27] Selective lesions of MST bring about bilateral reduction of pursuit gain over the entire movement field, although this is most pronounced for ipsilateral pursuit.^[28] Optokinetic nystagmus (OKN) gain is reduced by MST lesions.^[29] Optokinetic nystagmus occurs when a series of vertical bars or a similar pattern is passed in front of the eyes. There is a slow following phase and a rapid jerk in the opposite direction.^[30] Selective MT lesions produce impaired initiation of pursuit with motion in either direction in the contralateral hemifield of vision.^[31]

Large cortical lesions, involving either frontal or parietal lobes, generally are associated with ipsilateral conjugate eye deviation that lasts a few days.^[32] In these cases, forceful eye closure may be associated with conjugate eye deviation contralateral to the lesion.^[33] Bilateral posterior cerebral hemisphere lesions lead to Balint's syndrome,^[34] in which pursuit eye movements and OKN movements are defective in all directions and visually guided saccades have increased latency and diminished accuracy with relatively preserved intentional saccades. Involvement of angular gyrus and superior parietal cortex is thought to be responsible for the visual inattention that accompanies this syndrome. Optic ataxia refers to the inability of the patient to make accurate eye or limb movements under visual guidance. These patients also have a distinctive visual perceptual abnormality in which they cannot synthesize large visual figures that require multiple fixations to encompass. This is caused in part by the inability to make accurate saccades to the elements of the extended visual figure. This perceptual problem has been called amorphosynthesis or simultanagnosia by various authors.

Subcortical nuclei and pathways are undoubtedly important in generating smooth pursuit, although the result of focal lesions of these structures is uncertain. The thalamic pulvinar receives direct input from the retina and SC, and it projects to several cortical areas involved in the generation of eye movement. There is evidence that the pulvinar may function in visual suppression during saccades to eliminate perception of image motion as the eyes are traveling to a new fixation point. The pulvinar may also play a role in shifts in spatial attention and efference copy by which brain stem ocular motor structures provide feedback to cortical eye movement control systems about the moment-to-moment state of the eye movement. The internal medullary lamina of the thalamus receives input from brain stem nuclei, including the SC, vestibular nuclei, and nucleus prepositus hypoglossi, and provides reciprocal connections to the FEF, SEF, and PEF in the cerebral hemisphere. The clinical result of lesions involving the internal medullary lamina is uncertain. Such lesions may result in inaccuracy of memory-guided saccades, if another eye movement occurs between the saccade stimulus and the resulting saccade. Also, difficulties with disengaging fixation may occur, leading to increased saccade latency for visually guided saccades under certain stimulus circumstances.^[35]

Thus, there is a fundamental distinction to be made between cerebral hemisphere and brain stem conjugate gaze control. At the cerebral level, the direction of the saccade control (contraversive) is opposite to the direction of the pursuit control (ipsiversive), while at the brain stem level both control ipsilateral movement. Clinical evidence demonstrates that pathways that control saccadic movements decussate caudal to the diencephalon but rostral to the pons, while the pursuit pathways either do not cross, or cross and recross. Patient studies suggest that hemisphere bidirectionality is preserved as far caudal as the thalamus and that the pursuit and saccade pathways both operate via the ipsilateral FEF outflow through the thalamus. Alternatively, the pursuit system may have pathways in the corona radiata separate from the saccade system outflow but funnel through the same region in the thalamus as the frontal system. The fact that some frontal lesions are associated with an ipsidirectional pursuit defect in conjunction with a contraversive saccade disorder supports the concept that the pursuit system outflow occurs via a common frontal-thalamic-brain stem pathway. However, the repeated observation of frontal lesions with isolated contralateral saccade disruption and normal pursuit weigh against a common pathway.

The Vestibulo-ocular System

The vestibulo-ocular system maintains image stability on the fovea in the presence of head movement. The afferent arm of this reflex is initiated by acceleration

receptors in the inner ear. The equivalent of mathematical integration is performed on the acceleration signal by the dynamic properties of the semicircular canal and cupula (see [Chapter 12](#)). The result of this integration is a signal proportional to head rotational velocity in space that is supplied to the vestibular nuclei by way of the eighth cranial nerve. The information is then relayed to brain stem gaze centers, and slow eye movements with velocity equal to and direction opposite head rotation are generated. The arrangement of vestibular connections in the brain stem has been thoroughly reviewed. ^[36]

Because vertically acting rectus and oblique muscles exert mixed vertical and torsional rotations, the nystagmus resulting from vertical canal stimulation has mixed vectors and depends on the position of the eye in the orbit (abducted or adducted). The activation of the anterior semicircular canals produces upward and torsional slow phases, whereas activation of posterior canals induces downward and torsional movements. Each vestibular nucleus interacts with two motoneuron pools, one for each eye. Excitatory projections from vestibular nuclei cross the midline, but inhibitory connections do not. The pathways for upward and downward VORs differ.

Vestibular nuclei project to ocular motor neurons and to other nuclear groups that are important in various aspects of integrating the numerous inputs to eye movement. These include the nucleus prepositus hypoglossi and the nucleus of Roller, where integration of burst and step

(holding) discharge patterns are assembled into a final oculomotor command. Outputs of the nucleus prepositus hypoglossi to burst cells initiate saccades and produce the fast phase of nystagmus.

Internuclear Oculomotor Control: The Final Common Pathway

Zones within the tegmental reticular formation in the brain stem serve to combine the various eye movement commands and to present an integrated set of final motor commands to the ocular motor nuclei. The PPRF refers to the zone surrounding cranial nerve VI nucleus on either side of midline in the pontine tegmentum. This area contains burst and pause cells that are important for horizontal saccade generation. The *rostral interstitial nucleus of the medial longitudinal fasciculus (riMLF)*, the *interstitial nucleus of Cajal (iC)*, the *nucleus of Darkschewitsch (nD)*, the *nucleus of the posterior commissure (nPC)*, and adjacent portions of the *mesencephalic reticular formation (MRF)* probably supply burst and pause commands for vertical saccades, and pass the final innervation pattern to the nuclei of the third and fourth cranial nerves. The integration of these systems has been reviewed extensively by Leigh and Zee. ^[37]

Commands for saccades and pursuit descend in the brain stem via supranuclear eye movement pathways outlined earlier. In addition, the vestibular nuclei in the medulla and the flocculi and noduli of the cerebellum provide vestibular inputs to both the horizontal eye movement system in the PPRF and to the vertical eye movement zones of the mesencephalic reticular formation, primarily the riMLF and iC. The final command signal for saccades and pursuit movements that descend on the ocular motor nuclei is a composite of inputs from a direct pathway and a pathway through the neuronal circuitry that performs a mathematical integration on the direct signal. This neural integration is probably a distributed function with components from the cerebellum (especially flocculus and paraflocculus), the nucleus prepositus hypoglossi, and the medial vestibular nucleus (MVN) for horizontal gaze and the iC for vertical gaze. The PPRF was once thought to perform this function, but it has been established that lesions of this structure spare gaze holding, the primary function of the integrator for saccades.

Normal saccade velocity depends on normal function of *burst* neurons (velocity command) that provide the acceleration part of the movement. Without a proper burst, the resulting saccade is slow. The neural integrator produces a tonic *step* of innervation (position command) that is at just the right firing rate to sustain eye deviation at the endpoint of the saccade. When the neural integrator is leaky and produces a step innervation at too low a frequency of action potentials, the eyes reach the target accurately and with normal velocity on account of the burst. They then, however, drift back toward primary gaze, because the step or holding function is inadequate. After a certain amount of drift, a *position error* signal is generated calling for another saccade. This results in a repetitive cycle of saccades and back drifts that is called *gaze-evoked nystagmus* (see later).

When a novel visual stimulus calls for a saccadic refixation or when a command to look at a new fixation target is given, there is an obligate latent interval of between 100 and 200 milliseconds. This latent interval includes time for the visual stimulus in the peripheral field to travel along afferent pathways to the cerebral cortex, where the spatial coordinates of the object to be foveated are turned into motor commands or vectors having both direction and amplitude specifications. This computation of vectors and passage of the efferent commands to the brain stem requires additional time. It has also been postulated that the system works via intermittent data samples rather than continuous intake of afferent data. Thus, if a novel visual stimulus occurs just after a sample is taken, it will have to wait for the next sampling interval, perhaps 40 to 50 milliseconds later, before entry into the system. This could explain much of the latency variability observed for generation of individual saccades. The generation of saccades is a much more complex entity, however, and there is considerable controversy as to whether saccade vectors are calculated through intermittent or continuous sampling. It is also unclear whether saccade motor commands can be modified as the eyes are in motion during a saccade. Under ordinary circumstances, saccades behave as a *ballistic* movement--as with a thrown ball, the saccade trajectory is not modifiable after the movement begins. Under special test circumstances, however, it seems that some individuals are capable of modifying saccade trajectory in midflight. These special features of a few saccades in normals have not yet been adequately explained by existing models of brain stem circuitry.

Pursuit movements also depend on the combination of a velocity and position signal. When the direct innervation is not present, the eyes eventually attain the velocity of the stimulus, but the beginning acceleration to that velocity is slow. For pursuit commands, the direct pathway carries a step command, which is the velocity signal, and the neural integrator produces a ramp command that is the position signal. The slow eye movements of the vestibulo-ocular system also depend on a combined step-ramp signal for normal trajectory.

The organization of the vertical eye movement system is complex and incompletely understood at present. It appears that the riMLF contains primarily burst neurons that generate vertical saccades. Cells of iC, nD, nPC, and MRF carry the fully assembled burst-step firing pattern needed to perform saccades, pursuit, and vestibulo-ocular movements, as well as to hold the eyes in eccentric positions of gaze. Nuclei at the pontine and medullary levels are important in control of vertical eye movements. Bilateral lesions of the MLF, which carries complex ascending influences from vestibular nuclei and PPRF gaze centers, abolish vertical pursuit and VOR movements but spare saccades. Thus, the riMLF apparently has functional connections with the cerebral hemispheres independent of supranuclear pathways that operate via the PPRF. Although vertical saccades are spared with bilateral lesions of the ascending pathways, the eye position signal is abolished, and gaze paretic nystagmus occurs with upgaze and downgaze effort.

Efferents from the PPRF on one side connect with large motor cells in the ipsilateral sixth nerve nucleus for

abduction of the ipsilateral eye and with small cells in the same nucleus, which, in turn, connect via the MLF with the opposite medial rectus subnucleus of the third nerve for adduction of the contralateral eye. Thus, a contraversive (opposite direction) saccade command from the right hemisphere descends to the left PPRF, then to the left abducens nucleus for abduction of the left eye and adduction of the right eye via the right MLF. This circuitry thereby produces conjugate gaze contralateral to the hemisphere issuing the command and ipsilateral to the activated PPRF. This network is illustrated schematically with participating brain stem and hemispheric pathways for conjugate leftward gaze (Fig. 9-7 (Figure Not Available)). Thus, the brain stem connections for ocular motility are arranged to provide *conjugate* gaze. Lesions affecting the internuclear gaze pathways distal to the PPRF, through the MLF, produce disconjugate gaze palsy such that only the abducting eye ipsilateral to the activated abducens nucleus has full deviation, often with dissociated or monocular nystagmus. The contralateral adducting eye moves either incompletely or slowly. The eyes, however, remain *straight* with parallel visual axes when viewing objects at a distance in the primary position of gaze, which distinguishes INO from a cranial nerve III lesion or a primary defect of the medial rectus muscle, either of which causes divergence of the visual axes (exotropia) in primary gaze.

EXAMINATION OF CRANIAL NERVES III, IV, AND VI

Directed Neurological Examination

The examination should begin during the clinical history, when there is the opportunity to observe the patient's head,

Figure 9-7 (Figure Not Available) A. Schematic diagram of the brain stem pathways and centers that serve horizontal conjugate gaze. Multisynaptic pathways from the right frontal cortex decussate in the midbrain and form synapses in the left pontine paramedian reticular formation (PPRF), which relays innervation to two cell populations within the sixth cranial nerve nucleus. The large cells in the nucleus send axons to the lateral rectus muscle to abduct the left eye. The small cell population gives rise to the pathway that decussates and ascends in the contralateral medial longitudinal fasciculus (MLF) and makes synaptic contact with cells of the medial rectus subnucleus of the third cranial nerve complex. This pathway gives rise to coordinated adduction of the right eye to complete the act of conjugate leftward gaze, as illustrated B. A lesion in the MLF causes internuclear ophthalmoplegia, which is characterized by a failure of adduction of the ipsilateral eye during attempted conjugate gaze, as illustrated C. The abducting eye often manifests dissociated or monocular nystagmus. (From Goodwin JA: *Eye signs in neurologic diagnosis*. In Weiner WJ, Goetz CG: *Neurology for the Non-Neurologist*, 3rd ed. Philadelphia, J.B. Lippincott Company, 1994, pp 298-348.)

eyes, and eyelids over an extended interval. During this period, it is important to notice general abnormalities of the globe or eyelid position or asymmetries of eye movement. Eyelid twitch and flutter may accompany eye movements in ocular myasthenia, and myasthenic involvement of the levator palpebrae may bring about progressive ptosis with sustained upgaze or even during sustained fixation near primary gaze. Thyroid orbitopathy characteristically includes a distinctive set of changes in the general appearance of the eyes, including lid puffiness, prominent extraocular muscle insertions, conjunctival edema (chemosis), conjunctival injection, forward displacement of one or both eyes (*proptosis*), *stare*, and *lid lag*. Each globe floats in orbital fat suspended within the orbit by ligamentous structures and by the extraocular muscles. The globe is free to rotate in all directions, but any rotation can be adequately described by measuring vectors, or components of the rotation in the vertical (X axis of rotation), horizontal (Z axis of rotation) and torsional (Y axis of rotation) planes. These three axes of rotation, which intersect at the hypothetical center of rotation of the globe, were defined by Fick and are depicted in [Figure 9-1](#) in relation to Listing's plane. This plane is perpendicular to the visual axis (Y) with the eye in primary gaze, and any eye movement can be fully described by the rotation of the globe around a single axis in this plane.

In the subsequent sections, the examination of cranial nerves III (including the pupil--both parasympathetic and sympathetic components), IV, and VI, as well as the supranuclear control systems are first presented. This is followed by a detailed approach to the examination of a patient with diplopia. In examining the function of these cranial nerves, patients should always be asked to look forward, maintaining the primary position, and then be instructed to look in all secondary and tertiary positions.

EXAMINATION OF CRANIAL NERVE III AND THE PUPIL

The patient with complete cranial nerve III dysfunction presents with abnormalities of all its extraocular muscles, including weakness of the levator palpebrae superioris, medial rectus, superior rectus, inferior rectus, and inferior oblique. As a result, the ipsilateral eye does not move fully into adduction, elevation, or depression, and there is upper eyelid ptosis. Looking forward, the patient's eye tends to deviate down and outward (*exo*) from residual tone in the superior oblique muscle (cranial nerve IV) and the lateral rectus muscle (cranial nerve VI). In attempted downgaze, there is intorsion of the globe produced by the normal action of the superior oblique muscle. This can best be observed by using conjunctival blood vessels as landmarks to visualize rotation of the globe about its anteroposterior (Y) axis. With intorsion, vessels nasal to the limbus move down while vessels on the temporal side of the cornea stay stationary or move up.

Partial or incomplete cranial nerve III dysfunction can result in weakness of one or a number of extraocular muscles. Thus, certain eye movements may be abnormal, corresponding to selected extraocular muscle dysfunction. This may occur when either the superior ramus (supplying the superior rectus and levator) or inferior ramus (supplying the medial and inferior recti, the inferior oblique, and ciliary ganglion) is affected in isolation. Dysfunction of the extraocular muscles that turn the eye as well as the levator palpebrae are together referred to as *external* ophthalmoplegia.

When assessing lid position, one must be careful of illusions created by asymmetrical skin folds, by altered position of the eye in the orbit (extraocular muscle palsies and strabismus), and even by anisocoria. The examiner uses all of these landmarks for assessing where the lid margin is expected to fall and whether its position is the same in the two eyes. Eyelid position and the relation of lid margins to landmarks such as skin folds is often asymmetrical for a variety of non-neurological reasons.

Cranial nerve III also innervates muscles within the eye, including the sphincter of the pupil and the ciliary muscle. With pupillary sphincter paralysis, the involved pupil is large and it reacts less to light stimulation of the retina than the contralateral pupil. The ciliary muscle exerts pull on radially oriented ligaments called zonules that attach around the perimeter of the crystalline lens. Ciliary muscle contraction induces slack in the zonules and allows the crystalline lens to assume a more spherical configuration, which shifts the focal plane of the eye to a nearer point in space--a process called accommodation. The neurological control of accommodation is obligatorily linked to that of convergence of the visual axes and that of pupillary meiosis (constriction). The three functions together serve the process of looking at near objects--convergence foveates the image in either eye, accommodation shifts the focal plane to that object, and meiosis increases the depth of focus for near vision. These three actions together are referred to as the *near triad*. Dysfunction of pupillary constriction and lenticular accommodation are referred to as *internal* ophthalmoplegia.

On examining the pupil, the clinician seeks evidence of either parasympathetic or sympathetic dysfunction by measuring pupil size in both bright and dim ambient illumination.

The ocular sympathetics innervate the radially oriented dilator smooth muscles in the iris, which are most active in dim light. The parasympathetic system via cranial nerve III innervates the pupillary sphincter muscle and is most active in bright light. In dim light, the pupillary sphincter muscle is reciprocally inhibited, and in bright light, the same is true of the dilator muscles. As a consequence, with parasympathetic lesions the anisocoria is greater in bright light (larger pupil abnormal) and with sympathetic lesions the anisocoria is greater in dim light (small pupil abnormal). For practical purposes, under clinical testing conditions, the pupillary reaction to light remains normal with ocular sympathetic dysfunction. The parasympathetic system determines the dynamic characteristics of the pupillary light reaction.

Abnormal lid position is best determined by measuring the distance between a central corneal light reflex and the upper and lower lid margins, respectively, and comparing these for symmetry between eyes. The light reflex, produced by shining a focused source of light on the eyes, does not move appreciably with variation in eye position. The distance from the light reflex to the upper and lower lid margins is called the margin-reflex distance (MRD).

The distance to the upper lid is labeled MRD_1 and to the lower lid MRD_2 . Both the MRD_1 and the MRD_2 are reduced on the side of an ocular sympathetic lesion, because Muller's smooth muscle retracts both the upper and lower lids. Muller's muscles work in opposition to the orbicularis oculi muscle (innervated by cranial nerve VII) (see [Chapter 11](#)) that encircles both lids and is the primary muscle of eye closure. In the setting of sympathetic dysfunction, the upper lid falls, whereas the lower lid rises with the nonfunctioning smooth muscle. An erroneous diagnosis of seventh cranial nerve palsy can be made on the basis of apparent widening of one palpebral fissure (orbicularis oculi weakness) when the abnormality is a narrowed fissure on the other side secondary to an ocular sympathetic lesion. This error is more likely to occur if the normal range of facial asymmetry produces an apparent flattening of the nasolabial fold on the side of the wider palpebral fissure and if the pupillary meiosis is minimal or lacking in the ocular sympathetic palsy. Both the MRD_1 and the MRD_2 are larger on the side of a facial nerve palsy because the orbicularis is weak in both upper and lower lids. Pharmacological pupil testing for ocular sympathetic dysfunction can be a useful arbiter in this setting.

Cocaine (5- or 10-percent solution) can be used to diagnose the presence of Horner's syndrome, the clinical manifestation of ocular sympathetic dysfunction, including preganglionic and postganglionic types.^[38] Within 40 minutes of the instillation of 1 drop of cocaine into each eye, relative anisocoria will increase if Horner's syndrome is present. This phenomenon occurs because cocaine blocks reuptake of the ambient norepinephrine released at the neuromuscular junctions of the iris sphincter. On the side of the lesion, there is less norepinephrine normally being released and, as a result, blocking reuptake results in less accumulated norepinephrine as compared with the normal side. Antihypertensive medications may prevent pupillary dilatation produced by cocaine and need to be considered when interpreting the results of this test. Hydroxyamphetamine (1-percent solution) can be used to distinguish between preganglionic (primary and secondary ocular sympathetic neurons) from postganglionic lesions. If this drug is used, testing should be delayed at least 24 to 48 hours after the use of cocaine solutions. When 1 drop of hydroxyamphetamine is instilled in the eyes, the suspected pupil will not dilate to the extent of the normal eye if a postganglionic (tertiary neuron) lesion is present. This results because hydroxyamphetamine causes the release of norepinephrine stored in the cytoplasmic vesicles in the postganglionic nerve terminals. If the tertiary, postganglionic neuron is intact, this drug will dilate the abnormal pupil as well as the normal side. If this occurs and a preganglionic lesion is thus

suspected, further drug testing cannot delineate whether the neuronal abnormality is at the primary or secondary neuron.

EXAMINATION OF CRANIAL NERVE IV

Cranial nerve IV innervates the superior oblique muscle, which originates at the orbital apex and forms a tendon anteriorly that passes through a pulley-like structure called the trochlea. The superior oblique muscle, therefore, originates functionally from the trochlea at the superior medial orbital rim and inserts on the top of the globe behind its equator. When the eye is in adduction, this muscle exerts a more or less direct downward pull and depresses the eye. When the eye is in abduction, the superior oblique muscle pulls the 12 o'clock meridian of the iris toward the nose, rotating the globe around an anteroposterior (Y) axis. This movement is called incyclodeviation (intorsion). When the eye is in the intermediate horizontal positions between adduction and abduction, the superior oblique exerts combined torsional and depressive actions. Weakness of the superior oblique muscle causes failure of depression of the globe that is maximal in adduction. This results in vertical diplopia, with the widest separation of images occurring in gaze away from the involved side (adduction) and down. Isolated superior oblique muscle weakness or cranial nerve IV palsy is more likely than cranial nerve III lesions to result in torsional imbalance. This is because only one of the vertically acting muscles is affected, leaving the other torting vertical muscles unopposed. Superior oblique weakness results in excyclodeviation (extorsion) of the involved eye. To compensate for this problem, the patient automatically tilts the head to the side opposite the palsy. Simultaneous incyclodeviation of the normal eye establishes parallelism and allows for torsional fusion of the images.

If the examiner tilts the head of a person with a right cranial nerve IV palsy to the right, even more intorsion than normal is required. The superior rectus is recruited in an effort to maximize the intorsional power. This results in further inappropriate elevation of the right eye, because the primary effect of superior rectus contraction is eye elevation. This is the basis for Bielschowsky's test for a cranial nerve IV palsy. The patient is directed to gaze straight ahead, and then the head is tilted to the right and to the left, making sure there is no vertical or horizontal eye rotation away from primary gaze. If the degree of elevation of the eye on the side of the cranial nerve IV palsy increases as the head is tilted toward the side of the palsied muscle, the test is positive. In addition to compensatory head tilt, the patient is likely to hold the head down to keep his or her eyes in upgaze and out of the field of maximum image separation. The compensatory triad is completed by turning the head away from the affected side to keep the involved eye relatively abducted.

EXAMINATION OF CRANIAL NERVE VI

Cranial nerve VI innervates the lateral rectus muscle, which abducts the eye. With lesions of cranial nerve VI, the eyes are slightly crossed or convergent (esodeviated) in primary gaze. This is caused by the unopposed tone of the medial rectus, acting without the ipsilateral lateral rectus muscle. In gaze opposite the side of the palsy, the eyes are close to parallel, but as gaze is directed toward the side of the palsy, there is clear-cut failure of ipsilateral eye abduction and an increase in esotropia. In primary gaze, the involved eye may be used for target fixation, but this will result in deviation of the other eye. Which eye the patient chooses for fixation is a matter of habit that may not be disrupted by muscle paresis, even if the weakness is profound. The choice may also be influenced by visual acuity, and there is a strong tendency to fixate with the eye that has better vision. With acquired palsy of cranial nerve VI,

the degree of esodeviation in primary gaze is usually different depending on the fixating eye. To observe primary versus secondary deviation, cover and then uncover each eye, observing the angle of the deviation just after the eye is uncovered. Primary deviation refers to the angle that results from fixation with the normal eye, and secondary deviation results from fixation with the paretic eye. Secondary deviation is larger because in primary gaze, the eye with the weak muscle is struggling to abduct the eye even to the midposition against the tone of the medial rectus. For example, in the case of a right cranial nerve VI palsy, a great deal of rightward innervation is required by the right eye. According to Hering's law of equal innervation, the yoked medial rectus of the opposite (left) eye also receives this large amount of stimulation, and it adducts to a great degree, creating a large-angle esotropia. In contrast, when the nonparetic left eye is fixing, a standard quantity of rightward innervation is required, and a lesser deviation results from the failure of the right eye to abduct completely. On the examination, this difference between primary and secondary deviation is a good clinical clue to the presence of acquired nerve or muscle origin paretic deviation, as opposed to deviation caused by squint or childhood strabismus. In the latter disorder, the deviation remains the same regardless of the eye that is fixing.

EXAMINATION OF THE SUPRANUCLEAR CONTROL OF EYE MOVEMENTS

Saccade System. There is a growing body of literature showing that separate cortical zones are primarily involved in the generation of saccadic movements under different circumstances that can be tested individually. ¹⁴ *Intentional* saccades are internally generated by voluntary thought and the decision to act. *Reflexive* saccades are triggered by an external stimulus that the subject is instructed to look at when it occurs. This may be a visual or an auditory stimulus presented in the dark. *Goal-directed intentional* saccades have been further classified as *predictive* when they are made toward a repetitive stimulus that is presented at a predictable location, and as *interval*, or *memory-guided*, when they are made to a remembered location where the target is no longer present (could be auditory or visual). Also, *antisaccades* occur when the eye movement is in the direction opposite a saccade stimulus. Many of these conditions require elaborate stimulus presentation and eye movement recording systems, yet a bedside evaluation of some of these functions is possible.

The examiner can observe *spontaneous saccades*, which are internally triggered but not goal directed. These saccades can be observed throughout the history and examination by watching the patient produce these eye movements during speech or other motor activity.

In direct testing, the patient should first be given verbal directions to follow such as "look left" and "look down." This can be followed by *visually guided saccades*, which can be tested by asking the patient first to look at the examiner's nose and then to look at an object about 30 degrees to either side of midline. Appropriately placed objects are provided if the examiner holds his or her arms semiextended (elbows flexed about 90 degrees), with hands just a bit in front of his or her own facial plane. Patients should keep their heads stationary facing straight ahead during this type of testing to avoid introducing vestibulo-ocular components. Patients should be asked to refixate their gaze from the examiner's nose to one hand, then back to the nose. Reflexive, visually guided saccades are elicited in a slightly different manner. The examiner's hands should be extended in the same arrangement as noted earlier, but patients are instructed to refixate between the two hands, specifically when the examiner moves the fingers of one or the other hand. In this condition, the subject is waiting for a trigger signal that will result in a reflex eye movement.

The antisaccade task may also be completed at the bedside. In this maneuver, the patient is asked to look in the opposite direction to a novel visual target. The subject must suppress the natural tendency to make a saccade to a newly appearing visual stimulus. In all of these bedside studies, the examiner should observe the latency and accuracy of the eye movements, as well as whether multiple small saccades are necessary to complete the movement. Normal refixations (saccades) are smooth and accurate to verbally directed locations and in between visual stimuli. Abnormalities include an increased latency to the generation of the eye movement and eye movements that fall short of the target (hypometric saccades) or overshoot the target (hypermetric saccades). Additionally, patients with hypometric saccades may produce multiple small saccades in order to generate the desired movement or may be unable to fully move their eyes to the extremes.

Optokinetic nystagmus may be useful in the evaluation of volitional (saccadic) gaze palsies when pursuit movements are normal. To obtain optokinetic responses, a striped drum, squares on a flag, or a tailor's tape with stripes can be used. The patient is asked to look at the apparatus or strip and count the lines as they pass. In normal individuals, as the stimulus passes in front of the patient, a slow phase of eye movements in the direction of the movement is followed by a rapid jerk in the opposite direction that repeats as long as the stimulus is present. In patients with a left frontal lesion, there may be an inability to volitionally make eye movements to the right, but slow-moving targets produce smooth pursuit to the right. Because rightward pursuit and saccades to the left are normal, when the OKN stimulus is rotated to the right, a normal OKN response occurs. Yet, with leftward targets, the fast phase to the right cannot be generated and a tonic deviation to the left occurs.

Pursuit System. Maintenance of a target on fovea with motion of the target in space is the task of the pursuit system. The goal of the pursuit system is to generate a smooth eye velocity that matches the velocity of a visual target. Testing this system requires that a stimulus be present, because patients cannot produce voluntary smooth eye movements in a stationary visual environment or in darkness. If the viewer's head remains stationary, the tracking of a moving target is achieved by matching the angular velocity of the eyes turning in the orbits to the angular velocity of the target moving across visual space. Smooth pursuit can be selectively tested by having the patient hold the head still while following the examiner's finger with the eyes. The finger movement must be slow and within the patient's visual field. The target must not be moved too rapidly, because the pursuit system in normal

persons falls behind when the target velocities reach 40 to 50 degrees per second, producing saccadic pursuit. A target excursion that carries the patient's eyes from

extreme right to extreme left gaze should take about 5 seconds. Normal pursuit is smooth with no inserted saccades. Pursuit is pathological if the normally smooth following eye movement is interrupted by a series of jerky movements in the direction of pursuit. The most frequently observed abnormality of pursuit is subnormal gain, in which the eyes fall progressively behind the target. The examiner cannot perceive the velocity of a patient's pursuit movements by inspection. Fortunately, the visual system does not tolerate the retinal position error that develops as the eyes fall behind the target, and an easily observed saccade is generated as soon as the eye is sufficiently far behind. These inserted catch-up saccades occur rhythmically, because it requires about the same amount of time to generate the needed position error throughout the course of the pursuit movement. This pursuit abnormality, best referred to as *low-gain pursuit with catch-up saccades*, has engendered various descriptive names including *saccadic pursuit*, and even *cogwheel pursuit* in patients with Parkinson's disease. This movement should not, however, be linked to the pathophysiology of parkinsonian cogwheeling. The saccadic pursuit of parkinsonism is simply the manifestation of low gain in the pursuit system. This does not differ from low-gain pursuit in other pathological conditions.

As with saccadic eye movements, optokinetic responses can be useful tools in evaluating pursuit defects, in that lesions affecting the deep parietal lobe cause an interruption in the descending occipitomesencephalic system for slow (pursuit) eye movements. Such lesions produce a homonymous hemianopia (contralateral) and an abnormal OKN when the targets are moved in the direction of the affected side; lesions only in the occipital or temporal lobes, although associated with a hemianopia, do not produce an abnormal OKN response (see later).

Vestibulo-ocular System. Zee has developed a practical approach to bedside or office examination of the vestibular system using simple tools. ^[36], ^[38] The sequence of tests is as follows:

1. Look for static imbalance (bias) between the two vestibular systems on either side of midline.
2. Look for dynamic imbalance using head movement and head position change.
3. Estimate the VOR gain.
4. Elicit vestibular nystagmus by rotating the patient.
5. Perform caloric testing.

Static imbalance is manifest as spontaneous nystagmus, the slow-phase velocity of which reflects the degree of imbalance between the tonic states of the vestibular system on the two sides. Spontaneous nystagmus may be present in primary gaze, although it is typical for vestibular nystagmus to emerge when fixation is suspended. This can be done by covering the eye or having the patient wear Frenzel's goggles with strong spherical convex lenses that eliminate the patient's ability to focus and fixate. Small amplitude nystagmus can be observed ophthalmoscopically by asking the patient to fixate with one eye while viewing the other eye's optic disc or other ocular fundus landmark. Slow-phase drift and rapid returns indicate the presence of nystagmus. On covering the fixating eye, the nystagmus typically increases in amplitude or may appear first. The direction of fundus motion is opposite the direction of visual axis movement. Spontaneous nystagmus should be assessed in the primary position, and in upward, downward, right, and left gaze, with estimation of the relative amplitude in the various gaze positions. It should also be noted whether the nystagmus is rhythmical and steady, as occurs in vestibular dysfunction, or variable in amplitude and frequency, changing with the degree of effort exerted while the patient attempts to maintain the eccentric gaze angle, as occurs with gaze-evoked nystagmus.

Dynamic imbalance is manifest as directional preponderance during vestibular stimulation, in which the VOR gain is greater in one direction than the other. This finding indicates differential sensitivity of vestibular mechanisms to oppositely directed labyrinthine inputs. To test for this, patients should be asked to shake their heads, first horizontally and then vertically, for 10 to 15 seconds in each direction. After each movement interval, the eyes are observed for nystagmus. After horizontal oscillation, the induced nystagmus slow phases are toward the lesion side, and after vertical oscillation, the induced *horizontal* nystagmus slow phases are opposite to the lesion side. These phenomena depend on the presence of a velocity-storage mechanism, which may be disrupted with severe lesions. In such cases, the nystagmus cannot be induced by head shaking. Also, other factors may lead to inverse directionality of the nystagmus. A single rapid head movement to either side can be used instead of prolonged shaking. The eyes should remain fixed on a stationary visual target, but if there is dynamic imbalance, the eye will be drawn off fixation and the observer will then see a small saccadic eye movement as the patient refixates. Paroxysmal positional vertigo is tested by hanging the head with position shifts. The patient is seated on an examination surface, so that when brought to supine position, the head hangs over the end of the surface. While in a sitting position, the head is turned to the right or left or is positioned straight ahead for each of a series of repetitions. The patient is then brought rapidly into a supine position with the head down 45 degrees from vertical and in one of the three turned positions. Transient nystagmus induced by these maneuvers is usually a sign of benign positional vertigo (see [Chapter 12](#)).

True *assessment of VOR gain* requires electronic eye movement testing, in which slow-phase velocity can be measured and compared with stimulus rotation velocity. A bedside test can be used in which the abnormal feature is reduced visual acuity during head motion. To perform this test, the patient is asked to read a near acuity card with the head stationary and during horizontal and then vertical sinusoidal head oscillations at a velocity of around 2 cycles per second. If the VOR gain is normal, the eye remains fixed on the optotypes and acuity does not change with head motion. With decreased gain, however, the eyes slip off fixation during head movement and acuity is worse, sometimes by several lines. Observing refixational saccades during head rotation is another sign of abnormal gain. When VOR gain is reduced, the movement of the saccades will be the opposite direction from the head movement,

and if the gain is increased, the saccades occur in the same direction as the head movement.

Rotating the patient at a constant velocity in a swivel chair induces normal *vestibular nystagmus*. This maneuver is not practical for patient observation because the patient is moving relative to the examiner. After 45 seconds of constant rotation at a rate of about one turn every 3 seconds, the chair should be stopped and the patient's eyes observed for postrotational nystagmus. This is optimally performed through Frenzel's goggles, so the patient cannot suppress the nystagmus with visual fixation. Horizontal nystagmus can be induced by rotating the patient with the head upright, and vertical nystagmus is elicited by rotating with head tilted to one shoulder or the other. Rotation with the neck extended and head back normally induces torsional nystagmus.

Cold water caloric stimulation is another way to stimulate the various semicircular canals (see [Chapter 1](#)). In this setting also, the test is best performed with Frenzel's goggles.

APPROACH TO DIPLOPIA ([Table 9-3](#))

The primary function of the extraocular muscle, and the oculomotor system in general is to position the globes so that the object of regard is seen as a single image in the visual space regardless of the fact that it is viewed simultaneously by two eyes. Every point in the visual space has a corresponding retinal location in either eye. The two points in the eyes that serve a single locus in visual space are called homologous retinal locations. Normally, the eyes are positioned such that all images fall on homologous retinal locations, and the subject sees a single fused image. Binocular diplopia results when the visual axes of the two eyes are divergent. In this state, the image of the object of regard is formed at nonhomologous points on the retinas of the two eyes. As a result, the object appears to be in two places simultaneously. The resulting diplopia can be analyzed by measuring the direction of separation and the distance between the two images, which is a direct measure of the angle at which the two visual axes diverge.

The apparent location of an object in visual space depends on where the image of that object is formed on the retina. The retinal fovea serves the center of the visual field or the perceptual sense of being straight ahead. Under normal conditions, the visual axes of the eyes are slightly convergent, and the image of the object of regard is formed on both foveas (F_1 , F_2) ([Fig. 9-8](#)). Using a red Maddox rod, the image of a point light source is turned into a red line that can be oriented either vertically or horizontally ([Fig. 9-8 B-D insets](#)). The Maddox rod is an optical device that consists of a series of cylinders lying parallel to one another. A point of light viewed through a Maddox rod appears as a line perpendicular to the orientation of the cylinders ([Fig. 9-9](#)). The image line can be made to appear horizontal or vertical by reorienting the Maddox rod in front of the subject's eye. Retinal images formed on the nasal side of the fovea appear to be off center in the temporal visual field, whereas retinal images temporal to the fovea appear in the nasal field. Images formed on retinal sites above the fovea appear to be below the center, whereas images formed on the lower retina appear to be above the center.

Although each muscle has several vectors of force, a specific extraocular muscle turns the eye most efficiently in a single direction. Deviation of the eyes relative to one another is greatest when the patient attempts to look in the direction in which the weak muscle exerts its primary or maximal action. Using these basic principles, subjective and objective methods have been developed to analyze extraocular muscle imbalance. Subjective methods use the patient's own reported observations on the relative positions of images to measure image separation. Analysis of diplopia is aided if it can be established which image is being seen by which eye. The simplest method to perform this analysis is to place a colored glass over one eye and ask the patient where the colored image is relative to the white one as he or she

views a point light source.

The Maddox rod has two advantages in diplopia testing as compared with the simple colored-glass test. First, mixed horizontal and vertical diplopia can be examined more accurately, because the patient can easily judge the vertical deviation by viewing a horizontal line and the horizontal deviation by viewing a vertical line. Second, because two dissimilar images (point of light and colored line) are viewed with the two eyes, the images are more completely dissociated and deviation is maximized. In contrast, when the patient views two differently colored but otherwise

TABLE 9-3 -- EXTRAOCULAR MUSCLES: ORBIT AND GAZE POSITIONS RESULTING IN MAXIMAL DEVIATION AND IMAGE SEPARATION ON DIPLOPIA TESTING

Muscle	Deviation	Orbit Position with Maximum Deviation	Gaze Position with Maximum Deviation
Right medial rectus	Exotropia	Adduction	Left
Right lateral rectus	Esotropia	Abduction	Right
Right superior rectus	Left hypertropia	Elevation in abduction	Right, up
Right inferior rectus	Right hypertropia	Depression in abduction	Right, down
Right superior oblique	Right hypertropia	Depression in adduction	Left, down
Right inferior oblique	Left hypertropia	Elevation in adduction	Left, up
Left medial rectus	Exotropia	Adduction	Right
Left lateral rectus	Esotropia	Abduction	Left
Left superior rectus	Right hypertropia	Elevation in abduction	Left, up
Left inferior rectus	Left hypertropia	Depression in abduction	Left, down
Left superior oblique	Left hypertropia	Depression in adduction	Right, down
Left inferior rectus	Right hypertropia	Elevation in adduction	Right, up

Figure 9-8 The two eyes in various deviated positions under conditions of Maddox rod testing. The inset at the right of each figure illustrates the relative positions of images of the object of regard (OR) seen with the left eye and of the line created by viewing through the Maddox rod (MR) with the right eye. In all cases, the Maddox rod is placed over the right eye (by convention) and that makes the right eye always the deviating eye because the patient is instructed to "look at the light" and he or she can see the light only with the left eye. A. Orthophoria--both eyes are foveating the images and the line (right eye image) runs through the light (left eye image). Esophoria--the eyes are converged, and the right eye image falls on nasal retina so the image in that eye (line) appears to be on the temporal (right) side of the light (left eye image). This is called homonymous diplopia because both the Maddox rod and the image from viewing through the rod are on the right (sarC, Exophoria--the eyes are divergent, and the image of the deviating right eye falls on temporal retina so the line (right eye image) appears displaced nasal to the light (left eye). This is called crossed diplopia because the image formed by the Maddox rod is on the left, with the rod over the eye. Right e. hyperphoria--the right eye image falls on upper retina (above the fovea), and the right eye image (line) appears displaced below the light (left eye image).

similar images, as with the colored-glass test, the fusion mechanism may not be entirely suspended and a deviation smaller than maximum might result.

Because some patients are unable or unwilling to give accurate subjective descriptions of their diplopia during the red glass or Maddox rod testing, the alternate cover and cover-uncover tests were devised as more objective tests for eye deviation ([Table 9-4](#)). Moving a cover (occluder) quickly back and forth from one eye to the other constitutes the *alternate cover* test. Because one eye remains covered at all times, there is no opportunity for the fusion reflex to operate. With this test, *latent* deviation (heterophoria) and *manifest* deviation (heterotropia, or strabismus) can be detected, but these conditions cannot be distinguished. In the cover tests, the examiner observes the resulting eye movements while moving the cover back and forth between eyes. The patient is instructed to maintain fixation on the object of regard. When the cover is shifted from one eye to the other, if the newly uncovered eye was deviated under cover, it will make a saccadic

Figure 9-9 Diagram of a point light source viewed through a Maddox rod. The cylinders of the Maddox rod are oriented horizontally, and the image formed by the rod on the retina is a vertically oriented line or stripe.

movement to attain fixation on the object of regard. The direction of these refixation movements indicates the direction in which the eye was deviated under cover. A movement toward the nose indicates that the eye was exodeviated (temporally), whereas an outward movement toward the temple indicates esodeviation (nasal deviation). If an eye moves upward when it is uncovered, it was deviated downward under cover and vice versa.

The *cover-uncover* test is useful in distinguishing heterotropia from heterophoria. [Table 9-4](#) lists the movement of the two eyes as one eye is first covered and then uncovered in the three main conditions--orthophoria (no tendency to deviate, straight eyes with and without fusion), heterophoria (latent deviation, present only when fusion is suspended by cover), and heterotropia (manifest deviation, still present when fusion reflex is operational with both eyes uncovered). In using this table, one column (condition) should be considered at a time. Note that both the heterophorias and heterotropias are eye deviations relative to one another. In the heterophorias, the eye under the cover drifts into the deviated position relative to the other eye. When it is uncovered, the deviated eye makes a monocular movement to refixate. Patients with heterotropias commonly have a tendency for one eye to always be deviated when neither eye is covered. As an example, if a patient has exotropia with the right eye deviated, this occurs because the patient has chosen, usually unconsciously, to fixate with the left eye. This does not necessarily mean that the right eye has the weak muscle or muscles. If the left eye is covered, the patient can move the deviated right eye back to take up fixation, but because the refixation was a conjugate binocular movement, the patient's left eye is then deviated under the cover. On uncovering the left eye, the patient could subsequently maintain fixation with the right eye or make a conjugate binocular saccade to refixate with the left eye. A patient who is strongly left eye dominant or has better acuity with the left eye is likely to resume fixation with the left eye. A person who has no major visual dominance pattern or equal visual acuity with either eye may maintain fixation with the right eye. The cover tests are useful in patients with enough range of eye movement to make the various refixational movements. Even with nearly complete palsy of one or more muscles, it is still useful to measure angles of phoria in primary gaze as a measure of deviation tendency. This measurement can be followed over time for recovery or worsening.

Associated Neurological Findings

Cerebral. Cranial nerve III, IV, or VI neuropathies may be caused by meningeal infectious, inflammatory, and infiltrative lesions that may also affect cerebral function

TABLE 9-4 -- MOVEMENTS OF THE EYES DURING THE COVER-UNCOVER TEST

Test Condition	Phoria	RE Tropia	LE Tropia
Cover RE	RE deviates under cover, LE maintains fixation	None: LE keeps fixation	LE takes up fixation: conjugate binocular shift but only RE observed
Uncover RE	RE monocular refixation movement; fusion re-established	None: LE keeps fixation	RE resumes fixation: conjugate binocular shift observed
Cover LE	LE deviates under cover; RE maintains fixation	RE takes up fixation: conjugate binocular shift but only RE observed	None: RE keeps fixation
Uncover LE	LE monocular refixation movement fusion reestablished	LE resumes fixation: conjugate binocular shift observed	None: RE keeps fixation

with impairment of consciousness or altered cognitive and language function. Because of its long intracranial course and its proximity to bony structures of the calvarium, isolated sixth nerve paresis can occur with large intracranial masses (false localizing signs of elevated intracranial pressure), especially involving the middle cranial fossa. Lesions in the pontine and midbrain reticular activating system can lead to impaired levels of consciousness, together with defective conjugate gaze and nystagmus. Disorders of saccadic or pursuit movements may also be the direct result of cerebral pathology. Patients with pursuit abnormalities from parietal lobe lesions may have hemineglect or apraxia (nondominant) and language dysfunction or higher sensory dysfunction (dominant hemisphere). Abnormalities of saccades related to frontal lobe dysfunction may be accompanied by abulia, disinhibition, memory abnormalities, or apraxia. Patients with Wernicke's disease (see [Chapter 40](#)) may have ocular signs in the setting of disturbances in consciousness or mentation, including hallucinations, confusion, agitation, and anterograde amnesia. Abnormalities of saccadic or pursuit movements may also be accompanied by a homonymous hemianopia or quadrantanopia.

Cranial Nerves. Lesions in the cavernous sinus often involve the first two divisions of the trigeminal nerve as well as the oculomotor cranial nerves. Cranial nerve VI palsy with ipsilateral facial pain from trigeminal nerve dysfunction constitutes Gradenigo's syndrome of the petrous tip. It was commonly caused by spread of inflammation from adjacent mastoid air cells but has become infrequent in the antibiotic era. Tumors and even aneurysms in the same site can cause a similar presentation, so complete neuroradiological workup is in order. Optic neuritis may also coincide with disorders of cranial nerve III, IV, or VI in the setting of multiple sclerosis.

Motor/Reflexes/Cerebellar/Gait. Midbrain lesions involving the intramedullary fascicular portion of cranial nerve III can be associated with involvement of the cerebral peduncle with contralateral hemiparesis (Weber's syndrome), the red nucleus with ipsilateral tremor and chorea (Claude's syndrome), or ipsilateral cerebellar ataxia (Nothnagel's syndrome) (see [Chapter 22](#)). Raymond's syndrome of the pons consists of an ipsilateral sixth nerve paresis and contralateral hemiparesis, and when the seventh cranial nerve is also affected, the condition is termed Millard-Gubler syndrome. Because the cerebellum contributes to conjugate gaze mechanisms, lesions of the cerebellar pathways often cause abnormal conjugate gaze associated with unilateral or bilateral ataxia and tremor.

Parkinsonism or involuntary movements (chorea) in the setting of Parkinson's disease, Parkinson's plus syndromes, or Huntington's disease may be associated with abnormalities of saccadic eye movements (hypometria) or pursuit movements (cogwheel pursuit). Pyramidal signs may accompany INO with multiple sclerosis, and ataxia may be observed in patients with Wernicke's disease who often have nystagmus or cranial nerve VI palsy in addition. Finally, absent reflexes may be appreciated in conjunction with pupillary abnormalities in Adie's syndrome.

Sensory. An evaluation of the sensory system outside of that related to other cranial nerves is rarely helpful in the diagnosis of disorders of cranial nerves III, IV, and VI and their supranuclear control. Lesions in the brain stem tegmentum may cause syndromes involving cranial nerves III or VI with contralateral hemihypesthesia, often in conjunction with lateralized cerebellar or pyramidal tract findings.

Autonomic Nervous System. Beyond testing the sympathetic and parasympathetic innervation related to the pupil, additional evaluation of the autonomic nervous system is rarely necessary.

Neurovascular. The neck and orbit should be auscultated for bruits. Carotid artery atheromas, particularly when complicated by hemorrhage or ulceration, as well as carotid artery dissection may be associated with ocular sympathetic dysfunction (Horner's syndrome).

Associated Medical Findings

Because one of the most common causes of orbital infiltration is thyroid disease, patients with orbital signs such as proptosis, chemosis and conjunctival injection together with abnormal ocular motility should be examined for goiter, pretibial myxedema, smooth moist skin, and loss of lateral eyebrows. ^[40] In thyroid disease, the extraocular muscles can develop edema, lymphocytic infiltration, and fibrosis, resulting in loss of elasticity more than loss of contractile strength. The diplopia that results from this restrictive feature is due to the tethering of the eye in an abnormal position by one or more shortened inelastic extraocular muscles.

EVALUATION GUIDELINES (Table 9-5)

Neuroimaging. Lesions of cranial nerves III, IV, and VI may occur anywhere along the course of the nerves, from the nuclei in the brain stem to the orbits. The possibility of focal neoplastic or inflammatory lesions requires evaluation with neuroimaging. Magnetic resonance imaging is more reliable than computed tomography for detecting brain stem, subarachnoid space, or cavernous sinus lesions. Magnetic resonance imaging is also the best procedure for imaging the orbits when fat suppression (saturation) pulse sequences and gadolinium enhancement are used. Fat suppression renders the orbital fat dark so that any gadolinium enhancement (white) within the fat, muscles, or optic nerve can be reliably observed. Thin-section computed tomography is still a potent imaging technique for supratentorial brain lesions and orbital study. It also is a cost-effective means to measure the extraocular muscle diameter and is a sensitive indicator of thyroid orbitopathy.

Saccular aneurysms remain a frequent and important cause of cranial nerve III palsy, and cerebral angiography should be used in evaluating third nerve dysfunction because it is the only reliable way of finding such lesions. Because false-negative and false-positive results continue to be problematic, magnetic resonance angiography (MRA) cannot yet be used in place of standard angiography. False-positive MRA studies can lead the physician to interpret vascular loops as aneurysms, resulting in unnecessary surgical intervention. In the future, with improvements in MRA imaging quality, this procedure may become a reliable

TABLE 9-5 -- USEFUL STUDIES IN THE EVALUATION OF SYNDROMES INVOLVING CRANIAL NERVES III, IV, AND VI

Syndrome	Neuroimaging	Electrophysiology	Fluid and Tissue Analysis	Neuropsychology Tests	Other Tests
Anisocoria	MRI/CT brain and cervical spine; MRI: orbits with fat suppression and gadolinium	N/A	CSF analysis	N/A	Testing with pilocarpine, cocaine, hydroxyamphetamine; chest x-ray study
Adie's pupil	MRI: brain; orbits with fat suppression and gadolinium; CT: orbits	N/A	N/A	N/A	Testing with pilocarpine, cocaine, hydroxyamphetamine; chest x-ray study
Light-near dissociation	MRI brain: midbrain	EMG/NCV: peripheral neuropathy, Miller-Fisher variant of Guillain-Barre syndrome	CSF analysis, RPR, VDRL, fasting glucose	N/A	Testing with pilocarpine, cocaine, hydroxyamphetamine; chest x-ray study

technique for excluding an aneurysm in the setting of third nerve dysfunction.

Electrophysiology. Brain stem auditory evoked responses, somatosensory evoked responses, and pattern-reversal visually evoked responses are commonly used as indicators of demyelinating lesions, which can affect the conjugate gaze mechanisms and the individual cranial nerves as they course through the brain stem. There is no widely available electrophysiological method to examine the peripheral portions of the cranial nerves III, IV, and VI.

Fluid and Tissue Analysis. Thyroid function testing is important to identify patients with thyroid orbitopathy, but it must be remembered that nearly a half of patients have normal thyroid function at the time they present with orbital manifestations. Patients with lead and other heavy metal poisoning can present with elevated intracranial pressure and false-localizing cranial nerve VI palsy. Urine screen for heavy metals is an important adjunct to the workup of these patients.

Cerebrospinal Fluid. Cerebrospinal fluid (CSF) examination is often a critical part of investigation for dysfunction of cranial nerves III, IV, and VI because these nerves are often affected selectively in meningeal infections, as well as in inflammatory and neoplastic infiltrating disorders. In addition, patients with multiple sclerosis (see [Chapter 48](#)) may present a typical profile of CSF abnormalities, and patients with this disease often present with ocular motility disturbance from central lesions (gaze palsy, INO) and less frequently with ophthalmoplegia from plaques affecting the intramedullary portion of cranial nerves III, IV, or VI.

Neuropsychological Testing. There are no common specific indications for neuropsychological testing in patients with ocular motility disturbances, although altered pursuit or saccade dynamics may result from cerebral pathology that also affects higher cortical mental functions.

CLINICAL SYNDROMES (Table 9-6)

Pupillary Syndromes

ANISOCORIA

It is commonly written that 20 percent of the population has anisocoria of at least 0.4 mm in dim light, although published series cite highly variable percentages from 2 to 60 percent. The most common sort of variable anisocoria among healthy people has been called see-saw anisocoria or simple central anisocoria whereas the mechanism is indeterminate, this benign condition may vary from one examination to the next or even reverse sides. Light stimulation of one or both eyes decreases the anisocoria, and the pupillary reactions to light, near, and psychosensory stimulation are all normal. A different sort of anisocoria among seemingly healthy normal people results when the consensual response is weaker than the direct response. This type of anisocoria is present only when either eye is stimulated individually with light and alternates sides because the illuminated pupil is always the smaller one. This characteristic may result from the selective dysfunction of the intercalated neuron that connects the midbrain pretectal nuclei and the Edinger-Westphal subnucleus of cranial nerve III. These and other normal pupillary phenomena, such as hippus (pupillary unrest) and early release after maximum light response, may confound detection of a relative afferent pupillary defect. Finally, it is important to note that with age, the pupils normally become smaller, and the average diameter of the pupils in darkness decreases at approximately 0.5 mm per decade after the second decade of life. Neurologically significant anisocoria occurs with lesions affecting parasympathetic components in cranial nerve III and with disorders of the ocular sympathetic system.

Ocular Parasympathetic Syndrome, Preganglionic. Lesions affecting cranial nerve III often cause anisocoria in which the pupil is larger in the affected eye and the degree of anisocoria (difference in size) is greater in bright than in dim light. The important causes of cranial nerve III lesions in this setting include intracranial aneurysms (typically those of the posterior communicating artery at its junction with the internal carotid artery) ^[41] and small vessel disease with resulting ischemic nerve lesions, such as that associated with diabetes. The pupillary sphincter is usually involved in the setting of an aneurysm or other extra-axial compression like temporal lobe herniation, because the pupillomotor fibers are arranged on the outside of the nerve. In contrast, pupillary function is most often spared when ischemic lesions of the third nerve are present. ^[42], ^[43] As a rule, the pupil is not solely affected in cranial nerve III lesions, because the autonomic component fibers are intimately associated with axons carrying motor innervation to the other muscles innervated by that nerve.

Ocular Parasympathetic Syndrome, Postganglionic (Adie's Pupil). Damage to the postganglionic parasympathetic pathways in the long posterior ciliary nerves produces the condition known as *tonic pupil*. ^[44], ^[45] This type of pupil is large and reacts very little to light when the stimulus is presented briefly but may contract slowly if the light stimulus is maintained for up to 30 to 40 seconds. Redilatation after the light is turned off is also very slow on the involved side. There is a greater pupillary constriction when the patient looks at a near object, and this difference is referred to as light-near dissociation. Tonic pupils are associated with patchy or generalized loss of deep tendon reflexes in Adie's syndrome. ^[46] This disorder is more common in women and is pathologically characterized by an idiopathic degeneration of spinal root and ciliary ganglia. It does not result in any clinically important sensory or motor defect apart from the areflexia. In Adie's tonic pupil, the axons of the postganglionic nerve degenerate one by one, producing paralysis of progressively more segments of the iris sphincter muscle. ^[47] Examination of the iris under magnification allows the examiner to perceive the segmental loss of constriction around the margin of the pupil in the early and intermediate stages of the disease. When a tonic pupil has been present for a period of time, all sectors become involved and, in general, the pupil becomes fixed at a small diameter.

Ocular Sympathetic Syndromes. With ocular sympathetic lesions (Horner's or Claude Bernard's syndrome), the pathological pupil is the smaller one, and the anisocoria is greater in dim than in bright light. The light reflex is

TABLE 9-5 -- SELECTED ETIOLOGIES ASSOCIATED WITH DISORDERS OF CRANIAL NERVES III, IV, AND VI

Etiological Category	Specific Etiologies	Chapter
STRUCTURAL DISORDERS		
Developmental structural disorders	Arnold-Chiari malformation, cerebellar ectopias, basilar invagination	28
HEREDITODEGENERATIVE DISORDERS		
Storage diseases: lipidoses, glycogen disorders, and leukoencephalopathies	Tay-Sachs', Gaucher's, Nieman-Pick C, and Pelizaeus-Merzbacher diseases	30
Aminoacidopathies/organic acidopathies, mitochondrial enzyme defects, and other metabolic errors	Maple syrup urine disease, nonketotic hyperglycinemia; Leigh's disease mitochondrial myopathies	31
Chromosomal abnormalities and neurocutaneous disorders	Ataxia-telangiectasia	32
The degenerative dementias	Alzheimer's disease	33
Movement disorders	Parkinson's disease, progressive supranuclear palsy, Wilson's disease, Shy-Drager syndrome	34
Ataxias	Friedreich's ataxia, autosomal dominant cerebellar degeneration	35
Degenerative motor, sensory, and autonomic disorders	Parasympathetic dysautonomia, Shy-Drager-syndrome, acute pandysautonomia	36
ACQUIRED METABOLIC AND NUTRITIONAL DISORDERS		
Endogenous metabolic disorders	Diabetes, hypomagnesemia	38
Exogenous acquired metabolic disorders of the nervous system: toxins and illicit drugs	Botulism	39
Nutritional deficiencies and syndromes associated with alcoholism	Wernicke-Korsakoff syndrome, vitamin E deficiency	40
INFECTIOUS DISORDERS		
Viral infections	Brain stem encephalitis	41
Nonviral infections	Mucormycosis (diabetics), fungal meningitis	42
NEUROVASCULAR DISORDERS	Small vessel arteriosclerosis, berry aneurysm, artery dissection	45
NEOPLASTIC DISORDERS		
Primary neurological tumors	Brain stem glioma, medial sphenoid ridge and parasellar meningioma; Pancoast's carcinoma (lung), lymph node metastases (cervical)	46
Metastatic neoplasms and paraneoplastic syndromes	Paraneoplastic brain stem encephalitis; meningeal carcinomatosis, neuroblastoma, ovarian carcinoma	47
DEMYELINATING DISORDERS		
Demyelinating disorders of the central nervous system	Multiple sclerosis	48
AUTOIMMUNE AND INFLAMMATORY DISORDERS	Systemic lupus erythematosus, periarthritis nodosa, vasculitis, myasthenia gravis	50
TRAUMATIC DISORDERS	Blunt, penetrating head trauma	51
EPILEPSY	Seizures (nystagmoid movements)	52
HEADACHE AND FACIAL PAIN	Migraine, cluster headaches	53
DRUG-INDUCED AND IATROGENIC NEUROLOGICAL DISORDERS	Anticholinergics, phenytoin, carbamazepine, aminoglycosides	55

usually not perceptibly altered. This anisocoria is usually asymptomatic. Another finding in Horner's syndrome is mild ptosis of the upper eyelid from weakness of Muller's smooth muscle in the lids. Less well recognized, however, is that weakness of Muller's muscle in the lower lid also causes the lower lid to elevate. Upper lid ptosis and elevation of the lower lid together cause narrowing of the palpebral fissure. This contributes to an illusion that the involved eye is displaced backward in the orbit, which is the so-called apparent enophthalmos described with Horner's syndrome. A third component of Horner's syndrome involves sympathetic fibers serving the skin of the forehead just above the brow that travel with the nasociliary branch of the first (ophthalmic) division of the trigeminal nerve. With intracranial postganglionic sympathetic lesions, altered vasomotor tone and decreased sweating may be limited to a triangular patch of skin just above the brow extending to the midline. The sudomotor and vasomotor fibers to the skin of the lower face travel with branches of the external carotid artery after leaving the sympathetic paravertebral chain near the skull base and are spared with lesions rostral to this point of divergence.

The most important disorder that produces Horner's syndrome is malignancy involving the preganglionic sympathetic pathways in the neck or next to the apex of the lung. A minority of these preganglionic Horner's syndrome cases are secondary to trauma, usually resulting from penetrating neck wounds and root involvement in spinal injuries, and they should be obvious from the history and physical findings. In stellate ganglia anesthetic blocks, a transient Horner's syndrome predictably occurs because the preganglionic ocular sympathetic fibers go through this area. Inflammation, caused by suppurative infections and granulomatous diseases such as sarcoidosis or tuberculosis in cervical lymph nodes, is an occasional nonmalignant cause for preganglionic ocular sympathetic palsy. This etiology

has become more prevalent in the AIDS era. Another important cause is carotid artery dissection, which presents with pain in the neck along with signs of ipsilateral cerebral hemisphere ischemia.

Postganglionic ocular sympathetic palsy is commonly associated with pain in the ipsilateral orbit and eye. In the early part of this century, a Norwegian ophthalmologist named Raeder reported this combination of pain, meiosis, and ptosis as a *paratrigeminal syndrome* with localizing value for mass lesions in the middle cranial fossa.^[48] It is important to note that all four of his patients had, in addition to ocular sympathetic palsy, findings referable to the ipsilateral cranial nerves III through VI, either singly or in combination. During the past 2 decades, there has been growing awareness of patients with painful ocular sympathetic palsy without demonstrable middle fossa mass lesions. These patients often have histories of episodic retrobulbar and orbital pain that, in many cases, is typical of *cluster* or *histamine headache* (see [Chapter 53](#)).^[49] The ocular sympathetic lesion occurs during a cluster of headaches and sometimes resolves spontaneously after the cluster has ended, although at times, it remains as a permanent sequel. This benign condition, considered a migraine variant, has been referred to as *Raeder's paratrigeminal syndrome, type II*, and to qualify for this diagnosis, patients must have no objective neurological deficits of cranial nerves III through VI. It has been speculated that in type II Raeder's syndrome, the postganglionic ocular sympathetic fibers are affected by edema in the wall of the carotid artery.

CNS (hypothalamus, brain, or spinal cord) lesions are an uncommon cause of Horner's syndrome and are almost always recognizable by the associated cranial nerve, cerebellar, motor, or sensory findings. A classic example is *Wallenberg's lateral medullary syndrome*, which is usually caused by occlusion of one vertebral artery with infarction in the distribution of the *posterior inferior cerebellar artery* (see [Chapter 22](#) and [Chapter 45](#)). The attendant dorsolateral medullary lesion produces a syndrome that includes ocular sympathetic palsy along with facial numbness ipsilateral to the lesion, pain and temperature loss in the contralateral extremities, vertigo, dysphagia, and dysarthria.

LIGHT-NEAR DISSOCIATION

Light-near dissociation became a clinical sign relevant to etiological diagnosis when Argyll Robertson described it as a sign of neurosyphilis.^{[50], [51]} The features of the Argyll Robertson pupil include (1) meiosis, (2) a normal afferent visual system (retina, optic nerve, chiasm, optic tract), and (3) failure of pupillary meiosis to light stimulation but normal pupillary constriction in response to accommodation and convergence with near viewing. In the original description, patients with this phenomenon had *tabes dorsalis* as well, and the pupil became an invaluable aid to the diagnosis of neurosyphilis. Light-near dissociation is not specific for neurosyphilis, however, and merely refers to the phenomenon in which the pupillary constriction in response to looking at near objects is greater than that in response to a bright light stimulus. The definition is imprecise because there is no way to quantify the degree of near effort that determines the amount of pupillary constrictor tone that is produced by the near stimulus. Many individuals make a poor effort when looking close up, and this may mask the presence of light-near dissociation.

Light-near dissociation may be due to input or output failure. Input failure occurs in bilateral prechiasmal lesions of the optic nerve or retina, chiasmal lesions, and bilateral optic tract lesions. As such, the examiner should establish whether the afferent visual system is functioning normally. If these conditions are present, the light reaction may be reduced and the near reaction left unaffected, creating a false light-near dissociation. Output failure can be the cause of Argyll Robertson pupil and occurs in the setting of diabetes mellitus, peripheral neuropathies, Adie's pupil (see earlier), and the Miller-Fisher variant of acute idiopathic demyelinating polyradiculopathy (see [Chapter 49](#)). Patients with midbrain compressive and ischemic lesions generally demonstrate large, light-near dissociated pupils, in contrast to the classic description of Argyll Robertson, in which the pupils are small.^[52] The mechanism of neurosyphilis-related Argyll Robertson pupil remains unknown.

BILATERAL UNREACTIVE PUPILS

Failure of both pupils to react to both light and near stimuli has been described in cases of dorsal or rostral midbrain lesions, sometimes before the development of vertical gaze palsy or other ocular motility impairment.^{[52], [56]} An isolated unilateral (or bilateral) dilated, fixed pupil should also raise suspicion of pharmacological mydriasis. Patients or medical personnel may deliberately or inadvertently instill medications with parasympatholytic or anticholinergic activity into the eye. Pupils in this state will fail to constrict in the presence of pilocarpine (1 to 4 percent), whereas all fixed pupils from CNS or peripheral nervous system lesions become extremely meiotic in response to these concentrations of the drug.

Ocular Misalignment Syndromes

CRANIAL NERVE III PALSY

Lesions of the oculomotor nerve can involve the nucleus in the midbrain, or nerve fascicles within the ventral midbrain, subarachnoid space, cavernous sinus, superior orbital fissure, or orbit. As an example, in the setting of an isolated right nuclear third nerve lesion (see Fig. 9-7 (Figure Not Available)), there is complete disruption of the outflow of that nerve. Additionally, fibers from the *left* subnuclei for the superior rectus (contralateral outflow) and levator palpebrae (bilateral outflow) also are affected as they pass through the right-sided lesion. The combination of nuclear and fascicular damage results in partial bilateral ptosis and failure of elevation of both eyes. The ptosis contralateral to the lesion is usually incomplete because the levator receives some nondecussating neuronal fibers from the normal side of the caudal central nucleus. More ventral lesions in the brain stem only cause disruption of the fibers emerging from the ipsilateral third cranial nerve nucleus. The clinical characteristics of these *fascicular* third nerve lesions are the same as those of any lesion distal to the nucleus, and only the

functions of that ipsilateral nerve are affected. Localizing the lesion along the fascicular portion of the nerve depends on the presence of associated neurological features. Nuclear lesions are caused primarily by small infarcts secondary to occlusion of the medial penetrating vessels from the basilar artery (see [Chapter 22](#)),^[57] or rarely by small hemorrhages. Other intramedullary lesions associated with cranial nerve III dysfunction include masses, including neoplastic (lymphoma, metastatic), inflammatory (sarcoidosis), and infectious (tuberculosis, fungal) etiologies.

Cranial nerve III palsy with concomitant involvement of other CNS structures leads to a constellation of findings that have been given various eponyms and usually are seen as stroke syndromes (see [Chapter 22](#)). Aneurysms of the posterior communicating artery are an important cause of third cranial nerve lesions from compression of the nerve outside the CNS. Compression can occur as the nerve passes near the vessel, at its junction with the supraclinoid portion of the internal carotid artery near the cavernous sinus.^[41] Cranial nerve III palsy from an enlarging or bleeding saccular aneurysm of the posterior communicating artery is a neurological emergency, because the aneurysm is unstable and a fatal subarachnoid hemorrhage may occur. Clinical findings generally include third nerve innervated extraocular muscle dysfunction with pupillary sphincter paralysis. The latter dysfunction results from the compression of superficial parts of the nerve where the parasympathetic fibers are located.

In contrast, third nerve lesions from diabetes or hypertension^{[42], [43]} typically spare pupillary function. These disorders are associated with small vessel arteriosclerosis and affect deeper parts of the third nerve. Involvement of the pupillary sphincter is more variable in inflammatory and neoplastic compressive disorders, but typically

there is some degree of dysfunction. When attempting to determine whether a pupil-sparing cranial nerve III palsy is due to a medical or nonaneurysmal cause, knowledge of the degree of extraocular muscle dysfunction relative to the degree of internal ophthalmoplegia can be helpful. ^[41] A medical or ischemic cranial nerve III palsy is most likely when there is a total or near-total external ophthalmoplegia and complete or near-complete sparing of the pupillary sphincter. With incomplete external involvement, pupillary function is much less reliable as an indicator of whether the problem is caused by aneurysm or intrinsic ischemia.

CRANIAL NERVE IV PALSY

In the setting of major head trauma, the dorsal midbrain and both fourth nerves are impacted in the niche of the tentorium cerebelli, and both nerves tend to be contused together. Because of bilateral injury to the ascending reticular formation, the patient is usually unconscious for a protracted period of time after the injury, following which there are complaints of vertical double vision. On examination, a relative elevation of the right eye (right hypertropia) in left gaze and relative elevation of the left eye (left hypertropia) in right gaze can be found. This reversal of vertical deviation indicates bilateral fourth cranial nerve palsies. Unilateral fourth nerve palsy sometimes follows minor head trauma, and there is reason to believe that many of these cases represent decompensation of longstanding or congenital fourth nerve palsy that was not symptomatic. The mechanism of this occurrence is unclear, but it is important to ask patients with this disorder to bring in childhood photographs to search for head tilt that would indicate a congenital condition.

Fourth cranial nerve palsies can also occur secondary to intraneuronal microvascular disease in elderly patients and are often associated with diabetes or longstanding hypertension, just as with ischemic third or sixth cranial nerve palsies. The diplopia with ischemic fourth nerve involvement tends to improve over a period of several weeks or months following onset. Other causes of fourth nerve dysfunction include tumors in the region of the midbrain tectum and cavernous sinus, superior orbital fissure, and orbital disorders (see the section entitled Cavernous Sinus Syndrome).

CRANIAL NERVE VI PALSY

The abducens nucleus can be the site of a destructive lesion, particularly small vessel infarction or small focal hemorrhages. In these settings, ipsilateral paralysis of conjugate horizontal gaze results. In addition, peripheral cranial nerve VII palsy also occurs because the fascicles of nerve VII wrap over the superior aspect of the cranial nerve VI nucleus, forming a small bulge in the adjacent floor of the fourth ventricle (see [Chapter 11](#)). Nuclear cranial nerve VI lesions are also associated with more severely affected abduction of the ipsilateral eye than adduction of the contralateral eye, resulting in an esotropia and asymmetrical duction deficits. This phenomenon may be difficult to distinguish from a combined nuclear and fascicular lesion or separate lesions at the different sites. As with the third and fourth cranial nerves, fascicular abducens nerve palsies can occur secondary to microvascular lesions in hypertensive and diabetic patients, in which case the abduction deficit tends to improve over a 3- to 6-month period. Conditions that can cause sixth cranial nerve dysfunction include demyelination, neoplasia, inflammatory and infiltrating lesions of the cavernous sinuses, and leptomeninges (carcinomatous meningitis, chronic or acute infectious meningitis). Because of its long intercranial course along the bony ridges of the calvarium, the sixth cranial nerve is also susceptible to stretching and distortion more than other cranial nerves are. This phenomenon is characterized by failure of abduction in one or both eyes accompanying lesions remote from the sixth cranial nerve or the lateral rectus. This falsely localizing sixth nerve paresis occurs most commonly in the setting of raised intracranial pressure and as a transient phenomenon following lumbar puncture. This has been postulated to occur as a result of a transient shift of the brain stem secondary to changes in CSF pressure gradients. This unique susceptibility to small brain stem displacement is thought to result from the nerve's being fixed on one end at its emergence from the pons and at the other end, at Dorello's canal in the petrous tip.

INTERNUCLEAR OPHTHALMOPLÉGIA AND THE MEDIAL LONGITUDINAL FASCICULUS SYNDROMES

Lesions affecting the MLF cause failure of the adducting eye to move, whereas the abducting eye deviates laterally

to its full extent but has accompanying nystagmus during conjugate deviation. The medial rectus adducts without difficulty during convergence, distinguishing the paresis from a third nerve or muscle lesion.

This striking pattern of disconjugate eye movements is referred to as *INO* because the lesion disconnects the sixth and the third cranial nerve nuclei by causing failure of neural conduction in the internuclear pathway, the MLF. The peculiar monocular nystagmus can be either transitory (1 or 2 beats) or sustained. When the degree of dysfunction in the MLF is mild, the adducting eye may deviate fully but cannot attain the proper velocity during a saccadic refixation. In this case, there is a noticeable dissociation between the two eyes during the saccade, because the abducting eye completes the movement earlier than the adducting eye. To observe this phenomenon, it is necessary for the examiner to watch both of the patient's eyes simultaneously. This is best accomplished by looking at the bridge of the patient's nose from a distance of about 2 meters, so both of the patient's eyes can be clearly seen and differences can be appreciated in trajectory as the patient makes saccades to the right and left.

The clinical importance of diagnosing the MLF syndrome is its exquisite localizing value for lesions deep in the substance of the brain stem tegmentum. This general area in the brain stem contains the ascending reticular activating system, which is necessary for consciousness, along with several adjacent cranial nerve nuclei, and various ascending and descending sensory and cerebellar pathways. Therefore, the isolated occurrence of an MLF syndrome in an alert individual without other brain stem signs or symptoms suggests the presence of a highly discrete lesion. In the adult, this is caused by either small demyelinating plaques of multiple sclerosis, by small infarctions due to small vessel disease, and very occasionally can be encountered in the setting of head trauma. In children, the MLF syndrome can be the first sign of a brain stem glioma.

Differentiating between multiple sclerosis (see [Chapter 48](#)) and small vessel infarctions (see [Chapter 22](#) and [Chapter 45](#)) can be problematic, because both tend to evolve acutely or subacutely and resolve over a period of days or weeks. Patients with multiple sclerosis are typically younger than 40 years old, whereas most individuals with infarctions are older than 60 years. Bilateral MLF lesions indicate multiple sclerosis, because a plaque may occur in the midline, whereas vascular lesions are often limited to one side by the margins of the vascular territory.

Patients with myasthenia gravis (see [Chapter 50](#)) can present with failure of adduction in one eye with dissociated nystagmus of the other eye. The dissociation between medial rectus function on lateral gaze compared with near convergence is, however, not typical of myasthenia gravis. Nonetheless, any patient presenting with the motility pattern that characterizes a pure MLF lesion, either unilateral or bilateral, without other signs suggestive of demyelinating or ischemic brain stem diseases, should have an edrophonium chloride (Tensilon) test as part of the workup (see [Chapter 15](#)).

Monocular Diplopia

Monocular diplopia is generally a non-neurological condition in which images are split within the eye and fall on two places on the retina of that eye. This is commonly caused by irregularities in the refractive media of the eye, mostly in the crystalline lens (early cataract) or cornea. Deformity of the retina in or near the macula and fovea may also result in monocular diplopia. In these cases, two or more sets of photoreceptors are activated simultaneously when the image should stimulate only one set. This type of diplopia persists when the opposite eye is covered. There is a cerebral form of monocular diplopia, usually resulting from lesions in the occipital-parietal lobes. It usually is present in both eyes together and singly (binocular monocular diplopia).

Cavernous Sinus Syndrome

Cranial nerves are often involved in lesions of the cavernous sinuses, including the third, the fourth, the sixth, and the first two divisions of the fifth. The most commonly encountered lesions in this area are inflammatory diseases of unknown etiology, aneurysms of the subclinoid internal carotid artery (siphon), ^[50] carotid artery and dural branch-cavernous sinus fistula, ^[51] and tumors. Meningiomas of the medial sphenoid ridge and pituitary tumors expanding laterally from the sella can also involve the cranial nerves within the cavernous sinuses. ^[50] A mucocele of the sphenoid and ethmoid sinuses can, on rare occasions, present this way as well. ^[51]

Granulomatous or primarily lymphocytic inflammation in the cavernous sinus and superior orbital fissure is known as the *Tolosa-Hunt syndrome*.^[52], ^[53] It is manifest primarily by painful ophthalmoplegia and nearly always improves with steroid treatment. This relatively benign inflammatory disease must be distinguished, however, from other infiltrating lesions such as lymphomas, which may also respond transiently to steroid administration. An analysis of 108 patients with either benign lymphoid hyperplasia or malignant lymphoma revealed that there were no presenting or early clinical, laboratory, or tissue morphological features that reliably predicted the benign or malignant behavior of the lesion over the entire course of the illness. ^[54]

Conjugate Gaze Palsy Syndromes

Gaze palsies can be divided into disorders of vertical or horizontal gaze and further into nuclear or supranuclear lesions. Horizontal gaze palsies can be divided into impaired saccadic and pursuit eye movements.

IMPAIRED CONJUGATE SACCADIC EYE MOVEMENTS

The saccade system generates very high velocity ballistic movements called saccades used primarily to examine the elements of a stationary but large or extended visual scene. An adult scans a scene in a highly organized way, extracting data from the highest informational areas but directing relatively few saccades to nonspecific or uninformative areas in the display. This efficient ocular scanning behavior

develops progressively during infancy and can often be degraded in the presence of cerebral lesions, particularly those associated with dementia. This type of saccadic eye movement abnormality can be observed at the bedside examination, although quantitative characterization of saccadic behavior requires elaborate laboratory equipment. Where such facilities are available, saccadic eye movement *latency, velocity, metrics, and accuracy* can be measured. The average normal human takes about 200 milliseconds to generate a refixation eye movement or saccade to a new target presented in the visual periphery. A wide variation in the time required for each saccade exists, but the majority occur between 180 and 250 milliseconds.

Saccades have characteristic peak velocities that in normal persons bear a direct relationship to the size of the eye movement. Larger saccades are faster than smaller ones, but it is virtually impossible to perceive these subtle velocity variations by direct observation of the eyes in flight. Fortunately for diagnosis, pathology in the saccade system often slows refixational eye movements sufficiently that the movements are easily perceived as slow by direct inspection. Major reduction in saccade velocity generally indicates cerebellar or brain stem disorders, although minor slowing that usually requires electronic eye movement measurement to document can accompany cerebral hemisphere pathology, particularly if it involves the frontal lobes.

Another aspect of saccade abnormality is *dysmetria*, in which there is altered excursion amplitude--the eyes either fall short of their goal (*hypometric saccades*) or overshoot the target (*hypermetric saccades*). When saccades are hypometric, the eyes achieve the target by a series of small saccades, usually three or more. This gives the movement a jerky or ratchet-like quality that is easily observed. When counting the number of saccades necessary for the eyes to achieve a target 25 or 30 degrees to either side of center (*primary gaze*) in the examination, a normal patient often requires two and, occasionally, three saccades. A patient who consistently uses three or more saccades to make a 30-degree refixation can be considered abnormal. It is easier to be sure that saccade hypometria is significant if the number of saccades used for refixation to one side of primary gaze differs markedly from the number required to make an excursion of an equal distance to the other side. Overshoot, or *hypermetric*, saccades are also easily observed. Here, the eyes overshoot and attain the target via a series of decreasing amplitude reversals, each of which overshoots to a smaller degree than the preceding one. Each corrective saccade is separated from the last by the normal obligatory intersaccadic interval--around 200 milliseconds. This gives the movement a discontinuous quality as opposed to a smooth to-and-fro pendular appearance.

In the acute stages of vascular lesions--infarctions or hemorrhages--of one frontal lobe, the eyes are usually deviated tonically to the side of the lesion because of the suddenly unopposed tonic influence of the normal hemisphere. It can be deduced from this that the normal tone of a given hemisphere, and perhaps of the FEF specifically, brings about contralateral eye movements. This *contraversive* functional orientation is observed also in the disordered saccadic behavior that accompanies chronic frontal lobe lesions. In these cases, after the tonic eye deviation of the acute stage wears off and the patient is able to deviate the eyes fully in both directions, there remains a subtle disorder in which saccades directed away from the side of the lesion are *hypometric*. As an example, a patient with a right frontal lobe infarction has trouble looking volitionally to the left. During the first 4 or 5 days after the acute event, the patient's eyes may be strongly deviated to the right, sometimes along with forceful head and even torso deviation in the same direction. Gradually, the patient will be able to direct the gaze further to the left, and finally, full deviation is possible. An abnormally long latency period before initiating leftward eye movements during the acute stages may also be observed. This directional latency effect must be distinguished from bidirectional increased latency, which may represent altered mental function rather than a specific disorder of the saccade system.

In the chronic stages of this right hemispheric vascular lesion, leftward refixations may continue to evoke numerous hypometric saccades, whereas normometric single saccades are generated for rightward refixations. This contraversive organization is peculiar to the saccade system. The *pursuit* system operates in an *ipsiversive* mode, controlling eye movements toward the hemisphere that is active. This opposing functional orientation in the saccade and pursuit systems greatly enhances the diagnostic usefulness of eye signs related to these subsystems.

IMPAIRED SMOOTH PURSUIT EYE MOVEMENTS

The pursuit system is highly susceptible to degraded function, and bidirectional low-gain pursuit may be a nonspecific abnormality in a variety of clinical settings in which the finding has no localizing value. Fatigue and the effects of many drugs bring about bidirectional symmetrical low-gain pursuit. Bidirectional low-gain pursuit is relatively common in the elderly and has little prognostic or localizing value. *Unidirectional low-gain pursuit*, however, is highly specific for a lesion of the horizontal gaze pathway on one side. Pursuit function in the cerebral hemisphere is *ipsiversive*, and unidirectional defective pursuit suggests a lesion of the parieto-occipital convexity on the side toward which pursuit demonstrates low gain. As an example, a right-sided posterior hemispheric lesion will cause low-gain pursuit with catch-up saccades rightward but will leave leftward pursuit unaffected. Large hemispheric lesions may involve both saccade and pursuit functions, in which case there are hypometric saccades in one direction (opposite the lesion) and low-gain pursuit in the other (toward the lesion). Low-gain pursuit can also be observed as part of the supranuclear conjugate gaze disorder that accompanies lesions of the rostral pons and midbrain, usually in conjunction with altered saccade parameters, but here, the saccades and pursuit are defective in the same direction.

VERTICAL GAZE PALSY

Vertical gaze palsy refers to the condition in which neither eye moves fully upward or downward. In contrast to horizontal gaze, there are no clinical disorders in which

vertical gaze palsy is caused by cerebral hemisphere disease. Brain stem structures are thought to mediate vertical gaze through midbrain tectum and pretectal areas, and lesions in these regions commonly cause upward and downward gaze palsies in conjunction with other features. Aside from vertical gaze palsies, the common features include pupillary paralysis with unequal pupils (large or small), light-near dissociated pupils, convergence-retraction nystagmus, and variable degrees of ptosis or pathological lid retraction (Collier's sign). Retractory nystagmus is characterized by rhythmical backward movements of the globes into the orbits in a nystagmus-like cycle. In conjunction with globe retraction, there may be convergence movements of the two eyes with respect to one another. This constellation of symptoms constitute the *midbrain pretectal syndrome*, also referred to as the *periaqueductal gray matter syndrome* or *Parinaud's syndrome*.

This syndrome can result from mass lesions such as pinealomas compressing the midbrain pretectum as well as from intrinsic midbrain infarctions and/or hemorrhages. The syndrome is of localizing value but does not provide evidence for a specific etiology.

Skew Deviation

Skew deviation refers to any acquired vertical binocular deviation that is caused by lesions affecting supranuclear input to the nuclei of cranial nerves III, IV, and VI rather than lesions affecting the cranial nerves themselves. These lesions are limited to the brain stem, but the location is highly variable and may occur at any level from midbrain to medulla. The vertical deviation may be comitant, such as with strabismus, or incomitant, sometimes mimicking cranial nerve IV lesions (deviation greater in downgaze and in adduction). Skew deviation is not specific for any etiology.

Nystagmus Syndromes

Nystagmus is defined as a repetitive or cyclical ocular movement in which the slow phase of the motion is abnormal. Nystagmus can be further delineated by the

specific movement of the eyes. Nystagmus characterized by repetitive cyclical bidirectional slow phases is termed *pendular nystagmus*, whereas *jerk nystagmus* has alternating slow and fast phases in which the fast phase is a normal saccade returning the visual axis to its original position. A feature common to all forms of nystagmus is that the eyes repeatedly return to the starting position of the cycle. There are three basic functional types of nystagmus: (1) unfettered, cyclical eye movement command generators; (2) tonic bias; and (3) inadequate holding power in eccentric gaze. The first and second types are characterized by abnormal positive influences on the conjugate gaze mechanisms. The third type results from a deficit of function in the gaze-holding mechanism and was originally termed gaze paretic nystagmus, but now gaze-evoked nystagmus is the preferred term.

The most frequent clinical example of the first type of mechanism is congenital nystagmus, in which the eyes are pulled off the object of regard by cyclical abnormal signals that enter the conjugate gaze-generating systems from an unknown site or sites. The return fast phase is a normal saccade bringing about re-foveation whence the cycle resumes. It has been proposed that the variation of slow-phase trajectory from one patient to the next with congenital nystagmus reflects various strategies employed by the CNS as a whole to maintain fixation or foveation. The variable visual acuity in these patients attests to the varied success of these strategies. Patients who keep foveation longer can achieve better levels of visual acuity.

The second mechanism, bias nystagmus, is most frequently encountered with vestibular system disorders and with lesions causing asymmetry of smooth pursuit conjugate gaze systems. The factor in common is that both the pursuit mechanism and the vestibular system are organized into two bilaterally symmetrical, tonically active systems in which the right and left sides oppose each other. Each system feeds commands into the horizontal and vertical gaze-generating systems, and in health, each side is equally active so there is no *net* driving force in any direction away from primary gaze. When disease affects one side more than the other, a net tonic drive or *bias* develops. The function of the vestibular system is to keep the visual axis on a fixed point in external visual space despite movement of the head in all planes (see [Chapter 12](#)). For instance, as the head rotates rightward at 10 degrees per second, an induced leftward eye movement at 10 degrees per second occurs, so that the external world remains fixed on the fovea. The VOR, however, does not supply the entire eye movement drive and works together with the pursuit system to optimize function.

Tonic vestibular system imbalance passes a tonic directional bias to the brain stem gaze centers, which causes the eyes to drift toward the side with less activity. The tonic influence of each side is contraversive, and a lesion creates underactivity of the ipsilateral system, with relative overactivity of the opposite system. The unopposed contraversive tone of the system opposite the lesion imposes eye drift toward the lesion side. This drift is checked by rhythmically occurring saccades in the opposite direction. The ensemble effect is rhythmical jerk-type nystagmus with slow-phase movements toward the side with the lesion and fast phases away from the lesion. This nystagmus is rhythmical because the slow-phase drift is constant velocity, determined by the degree of bias or imbalance between the two lateral vestibular subsystems, and the corrective saccades occur whenever a certain fixed amount of retinal position error between object of regard and fovea occurs.

The third mechanism, or gaze-evoked nystagmus, occurs when the patient is unable to maintain eye deviation away from primary gaze. When neural integration in the brain stem circuits is faulty, an inadequate step or position command results, and saccades made to eccentric gaze positions are followed by a backward drift of the eyes toward primary position. When a sufficiently large retinal error signal is generated (the object of regard is now on a peripheral retinal point), another saccade is generated to refixate the eccentric point. This results in a series of saccades and back drifts that constitute gaze-evoked nystagmus. This third type of nystagmus differs from vestibular

and other bias forms of nystagmus in several ways. First, in gaze-evoked nystagmus, the velocity of the slow phase is determined by the difference between the oculomotor force being generated and the resisting forces that are tending to bring the eye back to primary position. These forces are largely contributed by elastic elements in the extraocular muscles and tendons and are greater when the eye is in a more eccentric position than when it is near primary gaze. This means that as the eyes drift back, the pulling force lessens as the elastic elements are less stretched, and the velocity of the slow phase declines exponentially. In vestibular nystagmus, on the other hand, the slow phase has constant velocity based on a fixed imbalance between the tonic forces of the two opposing vestibular systems. Second, gaze-evoked nystagmus depends on the continued effort of the subject to look in the direction of deficient holding power. As the urge to maintain the eccentric position wanes, the nystagmus slows down and may even stop with the eyes in a position close to primary gaze. Then if the subject is exhorted to look at the stimulus target, the nystagmus resumes. In general, vestibular nystagmus is faster than gaze-evoked nystagmus and keeps a fixed rate and rhythm. Third, gaze-evoked nystagmus is by definition not present in the primary position of gaze because it requires activation of a gaze shift. Vestibular nystagmus may be present in primary gaze if the intensity of the imbalance is great enough. Vestibular nystagmus is classified as first degree when it is present only with gaze in the direction of fast phase, second degree when it is present in primary gaze, and third degree when it is present in all positions of gaze.

Ocular Flutter and Opsoclonus

Abnormal repetitive eye movements in which the fast phase or saccades are abnormal include ocular flutter and opsoclonus. Opsoclonus is a continuous succession of multidirectional conjugate saccadic eye movements with no intersaccadic interval. In the acute stage, it is usually associated with violent ataxia and high-amplitude tremor of all limbs. As recovery occurs, some patients go through a phase in which there are spontaneous bursts of horizontal back-to-back saccades, again without intersaccadic interval. In adults, opsoclonus usually results from brain stem encephalitis, either sporadic or as a remote effect of carcinoma. In infants and children, opsoclonus can be a remote manifestation of neuroblastoma. Ocular flutter comprises bursts of saccades in one plane, typically horizontal, during forward fixation. There are no intervals between saccades. Patients can manifest ocular flutter when developing or recovering from opsoclonus, and both disorders probably share pathophysiological mechanisms. Multiple sclerosis, hydrocephalus, head trauma, midbrain glioblastoma, thalamic hemorrhage, and sialidosis (cherry-red spot--myoclonus syndrome) have all been reported in association with ocular flutter. ^[66]

Orbital Syndromes

In the orbit, the third, fourth, and fifth cranial nerves and the extraocular muscles themselves can be involved by a nonspecific inflammatory disease with pathology identical to that in Tolosa-Hunt syndrome. Such orbital disease, called *orbital inflammatory pseudotumor* when the collagenous tissues and fat are primarily involved and *orbital myositis* when the extraocular muscles are primarily involved, frequently involves both the orbit and the anterior cavernous sinus through the superior orbital fissure. ^[66] ^[66] The eye is painful and highly restricted in movement, usually in multiple directions. A condition with painful ophthalmoplegia reported as superior orbital fissure syndrome has no accompanying proptosis and has been most often ascribed to an inflammatory pachymeningitis from tuberculosis or syphilis, even when laboratory or pathological confirmation has been lacking. ^[69] Some cases have been thought to represent a sterile inflammatory reaction adjacent to infection in the paranasal sinuses. ^[70]

GENERAL MANAGEMENT GOALS

Many of the disorders affecting cranial nerves III, IV, and VI are remitting, so management issues involve patient comfort. The most troublesome symptom in disorders of these cranial nerves is binocular diplopia that can be simply managed by having the patient patch one eye. Occluding one eye restricts the patient's visual field and results in a loss of depth perception. For this reason, driving is not recommended. Prism correction can be placed in the spectacle of one or both eyes to eliminate diplopia, at least for a range of eye positions near the primary position of gaze. Prisms bend light rays without altering the vergence of the rays. Corrective prisms are oriented to shift the image of the object of regard to the fovea of the deviating eye. An inexpensive plastic form of a prism can be applied to the patient's own glasses for short-term treatment. If the diplopia is going to be permanent or long lasting, then it is desirable to have the prism ground into the spectacle, because this is optically superior to the paste-on prism.

HISTORY AND DEFINITIONS

The trigeminal system contains both sensory and motor components and thus subserves and controls ipsilateral facial sensation and masticatory movements. The trigeminal sensory and motor nuclei extend in the brain stem from the pons to the upper cervical spinal cord. Pain, thermal, tactile, and kinesthetic sensory stimuli are received from the facial skin, oropharynx, nasal mucous membranes, sinuses, teeth, palate, dura, and masticatory muscles themselves. Motor fibers extend to the muscles of mastication as well as the tensor tympani and tensor veli palatini. Clinically, trigeminal dysfunction commonly is manifested as sensory changes such as paresthesias, dysesthesias, or anesthesia; paroxysmal or chronic pain; or difficulty chewing and swallowing. Traumatic, vascular, infectious, inflammatory, neoplastic, and demyelinating disorders can affect the trigeminal nerve at multiple points along the anatomical pathway from cortex, through the brain stem and trigeminal sensory ganglion, and out into peripheral trigeminal branches.

The first adequate clinical description of trigeminal neuralgia was made by Fothergill in 1773. Thereafter, Charles Bell (1829) demonstrated that the trigeminal nerve subserved sensation to the face. The trigeminal ganglion was excised in the late 19th century by Rose (1890), and the celebrated surgeon Horsley first sectioned the fifth cranial nerve through an intradural middle fossa approach in 1891. Early 20th century studies focused primarily on physiology, and more modern research has integrated neurochemistry, neuropharmacology, and microsurgical interventions in the treatment of trigeminal lesions.

CLINICAL HISTORY

When interviewing a patient with complaints referable to the trigeminal system there are several key considerations to address. First is the nature of the patient's complaint (that is, pain, sensory changes, sensory loss, or motor difficulty) because the characteristic clinical features are critical components of an appropriate neurological diagnosis. For example, lancinating excruciating pain suggests trigeminal neuralgia and is distinguished from the more tolerable yet disturbing paresthesias of trigeminal sensory neuropathy. Determination of whether the symptoms are intermittent, paroxysmal, or chronic and the temporal profile of symptom development (i.e., whether symptoms began in an acute, subacute, or indolent fashion) also provides diagnostic clues. Thus, sudden complaints of sensory loss, paresthesias, or motor dysfunction in the face are consistent with vascular, traumatic, or demyelinating processes, whereas similar complaints developing over weeks more often reflect neoplastic or inflammatory etiologies. Inquiries regarding a family history of neurological disorders that may run in families and have a possible genetic link, such as multiple sclerosis, stroke, brain tumor, or aneurysm, should be sought. Possible precipitating elements such as recent trauma, toxic exposures, illicit drug abuse, and all medication usage should be identified. It is also important to elicit other neurological symptoms such as autonomic, visual, ocular or facial motor dysfunction, which may help to localize the lesion. Specifically, patients should be questioned regarding changes in facial sweating; recurrent corneal irritation or abrasions; and difficulty blinking, swallowing, or speaking. Specific trigger points of facial pain

18

psuggest trigeminal neuralgia, and associated oropharyngeal or jaw pain may imply temporomandibular joint disease. It is imperative to identify past or concurrent medical or neurological disorders that may be related etiologically to a patient's complaints of trigeminal dysfunction. Specifically, a history of collagen vascular diseases; prior strokes, diabetes, neoplasms, granulomatous diseases, bleeding disorders; or recent and recurrent infections may prove helpful.

ANATOMY OF CRANIAL NERVE V (Table 10-1)

Overview

The trigeminal nerve is a mixed cranial nerve, and the afferent and efferent projections of cranial nerve V (CN V) provide sensorimotor inputs and outputs to the face (Table 10-1).^{1,2} The multimodal sensory components (pain, temperature, position, and light touch) of the trigeminal system send projections via the thalamus to primary sensory cortices (Brodmann areas 3, 1, 2). The three primary sensory nerves of the trigeminal system are named for the facial regions they innervate (e.g., ophthalmic [V1], maxillary [V2], and mandibular [V3]) (Fig. 10-1 A). The unilateral cutaneous sensory distributions of these nerves overlap slightly in the facial midline, which has clinical relevance especially in assessing patients with nonorganic sensory loss (see later). In contrast, first order motor efferents originate in primary motor cortex (area 4) and project bilaterally to the pontine trigeminal motor nucleus. Axon collaterals extend to the thalamus and cerebellum. The motor projections innervate the muscles of mastication including the masseter, medial and lateral pterygoid, temporalis, mylohyoid, and anterior belly of the digastric muscles, as well as the tensors tympani and vela palatini. The motor portion of the trigeminal nerve runs with the mandibular (V3) sensory branch in the face.

Motor Portion

SUPRANUCLEAR CONTROL AND UPPER MOTOR NEURONS

Corticobulbar projections to the trigeminal motor nucleus (upper motor neurons) extend from facial regions of the precentral gyrus (first order neurons in primary and supplementary motor cortices, areas 4 and 6) via the corticobulbar tract to terminate directly on neurons within the pontine trigeminal motor nucleus or on adjacent pontine reticular interneurons, which project to motor nuclear cells.

PONTINE NUCLEUS AND LOWER MOTOR NUCLEUS

The motor nucleus of CN V is located in the rostral pons medial to the principal sensory nucleus. The motor nucleus also receives fibers from the mesencephalic nucleus and mediates the efferent portion of the jaw jerk reflex. Motor trigeminal axons from the lower motor neurons project from the trigeminal motor nucleus to pass

TABLE 10-1 -- CLINICO ANATOMICAL CORRELATION OF LOCALIZATION OF LESIONS OF CN V

Anatomical Site of Damage	CN V Finding	Other Neurological and Medical Findings	Common Etiologies
Supranuclear	Facial numbness, paresthesias	Neglect, apraxia, aphasia	Stroke, tumor, hemorrhage
Sensory cortex			
Internal capsule	Hemifacial sensory loss	Hemiparesis of arm	Stroke, tumor, hemorrhage, MS
Corona radiata		Central 7th paresis	
VPM thalamus	Facial numbness, paresthesias, pain, cheiro-oral syndrome	Anornia, hemisensory deficit	Stroke, tumor, hemorrhage
Midbrain	Facial numbness, paresthesias, pain	Ophthalmoparesis	Stroke, MS, tumor, aneurysm
Nuclear Pons	Facial numbness, paresthesias, pain, trigeminal neuralgia, facial weakness	Ophthalmoparesis, CN VI, VII, VIII, Horner's syndrome	Stroke, tumor, hemorrhage, MS, syringobulbia, abscess, trauma
Medulla	Facial numbness, paresthesias, pain, nystagmus, Horner's syndrome, trigeminal neuralgia	Ataxia, CN X, ophthalmoparesis, abscess, vasculopathy Wallenberg's syndrome	Stroke, MS, tumor, abscess, trauma
Preganglionic	Facial numbness	CN VII, VIII, headache, cerebellar dysergias	Neuroma, meningioma, meningitis (bacterial, TB, cancer),
Cerebellopontine angle			
Middle cranial fossa	Facial numbness, facial weakness	Craniocervical syndrome, CN VI, VII	Tumor, infection, trauma
Gasserian ganglion			
Skull base	Facial numbness, facial weakness	Headache, meningismus	Meningitis (bacterial, TB, cancer, sarcoid)
Trigeminal nerve branches V1	Facial numbness, pain	Headache, ophthalmoparesis, Horner's syndrome	Tumor, thrombosis, infection, trauma
Cavernous sinus			
Carotid cavernous fistula	Facial numbness	Proptosis, bruit, ophthalmoparesis	Trauma
V2	Facial numbness, numb cheek syndrome		Tumor, infarct, vasculopathy, trauma
Maxillary region			
V3	Weakness of mastication, numb chin syndrome		Tumor, trauma, infarct
Mandibular region			

CN, Cranial nerve; VPM, ventroposteromedial; MS, multiple sclerosis; TB, tuberculosis.

Figure 10-1 A. Cutaneous distribution and facial innervation of V1-V3. Anatomical relationship between cutaneous trigeminal fibers, the gasserian ganglion, and brain stem trigeminal nuclei and pathways. Note termination of afferent fibers via the descending (spinal) trigeminal tract into the spinal (descending) nucleus. The anterior innervation of the nose and mouth blends laterally with maxillary and preauricular innervation in a characteristic onion skin. (From Patten JP: Neurological differential diagnosis: An illustrated approach, 2nd ed. Copyright © 1995 by Springer-Verlag, Berlin, Heidelberg. Used by permission of the publisher.)

through the trigeminal sensory (gasserian or semilunar) ganglion (see later; Fig. 10-1 B). Motor axons extend from the motor trigeminal nucleus in the pons and travel along the petrous portion of the temporal bone through Meckel's cave, which is a dural-lined cavity adjacent to the petrous apex housing the gasserian ganglion. Motor efferents pass through the gasserian ganglion, join sensory V3 fibers, and exit the skull base via the foramen ovale. Motor efferents in the face travel in association with sensory V3 fibers and reach the masticatory muscles via the medial and lateral pterygoid, deep temporal, masseteric, and mylohyoid nerves. These muscles serve to open (lateral pterygoids, digastric, and mylohyoid) and close (masseter, temporalis, and medial pterygoids) the jaw and provide medial and lateral jaw movements necessary for effective mastication. Small motor branches also extend to the tensor veli palatini and tensor tympani muscles. The tensor veli palatini in the posterior pharynx is active during swallowing and tenses the soft palate against the tongue. The tensor tympani is a small muscle in the middle ear recruited during continuous

loud sound; it serves to draw the malleus and tympanic membrane toward the medial wall of the middle ear to dampen the vibrations of the tympanic membrane.

Sensory Portion

RECEPTORS

Cutaneous receptors for the trigeminal nerve are primarily mechano-, thermo-, and nociceptive endings. These include pacinian corpuscles, free nerve endings, Merkel's discs, and Ruffini's endings. Although these are often associated with facial hairs, areas of particularly dense innervation include the lips, buccal and gingival surfaces, and the cornea. Some sensory nociceptive afferents are not myelinated, whereas others, and tactile and mechanical afferents, are heavily so. In addition, muscle spindles and Golgi tendon organs exist within facial muscles and extend via type Ia and Ib fibers to the pons.

FIRST ORDER NEURONS

Primary sensory neuron cell bodies for the afferent trigeminal fibers (V1-V3) are within the trigeminal (gasserian or semilunar) ganglion, which is embedded in the petrous portion of the temporal bone in the middle cranial fossa.^[1],^[2] In this area is Meckel's cave, a dural-lined cavity in the middle cranial fossa adjacent to the temporal lobe, which surrounds the gasserian ganglion and its branches as they exit into the petrous temporal bone. This region may be viewed by magnetic resonance imaging and is important clinically. A single large trigeminal sensorimotor root passes into the gasserian ganglion and then emits the three trigeminal divisions that exit the skull base via distinct foramina: V1 exits via the superior orbital foramen, V2 via the foramen rotundum, and V3 via the foramen ovale.

The ophthalmic division of the trigeminal nerve is entirely sensory (all modalities) and its branches innervate the orbit and eye (lacrimal and nasociliary branches), upper eyelid, forehead, and nose (frontal branches), nasal cavity, and nasal sinuses (nasociliary branches). V1 passes within the cavernous sinus where it lies inferolateral to the oculomotor, trochlear, and abducens nerves. From the cavernous sinus, V1 extends through the superior orbital fissure again in association with cranial nerves III, IV, and VI, before dividing into the lacrimal, frontal, and nasociliary nerves. Cutaneous fibers reach the skin via the supraorbital foramen along the ridge of the brow. V1 sensory afferents from the cornea provide afferents for the corneal reflex (see later). Smaller tentorial and dural branches innervate the tentorium cerebelli and dura mater.^[3] Vasomotor fibers also branch from the trigeminal system (trigeminovascular innervation) to provide autonomic inputs to intracranial blood vessels. The majority of these fibers are believed to use calcitonin gene-related peptide, substance P,^[4] and vasoactive intestinal peptide as transmitters.^[5] Stimulation of the trigeminal ganglion in experimental animals and humans increases brain blood flow.^[6],^[7] Autonomic fibers to the lacrimal gland extend from the facial nerve and pterygopalatine ganglion to run with the lacrimal branch of V1, but they originate from the superior salivatory nucleus.

The maxillary division (V2) is also completely sensory; it innervates the skin of the cheek, nose, lower eyelid, upper lip, nasopharynx, soft and hard palate, maxillary sinus, and upper teeth. A small meningeal branch follows the middle meningeal artery and supplies the dura.^[8] V2 fibers leave the gasserian ganglion, exit the foramen rotundum, and run inferiorly within the cavernous sinus. V2 axons pass through the pterygopalatine fossa, to exit the infraorbital foramen. These cutaneous branches include the zygomaticotemporal, zygomaticofacial, and infraorbital nerves, whereas branches innervating the nasopharynx and maxillary sinuses include the greater and lesser palatine nerves, nasopalatine nerve, and pharyngeal nerve. V2 innervation of the upper teeth, maxillary sinuses, and palate is via the anterior, middle, and posterior superior alveolar nerves, respectively. Autonomic fibers that originate from the facial nerve (superior salivatory) nuclei accompany V2 branches and comprise the superficial petrosal nerve. These fibers synapse within the pterygopalatine ganglion and provide parasympathetic input to the lacrimal, nasal, and palatine glands. Fibers of the superficial petrosal nerve unite with the deep petrosal nerve to form the nerve of the pterygoid canal. The deep petrosal nerve is a branch of the internal carotid plexus and carries postganglionic sympathetic fibers from the superior cervical ganglion to the lacrimal glands.

The mandibular division (V3) carries both sensory and motor fibers (see earlier) to the lower face. V3 axons leave the gasserian ganglion to exit the skull base via the foramen ovale. The fibers ramify through the deep face lateral to the medial pterygoid muscles and then divide into branches that provide sensation to the skin around the mandible, chin, and ear (lingual, auriculotemporal, and mental branches); mucosa around the inner cheek (buccal branch), lower teeth (inferior alveolar nerves), and dura (meningeal branch). Parasympathetic fibers synapse within the otic and submandibular ganglia and project to the submandibular and parotid glands, respectively.

Proximal connections of the primary sensory neurons synapse in the brain stem in three sensory subnuclei that extend from the cervical spine to the pontomesencephalic junction. These include the spinal (descending) trigeminal tract and nucleus, the principal sensory nucleus, and the mesencephalic nucleus, each of which subserve a distinct trigeminal function. Sensory axons from V1- to V3-innervated regions of the face reach the trigeminal ganglion where cell bodies of these peripheral axons send central axons in a solitary sensory root into the midpons. Within the brain stem, these axon bundles bifurcate into fascicles that terminate rostrally in the principal sensory nucleus or caudally in the spinal trigeminal tract and nucleus.^[9]

Fibers entering the spinal trigeminal tract pass caudally to the spinal nucleus in an inverted somatotopic organization (V1 ventrally, V2 medially, and V3 dorsally) and convey most of the nociceptive and cutaneous inputs mediated by the trigeminal system. The spinal trigeminal tract extends into the upper cervical spinal cord, and afferents synapse on immediately adjacent cells within the nucleus of the spinal trigeminal tract that lie medial to the tract for its entire length. The nucleus of the spinal trigeminal tract blends at its most rostral extent with the principal sensory nucleus (see later) and caudally with the substantia gelatinosa

in the cervical spinal cord (see [Chapters 19](#) and [20](#) on pain).

The spinal trigeminal nucleus may be divided cytoarchitecturally into a pars oralis, which receives sensory inputs from the oral and nasal regions, the pars interpolaris and pars caudalis, which receive afferents from cutaneous portions of the face. Within the pars caudalis, four somatotopically organized laminae (I-IV) similar to the central gray area of the spinal cord parcel sensory inputs into pain and tactile stimuli. Two somatotopic homunculi for facial representation of pain are proposed within the spinal trigeminal nucleus. First, a rostrocaudal representation of facial innervation such that mandibular regions terminate more rostrally, followed by maxillary and ophthalmic regions more caudally extending into the cervical cord, has been proposed. This facial representation is distinct from the second homuncular pattern proposed, the so-called "onion skin" pattern, in which the mouth and nose (central regions) are represented rostrally in the brain stem, whereas the cheeks, eyes, and ears (more peripheral facial areas) are represented more caudally.

Impulses carrying tactile and pressure sense enter the midpons and extend rostrally to terminate in the principal trigeminal sensory nucleus. These inputs are somatotopically organized similar to the spinal trigeminal tract. Cells within the principal sensory nucleus have large receptive fields; they respond to various tactile and pressure stimuli applied to the skin, mucous membranes, palate, orbit, and teeth.

The third brain stem nucleus, the mesencephalic nucleus, is located dorsolaterally above the middle cerebellar peduncle near the pontomesencephalic junction and adjacent to the fourth ventricle. Afferent fibers to the mesencephalic nucleus travel within the motor root of the trigeminal nerve and convey primarily kinesthetic sensation from the teeth, oropharynx, and jaws. These afferents synapse on unipolar-shaped neurons. Stretch receptors in masticatory muscles send information regarding bite force to the mesencephalic nucleus and function as the afferent portion of the jaw jerk reflex (see later).

SECOND AND THIRD ORDER SENSORY NEURONS

The second order sensory neurons located within the spinal trigeminal, main sensory, and mesencephalic nuclei send projections rostrally via the trigeminothalamic tract.^[10],^[11] Neurons within the pars oralis and caudalis of the spinal trigeminal nucleus and cell bodies from the mesencephalic and principal nuclei project medially into the pontine reticular formation, cross within the median raphe, and ascend contralaterally within the trigeminothalamic tract closely adjacent to the medial lemniscus.

Axons from the second order neurons terminate somatotopically within the venteroposteromedial nucleus (VPM) of the thalamus contralateral to their nucleus.^[12],^[13] A smaller proportion of fibers terminate within the intralaminar nuclei. In contrast, a small fascicle of ipsilateral projections extend rostrally via the dorsal trigeminal tract to terminate in the VPM. Trigemino-cerebellar fibers project bilaterally from the mesencephalic and motor trigeminal nuclei.

Third order thalamocortical projections from the VPM travel in the anterior limb of the internal capsule and terminate primarily in sensory cortical areas 3, 1, and 2.^[14] Less dense projections reach the parietal lobule and the precentral gyrus. The presence of some sensory afferents in the cortical motor region explains why sensory abnormalities may be reported by patients with lesions affecting only the precentral gyrus.

EXAMINATION OF THE TRIGEMINAL NERVE

Directed Neurological Examination

SENSORY FUNCTION OF CRANIAL NERVE V

When assessing the trigeminal system, it is important to perform a directed and assiduous neurological examination because subtle alterations in function may provide clues to detect potentially serious neurological disease. Sensory and motor components should be tested separately, comparing right and left sides, and light touch, pin, and temperature sensation should be tested individually in V1 to V3. The cornea and sclera should be inspected for evidence of keratitis, which may be suggestive of diminished corneal (trigeminal) sensation or lacrimation, as well as the facial skin, oropharynx, teeth, gums, and nares for evidence of inflammatory, infectious, or neoplastic disorders. When considering trigeminal neuralgia or, less often, post-herpetic neuralgia, trigger points that elicit pain should be identified (see later). Localizing signs from involvement of the neuraxis in close proximity to the affected trigeminal region may be helpful. For example, other cranial neuropathies such as ocular motor dysfunction or facial weakness and Horner's syndrome may provide clues as to the lesion locus in combination with the trigeminal symptoms. In general, lesions that affect branches of V1 to V3 distal to the gasserian ganglion result in highly focal, circumscribed sensory loss within one division or subdivision of the trigeminal nerve. In contrast, pathological processes affecting the ganglion itself typically cause ipsilateral hemifacial sensory dysfunction. Lesions within the brain stem that affect the individual trigeminal nuclei may give a distinct picture of dissociated sensory loss in which pin, temperature, and light touch sensory modalities are differentially affected.

Sensory examination should assess pain, temperature, light touch, and vibration as well as checking the corneal and jaw jerk reflexes. Painful stimuli can reliably be delivered with a non-reusable pin applied evenly and gently to the skin (Fig. 10-2 A through 10-2C). Two-point discrimination testing, especially on the lips, can be useful. Although temperature discrimination can best be assessed with glass tubes of hot or cold water, in clinical practice, touching the face with a tuning fork and asking if it feels cold is effective. Light touch can be tested with a cotton wisp or tissue paper stroked gently against the skin. Vibration may be assessed with a 125-Hz tuning fork held against the frontal bones, maxilla, and mandible.

It is important when performing a sensory examination to avoid suggesting or directing the patient into desired

Figure 10-2 Sensory examination of the trigeminal nerve. Testing pain sensation in the cutaneous distribution A) V1, (E) V2, and (C) V3 by lightly touching the skin with a pin. Light touch and temperature modalities should also be assessed in the same distributions.

responses and to be vigilant for the malingering or hysterical patient. Thus, a conservative way to test sensation is to ask the patient to respond *yes* if present or *no* if not and then to determine a more subjective difference between the two responses. Comparisons should be made with the contralateral face. It is especially important to pay attention to upper cervical dermatomal distributions when assessing sensation along the angle of the jaw because there may be close overlap between sensory loss from a lesion affecting V3 and cervical spinal nerves of C2 to C3. Similarly, the distribution of the sensory fibers to the upper face and into the scalp merges near the vertex with fibers of the greater occipital nerve, which innervate the posterior scalp. The overlap in the midline of V1 to V3 cutaneous sensory fields is helpful in determining a malingering or hysterical patient. Thus, in patients complaining of hemifacial sensory loss, it is important to determine whether the pattern of loss abruptly stops at the midline or if there is a subtle gradation of loss proceeding from the affected to the normal side. In the former case, nonorganic causes should be suspected. By testing vibratory sensation on the frontal bone, malingering or hysterical patients can often be identified as those who report a difference in sensation despite the physiological impossibility of differences in vibratory sensation when essentially applying the tuning fork to the same albeit "right" or "left" bone. Similarly, loss of sensation on the forehead, which ends abruptly at the hairline, may suggest a nonorganic etiology, although facial sensory loss from leprosy affects facial cutaneous regions, which have a cooler temperature, but spares fibers at the hairline where the skin is warmer (personal communication, MJ Brown).

MOTOR FUNCTION OF CRANIAL NERVE V

Evidence of trigeminal motor involvement such as muscle atrophy, spasm, or fasciculations; jaw deviation; difficulty chewing; and hyperacusis may be present. Atrophy of the temporalis is often easy to observe. To assess muscle bulk, the masseter may be pinched between the fingertips and the temporalis muscle should be palpated as the patient opens and closes the mouth (Fig. 10-3 A). The strength of jaw opening (Fig. 10-3 B), closure, and lateral deviation should be assessed because jaw closure is very strong and difficult to evaluate clinically, and subtle changes may not be easily detected.

If it is difficult for the patient to open the mouth against resistance, some degree of facial motor weakness is likely

Figure 10-3 Motor examination of the trigeminal nerve. A, palpation of the masseter muscles to assess muscle bulk, which may be diminished in lesions affecting the trigeminal motor nucleus or trigeminal nE. Assessing strength of jaw opening is clinically easier than jaw closure.

to be present. Weakness of the pterygoids resulting from nuclear or nerve lesions may produce ipsilateral jaw deviation (Fig. 10-3). Lower motor neuron processes involving the trigeminal motor nucleus such as motor neuron disease may produce fasciculations in association with muscle weakness and atrophy. One useful sign is the presence of masseteric spasm and contracture in association with ipsilateral hearing loss, facial numbness, diminished corneal reflex, and paretic facial muscles in patients with tumors infiltrating the dorsal pontine tegmentum. ^[12], ^[13]

TRIGEMINAL REFLEXES

The corneal reflex is a reliable measure of afferent trigeminal V1 and efferent facial seventh nerve fibers (a V-VII reflex) and is present at infancy. Lightly touching the cornea with a tissue or cotton swab induces a rapid bilateral blink reflex (Fig. 10-4 A). Touching the sclera or eyelashes, tapping the glabellar regions (glabellar blink reflex), presenting a light flash, or stimulating the supraorbital nerve induces a less rapid but still reliable response. Anatomically, afferent corneal V1 fibers may synapse within the spinal trigeminal nucleus as well as the main sensory nucleus. Short projection neurons project bilaterally to the facial nuclear neurons, which in turn project to the orbicularis oculi muscles. The latency of this response is between 25 and 72 msec and increases with advancing age. A brief latency difference exists between the stimulated and contralateral side of less than 6 msec. Extensive electrophysiological studies have characterized this reflex in great detail ^[14] in a number of neurological disorders. The corneal reflex may be slowed in various disorders affecting the trigeminal nerve, ganglion, or brain stem nuclei including posterior fossa and cerebellopontine angle tumors such as acoustic

Figure 10-4 Trigeminal reflexes. A, The corneal reflex is elicited by lightly touching the cornea with a tissue or cotton swab. The jaw jerk reflex may be elicited by gently tapping a finger placed on the jaw. Both of these reflexes may be brisk in supranuclear processes but diminished in nuclear or peripheral lesions.

neuromas, multiple sclerosis, brain stem strokes (especially in Wallenberg's syndrome), and Parkinson's disease. Rarely, a delay in the corneal reflex has been reported ipsilateral to a hemispheric lesion. ^[15]

The jaw jerk reflex may indicate dysfunction of afferent sensory or efferent motor V3 fibers. Afferent axons for the jaw jerk reflex are from stretch receptors (muscle spindles) within the masseter, temporalis, and medial pterygoid muscles, which project centrally to the mesencephalic nucleus and induce a rapid, single jaw closure (jerk) mediated via motor trigeminal neurons that project back to these muscles. The jaw jerk is elicited by tapping the chin when the mouth is closed and the jaw

relaxed ([Fig. 10-4 B](#)). Other variations include tapping the thumb placed on the chin or a tongue blade placed on the lower teeth. Peripheral or brain stem nuclear processes that affect V3 neurons attenuate the jaw jerk reflex, whereas in lesions involving supranuclear trigeminal motor projections, exaggeration of the jaw jerk may be identified. Other trigeminal reflexes include the oculocardiac, corneomandibular, snout, and trigemino-abducens reflexes. ^[16]

Associated Neurological Findings

Cerebral. The presence of apraxia, hemispatial neglect, aphasia, or Gerstmann's syndrome in association with facial numbness is very helpful in identifying parietal lobe dysfunction in affected patients. Other important manifestations of parietal lobe dysfunction include a homonymous hemianopia (especially within the inferior quadrant); a cortical sensory syndrome in which astereognosis, diminished two-point discrimination, and agraphesthesia are features; and abolition of optokinetic nystagmus toward the side of the lesion.

Cranial Nerves. Ophthalmoparesis involving cranial nerves III, IV, or VI with trigeminal symptoms suggests cavernous sinus or superior orbital fissure pathology. If cranial nerves VI, VII, and/or VIII are involved (ophthalmoparesis, nystagmus, hearing changes), a petrous apex process such as Gradenigo's syndrome (see later) or lesion such as tumor within the lateral pons or cerebellopontine angle should be suspected. Similarly, detection of Horner's syndrome may indicate lateral brain stem or upper cervical spinal cord pathology.

Motor/Reflexes/Cerebellar/Gait. Hemiparesis can result from lesions within the postcentral gyrus and can overlap with sensory loss. Cerebellar abnormalities such as gait ataxia or nystagmus in association with facial numbness may point to a process within the cerebellopontine angle. Detection of Horner's syndrome alone or in combination with dysphasia and ataxia is consistent with a lesion in the lateral medullary region.

Sensory. Although the distribution of sensation on the lower face is via V3, the angle of the jaw is innervated by the C2 to C3 spinal nerves. Numbness or paresthesias in this region may reflect an intramedullary cervical cord process, but a psychogenic etiology should also be considered. "Crossed sensory" syndrome, wherein facial hypesthesia is central to body hypesthesia, indicates a brain stem lesion. Face and body hypesthesia on one side suggest a cortical, subcortical, or midbrain lesion.

Neurovascular. The detection of a bruit over the orbit is suggestive of a carotid-cavernous sinus fistula, especially in the setting of recent head trauma, and may be helpful in discerning trigeminal dysfunction from a cavernous sinus process. Other signs suggestive of carotid or systemic vascular disease increase the suspicion of stroke syndromes.

EVALUATION GUIDELINES

In virtually every patient who presents with overt or subtle manifestations of trigeminal nerve dysfunction, some form of laboratory evaluation is indicated ([Table 10-2](#)). Careful and directed neurological examination dictates the most important tests to obtain.

Neuroimaging. Once a lesion has been reasonably localized to the cortex, white matter pathways, thalamus, or brain stem, neuroimaging is essential to support a definitive clinical diagnosis (for complete text, see reference [17](#)). Although computed tomography (CT) scanning can provide useful information regarding bony change or intracranial hemorrhage, magnetic resonance imaging (MRI) renders

TABLE 10-2 -- USEFUL STUDIES IN THE EVALUATION OF THE TRIGEMINAL NERVE

Syndrome	Neuroimaging	Eleetrophysiology	Fluid and Tissue Analysis	Neuropsychological Tests
Supranuclear	MRI with gadolinium for stroke, tumor, MS	EEG focal slowing or sharp waves	Increased protein, mild pleocytosis	Acalculia neglect
Nuclear lesions	MRI with gadolinium for stroke, tumor, MS	Abnormal BAEP, slowed blink reflex (V1)	Increased or normal protein, pleocytosis	NA
Preganglionic C-P angle	MRI with gadolinium for stroke, tumor, MS, meningitis, brain stem compression	Slowed blink reflex (V1)	Increased protein, pleocytosis, decreased glucose, abnormal cytology, positive CSF culture	NA
Gasserian ganglion	MRI with gradolinium for infection, tumor	Slowed blink reflex (V1)	Increased or normal protein, abnormal cytology, positive CSF culture	NA
Cavernous sinus	MRI with gadolinium for infection, thrombosis, aneurysm	Slowed blink reflex (V1)	CSF pleocytosis, low CSF glucose	NA
Peripheral CN V branches	Neuropathies	Slowed blink reflex (V1)	Increased or normal protein	NA
Trigeminal neuralgia	CN V root compression on MRI	No change	No change	NA

C-P, Cerebellopontine; MRI, magnetic resonance imaging; BAEP, brain stem auditory evoked potentials; NA, not applicable.

high-resolution models of regions not readily visible by CT such as the brain stem. In addition, subtle abnormalities such as early multiple sclerosis plaques, small tumors, or infarcts can often be visualized with gadolinium-enhanced MR images. MRI with gadolinium is a very useful way to visualize Meckel's cave [18](#) and to detect enhancement within the trigeminal nerve roots or gasserian ganglion. MRI with fine sections through the orbits is useful in assessing an orbital mass lesion and pain referable to V1. Orbital CT may also be useful. MR angiography and CT may be utilized to identify compression of the trigeminal nerve by the superior cerebellar artery. CT is the method of choice to evaluate the petrous apex especially in disorders such as Gradenigo's syndrome.

Electrophysiology. Electroencephalography (EEG) may reveal focal slowing or epileptiform abnormalities such as sharp waves or spikes in patients with significant cortical or hemispheric lesions. Because tumors, infarctions, and hemorrhages may also cause seizures in addition to sensorimotor trigeminal dysfunction, EEG may be very useful. In addition, if symptoms described are paroxysmal or intermittent, focal seizures must be considered in the differential diagnosis. Brain stem auditory evoked potentials (BAEPs) may be useful in assessing the possibility of an intrinsic brain stem process as well as lesions within the adjacent cerebellopontine angle. For example, BAEPs may assist in identifying people with occult multiple sclerosis or small vessel brain stem strokes that may have subclinically affected pontine or medullary regions in adjacent to the trigeminal nuclei.

Electrophysiological assessment of the corneal (blink) reflex latency can be reliably measured in an attempt to further localize a supranuclear, nuclear, or peripheral nerve process.[19](#) This electrically elicited response is similar to that tested at the bedside, and it allows measurement of the response latency after stimulating either the afferent trigeminal or efferent facial nerve components. The facial nerve can be stimulated directly at its exit near the mastoids and the direct response latency (contraction of the ipsilateral orbicularis oculi muscles) measured. For normal adults, this value is typically between 3.0 and 5.0 msec. In contrast, the afferent and efferent limbs of the blink reflex can be tested by stimulating the supraorbital nerve or tapping the glabellar regions and measuring response time to bilateral orbicularis contraction (normal values, approximately 30 msec; ipsilateral and contralateral latency differences less than 5 msec). Prolongation of the blink latency may be seen in compressive lesions of the trigeminal nerve, acoustic neuroma, Guillain-Barre syndrome, hereditary motor and sensory neuropathy type I, diabetes, and intrinsic brain stem processes. In contrast, clinical utility of trigeminal somatosensory evoked potentials is limited by technical problems of reliability and reproducibility.

Fluid and Tissue Analysis. Laboratory studies may reveal evidence of vasculopathies like systemic lupus erythematosus or Sjoren's syndrome. White blood count elevations may suggest infections, and eosinophilia may indicate fungal disease. Altered glucose tolerance is seen with diabetes mellitus. Vitamin levels may indicate deficiencies of thiamine, folate, B₁₂, pyridoxine, or vitamin A.

Cerebrospinal Fluid Evaluation. If infectious, neoplastic (especially meningeal carcinomatosis), or inflammatory (sarcoidosis) etiologies are suspected, cerebrospinal fluid (CSF) evaluation is warranted. CSF glucose level, protein level, differential white and red blood cell counts, and cytology tests are compulsory, whereas other studies to isolate mycobacterial, fungal, rickettsial, parasitic, and viral pathogens should be addressed on an individual basis. In the immunocompromised person (e.g., one with cancer, acquired immunodeficiency syndrome [AIDS], and organ transplant), opportunistic pathogens causing infections such as cryptococcosis, candidiasis, mucormycosis, toxoplasmosis, and cytomegalovirus need to be seriously considered in the setting of any acute or subacute neurological presentation.

CLINICAL SYNDROMES

The trigeminal nerve may be involved in various neurological conditions and, in most instances, the patient complains of sensory loss, paresthesias, pain, or difficulty eating (for complete review, see reference ^[16]) ([Table 10-3](#)).

Supranuclear Syndromes

Facial sensory loss may occur in the setting of lesions involving the trigeminothalamic pathways, corona radiata or internal capsule white matter projections from the VPM nucleus of the thalamus to primary sensory cortex, or within sensory cortex itself. Specific pathological processes affecting these pathways include ischemia, hemorrhage, neoplasm, and demyelinating diseases. All result in contralateral hemifacial and hemibody numbness. In seizures, facial tingling often occurs in association with hand numbness and suggests a lesion in the postcentral gyrus. In the cheiro-oral syndrome, ipsilateral numbness in the hand and at the corner of the mouth reflects an insult, typically vascular, at adjoining portions of the ventroposterolateral and VPM nuclei of the thalamus where the anatomical distributions of these regions are directly adjacent to one another. In contrast, a persistent deep, aching, poorly localized facial pain has been reported in patients with thalamic lesions including tumors, infarctions, and multiple sclerosis affecting the VPM nucleus. Often this syndrome is associated with small vessel infarctions of the thalamogeniculate artery. ^[20] The syndrome begins with transient facial hemisensory loss but then evolves into painful facial dysesthesias. Migraine headache may be misdiagnosed as trigeminal neuralgia, especially if pain is unilateral, although the duration of most headaches makes this distinction straightforward.

Nuclear (Brain Stem) Syndromes

Trauma, ischemic injury, and tumors may affect the trigeminal system within the brain stem. These syndromes are characterized by sensory paresthesias, numbness, or pain in the distribution of the V1 to V3, along with combinations of cranial nerve palsies and distinct sensory and cerebellar system signs. Reflecting the lateral circumferential

TABLE 10-3 -- SELECTED ETIOLOGIES ASSOCIATED WITH TRIGEMINAL NERVE DISORDERS

Etiological Category	Selected Specific Etiologies	Chapter
STRUCTURAL DISORDERS		
Developmental	Brain stem vascular loop, syringobulbia	28
Degenerative and compressive	Paget's disease	29
HEREDITARY AND DEGENERATIVE DISORDERS		
Chromosomal abnormalities and neurocutaneous disorders	Hereditary sensorimotor neuropathy 1 Neurofibromatosis (schwannoma)	32
Degenerative motor, sensory, and autonomic disorders	Amyotrophic lateral sclerosis	36
ACQUIRED METABOLIC AND NUTRITIONAL DISORDERS		
Endogenous metabolic disorders	Diabetes	38
Exogenous disorders: Toxins and illicit drugs	Trichloroethylene, tnehlroacetie acid	39
Nutritional deficiencies., and syndromes associated with alcoholism	Thiamine, folate, B ₁₂ , pyndoxine, pantothenie acid, vitamin A deficieny	40
INFECTIOUS DISORDERS		
Viral infections	Herpes zoster, unknown	41
Non-viral infections	Bacterial, tuberculous meningitis, brain abscess, Gradenigos syndrome,leprosy, cavernous sinus thrombosis	43
HIV and AIDS	Opportunistic infections abscesses, herpes zoster	44
NEUROVASCULAR DISORDERS	Stroke, hemorrhage, aneurysm	45
NEOPLASTIC DISORDERS		
Primary neurological tumors	Glial tumors, meningioma, schwannoma	46
Metastatic neoplasms and paraneoplastic syndromes	Lung, breast, lymphoma, carcinomatous meningitis	47
DEMYELINATING DISORDERS		
Demyelinating disorders of the central nervous system	Multiple sele0rosis, acute demyelinating encephalomyelitis	48
Demyelinating disorders of the peripheral nervous system	Guillain-Barre syndrome, chronic inflammatory demyelinating polyneuropathy	49
AUTOIMMUNE AND INFLAMMATORY DISORDERS	Tolosa-Hunt syndrome, sarcoidosis, lupus, orbital pseudotumor	50
TRAUMATIC DISORDERS	Carotid cavernous fistula, cavernous sinus thrombosis, maxillary/ mandibular injury	51
EPILEPSY	Focal seizures	52
HEADACHE AND FACIAL PAIN	Raeders neuralgia, cluster headache	53
DRUG-INDUCED AND IATROGENIC NEUROLOGICAL DISORDERS	Orbital, facial, dental surgery	55

arterial supply to the lateral pons, ischemic lesions of the pontine tegmentum are often associated with dissociation of sensory modalities such that pain and temperature perception are dramatically diminished, whereas midline fiber tracts carrying light touch and deep pressure are spared. Pain similar to that of trigeminal neuralgia is rare. The lateral medullary or Wallenberg's syndrome ^[21] typically results from ischemic infarction of either the vertebral or posterior inferior cerebellar arteries, which provide vascular supply to the lateral medulla ([Fig. 10-5](#)). Sensory loss may affect the entire ipsilateral face. Sensory loss results from damage to the spinal trigeminal tract, its nucleus, and rostral trigeminothalamic projections. Interestingly, some patients with Wallenberg's syndrome report facial pain or headache before neurological deficit. ^[22]

Persistent ipsilateral pain may be present in up to 50 percent of patients with a lateral medullary syndrome ^[21] typically in V1 or V2 distribution, which in some persists for months to years after the acute insult. The pattern of facial analgesia in patients with lateral medullary syndrome typically adheres to the cutaneous distribution of V1 to V3, although an onion-skin or radicular pattern of sensory loss has been described in which lesions affecting more rostral portions of the trigeminal sensory nuclei result in sensory loss in the nose and lips, whereas rostral and caudal lesions yield sensory loss in the cheeks and forehead. Associated neurological symptoms with Wallenberg's syndrome include ipsilateral Horner's syndrome, ataxia, and difficulty swallowing, with pain and temperature loss on the contralateral body (due to damage to the ascending spinothalamic tract). Lesions affecting the spinothalamic and spinal trigeminal tracts in the lateral medulla typically result in this crossed pattern of hemifacial and hemibody sensory loss (ipsilateral facial numbness with contralateral arm and leg numbness). Lesions involving more medial medullary regions result in unilateral facial and bodily sensory deficits contralateral to the lesion. ^[23] Medial medullary lesions presumably injure the crossed ventral trigeminothalamic tract.

Other pathological processes within the brain stem can produce trigeminal dysfunction. Tumors, hemorrhage (hypertensive, ruptured arteriovenous malformation), infarctions, demyelinating disease such as multiple sclerosis, infections such as brain stem abscesses and brain stem encephalitis, and inflammatory conditions such as tuberculosis or sarcoidosis affecting the lateral pons or midbrain may result in ipsilateral or contralateral facial sensory loss, respectively, as well as severe paroxysmal hemifacial pain. Facial weakness, muscle atrophy, difficulty chewing, and diminished jaw jerk reflex may be identified in amyotrophic lateral sclerosis as

well as other motor neuron disorders damaging the motor trigeminal nuclei. Traumatic or congenital syringobulbia can affect the sensory and motor portions of the trigeminal system within the midbrain, pons, or medulla.

Figure 10-5 Left-sided trigeminal nerve involvement from sarcoid involving the skull base and meninges. Weakness of the pterygoids and masseters manifested as ipsilateral (leftward) jaw deviation and weakness of jaw opening.

Preganglionic Syndromes

Trigeminal nerve compression can occur in the area between the brain stem nuclei and the gasserian ganglion, specifically within the brain stem itself or in the cerebellopontine angle. Patients can present with reduced facial sensation in association with poor hearing, nystagmus, limb ataxia, facial weakness, and a diminished corneal reflex. Common lesions in this area include tumors^[24] such as acoustic or trigeminal neuromas,^[25] meningiomas, metastatic cancers, carcinomatous meningitis, and invasive nasopharyngeal carcinomas, inflammatory disorders such as sarcoidosis, or infectious processes such as mycobacterial (especially tuberculosis), fungal (candidal, histoplasmosis), parasitic, and bacterial organisms. Traumatic injury to this region may also result in sensory loss or motor deficits. Extensive brain stem and cerebellar signs may be evident from lesions in the cerebellopontine angle.

Gasserian Ganglion Syndromes

Numerous pathological processes occurring within the middle cranial fossa can result in trigeminal dysfunction by affecting the gasserian ganglion. In children, osteitis of the petrous apex following suppurative otitis media or mastoiditis, which leads to inflammation and infection affecting the trigeminal ganglion, may result in Gradenigo's syndrome. The syndrome is characterized by facial pain, headache, or sensory loss and a sixth cranial nerve palsy, facial palsy (due to seventh nerve involvement), and deafness (due to eighth nerve involvement). The pain is described as boring or throbbing, worse at night. Pain is aggravated by jaw or ear movement. It has been hypothesized that some of the dysesthetic sensation patients experience before or during episodes of Bell's palsy may reflect involvement of the trigeminal ganglion or nuclei in the brain stem.^[26] A benign, self-limited trigeminal sensory neuropathy has been reported in children 7 to 21 days following a nonspecific febrile illness or upper respiratory infection.^[27] Like other postinfectious cranial neuropathies involving the abducens, glossopharyngeal, or hypoglossal nerves, laboratory evaluations are normal or show only a mild CSF pleocytosis. Symptoms resolve usually within 1 to 2 months. It is unknown whether these postinfectious neuropathies result from peripheral nerve, ganglion, or brain stem pathology.

Trigeminal sensory neuropathy may occur in association with connective tissue disorders such as mixed connective tissue disease, systemic sclerosis, Sjogren's syndrome, and systemic lupus erythematosus.^[28] Symptoms including facial dysesthesias, numbness, and loss of taste may be the presenting complaints.^[30] In such cases, based on radiographical and electrophysiological testing, involvement of the gasserian ganglion is likely. Various infectious processes within the middle cranial fossa including syphilis, tuberculosis, and bacterial meningitis can affect the gasserian ganglion by inflammation, ischemia, or direct compression. Similarly, neoplasms in this region (meningiomas, schwannomas) can compress the ganglion within Meckel's cave.

Syndromes of Lesions Involving Peripheral Branches of Cranial Nerve V

Another disorder similar to both cluster headache and trigeminal neuralgia is Raeder's paratrigeminal neuralgia.^[31] This syndrome is characterized by intense pain in the distribution of V1, lacrimation, conjunctival injection, rhinorrhea, and ipsilateral pupillary mydriasis (Horner's syndrome). This syndrome may be idiopathic or may result from pathology affecting the ipsilateral carotid artery or structures within the middle cranial fossa. In the idiopathic form, patients tend to be middle-aged or elderly males who develop a severe throbbing orbital or retro-orbital headache upon awakening. Additional signs such as lacrimation, conjunctival injection, and oculosympathetic dysfunction develop later. Therapy includes ergotamine tartrate, methysergide, and systemic corticosteroids. In both cluster headache and Raeder's syndrome, the pain in V1, duration of attacks, and associated features help distinguish the condition from trigeminal neuralgia. Raeder's paratrigeminal neuralgia may not actually represent a distinct clinical entity because those patients with an isolated Horner's syndrome likely have cluster headaches, whereas those with ocular motility impairment have a cavernous sinus process until proven otherwise. Furthermore, it is important to consider the possibility of a carotid dissection in a patient who presents with an isolated painful Horner's syndrome.

The skull base and exit points of V1 to V3 (i.e., at the superior orbital fissure, foramen ovale, or foramen rotundum) can be diseased and can result in focal sensory or sensorimotor trigeminal dysfunction. For example, acute or resolved bacterial, tuberculous, carcinomatous, or granulomatous

(sarcoid) meningitis can result in inflammation, infiltration, or congestion of the basal meninges through which V1 to V3 nerve roots exit the skull. In Paget's disease, narrowing of the skull foramina can also lead to cranial (trigeminal) neuropathy. If V3 is affected, motor and sensory manifestations may be identified (see [Fig. 10-5](#)) in one or more branches of the trigeminal system.

Various pathological processes including tumors, aneurysms, infarctions, trauma, and infections can damage the ophthalmic division of the trigeminal nerve.^[32] Superior orbital fissure involvement is characterized by numbness, paresthesias, or pain in the distribution of V1 and within the orbit, Horner's syndrome, and ophthalmoparesis. Involvement of the optic nerve suggests extension into the orbital apex. If, on funduscopic examination, there is evidence of venous congestion, cavernous sinus thrombosis is likely. Cavernous sinus thrombosis is almost always caused by spread of an infection from the face, nose, or mouth. Patients may initially complain of fever, malaise, and frontal headache, but they subsequently develop proptosis, ptosis, ophthalmoparesis, and vasocongestion. Initially the CSF test result may be normal, but findings characteristic of meningitis may occur if treatment is delayed. Mortality is linked to spread of bacteria to the meninges, which warrants early and intensive antibiotic therapy. In contrast, carotid-cavernous sinus arteriovenous fistulae may be congenital in children but in adults are more commonly the result of trauma. Carotid-cavernous sinus arteriovenous fistulae also occur in women during pregnancy or at childbirth. On examination, pulsating proptosis, conjunctival erythema, ophthalmoparesis, and a bruit over the globe may be found. Diagnosis by CT or angiography is usual, and treatment with neurosurgical or invasive radiological approaches is warranted.

In addition, there are several syndromes involving the peripheral trigeminal branches. Cluster headache appears as multiple attacks of severe head or facial pain and may be confused with trigeminal neuralgia.^[33] Cluster headache typically occurs in middle-age men and is more prominent at night. Attacks are of short duration; they occur in clusters that recur with variable frequency. Unlike trigeminal neuralgia, trigger points are not a characteristic feature. The associated symptoms of cluster headache such as lacrimation, conjunctival injection, sweating, ipsilateral nasal blockage, miosis, and ptosis are quite distinct from symptoms of trigeminal neuralgia. Studies have suggested, however, that disruption of normal autoregulatory trigeminovascular innervation may be responsible for cluster headache.^[33]

Crescendo orbital pain or frontal headache can herald impending internal carotid artery occlusion presumably from irritation or ischemia to peripheral trigeminal branches. Similarly, a cluster of symptoms including facial, orbital, or neck pain or facial paresthesias in association with an ipsilateral Horner's syndrome may reflect dissection of the cervical portion of the internal carotid artery.^[34] These symptoms may also be prodromal. Excruciating pain in the supraorbital headache in association with a pupil involving third nerve palsy is almost pathognomonic for an intracranial (especially posterior communicating artery) aneurysm. Ipsilateral orbital or ocular pain has also been reported in association with posterior cerebral artery occlusion, which may reflect ischemic damage to regions of the tentorium adjacent to the occipital lobes that are innervated by V1.

Circumscribed facial paresthesias in V1 to V3 distributions have been identified in patients with diabetes mellitus, Guillain-Barre syndrome, hereditary sensory motor neuropathy I,^[35] chronic inflammatory demyelinating polyneuropathy, nutritional deficiencies, and other peripheral neuropathological disorders. Vascular infarction of the nerve branches, for example, in vasculitis can also result in sensory loss. Compressive or infiltrative processes affecting any of the peripheral trigeminal branches result in focal, well circumscribed sensory loss or paresthesias (see numb chin syndrome, later). Dental trauma and exposure to various toxic substances such as trichloroethylene and trichloroacetic acid can also result in circumscribed facial sensory loss or paresthesias in the trigeminal distribution.

The temporomandibular joint (TMJ) syndrome refers to recurrent pain in the region of the jaw, ear, occiput, and supraorbital regions, which is believed to result from degeneration or malocclusion of the TMJ. Erosion of the bony surfaces within the glenoid fossa may cause irritation of several adjacent nerves including the auriculotemporal and chorda tympani trigeminal nerves. Patients may report an increase in pain in the evening and pain referred to the oropharynx. Rarely, a

sensation of hearing dullness or auricular congestion may be noted. The TMJ syndrome may result from local trauma, neoplastic invasion, ankylosis, or inflammation, although some cases reflect nonorganic or ill-defined joint pain syndromes. On examination, the TMJ may appear lax and may be painful to passive motion or palpation. Correction of an underlying malocclusion may be curative, but other measures include analgesics, jaw exercises, soft diet, and tricyclic antidepressants. [36]

The numb chin syndrome (mental neuropathy) often reflects a bony lesion affecting the mental foramen through which V3 passes to innervate the chin and mandible. [37], [38] Patients often report numbness or pain on one or both sides of the chin, which may extend to the lip or submandibular region. Frequent causes include granulomatous diseases such as histiocytosis X; primary bony malignancies such as osteosarcoma, fibrosarcoma, and plasmacytoma; and metastatic lesions from lung, breast, and prostate carcinoma [39] as well as lymphoma (especially Burkitt's lymphoma). Development of a numb chin in a patient with cancer in remission may indicate relapse. Nonmalignant etiologies include collagen vascular disorders, trauma, periodontal disease, benign bony cyst, focal idiopathic osteolysis (Gorham's disease), [40] and sickle cell disease. A variant of the numb chin syndrome is the numb cheek syndrome, which results from a bony lesion affecting the infraorbital foramen or the maxillary sinus and trigeminal branch V2. [41] On rare occasions, focal motor weakness affecting the masticatory muscles results from damage to motor branches of V3.

Evaluation of patients with focal sensory loss over the chin or malar region begins with a full, careful sensory examination to determine whether the sensory loss results from a distal or proximal trigeminal lesion. Specifically, mental neuropathy causes focal sensory loss over the lower lip and chin, whereas more proximal V3 dysfunction results in more widespread sensory disturbance and may be associated with dysfunction of other cranial nerves. Motor

involvement is characterized by ipsilateral jaw deviation, flaccidity of the floor of the mouth, and wasting of the ipsilateral temporalis muscle. Weakness of the tensor tympani results in difficulty detecting low-pitched sounds. Careful examination of the oropharynx, dentition, and skin over the chin should also be performed because erythema and edema may be present over a focal bony lesion. Plain radiographs of the mandible may be very useful in establishing the diagnosis because they may be revealing in about 50 percent of cases. If the result is abnormal, bone scan and biopsy of the lesion itself may be indicated. A search for occult malignancy employing CT of the chest and abdomen, prostate-specific antigen (in men), and bone marrow biopsy may be necessary. If radiographs are normal, evaluation of the brain and cranial nerves by MRI (with contrast) and lumbar puncture for cytology is indicated because a brain stem lesion or carcinomatous meningitis may cause focal trigeminal dysfunction.

Corneal hypesthesia and orbital pain may result from local corneal dystrophies or reflect damage to branches of V1, which innervate these structures. Viral (herpetic) infections, diabetes, leprosy, and vitamin A deficiency can result in unilateral or bilateral corneal hypesthesia. In addition, the pain associated with anterior uveitis, acute angle-closure glaucoma, and optic neuritis is mediated through V1 orbital sensory fibers. Clinically, a diminished corneal reflex may be detected. In the orbit, inflammatory conditions such as cellulitis, pseudotumor, or neoplasms (lymphoma, metastatic tumors) may present as orbital pain in association with ophthalmoparesis. Trigeminal involvement in orbital pseudotumor is uncommon. Infections within the orbit including those from bacterial and fungal pathogens such as *Streptococcus* and *Mucor*, respectively, can also result in a painful ophthalmoplegia. The Tolosa-Hunt syndrome (painful ophthalmoplegia) is characterized by steady, unremitting retro- and supraorbital pain (in the cutaneous V1 distribution) in association with paresis of nerves III, IV, and VI, and a diminished corneal reflex (for review, see reference 42). Sensory loss and pain in V2 distribution may also occur. Less frequently, the optic nerve and oculosympathetic fibers may be affected as well. Symptoms may persist for weeks to months. Pathologically, a low-grade, granulomatous, noninfectious, inflammatory process adjacent to the cavernous sinus or within the superior orbital fissure has been identified consisting of lymphocytes and plasma cells. The Tolosa-Hunt syndrome typically responds dramatically to systemic corticosteroids, although symptoms may recur over months to years. Spontaneous remissions have also been reported.

Other causes of decreased sensation within the globe and conjunctiva are orbital surgery or orbital trauma, which affect nasociliary and frontal branches of V1. In herpes zoster ophthalmicus (Fig. 10-6), inflammation and vesicular eruption involving all branches of V1 as well as small arterioles within the gasserian ganglion may result in excruciating, lancinating pain in the periorbital region. [43] Symptoms of herpes zoster ophthalmicus typically begin 2 to 3 days before the appearance of vesicles and may diminish after 2 to 3 weeks. Hypalgesia and paresthesias may be noted during and after lesions heal. Pain may persist after the rash is gone only to evolve into post-herpetic neuralgia. This syndrome consists of burning, lancinating, aching pain in the V1 territory often in association with paresthesias and hyperpathia. As in trigeminal neuralgia, trigger points can evoke pain in response to cutaneous stimuli. [44], [45]

Atypical facial pain can also reflect trigeminal branch disorders. [46], [47] Some patients experience persistent facial pain that is not confined to the distribution of V1 to V3

Figure 10-6 Acute (A) and resolving (B) herpes zoster (arrows). In A, there is selective involvement of the nasociliary branch of the trigeminal nerve.

and that differs in character from classic trigeminal neuralgia. Many of these atypical facial pain syndromes including Charlin's nasociliary neuralgia, Sluder's pterygopalatine ganglion syndrome, and Vail's vidian neuralgia, all involve portions of the trigeminal nerve. They are also characterized by numerous autonomic symptoms such as lacrimation, conjunctival injection, altered sweating, salivation, facial flushing, and nasal congestion, which are believed to result from involvement of the autonomic ganglia (ciliary, pterygopalatine) in the face. These atypical facial neuralgias are additionally characterized by nondermatomal localization of pain; bilateral symptoms; continual instead of paroxysmal pain; lack of clear trigger zones; and deep, poorly localized pain. [48] Appropriate therapy for these debilitating and often refractory disorders is often unsatisfactory and has consisted of surgical ablation of peripheral pain fibers, peripheral or sympathetic nerve blockade, transcutaneous electrical stimulation, tricyclic antidepressants, and narcotic and non-narcotic analgesics.

Trigeminal Neuralgia (Tic Douloureux)

Painful neuralgia of the trigeminal nerve results in the clinical syndrome of tic douloureux or trigeminal neuralgia. [49] The paroxysmal disorder presents as excruciating, lancinating painful spasms affecting one or more divisions of CN V. Trigeminal neuralgia is unilateral and usually affects the second or third division of CN V (3rd>2nd>1st). In less than 5 percent of cases V1 is affected, whereas V3 is affected in more than 70 percent of cases. [50] Rarely, pain may occur bilaterally, although simultaneous bilateral spasms are quite atypical. The pain occurs spontaneously as brief lightning-like spasms lasting seconds to minutes, or pain may be precipitated by cutaneous or auditory stimuli. In many instances, there is a demonstrable trigger point that can reproduce pain, and some patients may be unable to chew, eat, drink, shave, or brush their teeth for fear of triggering a spasm. [51] Paroxysms recur throughout the day and night. Between attacks, there are no symptoms, but the patient is usually anxious about having another attack. Objective sensory or motor deficits are not a feature, although a subjective report of hypesthesias over the face may be reported. Often there is a temporal summation of stimuli necessary to invoke a response. The pain is reported as lancinating, stabbing, searing, burning, or electrical, and the intensity is such that the patient often winces or grimaces in a tic-like fashion. Trigeminal neuralgia affects approximately 155 people per million population and has a slight female predominance (3:2). It is the most common neuralgia, and its incidence peaks in middle age. The age of onset is important, however, because the appearance of trigeminal neuralgia in a young patient should raise the suspicion of demyelinating disease such as multiple sclerosis [52], [53] or another structural brain stem disorder. [54], [55]

Pathological analyses of trigeminal biopsy specimens taken during vascular decompression have described focal demyelination but no inflammatory cells. [56], [57] Abnormal ephaptic nonsynaptic neurotransmission between demyelinated trigeminal axons within the nerve root, ganglion, or spinal trigeminal nucleus may provide the physiological substrate for the paroxysmal pain characteristic of trigeminal neuralgia, especially if initiated by cutaneous stimuli.

On physical examination, objective neurological deficits are not present. The patient, however, may appear emaciated if, for example, a trigger point is initiated during chewing, or males may appear disheveled if shaving induces a spasm. Laboratory study results are normal. Careful inspection and palpation of the teeth, gums, nares, nasal sinuses, palate, and pharynx should be performed because disease processes such as infections or inflammatory disorders in these regions can cause significant facial pain. MRI of patients with trigeminal neuralgia may be helpful in identifying other etiologies or associated disorders.

The diagnosis of tic douloureux can usually be made by history alone, but the disorder must be distinguished from other causes of facial pain syndromes such as glossopharyngeal neuralgia, which can be confused with tic douloureux that involves the third division of CNV. Herpes zoster or post-herpetic neuralgia may also provide some diagnostic confusion. Tumors or vascular lesions of the cerebellopontine angle [58] or within the trigeminal ganglion itself may induce pain similar to that

of trigeminal neuralgia, although these disorders can be distinguished by findings of trigeminal sensory loss, atrophy of facial masticatory muscles, diminished corneal reflexes, and involvement of other adjacent brain stem structures that are not characteristic of trigeminal neuralgia. The nature of the pain in these cases is also distinct from that of trigeminal neuralgia in that it is often continuous and unremitting rather than episodic.

GENERAL MANAGEMENT GOALS

In approaching any patient with symptoms referable to the trigeminal system, it is necessary to localize the pathological process; identify associated symptoms; determine prognosis; and provide relief from pain, discomfort, and functional disability. Regardless of etiology, a detailed and directed neurological examination most often yields the correct anatomical localization.

Once determined that the likely etiology is, for example, within the brain, brain stem, or cranial vault, a rational first step is MRI of the brain with and without gadolinium contrast. Fine cuts may be obtained through the orbits, using fat saturation sequences to diminish intraorbital fat artifact. Similarly, dedicated coronal images may be taken to focus on the cavernous sinus. Once appropriate neuro-imaging has been performed, other diagnostic studies such as lumbar puncture may be indicated, especially if infectious or carcinomatous processes are suspected. Electrophysiologic studies such as somatosensory evoked potentials may be somewhat helpful in peripheral trigeminal neuropathies. In either central or peripheral causes, neurosurgical consultation may be warranted, especially when there is compression of the trigeminal nerve roots or branches.

Prompt relief of the severe pain associated with this disorder must not be neglected. Both medical and surgical approaches should be considered when appropriate.

Over

10

the short term, nonsteroidal anti-inflammatory agents and narcotics may provide symptomatic relief. In patients with refractory neuropathic pain, treatment with tricyclic compounds such as amitriptyline, nortriptyline, or carbamazepine may be indicated.

HISTORY AND DEFINITIONS

The first significant contribution to facial nerve anatomy was the description of its course through the temporal bone by Gabriel Fallopius in 1550. The British neurologist Sir Charles Bell made the next important discovery in 1829, when he described that the sensory innervation to the face was provided by cranial nerve V (CN V), whereas the motor function was supplied by cranial nerve VII (CN VII).^[1] Over the years, much more has been learned about the anatomy and function of the facial nerve.

The facial nerve has a mixed function, primarily motor, but also sensory and parasympathetic. Consisting of approximately 10,000 fibers, CN VII has two segments, a skeletal motor root (contributing about 70 percent of the axons) and the nervus intermedius, which carries the sensory and autonomic fibers (the remaining 30 percent).^[2] A lesion may involve the facial nerve anywhere along its course, and based upon specific signs and symptoms, the location of the pathology can be deduced. A distinction can be made between central and peripheral facial weakness. Because of bilateral supranuclear innervation of the upper facial musculature, a central palsy spares forehead and brow motion. A peripheral palsy, however, involves both upper and lower facial muscles. In addition, with a central palsy, there may be preservation of emotional or involuntary facial motion, which is not seen with a peripheral paralysis.^[3], ^[4]

The most common cause of facial nerve dysfunction is Bell's palsy, an idiopathic peripheral facial weakness. Named after Sir Charles Bell, Bell's palsy is a diagnosis of exclusion, applied only after other causes of facial paralysis are ruled out.

[PreviousNext](#)

CLINICAL HISTORY

Many aspects of the patient's history help the clinician determine the anatomical site of lesion for a facial nerve disorder, as well as lead to the proper diagnosis. Some basic historical information to gather includes the following:

Temporal presentation: Sudden onset suggests an inflammatory or vascular etiology (e.g., Bell's palsy or stroke), whereas a slowly progressive palsy suggests a neoplastic process, especially if there are episodes of facial twitching (e.g., facial nerve neuroma). The length of time with the paralysis and any spontaneous improvement should be noted, because Bell's palsy should improve within 6 months, whereas palsy caused by a tumor does not. In patients with a history of trauma or surgery, a palsy occurring immediately afterward suggests transection of the nerve (which requires prompt surgical evaluation), whereas a delayed onset usually implies edema of the nerve (which usually improves with time). If there are recurrent episodes of palsy on the same side, one should consider tumor as the etiology; however, if the recurrence is contralateral, one should consider Bell's palsy.

Extent of involvement: It is important to assess the amount of facial palsy present initially, so that changes

over time can be documented. The exact areas of weakness should be noted, because sparing of forehead motion or emotional facial expression suggests a central etiology, whereas palsy of both the upper and lower face suggests a peripheral lesion. If only one or two distal branches of the facial nerve are affected, possible etiologies include parotid gland tumors, facial surgery, or facial trauma. Bilateral involvement, which are called facial diplegia, can be found in Lyme disease, Mobius' syndrome, Bell's palsy, and Guillain-Barre(c) syndrome. ¹³, ¹⁴

Precipitating elements: Alcoholism, diabetes mellitus, autoimmune diseases, malignancy, hypertension, sarcoidosis, acute porphyria, hyperthyroidism, and pregnancy have been associated with facial palsy. In addition, many infectious diseases can cause CN VII palsy, such as tuberculosis, mononucleosis, poliomyelitis, syphilis, and human immunodeficiency virus. A recent ear infection, with or without otorrhea, is suspicious for an otological infection or cholesteatoma as the possible etiology. An upper respiratory infection commonly precedes Bell's palsy. Facial palsy has been seen after immunizations for polio and rabies and after exposure to toxins like arsenic, carbon monoxide, and ethylene glycol. A family history of facial nerve palsy is seen with Melkersson-Rosenthal syndrome and occasionally with Bell's palsy. Maternal infections (e.g., rubella), drugs used during pregnancy (e.g., thalidomide), and a difficult delivery, especially if forceps were used, have been associated with facial palsy at birth. ¹⁵

Associated features: A history of other neurological disorders or any evidence of neurological symptoms (e.g., headache, hemiplegia, loss of sensation, cranial nerve dysfunction, changes in balance or tendency to veer toward the same side) should be elicited, while seeking evidence of central pathology. In addition, it is imperative to check for signs and symptoms referable to the ear (e.g., otalgia, otorrhea, hypersensitivity to sound, hearing loss, tinnitus, or vertigo). To help localize the site of lesion, one should note whether other functions of CN VII are involved in patients with facial weakness (e.g., change in tearing, change in taste, reduced salivation). A history of vesicles in the ear, especially if there are CN VIII symptoms, suggests Ramsay Hunt syndrome. A history of tick bites and rash (erythema chronicum migrans) suggests Lyme disease. Facial swelling and fissuring of the tongue is seen with Melkersson-Rosenthal syndrome.

ANATOMY OF CRANIAL NERVE VII (Table 11-1)

Motor Division

The motor root contains myelinated special visceral efferent fibers for the muscles of facial expression (including the buccinator and the platysma), muscles of the external ear, stapedius, stylohyoid, and posterior belly of the digastric.

UPPER MOTOR NEURON: SUPRANUCLEAR CONTROL

The cortical projections (corona radiata) originate from pyramidal neurons located in the lower third of the precentral gyrus of the frontal motor cortex. The cortical representation of the face, from uppermost cortex to lower, begins with the forehead, followed by the periorbital muscles, midface, and perioral muscles. Motor cortex for the tongue is next in line. These fibers join the corticobulbar tract and pass caudally within the posterior aspect of the internal capsule near its genu. When the fibers reach the midbrain, they join the medial third of the cerebral peduncle. Continuing through the basal portion of the pons with the pyramidal tract, most fibers cross in the caudal pons to reach the contralateral facial motor nucleus. Some fibers descend lower than the nucleus, cross to the other side, and then ascend to that side's nucleus (recurrent bundle of Dejerine). Other fibers, however, never decussate and synapse in the ipsilateral facial nucleus. The cortical fibers for the upper face (i.e., the frontalis, upper portion of the orbicularis oculi, and the corrugator superciliarum) project to both the ipsilateral and contralateral facial nucleus. The supranuclear fibers for the lower facial muscles, however, travel only to the contralateral facial nucleus. This anatomical fact explains how unilateral supranuclear lesions characteristically spare the function of the upper face.

Emotional control of facial motion is provided by extrapyramidal input, which travels within the reticular formation from the frontal areas, thalamus, and globus pallidus to the facial motor nucleus. If a supranuclear lesion spares this input, emotional facial expressions (e.g., surprise or pain) are generally preserved despite facial palsy. Conversely, lesions of the midbrain or thalamus can cause contralateral palsy of emotional facial expressions with intact voluntary motion. In addition, lesions of the globus pallidus or its projections to the facial nucleus can cause facial bradykinesia. Despite the resulting masklike facies, some facial motion is detectable, originating from the cortical volitional and other extrapyramidal emotional pathways. [1], [2]

PONTINE NUCLEUS

The motor nucleus of the facial nerve lies within the reticular formation of the lower third of the pons, bordered dorsally by the trigeminal nucleus and ventromedially by the superior olivary nucleus. Within the motor nucleus, four cell groups have been described that innervate specific muscles. The dorsomedial cell group sends fibers to the auricular and occipital muscles via the posterior auricular nerve. The ventromedial cell group gives rise to the cervical branch, which innervates the platysma. Fibers for the stapedius muscle and the temporal and zygomatic branches originate from the intermediate cell group. The lateral cell group contributes to the buccal and possibly to the mandibular branches. The exact cell group innervating the stylohyoid and posterior belly of the digastric is uncertain, but some feel that the origin may be the dorsal or accessory facial nucleus. [3], [4]

The special visceral efferent fibers emerge from the dorsal side of the facial motor nucleus and travel dorsomedially under the floor of the fourth ventricle. In this location, the fibers are called the *funiculus teres*, and the elevation of this bundle within the upper half of the floor of the ventricle creates the eminentia teres. The motor root fibers extend medially and cephalad towards the abducens

TABLE 11-1 -- CLINICO-ANATOMICAL CORRELATION OF DISORDERS OF CRANIAL NERVE VII

Anatomical Site of Damage	CN VII Finding	Other Neurological and Medical Findings	Common Etiologies	Comments
Motor cortex	Palsy of lower face (upper face spared); tone and emotional movements intact; tearing, salivation, taste intact	Hemiparesis (ipsilateral) Tongue weakness (ipsilateral) Frontal lobe signs	Vascular lesion of motor cortex or internal capsule on the side contralateral to the weakness	Facial weakness rarely seen as sole finding. Spasticity and hyperreflexia are found
Pontine nucleus	Facial palsy on same side as the lesion (upper and lower); tearing, salivation, taste intact	Hemiparesis (contralateral) Abducens palsy (ipsilateral)	Infarction (Millard-Gubler and Foville syndromes), pontine glioma, multiple sclerosis, thalidomide toxicity, Mobius' syndrome	The lesion is below the facial decussation and above the corticospinal decussation. If congenital, may see anomalies of the ear or jaw
Cerebellopontine angle	Facial palsy on same side as the lesion (upper and lower); tearing, salivation, taste may be abnormal	Decreased hearing, increased tinnitus, vestibular impairment (CN VIII); facial numbness (CN V); ataxia incoordination (cerebellum)	Acoustic neuroma, meningioma, facial nerve neuroma, cholesteatoma	CN VIII is usually involved, and its symptoms are usually the chief complaint, especially unilateral hearing loss. As lesions enlarge, other structures are involved
Internal auditory meatus (meatal segment)	Facial palsy on same side as the lesion (upper and lower); tearing, salivation, taste probably involved	Decreased hearing, increased tinnitus, vestibular impairment (CN VIII)	Intracanalicular neuroma (acoustic or facial)	Signs and symptoms from CN VII and CN VIII only
Facial canal: labyrinthine segment	Facial palsy on same side as the lesion (upper and lower); tearing, salivation, taste probably involved	Decreased hearing, increased tinnitus, vestibular impairment (cochlea or vestibule involvement)	Bell's palsy, Ramsay Hunt syndrome, temporal bone fracture, hemangioma	When the facial canal is involved, the cochlea and/or the vestibular organs may be involved. Hearing loss can be conductive or sensorineural
Facial canal: tympanic segment	Facial palsy on same side as the lesion (upper and lower); salivation, taste probably involved (tearing spared)	Decreased hearing, increased tinnitus, vestibular impairment	Bell's palsy, otitis media, cholesteatoma, temporal bone fracture	If there was trauma, check for CSF otorrhea, blood in ear canal, Battle's sign, impaired consciousness
Facial canal: mastoid segment	Facial palsy on same side as the lesion (upper and lower); salivation, taste may be involved (tearing spared)	Decreased hearing, increased tinnitus, vestibular impairment	Bell's palsy, otitis media, cholesteatoma, glomus tumor	Lesions before the chorda tympani have impaired salivation and taste
Stylomastoid foramen	Facial palsy on same side as the lesion (upper and lower); tearing, salivation, taste not involved	Evidence of facial trauma, parotid or pharyngeal mass, uveitis	Facial laceration, fracture, or surgery; parotid tumors; sarcoidosis	Sparing of peripheral branches may be seen

CSF, cerebrospinal fluid.

nucleus. When the fibers reach the area below the medial part of the abducens nucleus, they turn laterally to cross the front of the abducens nucleus and continue to curve around its lateral border. After looping around the abducens nucleus, the fibers travel caudally between the medial border of the trigeminal nucleus and the lateral edge of the facial motor nucleus. The motor fibers exit the caudolateral border of the pons in the cerebellopontine angle medial to CN VIII. The medial-to-lateral loop around the abducens nucleus is called the *internal genu of the facial nerve* (Fig. 11-1). This anatomical relationship explains how certain disorders of facial nerve motor function can be associated with abducens palsy. [5], [6]

Nervus Intermedius

Also called the nerve of Wrisberg, the nervus intermedius contains general visceral afferent, special visceral afferent, and general visceral efferent fibers that convey sensation from the posterior region of the external auditory canal and concha, taste from the anterior two thirds of the tongue; and secretomotor function for the lacrimal glands; submandibular and sublingual glands; and minor salivary glands in the nasal cavity, paranasal sinuses, and palate ([Fig. 11-2](#)). In the cerebellopontine angle, the nervus intermedius travels from the pons to the internal auditory meatus between the motor root and CN VIII. The geniculate ganglion, found within the temporal bone along the course of the facial nerve, contains the primary cell bodies of the special visceral afferent taste fibers and general somatic afferent sensory fibers. The preganglionic general visceral efferent fibers and special visceral efferent fibers pass through the geniculate ganglion without synapsing. The chorda tympani and the greater superficial petrosal nerve are subdivisions of this nerve.

SENSORY NUCLEUS

The general somatic afferent fibers from the posterior aspect of the external auditory canal, lateral pinna, and mastoid region (carried within the posterior auricular

114

Figure 11-1 Facial nerve projections within the pons.(From LaRouere MJ, Lundy LB: Anatomy and physiology of the facial nerve. In Jackler RK, Brackmann DE [eds]: Neurotology. St. Louis, Mosby-Year Book, 1994, pp 1271-1281.)

nerve) travel centrally in the nervus intermedius to the dorsal part of the primary sensory nucleus of CN V within the pons. Hypesthesia of the posterior external auditory canal has been found to be an early sign of tumors within the internal auditory canal (e.g., acoustic neuroma). It is speculated that sensory fibers are more susceptible to the effects of pressure than motor axons.^[1]

PARASYMPATHETIC NUCLEUS

The general visceral efferent fibers originate from the superior salivatory nucleus and the lacrimal nucleus in the dorsal pons and are carried distally within the nervus intermedius. After joining the motor root of the facial nerve, two main branches carry the parasympathetic fibers

Figure 11-2 Diagram of facial nerve anatomy. GVE, general visceral efferent; SVA, special visceral afferent; GSA, general somatic afferent; SVE, special visceral efferent; IAC, internal auditory canal.

115

to their destination. At the geniculate ganglion, the greater superficial petrosal nerve branches at the hiatus of the facial canal and travels anteromedially through the middle fossa within the pterygoid canal. Contained within this nerve are preganglionic fibers destined for the lacrimal gland and the minor salivary glands of the nasal cavity, paranasal sinuses, and palate. The deep petrosal nerve, carrying postganglionic sympathetic fibers, joins the greater superficial petrosal nerve to form the nerve of the pterygoid canal (vidian nerve). At the pterygopalatine ganglion (found within the pterygopalatine fossa), the parasympathetic fibers synapse with postganglionic neurons, which continue toward their target organs.

The preganglionic fibers for the submandibular and sublingual salivary glands pass through the geniculate ganglion and then leave the mastoid segment of the facial nerve within the chorda tympani. The chorda tympani travels through the temporal bone within the canal of Huguier and enters the infratemporal fossa via the petrotympanic fissure, where it joins the lingual nerve (CN V). Within the submandibular ganglion, the parasympathetic fibers synapse with the postganglionic cells that innervate the submandibular and sublingual salivary glands.

GUSTATORY NUCLEUS

The special visceral afferent fibers from the taste buds of the anterior two thirds of the tongue (i.e., tongue anterior to the sulcus terminalis) also travel within the chorda tympani. As stated earlier, the cell bodies for taste fibers are located within the geniculate ganglion. The gustatory afferent fibers are carried centrally by the nervus intermedius to cells in the rostral part of the nucleus of tractus solitarius in the medulla. Also synapsing within this nucleus are the taste fibers from other areas of the oral cavity, pharynx, and larynx carried by CN IX and CN X. Intermingling of these three cranial nerves occurs here.^[2]

Lower Motor Neuron: Peripheral Route of CN VII

CEREBELLOPONTINE ANGLE

The intracranial segment (within the angle) measures about 23 to 24 mm long and 1 to 2 mm wide and runs obliquely (anteriorly and laterally) from the pontomedullary sulcus to the internal auditory canal.^[2], ^[3] Both the motor root and the nervus intermedius emerge from the brain stem ventrolaterally near the posterior aspect of the pons, 9.5 to 14.5 mm from the midline and 0.5 to 2.0 mm medial to where CN VIII enters the brain stem. At times, the facial nerve axons pass through the transverse fibers of the middle cerebellar peduncle.^[2] Within the subarachnoid space of the cerebellopontine angle, CN VII is joined by CN VIII, which travels lateral and slightly inferior to the facial nerve ([Fig. 11-3](#)). The nervus intermedius runs between CN VIII and the motor root of CN VII (hence its name). While in the cerebellopontine angle, the facial nerve has no epineurium and is covered only with pia mater. The trigeminal nerve is located anteriorly. The anterior

Figure 11-3 Relationship of the facial nerve to the cochlear and vestibular nerves from the cerebellopontine angle through the internal auditory (From LaRouere MJ, Lundy LB: Anatomy and physiology of the facial nerve. In Jackler RK, Brackmann DE [eds]: Neurotology. St. Louis, Mosby-Year Book, 1994, pp 1271-1281.)

inferior cerebellar artery is associated with the nerves and usually is found ventrally, between the nerves and the pons.^[3]

INTERNAL AUDITORY MEATUS OF TEMPORAL BONE

The meatal segment (within the internal auditory canal) is about 7 to 8 mm long. The nervus intermedius joins the motor root to form a common trunk that occupies the area nervi facialis, which lies within the anterosuperior segment of the meatus. The motor fibers are more anterior, whereas the nervus intermedius fibers remain posteriorly. At the lateral end of the meatus, a horizontal partition, the transverse or falciform crest, separates the facial from the cochlear nerve inferiorly. In addition, a vertical crest (Bill's bar) separates the facial from the superior vestibular nerve located posteriorly. The blood supply to this region is the labyrinthine artery, a branch of the anterior inferior cerebellar artery.

FACIAL CANAL

Beginning at Bill's bar and ending at the stylomastoid foramen, this portion is comprised of three segments: (1) labyrinthine (3 to 4 mm long); (2) tympanic (12 to 13 mm long); and mastoid (15 to 20 mm long). The labyrinthine segment, which lies within the narrowest portion of the bony facial canal, extends from the anterosuperior region of the fundus to the geniculate ganglion. To reach the geniculate fossa, it passes between the ampulla of the superior semicircular canal and the cochlea and travels forward and downward. At the geniculate ganglion, the

116

nerve turns 75 degrees posteriorly, thus creating the external genu. This marks the beginning of the tympanic segment. Exiting 90 degrees anteriorly from the geniculate is the first branch of CN VII, the greater superficial petrosal nerve.

The tympanic segment continues along the medial wall of the tympanic cavity, a few millimeters medial to the incus. It courses superior and posterior to the cochleariform process, along the upper edge of the oval window, and inferior to the lateral semicircular canal. At the origin of the stapedius tendon from the pyramidal process, the nerve turns 120 degrees, continuing inferiorly as the mastoid segment. The mastoid segment has two branches--the nerve to the stapedius and the chorda tympani. During its course through the mastoid along the posterior aspect of the external auditory canal, the nerve travels slightly posteriorly and usually passes lateral to the inferior aspect of the tympanic annulus. At times, however, the facial nerve may be lateral to the annulus during its entire descent, which puts the nerve at risk during mastoid surgery.^[14], ^[15] The major blood supply for the facial nerve within the facial canal is the superficial petrosal branch of the middle meningeal artery (proximally) and the stylomastoid artery (distally).^[16]

STYLOMASTOID FORAMEN

CN VII exits the temporal bone via the stylomastoid foramen, which is between the mastoid and styloid processes and deep to the posterior belly of the digastric. Almost immediately, the nerve enters the parotid gland. After traveling anteriorly about 2 cm within the parotid, the nerve divides at the posterior border of the ramus of the mandible into an upper temporofacial and a lower (and smaller) cervicofacial nerve. Classically, these divide again at the pes anserinus into the temporal, zygomatic, buccal, mandibular, and cervical branches. Many anastomoses exist between these branches, and many variations in the branching patterns have been described.^[17] After emerging from the superior, anterior, and inferior margins of the parotid gland, these branches enter the deep surface of their target muscle. Ultimately, all the facial muscles are innervated by CN VII, except for the levator palpebrae superioris (CN III). The extratemporal portion of the facial nerve derives its blood supply from the stylomastoid, posterior auricular, superficial temporal, and transverse facial arteries.^[18]

[PreviousNext](#)

EXAMINATION OF CN VII

Directed Neurological Examination

MOTOR

First, the clinician should observe the patient at rest for symmetry and the presence of any involuntary movements (e.g., fasciculations, tics). Signs of facial weakness include flattening of the nasolabial groove, slower blinking, and loss of facial wrinkles. Next, clinicians should check the amount of voluntary motion in each of the five peripheral branches by having the patient perform the following: (1) temporal--raise the eyebrows, wrinkle the brow; (2) zygomatic--close the eyes gently, and with maximal effort try to keep the eyes closed while the examiner attempts to open them; (3) buccal--smile, show teeth, puff out the cheeks; (4) mandibular--pout, purse the lips; (5) cervical--sneer. The clinician should determine if the patient exhibits Bell's phenomenon, which is an upward and outward rolling of the globe when eyelid closure is attempted. When there is incomplete closure, this phenomenon protects the cornea by placing it under the upper eyelid and moving it laterally. While testing the facial expressions, synkinesis should be sought, which is unintentional motion of a group of muscles when another group is voluntarily contracted (e.g., contraction of the eyelid during smiling). To differentiate a central palsy, clinicians should look for sparing of upper facial motion and for preservation of emotional facial expressions (e.g., surprise, pain). Both sides of the face should be examined closely to rule out bilateral involvement. A change in loudness perception suggests involvement of the nerve branch to the stapedius muscle. This hyperacusis can be confirmed subjectively by checking auditory function with finger rub or tuning forks and can be documented objectively by acoustic reflex testing during an audiometric evaluation.

Examiners must be careful not to confuse transferred contralateral motion with weak motion of the involved side. For example, the contralateral frontalis can create some wrinkles in the forehead of the involved side, and contralateral midfacial muscles can cause motion of the involved side. To prevent confusion, the examiner should cover the contralateral side to focus solely on the involved side before comparing the two sides. In addition, by holding the skin of the uninvolved side against the facial skeleton, midfacial motion from the contralateral side can be minimized. Likewise, examiners should not confuse active eye closure with the normal, gravity-assisted passive closure of the eyelids, which occurs after the levator palpebrae superioris is relaxed. ^[18]

SENSORY

The response to solutions of the four fundamental tastes (sweet--sucrose, sour--citric acid, salty--sodium chloride, and bitter--quinine sulfate) should be evaluated in the anterior two thirds of the tongue. The patient should be instructed not to eat or smoke for several hours before testing. Before test solutions are applied, the mouth is rinsed with distilled water. Then, using cotton swabs, a test solution is placed on the lateral, anterior tongue. The patient should be instructed to state whether the solution is sweet, sour, salty, bitter, unknown, or without taste. Between test solutions, the mouth should be swished with distilled water. Each side should be tested separately. To eliminate olfaction, patients should pinch their nose or hold their breath during the testing.

The somatic sensation of the posterolateral external ear canal and concha should be tested in the usual fashion (cotton wisp, pinprick, and other) and the results compared with the sensation of the surrounding areas and with the contralateral side.

REFLEXES

Several reflexes related to facial nerve function can be tested, including the following: (1) corneal reflex--tactile stimulation of the cornea normally causes both eyes to blink simultaneously. The afferent limb is from CN V (ophthalmic division), whereas the efferent limb is from CN VII (motor root). Depending on the reflex patterns elicited, one can differentiate between a CN V or CN VII lesion. For example, if right-sided corneal stimulation does not cause both right and left eyelid closure, but left-sided stimulation does, there is a right CN V deficit. Similarly, if both right- and left-sided corneal stimulation cause the left eye to blink, but not the right, there is a right CN VII lesion. (2) Orbicularis oculi reflex--the examiner pulls the skin lateral to the lateral canthus with the thumb and index finger and then taps the thumb lightly with a reflex hammer, resulting in orbicularis oculi contraction. This stretch reflex shows hyporeflexia in peripheral palsy and hyperreflexia with central palsy. (3) Blink reflex--normally every 2 to 15 seconds there is spontaneous bilateral blinking. (4) Auditory palpebrae reflex--sudden, unexpected loud sound causes a single bilateral eyelid closure. Sudden bright lights also cause reflex eyelid closure. (5) Palmomentalis reflex--tapping or stroking of the palm causes contraction of the ipsilateral mentalis muscle. This pathological reflex is seen with pyramidal tract disease and helps diagnose a central palsy. Another reflex seen with central lesions is the snout reflex, in which tapping of the lips causes pursing of the lips. (6) Other reflexes associated with CN VII include the glabellar (tapping of the glabella causes both eyes to blink), supraorbital (tapping of the supraorbital ridge causes the ipsilateral eye to blink), nasolacrimal (irritative or painful nasal stimulation causes tearing), nasal (ipsilateral facial contraction after tickling of the nasal mucosa), and oculogyric-auricular (contraction of the auricular muscles after lateral gaze). ^[19]

PARASYMPATHETIC

Infranuclear lesions can cause a reduction in ipsilateral tear production if they occur at, or proximal to, the geniculate ganglion. The Schirmer test provides a quantitative evaluation of tear production. Sterile strips of filter paper are folded into the shape of a hook and placed into each lower conjunctival fornix. After 5 minutes, the degree of wetting is measured and compared between sides. A unilateral reduction of more than 30 percent of the total amount of lacrimation of both eyes or bilateral tearing of less than 25 mm is considered significant. This test consists of an afferent limb (CN V) and an efferent limb (CN VII); however, unilateral corneal stimulation from the filter paper should cause bilateral, equal lacrimation. Therefore, because both eyes are tested simultaneously, a unilateral CN V lesion does not result in decreased tearing. ^{[20], [21]}

A lesion distal to the geniculate ganglion may result in excessive tear production. If there is corneal irritation resulting from poor eye closure, lacrimation may be increased. In addition, ectropion resulting from orbicularis oculi weakness and loss of facial tone disrupts the normal flow of tears. Instead of being circulated by blinking and cleared by the canaliculi (aided by the pumping action of the periorbital muscles), tears pool in the lower conjunctival sac and spill over the lower lid margin. ^[22]

Associated Neurological Findings

Cerebral. Cognitive function and abilities with language should be examined, as the clinician seeks impaired attention or concentration, slurred speech, dysarthria, or aphasia. Affect and emotions should be noted, looking for personality changes, apathy, inappropriate crying, or emotional outbursts. Memory should be assessed for deficits. Subfluent aphasia occurs in the context of a right central CN VII lesion, whereas cerebellar speech deficits may be found with peripheral disorders of CN VII, especially if the cerebellopontine angle is involved.

Cranial Nerves. The optic discs should be visualized for signs of increased intracranial pressure or stigmata of systemic conditions like hypertension or diabetes. Direct and consensual pupillary reflexes and extraocular movements, especially abduction of the globe (CN VI), should be evaluated. Facial sensation in the three divisions, as well as motor function of the muscles of mastication, should be checked to assess if CN V is also involved, as in a cerebellopontine lesion. Audition should be evaluated with tuning forks, looking for ipsilateral sensorineural or conductive hearing loss. If nystagmus is present, its direction and other characteristics should be documented. Unilateral vestibular weakness should be tested with the Mittelmeyer test (the patient marches in place with eyes closed and hands outstretched; there is a tendency to turn toward the side of vestibular weakness). Palatal sensation and movement, vocal cord motion, trapezial strength, and tongue function should be evaluated.

Motor/Reflexes/Cerebellar/Gait. Hemiparesis ipsilateral to the facial paralysis suggests a cortical or subcortical lesion, whereas contralateral hemiparesis suggests a pontine lesion near the facial motor nucleus. Reflexes should be checked for increased function, as is seen with a central nervous system lesion, or decreased function, as is seen in various neuropathies. The existence of flaccidity, atrophy, and fasciculations should be noted, which are indicative of a neuropathic process. Involuntary movements of the face in the form of synkinesis may suggest an old lesion with reinnervation. In patients with facial diplegia, ascending diffuse distal weakness with loss of reflexes suggests Guillain-Barre(c) syndrome, whereas facial diplegia with diffuse proximal muscle weakness is seen more often in myopathies. When associated with facial weakness, the complex of ataxia, incoordination, and other signs of cerebellar disease suggest a brain stem or cerebellopontine angle lesion.

Sensory. A loss of sensation to pinprick, temperature, light touch, or vibration of the face or body (contralateral or ipsilateral) suggests lateral brain stem involvement

or a cerebellopontine angle lesion. With ischemic damage from mid-pons to lower medulla, there is a loss of pain, temperature, and corneal reflex from the ipsilateral side of the face (descending tract of CN V), combined with pain and temperature loss from the contralateral side of the body (spinothalamic tract). Patients with lower brain stem lesions usually have intact proprioception and other signs of lateral medullary damage (Wallenberg's syndrome), whereas those

with upper brain stem injury have impaired proprioception. In addition, those with upper pontine lesions have sensory loss from the contralateral side of the face and body.

Neurovascular. Because it is both a risk factor for and cause of intracranial vascular disorders, the presence of hypertension should be evaluated by both blood pressure determination and systemic examination (e.g., retinal vessel evaluation). Bruits and other evidence of carotid artery disease may point to thromboembolic disease as an etiology. A tender and enlarged temporal artery, especially with an elevated erythrocyte sedimentation rate, suggests temporal arteritis.

Associated Medical Findings

The skin should be checked for rashes, lesions, or evidence of insect bites. The head and neck should be examined for masses, signs of trauma, or postoperative scars. The auricle and ear canal should be examined thoroughly for vesicles, ulcers, or other lesions. The tympanic membrane should be checked for perforation, drainage, or cholesteatoma. Infections, neoplasms, and evidence of prior otological surgery should be sought while examining the middle ear. The oral cavity and pharynx should be checked for masses, ulcerations, fissuring of the tongue, and other lesions. The parotid should always be palpated for tumors and inspected for inflammation. If nonsuppurative parotitis, uveitis, and mild fever are found, Heerfordt's disease, a variant of sarcoidosis, may be present. Endocrinological function should be evaluated, because diabetes insipidus or other evidence of pituitary dysfunction can signify neurosarcoidosis. If there is incomplete eyelid closure, the cornea should always be checked for ulceration or infection, because loss of vision from exposure keratitis can occur.

[Previous](#)[Next](#)

EVALUATION GUIDELINES

Neuroimaging. Radiographical studies are helpful in determining the site of lesion and should be obtained whenever the etiology is unclear, when the paralysis is recurrent, progressive, or atypical, or if there was trauma ([Table 11-2](#)). If there is evidence of cerebellopontine angle or internal auditory canal pathology (e.g., facial weakness with ipsilateral sensorineural hearing loss, tinnitus, and/or vestibular abnormalities), magnetic resonance imaging (MRI) with gadolinium enhancement should be obtained. MRI can also demonstrate intracranial, temporal bone, base of skull, and facial soft tissue lesions. High-resolution computed tomography (CT) is useful in defining the bony anatomy of the facial canal. CT readily demonstrates fractures (face, mandible, temporal bone) and bony abnormalities (congenital anomalies, osteopetrosis). It helps differentiate between intratemporal facial nerve neuromas (smooth upward displacement of bone overlying the geniculate with expansion of the tympanic segment) and hemangiomas (irregular bony erosion around the geniculate). In addition, CT can show the extent of bone erosion with lesions like cholesteatoma, glomus tumors, carcinoma, and skull base osteomyelitis.

TABLE 11-2 -- USEFUL TESTS IN THE EVALUATION OF DISORDERS OF CRANIAL NERVE VII

	Neuroimaging	Electrophysiology	Fluid and Tissue Analysis	Neuropsychology Tests	Other Tests
Supranuclear facial paresis	MRI, CT for infarction, tumor	EEG: abnormal wave patterns in seizures	CSF: increased RBC	Mental status impairment	NA
Nuclear lesions: Millard-Gubler and Foville syndromes	MRI for infarction, tumor		CSF: increased RBC	NA	NA
Cerebellopontine angle lesion	MRI for tumor	ABR: delay in wave V or increased interaural difference	NA	NA	Audiogram: sensorineural hearing loss ENG: vestibular weakness
Facial canal lesion	MRI, CT for tumor, fractures, inflammation		NA	NA	Audiogram: sensorineural or conductive hearing loss; acoustic reflex: absent; electrogustometry: reduced; salivary flow: reduced; Schirmer's test: reduced
Stylomastoid foramen syndrome	MRI for tumor, fracture		NA	NA	
Hemifacial spasm	MRI for vascular loop compression		NA	NA	
Postparalytic movements and synkinesis		NA	NA	NA	NA
Myokymia	MRI for pontine tumor, MS plaques	EMG: spontaneous activity at 30-70 per second	CSF: elevated IgG and gamma globulin	NA	NA

MRI, magnetic resonance imaging; CT, computed tomography; EEG, electroencephalogram; ABR, auditory brain stem response; CSF, cerebrospinal fluid; RBC, red blood cell; ENG, electronystagmography; MS, multiple sclerosis; EMG, electromyography; NA, not applicable.

Electrophysiology. Electroencephalography may help distinguish supranuclear causes of facial nerve dysfunction, especially in the instances of suspected epilepsy with a post-seizure paresis, called *Todd's paresis*. Nerve conduction studies should be performed in patients with a unilateral complete paralysis. In testing the involved side, if the threshold is 3.5 mA greater than the contralateral ("normal") side, there is a poor prognosis for spontaneous recovery. This test, however, is not absolutely reliable, and even when there is complete transection of the facial nerve, it conducts impulses distal to the injury for up to 72 hours (until wallerian degeneration occurs).^[21] Electroneurography can be used to determine the peak-to-peak amplitude of the evoked compound action potential of the involved side compared with the other side. Because the amplitude is considered proportional to the number of functioning motor fibers, if there is a 90 percent or greater reduction in the amplitude of the affected side (which represents more than 90 percent degeneration of the nerve), the prognosis is poor.

Muscle action potentials generated by voluntary and spontaneous activity can be measured through electromyography. By placing needles within the facial musculature, electrical silence can be seen in acute paralysis, severe muscle wasting, hypoplasia of the nerve or muscle, or normally innervated muscle in a resting state. Voluntary potentials are present with voluntary contraction. Polyphasic potentials appear during nerve regeneration from 4 to 6 weeks after onset of the paralysis. Fibrillation potentials represent degeneration of the motor nerve; they are usually seen 10 to 14 days after nerve injury. Electromyography is helpful in patients with long-standing facial paralysis and in infants with congenital facial paralysis, but it is not very useful with acute paralysis.

By using electrodes to record the blink reflex after percutaneous stimulation of the supraorbital nerve, a trigeminofacial reflex can be tested. Measuring conduction of the reflex arc between CN V (afferent) and CN VII (efferent) tests both central and peripheral segments of the facial nerve. Currently, the trigeminofacial reflex is the only direct test able to measure intracranial pathology of the facial nerve.^[23]

Auditory brain stem response can be further used to evaluate brain stem anatomy when a retrocochlear or nuclear cause of facial nerve dysfunction is considered. Delay in the absolute latency of ipsilateral wave V or an interaural difference in wave V of more than 0.2 ms suggests retro-cochlear involvement of CN VIII. This observation helps localize the etiology of facial palsy as within or proximal to the internal auditory canal (e.g., acoustic or facial nerve neuroma).

Fluid and Tissue Analysis. Basic tests to obtain include complete blood count with differential (for infectious mononucleosis, leukemia, inflammation), chemistry panel (for systemic diseases), fluorescent treponemal antibody titer (for syphilis), and erythrocyte sedimentation rate/antinuclear antibody test/ rheumatoid factor (for collagen vascular disease). Depending upon the clinical presentation, other tests may be helpful, including thyroid function tests, glucose tolerance test, angiotensin-converting enzyme levels (sarcoidosis), antibody titers (Lyme disease, Epstein-Barr virus, herpes zoster virus, human immunodeficiency virus), monospot test/heterophile antibody titers (mononucleosis), serum heavy metal/toxin levels (lead, arsenic, mercury, carbon monoxide), urine analysis (porphyria, diabetes, sarcoidosis), and stool analysis (*Clostridium botulinum* toxin).

Muscle biopsies are helpful in determining the existence of a mitochondrial myopathy. In addition, if a facial reanimation procedure is considered in patients with longstanding facial paralysis or in infants with congenital facial paralysis, facial muscle biopsy should be performed to determine whether viable muscle fibers are present. If the musculature has degenerated and has been replaced by fibrosis, any procedure attempting to bring only neural input to the area will fail.^[21] In patients requiring a tissue diagnosis, biopsies of skin lesions, subcutaneous nodules, enlarged lymph nodes, or salivary gland tissue may reveal disorders such as sarcoidosis, parotid gland tumor, or vasculitis (e.g., temporal arteritis or periarteritis nodosa).

Cerebrospinal Fluid. If the possibility of central nervous system infection or malignancy exists, a lumbar puncture should be performed. After noting the opening pressure and qualities of the fluid, samples should be sent for cell count, chemistry levels, microbiological staining and culture, antigen titers, and cytology testing. Intracranial hypertension, meningitis (bacterial, fungal, mycobacterial, viral, carcinomatous, aseptic), and malignant processes such as metastasis (lung, breast, melanoma), leukemia, lymphoma, and other primary intracranial neoplastic processes can be detected. In addition, the diagnosis of other etiologies can be supported, like Guillain-Barre(c) syndrome (increased protein level), multiple sclerosis (elevated IgG and gamma globulin levels), syphilis (positive serology result), and subarachnoid or intracerebral hemorrhage (red blood cells).

Other Tests. Audiometry should be performed in all patients with facial palsy. Because CN VII is intimately related to CN VIII in the cerebellopontine angle and internal auditory canal and because the facial canal courses by the cochlea and through the middle ear, many causes of palsy have an associated hearing loss. The

type of loss (sensorineural versus conductive) as well as the extent (mild to profound) are essential factors for localization and planning of treatment. Another useful audiometrical test is the acoustic reflex test, which measures the contraction of the stapedius muscle in response to auditory stimuli. The result can localize the site of lesion as proximal or distal to the branch to the stapedius (mastoid segment of the facial nerve). Tests of vestibular function, like electronystagmography, may be helpful in differentiating central from peripheral lesions in patients who have accompanying vertigo.

By evaluating taste or salivation, the status of the chorda tympani nerve can be determined. Based upon impairment, lesions can be localized as proximal or distal to this branch of the mastoid segment. For example, electrogustometry can measure the taste threshold in response to a small electric current applied to the anterior tongue. The current elicits a metallic or bitter taste, and by controlling the amount of current, the threshold for gustation can be obtained. An elevated threshold suggests involvement of the chorda tympani. Salivary flow can be analyzed by cannulating Wharton's duct. The salivary production is measured for 5 minutes, and a reduction of 25 percent between

100

sides signifies chorda tympani involvement. In addition, salivary flow can be evaluated indirectly by checking the pH of the saliva, because the pH rises with increased salivation. A pH of 6.1 or less is considered to be significant for reduced flow. ¹²

When certain systemic disorders are suspected to be the etiology of the facial palsy, chest radiography should be obtained. Based upon characteristic radiographic findings, the diagnosis of sarcoidosis, tuberculosis, lymphoma, or lung cancer can be supported.

CLINICAL SYNDROMES ([Table 11-3](#))

Syndromes of Paresis

SUPRANUCLEAR FACIAL PARESIS--CENTRAL FACIAL PALSY

In a central facial palsy, only the lower face is paralyzed, especially perioral musculature. Facial tone is intact (no atrophy), and there are no fasciculations. Despite loss of voluntary motion, emotional expression is preserved. With cortical lesions, hemiplegia of the same side as the facial palsy can be found, with upper extremity involvement more than lower. Lesions of the cortex or internal capsule on the side opposite the facial palsy cause the aforementioned symptom complex. If the dominant hemisphere is involved, aphasia may be present. With corticobulbar involvement of other cranial nerves, impairment of speech or swallowing may result. If the lesion is deeper (e.g., basal ganglia), volitional motion may be intact; however, the facial motor response to emotional stimuli is impaired. In acute supranuclear lesions, initially there may be hyporeflexia, which over time is replaced with hyperreflexia.

NUCLEAR OR PONTINE LESIONS

If the lesion is near the facial nucleus, an ipsilateral facial palsy is seen with a contralateral hemiplegia (corticospinal tract has not crossed yet). A concomitant deficit of CN VI may be seen because of the internal genu's relationship with the abducens nucleus. Two syndromes involving this region have been described. ^[4]

Millard-Gubler syndrome yields ipsilateral paralysis of CN VII, with contralateral hemiplegia of the extremities. The syndrome is usually caused by interruption of blood supply to the pons, with involvement of CN VII after its decussation and the corticospinal tract before its decussation.

Foville's syndrome is similar to Millard-Gubler syndrome, in that there is ipsilateral facial paralysis with contralateral hemiplegia; however, in addition, there is ipsilateral abducens palsy and paralysis of conjugate gaze due to concurrent involvement of the abducens nucleus.

PERIPHERAL NERVE LESIONS

Cerebellopontine Angle Syndrome. Pathology involving CN VII in this region often involves CN VIII (sensorineural hearing loss, tinnitus, vestibular weakness). Depending on the size and exact location of the lesion, other structures in this region can be affected, like the cerebellum (ataxia, incoordination) and CN V (reduced facial sensation, impaired corneal reflex). Common etiologies include acoustic neuromas and meningiomas.

Facial Canal Syndrome. The location of the lesion determines the actual deficit. In the labyrinthine segment, facial palsy is seen with ipsilateral hearing loss and vestibular weakness. In addition, hyperacusis and a decrease in tearing and in salivation with loss of taste can be detected. With lesions of the tympanic segment that are distal to the greater superficial petrosal nerve, all of the above may be found, except that lacrimation is intact. If the mastoid segment is involved, as with tympanic lesions, hearing and balance may be affected, and lacrimation is preserved. Whether the lesion is proximal to the nerve branch for the stapedius or to the chorda tympani determines whether there is hyperacusis, decreased salivation, or loss of gustation. Hemangiomas, neuromas, cholesteatomas, temporal bone fractures, and the inflammation causing Bell's palsy are some disorders of the facial canal that can cause facial palsy.

Stylomastoid Foramen Syndrome. A lesion after the nerve leaves the temporal bone results in only a lower motor neuron deficit of the mimetic muscles. Atrophy and fasciculations are found. Pathology of individual nerve branches can be seen with parotid tumors (e.g., adenoid cystic carcinoma), facial or mandibular trauma, and after facial surgery (e.g., parotidectomy, face lift, and submandibular gland excision).

Idiopathic Facial Palsy. Despite a thorough workup, 60 to 75 percent of all cases of facial paralysis are of unknown etiology and are called Bell's palsy. ^[24] The annual incidence of Bell's palsy is about 20 per 100,000, with an increasing incidence seen with increasing age. The male-to-female and left-to-right ratio is approximately equal. Seven to 9 percent have a history of prior facial palsy, and 4 to 9 percent have a positive family history for Bell's. High-risk patients include pregnant women and patients with diabetes mellitus or multiple sclerosis. Without treatment, improvement is noted within 3 weeks in 85 percent of patients, with the remainder showing improvement by 3 to 6 months. In addition, about 70 percent regain normal function, about 15 percent have some residual weakness, and the remainder have poor return of function. By 6 months, therefore, all patients with Bell's palsy should show some improvement, and thus none should have a persistent total facial paralysis. ^{[25], [26]}

Clinical characteristics of typical Bell's palsy include the following: peripheral CN VII dysfunction involving all distal branches; sudden onset with maximal facial weakness usually reached within several days; impaired result on acoustic reflex test in 90 percent; viral prodrome in 60 percent; numbness or pain of the ear, tongue, or face in 50 percent; chorda tympani nerve appears red in 40 percent; reduction in ipsilateral tearing or salivary flow in 10 percent; and spontaneous improvement within 6 months. ^[3]

Based on accumulated clinical and experimental evidence, the most commonly accepted cause of Bell's palsy is herpes simplex infection. Treatment, therefore, consists of acyclovir and steroids, which have been shown to hasten the recovery and to lessen the ultimate degree of dysfunction. ^{[24], [27], [28]}

TABLE 11-3 -- SELECTED ETIOLOGIES ASSOCIATED WITH DISORDERS OF CRANIAL NERVE VII

Etiological Category	Selected Specific Etiologies	Chapter
STRUCTURAL DISORDERS		
Developmental	Mobius' syndrome, absence of facial musculature	28
Degenerative and compressive	Osteopetrosis, sclerosteosis, hyperostosis corticalis generalisata, benign intracranial hypertension	29
HEREDITARY AND DEGENERATIVE DISORDERS		
Amino/organic acidopathies, mitochondrial enzyme defects and other metabolic errors	Acute porphyria	31
Movement disorders	Hemifacial spasm, Parkinson's disease, Gilles de la Tourette's syndrome, facial dystonia Meige's disease or Brueghel's syndrome, facial contortion, bilateral	34
Degenerative motor, sensory, and autonomic disorders	Amyotrophic lateral sclerosis	36
Inherited muscle, neuromuscular, and neuronal disorders	Dystrophia myotonica	37
ACQUIRED METABOLIC AND NUTRITIONAL DISORDERS		
Endogenous metabolic disorders	Diabetes mellitus, hyperthyroidism	38
Exogenous acquired metabolic disorders of the nervous system		
Toxins and illicit drugs	Thalidomide, carbon monoxide, ethylene glycol, arsenic	39
Nutritional deficiencies and syndromes associated with alcoholism	Wernicke-Korsakoff syndrome	40
INFECTIOUS DISORDERS		

Viral infections	Herpes zoster, herpes simplex, influenza, coxsackie, enterovirus, polio, mumps, mononucleosis	41
Nonviral infections	Otitis externa, otitis media, mastoiditis, syphilis, tuberculosis, leprosy, Lyme disease, cat scratch disease, mucormycosis, botulism, malaria	42
NEUROVASCULAR DISORDERS		
NEOPLASTIC DISORDERS		
Primary neurological tumors	Pontine glioma, neuroma (acoustic, facial), meningioma, hemangioma, cholesteatoma, glomus tumor	46
Metastatic neoplasms and paraneoplastic syndromes	Leukemia, lymphoma, myeloma, from salivary gland (adenoid cystic), skin (melanoma), breast, lung, kidney, head/neck	47
DEMYELINATING DISORDERS		
Demyelinating disorders of the central nervous system	Multiple sclerosis	48
Demyelinating disorders of the peripheral nervous system	Guillain-Barre syndrome	94
AUTOIMMUNE AND INFLAMMATORY DISORDERS		
	Bell's palsy, sarcoidosis, myasthenia gravis, Sjogren's syndrome, temporal arteritis, systemic lupus erythematosus, periarteritis nodosa	50
TRAUMATIC DISORDERS		
EPILEPSY		
HEADACHE AND FACIAL PAIN		
DRUG-INDUCED AND IATROGENIC NEUROLOGICAL DISORDERS		
	Parotid or facial cosmetic surgery, otological or neurotological surgery, local anesthesia, arterial embolization	55

Adour and colleagues have shown that 92 percent of patients regain normal facial motion when given a 10-day course of acyclovir (400 mg by mouth 5 times daily) and prednisone (60 mg a day orally for 5 days, then tapered down by 10 mg/day for 5 days).^[26] In addition to the specific treatment, all patients with weak eyelid closure should take general precautions to avoid ocular complications. Patients should use artificial tears throughout the day, ophthalmic ointment at night, and either an eye moisture chamber or taping closed of the affected eyelid during sleep.

Despite using acyclovir and prednisone, some patients never regain good facial function. This subset of patients with poor prognosis may benefit from surgical decompression of the entire infratemporal facial nerve. To determine which patients will have a poor return of function, electroneurography is used, and those showing more than 90 percent degeneration within 21 days have been found to benefit from surgical decompression.^[27],^[28] Decompression in this setting, however, is controversial.^[27],^[29] If surgery is offered, both a middle cranial fossa and a transmastoid approach are required. Because the presumed site of entrapment is the meatal foramen (beginning of the labyrinthine segment), middle fossa access is needed to decompress this region. The remainder of the infratemporal facial nerve can then be decompressed via the transmastoid approach.^[28],^[30]

Syndromes of Overactivation

HEMIFACIAL SPASM

This movement disorder is characterized by unilateral, involuntary, episodic tonic and clonic contraction of muscles innervated by CN VII. It usually begins as twitches around the eye and progresses to involve the remaining

ipsilateral facial muscles, even during sleep. The spasms are painless, can be provoked by voluntary facial motion and emotional stress, and occur most often in middle-aged women. The exact etiology is unknown, but many believe that compression of the motor nerve root at the brain stem by a vascular loop causes focal demyelination and focal ectopic excitation. Impulses resulting from the chronic stimulation conduct centrifugally to the facial nerve nucleus, which causes hyperactivity of the nucleus with resultant bursts of hemifacial spasm.^[31] The condition also has been seen after recovery from Bell's palsy. Hemifacial spasm must be differentiated from blepharospasm, which is an involuntary spasm involving both orbicularis oculi muscles.

MYOKYMIA

This is a progressive, irregular fibrillation of individual facial muscle fibers. Usually, it begins in the frontalis and extends to involve all the ipsilateral facial muscles. Electromyographic findings include spontaneous activity of motor units at a rate of 30 to 70 per second. Common causes include pontine gliomas and multiple sclerosis.^[4]

Re-innervation Syndromes

POSTPARALYTIC MOVEMENTS AND SYNKINESIS

Synkinesis is unintentional motion of a group of muscles when another group is voluntarily contracted. It results from postparalytic re-innervation of different muscles by axons from the same motor neuron. An example is eyelid closure when the patient smiles.

CROCODILE TEARS

Also called Bogorad's syndrome, it is characterized by unilateral lacrimation during meals in patients with a history of facial palsy. After paralysis with neural degeneration, regenerating axons from the superior salivatory nucleus intended for the chorda tympani instead enter the greater superficial petrosal nerve. Rather than synapsing in the submandibular ganglion to regulate the sublingual and submandibular glands, these preganglionic parasympathetic fibers end up in the pterygopalatine ganglion. Therefore, during meals, the stimulus for increased salivation results in stimulation of the lacrimal gland, with a resultant increase in tearing.

GUSTATORY SWEATING

Also known as Frey's syndrome, this results from anomalous re-innervation of sweat glands by axons intended for the parotid gland. Normally, sweat glands are innervated by postganglionic sympathetic fibers which are unique in that they use acetylcholine as the transmitter (rather than norepinephrine). The parotid gland is innervated by postganglionic parasympathetic fibers also using acetylcholine as their transmitter to regulate salivary flow. After parotidectomy, the cholinergic fibers originally intended for the parotid gland end up innervating the sweat glands. While eating, stimuli that should cause an increase in salivation instead lead to facial sweating. Parotidectomy is the most common cause.

GENERAL MANAGEMENT GOALS

General treatment for patients with facial palsy is concerned mainly with protection of the eye from exposure keratitis, especially when an ipsilateral CN V deficit exists. During the day, artificial tears should be used frequently to keep the eye moist. Sunglasses are worn outside. Areas with air contaminated by excessive particulate matter or noxious fumes (e.g., construction sites, textile factories) should be avoided. To protect the cornea while asleep, ophthalmic ointment is instilled. Then, either the eyelid is carefully taped shut or a moisture chamber is used. Other measures to protect the eye are room humidifiers, tape for lid support, and soft contact lenses. Any corneal abrasion or infection should be treated immediately to avoid possible visual complications. If there is deterioration in visual function, ophthalmology consultation is needed.

Specific treatments for facial palsy are aimed at the underlying etiology. Consultation with the appropriate specialist is necessary for facial palsy caused by tumors, cholesteatoma, skull base osteomyelitis, or middle ear infection. Infectious, metabolic, collagen vascular, or toxic causes should be corrected as required by the particular disease. Prompt surgical consultation is needed for patients with facial nerve paralysis after either blunt or penetrating trauma. ^[32]

For the patient with a permanent facial paralysis despite medical and surgical treatment, many surgical options are available to improve facial function and appearance. These include static sling procedures with fascia lata or alloplastic strips, dynamic procedures with temporalis or masseter transposition, hypoglossal-facial nerve anastomosis, cross-facial nerve grafting, free muscle grafts, and microvascular free nerve-muscle grafts. ^[33] In addition, the placement of gold weights or springs within the upper eyelid, canthoplasty, and lower lid shortening can help with eye closure. Associated procedures include brow or face lift, entropion or ectropion repair, and lip transposition. ^[34]

HISTORY AND DEFINITIONS

Sound consists of sinusoidal waves of air pressure, and *hearing* is the perception of sound. The understanding of speech depends on the perception of complex, time-varying multifrequency sound. Hearing is possible when the pitch or frequency range of sound is between 20 and 20,000 cycles/sec (Hz) and when the sound is appropriately loud. The *loudness* of sound is measured in decibels. Clinically, such as during audiometry, decibels are expressed as units of hearing level, and are computed by the formula $DB = 20 \log P_{\text{test}}/P_{\text{ref}}$, where P_{test} is the sound pressure level in question and P_{ref} is the sound pressure just barely audible by a group of young adults. *Tinnitus* is the false perception of a sound, or the perception of a sound that is not normally perceived, such as the pulse. A single sinusoidal tone corresponds to a ringing noise. Complex multifrequency sounds may be perceived as hissing, buzzing, roaring, or even as speech or music.

Hearing loss consists of a reduction, relative to normal standards, of the ability to perceive sound. Three subtypes are recognized: conductive, sensorineural, and central. In conductive hearing loss, mechanical transmission of sound into the sensory receptors in the cochlea is impaired. In sensorineural hearing loss, there is a loss of function in the sensory receptors in either the cochlea or the auditory nerve. In central hearing loss there is a lesion in the brain stem or auditory cortex.

Vertigo is a false sensation of movement that is usually caused by disorders of the vestibular system, including the inner ear and/or parts of the central nervous system involved in processing of vestibular signals. Vertigo is often accompanied by imbalance as well as secondary symptoms such as nausea and fatigue. *Dizziness* is a less specific term often used by patients to indicate vertigo as well as a host of other symptoms such as giddiness or lightheadedness, confusion, and imbalance. The vestibular system senses movement by detecting angular velocity and linear acceleration. The semicircular canals are excellent detectors of angular (rotational) velocity. The otolith organs are detectors of linear acceleration that may be related to either movement of the head or changes in orientation to the earth's gravitational field.

The history of the vestibulocochlear system can be traced from the times of the ancient Greeks. [1] Plato theorized that "hearing is motion initiated by sound in the ears and ending in the region of the liver." Aristotle (384 BC to 322 BC) outlined the concept of "inner ear" in the occiput of the skull as forming the basis of hearing. In 97 AD, Rufus of Ephesus described the auricular anatomy of the inner ear using the words *helix*, *antihelix*, and *tragus*, which are terms that are still in use today. Galen (130-200 AD) introduced the term *labyrinth* to describe the inner structure of the inner ear in temporal bone.

Vesalius (1564) named two of the ossicles, the malleus (drumstick or hammer) and incus (anvil). Eustachio (1510-1571) discovered the eustachian tube, which maintains equal pressure on both sides of the tympanic membrane. In 1850, Corti described the sensory epithelium of the cochlea and the organ of Corti is his namesake. Rinne, in

185

1855, developed the use of tuning fork tests in the diagnosis of middle ear disease. Meniere, in 1861, described a disorder of increased pressure in the inner ear, a disease that now bears his name. Barr, in 1901, described the use of a ticking watch to quantify hearing loss. Barany received the Nobel Prize in 1909 for his work describing the caloric test. Fletcher in 1923 described the electric audiometer. Bekesy received the Nobel Prize in the 1950s for his discovery of the traveling wave mechanism for the stimulation of the cochlea. In more recent years, the surgical specialty of neuro-otology has emerged, driven by availability of the operative microscope and the need for advanced training and subspecialization to surgically treat otosclerosis and acoustical neuromas.

CLINICAL HISTORY

Disorders of the vestibulocochlear system, namely dizziness and hearing disturbances, are common and have diverse causes. Accordingly, the history must be unusually thorough. To be adequate, the history should be all-encompassing or should follow a heuristic approach in which questions are dynamically selected as the interview progresses. In the all-encompassing approach, the examiner should first obtain a definition of symptoms. Does the patient complain of vertigo, a secondary symptom (such as nausea), a nonspecific symptom (giddiness or lightheadedness), or something unlikely to be caused by dysfunction of cranial nerve VIII (e.g., confusion or syncope)? With respect to hearing complaints, the clinician should ascertain whether one or both sides is affected, what types of sounds are poorly perceived (low-pitched, high-pitched, speech only, speech with background noise), whether there is an accompanying tinnitus (ringing, pulsatile, multifrequency sound such as roaring, auditory hallucinations), and whether there is otalgia or an abnormal sensation in the ear such as fullness. It is particularly important to inquire about coincident headaches, because migraine is a frequent source of vertigo.

Next, the physician should inquire about timing. Are symptoms constant or episodic? If episodic, how long do they last? Vertigo caused by benign paroxysmal positional vertigo (BPPV) usually lasts 10 seconds. Vertigo from attacks of Meniere's disease typically last 2 hours. Vestibular neuritis persists for weeks, and central vertigo may persist for years. The clinician should establish whether the various symptoms are related in time. This finding is particularly important for certain disorders that present as symptom complexes, such as the headache and dizziness of vertebrobasilar migraine or the typical quadrad of tinnitus, vertigo, aural fullness, and fluctuating hearing, which typifies Meniere's disease.

All patients with vertigo should be queried regarding *triggering or exacerbating factors* ([Table 12-1](#)). In vertiginous patients, it is particularly important to inquire about positional triggers, because about 20 percent of all vertigo is caused by BPPV (see later).

A medication history should be taken because numerous medications can induce vertigo or impair hearing. Anticonvulsants, antihypertensives, and sedatives are common

TABLE 12-1 -- TRIGGERING OR EXACERBATING FACTORS FOR VERTIGO

Changes in position of the head or body
Standing up
Rapid head movements
Walking in a dark room
Loud noises
Coughing, blowing the nose, sneezing, straining, or laughing
Underwater diving, elevators, airplane travel

Foods, not eating, salt, monosodium glutamate
Alcohol
Menstrual periods or hormonal manipulations
Boat or car travel
Anxiety or stress

sources of dizziness and vertigo, and ototoxic medications ([Table 12-2](#)) may additionally be the source of hearing disturbances or ataxia. All current medications as well as previous exposure to ototoxins should be noted. In persons with hearing complaints, a history of noise exposure should also be obtained.

The *family history* is important to obtain, because there may be other family members who have migraine, seizures, Meniere's disease, otosclerosis, or early-onset hearing loss. The *review of systems* should explore psychiatric problems (especially anxiety and panic); vascular risk factors; cancer; autoimmune disease; neurological problems (especially migraine, stroke, transient ischemic attack, seizures, multiple sclerosis); otological surgery; and general medical history (especially thyroid dysfunction, diabetes, and syphilis).

Middle ear	Hearing loss Tinnitus	

ossicular chain, ending at the stapes. Sound energy is then converted into changes in neural firing, which is passed more centrally through a complex cross-connected network of neurons. This neural network can be considered as a series of four orders of neurons. First order neurons are derived from the auditory (spiral) ganglion, second order neurons are those in the neighborhood of the cochlear nuclei in the brain stem. Third order neurons are found at the level of the inferior colliculus, and fourth order neurons travel from the medial geniculate body in the thalamus to the auditory cortex. Considerably more detail about these pathways can be found in Webster and colleagues.

FIRST ORDER NEURON

The vestibular and cochlear divisions of the inner ear are depicted in Figure 12-1 (Figure Not Available) A. Longitudinally (Figure 12-1 (Figure Not Available) B), the labyrinth is composed of an outer compartment containing perilymph (similar to extracellular fluid), and an inner compartment containing endolymph (similar to intracellular fluid). The hair cells are embedded in the

		Pressure sensitivity

floor of the inner compartment, the basilar membrane. Two types of hair cells are in the cochlea, inner and outer. When sound is transmitted to the cochlea, oscillations are set up in the basilar membrane, and this stimulates the *inner hair cells*. Place-code mapping occurs between frequency of sounds to areas of the cochlea called a *tonotopic distribution*, which results in registration of higher frequencies at the base of the cochlea and lower frequencies at the apex.

The more numerous *outer hair cells* are motile and may help to dynamically tune the system. Appreciation of the motile nature of outer hair cells has led to a new test of hearing called *otacoustical emissions* or *OAEs* (see later). *Reissner's membrane* roofs the compartment containing the hair cells. In certain conditions in which endolymph pressure is increased (e.g., Meniere's disease), Reissner's membrane may bow out or rupture. The *spiral ganglion of the cochlea* is wrapped around the cochlea and receives output from the hair cells to create the *auditory nerve*, which runs with the vestibular nerve and facial nerve in the internal auditory canal (IAC). In addition to the afferent fibers in the vestibulocochlear nerve, there are also *efferent fibers*, which supply the outer hair cells.

Figure 12-1 (Figure Not Available) The cochlea(A) and vestibular labyrinth(B). (From Kandel ER, Schwartz JH, Jessell TM [eds]: *Principles of Neural Science*, 3rd ed. East Norwalk, CT, Appleton & Lange, 1991.)

SECOND ORDER NEURON

The cochlear nerve enters the brain stem at the pontomedullary junction, where it bifurcates and terminates in the two major subdivisions of the cochlear nucleus--the dorsal and ventral cochlear nuclei (Fig. 12-2). The most important outflow is to the *trapezoid body*, which contains fibers destined for the bilateral superior olivary nuclei in the brain stem. The *superior olive* is concerned with sound localization, based in interaural differences in sound timing and intensity. The superior olive is also an essential part of the stapedius reflex, which is a protective reflex in the middle ear. The simplest stapedius reflex arc involves the spiral ganglion neurons, the cochlear nucleus, superior olive, and facial nerve nucleus. Output from the superior olive joins crossed and uncrossed axons from the cochlear nucleus to form the *lateral lemniscus*. This pathway ascends to the inferior colliculus. Because the lateral lemniscus contains second order neurons from the cochlea and third and fourth order neurons from the superior olive, it contributes to three waves of the auditory brain stem response (described later). The tonotopic arrangement of the cochlea is maintained in the cochlear nucleus, lateral lemniscus and reticular formation. Because of the extensive crossing that occurs early in the central auditory circuitry, central auditory lesions usually do not cause monaural hearing loss.

THIRD ORDER NEURON

The inferior colliculus is a major integrating center for the auditory system and serves as a center for feedback pathways to the lower auditory system. Output from the

Figure 12-2 Central auditory pathways(Reprinted with permission from Kandel ER, Schwartz JH, Jessell T: *Principles of Neural Science*, 3rd ed. East Norwalk, CT, Appleton & Lange, 1991, p 495.)

inferior colliculus ascends to the medial geniculate body of the thalamus.

FOURTH ORDER NEURON

The medial geniculate body is the major auditory nucleus of the thalamus. Parts of the medial geniculate are hypothesized to function in directing auditory attention. The medial geniculate body sends output to the primary auditory cortex, also known as the *transverse temporal gyri of Heschl* (Brodmann areas 41 and 42) and auditory association cortex (areas 22 and 52) (Fig. 12-3 (Figure Not Available)). The medial geniculate also sends output to the auditory motor cortex, which controls body responses to sound. The auditory cortex is divided into three areas, including a primary area (AI), a secondary area (AII), and a remote projection region (Ep). Investigators have varied in assigning area 42 to the primary or secondary auditory cortex. The ventral medial geniculate projects almost entirely to AI, whereas the surrounding auditory areas receive projections from the rest of the geniculate body. As with the lower auditory systems, tonotopic relationships are maintained.

Vestibular System

The peripheral vestibular system consists of a set of three-dimensional angular velocity transducers, the semicircular canals, and a set of three-dimensional linear acceleration transducers, the otoliths (utricle and saccule) (see Fig. 12-1 (Figure Not Available)). These transducers are suspended by an assembly of membranes and connective tissue, the *membranous labyrinth*, within channels in the temporal bone, the *bony labyrinth*. Three important spatial arrangements characterize the semicircular canals. First, each canal within each

Figure 12-3 (Figure Not Available) Cortical auditory areas. Portions of the frontal and parietal lobes have been cut away above the sylvian fissure to expose the insula and the superior temporal lobe. The number of Heschl's gyrus is variable. In this illustration, primary auditory cortex (41) is shown on the first transverse gyrus of Heschl, and area 42 is shown on the second transverse gyrus. PT, planum temp.(Modified from Webster DB, Popper AN, Fay RF: *The mammalian auditory pathway: neuroanatomy*. New York, Springer-Verlag, 1992, p 17.)

labyrinth is *perpendicular* to the other canals, which is analogous to the spatial relationship between two walls and the floor of a rectangular room. Second, the planes of the semicircular canals, between the labyrinths, conform very closely to each other. The six individual semicircular canals become three *co-planar* pairs: (1) right and left lateral; (2) left anterior and right posterior; and (3) left posterior and right anterior. Third, the planes of the canals are close to the planes of the extraocular muscles. This relationship allows relatively simple connections between sensory neurons related to individual canals and motor output neurons, which are related to individual ocular muscles.

The otoliths register linear acceleration, and they respond both to linear head motion and to static tilt with respect to the gravitational axis. The otolithic membranes contain calcium carbonate crystals called *otoliths* and, therefore, they have substantially more mass than the surrounding structures. The increased mass of the otolithic membrane causes the maculae to be sensitive to gravity. In contrast, the cupulae of the semicircular canals have the same density as the surrounding endolymphatic fluid and are insensitive to gravity. Like the canals, the otoliths are arranged in a manner to enable them to respond to motion in all three dimensions. In an upright person, the saccule is vertical (parasagittal), whereas the utricle is horizontally oriented (near the plane of the lateral semicircular canals). In this posture, the saccule can sense linear acceleration in its plane, which includes the acceleration oriented along the occipitocaudal axis and linear motion along the anteroposterior axis. The utricle senses acceleration in its plane, which includes lateral accelerations along the interaural axis, as well as anteroposterior motion.

VESTIBULAR GANGLION AND NERVE

Vestibular nerve fibers are the afferent projections from the bipolar neurons of Scarpa's ganglion. The vestibular nerve transmits afferent signals from the labyrinths through the *internal auditory canal* (IAC). In addition to the vestibular nerve, the IAC also contains the cochlear nerve (hearing), the facial nerve, the nervus

intermedius (a branch of the facial nerve), and the labyrinthine artery. The IAC travels through the petrous portion of the temporal bone to open into the posterior fossa at the level of the pons. The vestibular nerve enters the brain stem at the pontomedullary junction and contains two divisions, the superior and inferior vestibular nerves. The *superior vestibular nerve* innervates the utricle, as well as the superior and lateral canals. The *inferior vestibular nerve* innervates the posterior canal and the saccule.

VESTIBULAR NUCLEI

The primary vestibular afferents transmit information mainly to the vestibular nuclear complex and the cerebellum. The vestibular nuclear complex is the primary processor of vestibular input, and it implements direct, fast connections between incoming afferent information and motor output neurons. The cerebellum monitors vestibular performance and keeps it "calibrated." In both locations, vestibular sensory input is processed in association with somatosensory and visual sensory input.

The *vestibular nuclear complex* consists of four "major" nuclei (superior, medial, lateral, and descending) and at least seven "minor" nuclei. It is a large structure, located primarily within the pons but also extending caudally into the medulla. The superior and medial vestibular nuclei are relays for the vestibulo-ocular reflex (VOR). The medial vestibular nucleus is also involved in vestibulospinal reflexes (VSR), and it coordinates head and eye movements that occur together. The lateral vestibular nucleus is the principal nucleus for the vestibulospinal reflex. The descending nucleus is connected to all of the other nuclei and the cerebellum, but it has no primary outflow of its own. The vestibular nuclei are linked together via a system of *commissures*, which for the most part are mutually inhibitory. The commissures allow information to be shared between the two sides of the brain stem, and they implement the pairing of canals (discussed earlier).

In the vestibular nuclear complex, processing of the vestibular sensory input occurs concurrently with the processing of extravestibular sensory information (proprioceptive, visual, tactile, and auditory). Extensive connections between the vestibular nuclear complex, cerebellum, ocular motor nuclei, and brain stem reticular activating systems are required to formulate appropriate efferent signals to the VOR and VSR effector organs, the extraocular and skeletal muscles. The vestibular nucleus sends outflow to the oculomotor nuclei, spinal cord, cerebellum, and vestibular cortex.

Three major white matter pathways connect the vestibular nucleus to the anterior horn cells of the spinal cord. The *lateral vestibulospinal tract* originates from the ipsilateral lateral vestibular nucleus, which receives the majority of its input from the otoliths and the cerebellum. This pathway generates antigravity postural motor activity, primarily in the lower extremities, in response to the head position changes that occur with respect to gravity. The *medial vestibulospinal tract* originates from the contralateral medial, superior, and descending vestibular nuclei; it mediates ongoing postural changes in response to semicircular canal sensory input (angular head motion). The medial vestibulospinal tract descends only through the cervical spinal cord in the medial longitudinal fasciculus; it activates cervical axial musculature.

The *reticulospinal tract* receives sensory input from all of the vestibular nuclei, as well as all of the other sensory and motor systems involved with the maintaining balance. This projection has both crossed and uncrossed components, and it is very highly collateralized. As a result, its pathway through the entire extent of the spinal cord is poorly defined. The reticulospinal tract is probably involved in most balance reflex motor actions, including postural adjustments made to extravestibular sensory input (auditory, visual, and tactile stimuli).

The cerebellum is a major recipient of outflow from the vestibular nucleus complex, and it is also a major source of input to the vestibular nucleus itself. Most of the signal traffic is routed through the inferior cerebellar peduncle. The cerebellum is not required for vestibular reflexes, but when removed, vestibular reflexes become uncalibrated and ineffective. Originally, the *vestibulocerebellum* was defined as the portions of the cerebellum that received direct input from the primary vestibular afferents. It is now appreciated that most parts of the cerebellar vermis (midline) respond to vestibular stimulation. The cerebellar projections to the vestibular nuclear complex have an inhibitory influence on the vestibular nuclear complex. The *cerebellar flocculus* adjusts and maintains the gain of the VOR. Lesions of the flocculus reduce the ability of experimental animals to adapt to disorders that reduce or increase the gain of the VOR. The cerebellar *nodulus* adjusts the duration of VOR responses; it is also involved with processing of otolith input.

Vascular Anatomy

The arterial circulation of the inner ear (Fig. 12-4 (Figure Not Available)) is completely supplied by the *labyrinthine artery*. The labyrinthine artery has a variable origin. Most often it is a branch of the *anterior inferior cerebellar artery* (AICA), but occasionally, it is a direct branch of the basilar artery. As it enters the inner ear, it divides into the *anterior vestibular artery* and the *common cochlear artery*. The anterior vestibular artery supplies the vestibular nerve, most of the utricle, and the ampullae of the lateral and anterior semicircular canals. The common cochlear artery divides into a main branch, the *main cochlear artery*, and the *vestibulocochlear artery*. The main cochlear artery supplies the cochlea. The vestibulocochlear artery supplies part of the cochlea, ampulla of the posterior semicircular canal, and inferior part of the saccule. The labyrinth has no collateral anastomotic network and is highly susceptible to ischemia. Only 15 seconds of selective blood flow cessation is needed to abolish auditory nerve excitability.

The *vertebral-basilar arterial system* provides the vascular supply for both the peripheral and central auditory vestibular system. The posterior inferior cerebellar arteries (PICA) branch off the vertebral arteries. They supply the surface of the inferior portions of the cerebellar hemispheres, as well as the dorsolateral medulla, which includes the inferior aspects of the vestibular nuclear complex. The *basilar artery* is the principal artery of the pons. The basilar artery supplies central vestibular structures via *perforator branches*, which penetrate the medial pons, *short circumferential branches*, which supply the anterolateral aspect of the pons, and *long circumferential branches*, which supply the dorsolateral pons. The *anterior-inferior cerebellar artery* (AICA) supplies both the peripheral vestibular system, via the labyrinthine artery, as well as the ventrolateral cerebellum and the lateral tegmentum of the lower two thirds of the pons. Central auditory cortex is mainly supplied by the middle cerebral artery.

EXAMINATION OF THE VESTIBULOCOCHLEAR SYSTEM

Directed Neurological Examination

The "directed" or focused neurological examination for the assessment of cranial nerve VIII includes an evaluation of the external ear, hearing, and vestibular responses. The examination begins with an assessment of *gait and balance*.

Figure 12-4 (Figure Not Available) Arterial supply of the inner ear (From Schuknecht HF: *Pathology of the Ear*. Philadelphia, Lea & Febiger, 1993, p 64.)

Gait can often be observed as the patient walks into the examination room. The most useful test to quantify balance is the *eyes-closed tandem Romberg's* test. Low-normal performance consists of the ability to stand for 6 seconds, heel to toe, with eyes closed. Young adults should be able to perform this test for 30 seconds, but performance declines with age. It is helpful to develop a judgment as to how much ataxia is appropriate for a given degree of vestibular injury. Patients with *bilateral vestibular loss* are moderately ataxic—they make heavy use of vision and (with a narrow base) are unsteady when their eyes are closed. No patient with *bilateral vestibular loss* can stand in eyes-closed tandem Romberg's test position for 6 seconds. Patients with an additional superimposed posterior column position sense deficit, as well as patients with cerebellar dysfunction, are unsteady even with their eyes open. Patients with *chronic unilateral vestibular loss* show very little ataxia, and they can usually perform the eyes-closed tandem Romberg's test. The need to quantify ataxia does not come up in patients with recent unilateral vestibular imbalance, because these patients have a prominent nystagmus. Although numerous vestibulospinal tests have been described over the years, such as the Unterberger and Fukuda stepping test, the test results are not clinically useful because of variable performance in the normal population. In patients with head injury or in those in whom there are other reasons to suspect a central nervous system (CNS) origin of imbalance, basal ganglia function (pulsion/retropulsion tests) should also be performed.

The examination proceeds with an inspection of the external ear and ear canal looking for malformations, infections, masses, or asymmetry. Next, the tympanic membranes should be inspected for wax, perforation, otitis, or mass lesions. It is usually prudent to remove wax before embarking on more sophisticated diagnostic procedures. The tympanic membranes contribute about 20 db to the hearing level. Disorders such as perforation, scarring, fluid accumulation, or wax impaction can cause a conductive hearing loss. A normal tympanic membrane is translucent. Fluid behind the tympanic membrane imparts a straw color.

For *bedside hearing assessment*, the Rinne's and Weber's tests can be used. In the Weber's test, a vibrating 512-Hz tuning fork is placed on the patient's forehead. If the sound predominates in one ear, the patient may have either a conductive hearing loss in that ear or a contralateral sensorineural hearing loss. In the Rinne's test, the base of a vibrating tuning fork is placed on the mastoid and then placed about an inch away from the ear. Sound is normally appreciated better through air than through bone. If sound is heard better through bone, it is likely that there is a conductive hearing loss. Other tuning fork tests include the Bing's and Schwabach's tests. In the Bing's test, the fork is struck and placed on the mastoid tip. The examiner alternately occludes the patient's ipsilateral external meatus. If the patient has normal hearing or a sensorineural loss, he or she notices a change in intensity with occlusion. If the patient has a conductive hearing loss, he or she notices no change. The Schwabach's test is contingent on the examiner having normal hearing; the patient's hearing is compared with the examiner's. For bone conduction testing, if the patient stops hearing the sound before the

examiner, this finding is consistent with a sensorineural loss. If the patient hears the sound longer than the examiner, it suggests a conductive hearing loss.

In current clinical practice, the wide availability of excellent audiometric testing allows a much briefer screening maneuver to be used with excellent results. The examiner's thumb and second finger are rubbed together at an arm's length from one of the patient's ears. Persons with normal hearing can perceive this sound at this distance. If the sound is not perceptible, this noise is brought closer and closer until it is heard, and the distance is recorded. This simple test identifies high-tone hearing loss, and an unexpected loss or asymmetrical findings may warrant formal audiogram studies or further investigations with the tuning fork maneuvers described earlier.

Spontaneous nystagmus is next assessed using Frenzel's goggles, which are illuminated, magnifying goggles worn by the patient. The goggles are placed on the patient, and over the next 10 to 15 seconds, the eyes are observed for the presence of spontaneous nystagmus. The typical nystagmus produced by inner ear dysfunction is a "jerk" nystagmus—the eyes slowly deviate off center and then there is a rapid jerk, which brings them back to the center position. Most other patterns of nystagmus (e.g., sinusoidal, gaze-evoked) is of central origin. If Frenzel's goggles are not available, clinicians can obtain similar information about nystagmus from the ophthalmoscopic examination, by monitoring the movement of the back of the eye. As the back of the eye moves in the opposite direction to the front of the eye, for horizontal and vertical movements, the examiner must remember to invert the direction of the nystagmus when noting the direction of the fast phase. Furthermore, an attempt should be made to determine the effect of fixation on nystagmus. Nystagmus derived from the inner ear is increased by removal of fixation, whereas nystagmus of central origin is variably affected by fixation. Some types of central nystagmus, such as congenital nystagmus, may increase with fixation. Most forms of central nystagmus, however, decrease with fixation. Frenzel's goggles are an excellent means of removing fixation. In the ophthalmoscope test, fixation can also be removed by covering the opposite eye.

If there is little or no spontaneous nystagmus and if Frenzel's goggles are available, the *head-shake test* may be performed in an attempt to provoke a nystagmus. In this maneuver, the patient's eyes are closed and the head is moved in the horizontal plane, back and forth, for 20 cycles. A 45-degree excursion of the head to either side, and a 2-cycle/second frequency should be used. Nystagmus lasting 5 seconds or more is indicative of an organic disorder of the ear or CNS and supports further detailed investigation.

All patients with vertigo should receive a *Dix-Hallpike positional test* (Fig. 12-5). The patient is first positioned on the examination table, so that when lying flat the head will extend over the end of the table. If Frenzel's goggles are available, they are used; however, the test may be adequately performed without them. The patient is moved backward rapidly to lie on the table in the head-hanging-down position. The eyes are observed for the development of nystagmus. If no dizziness or nystagmus is appreciated after 20 seconds, the patient is returned to the sitting

Figure 12-5 Dix-Hallpike Maneuver (From Baloh RW, Halmagyi GH [ed]: *Disorders of the Vestibular System*. New York, Oxford University Press, 1996, p 331.)

position. The head is then repositioned 45 degrees to the right, and the patient is again brought down to the head-right supine position. After another 20 seconds, the patient is returned to the sitting position, and the procedure is repeated to the left (head-left). A burst of nystagmus, provoked by either the head-right or head-left position, should be sought. The nystagmus of classic BPPV beats upward and also has a rotatory component, such that the top part of the eye beats toward the down ear. The nystagmus typically has a latency of 2 to 5 seconds, lasts 5 to 60 seconds, and is followed by a downbeating nystagmus when the patient is placed upright in sitting position. A lateral-canal variant of BPPV occurs in which the eyes beat horizontally, toward the down ear. Nystagmus that is sustained longer than 1 minute is unlikely to be BPPV.

Although other positional tests can be used, they are of considerably less utility than the Dix-Hallpike test because of the relatively low incidence of causes of positional nystagmus other than BPPV. Central positional nystagmus such as a persistent downbeat or lateral beating nystagmus may be registered best by simple positional maneuvers wherein the head is supine rather than hyperextended, as in the Dix-Hallpike maneuver. Rarely, patients may develop nystagmus related to the position of their head on neck rather than with respect to gravity, and in these instances maneuvers should be done wherein the trunk is rotated with respect to a stable head.

Maneuvers used at the *assessment of VOR gain* are aimed at documenting bilateral vestibular loss. They need

not be done unless the patient has failed the eyes-closed tandem Romberg's test (see earlier). *The dynamic illegible E test* is the easiest and most sensitive of these

tests. Using an eye chart located at least 10 feet away from the patient, visual acuity is recorded with the head still. Then, the examiner moves the patient's head horizontally at roughly 1 Hz, ± 30 degrees, and visual acuity is again recorded. Normal individuals lose zero to two lines of acuity with head movement. Patients with partial to complete loss of vestibular function have a reduction of three to seven lines of acuity. The *ophthalmoscope test* is done when the dynamic illegible E test result is positive. The examiner focuses on the optic disc and then gently moves the head as described earlier. If the disc moves with the head, it confirms that the VOR gain is abnormal. This test is less sensitive than the illegible E test but is objective in nature. The *rapid doll's head test* can also be used when the illegible E test result is positive. The examiner stands in front of the patient, and the patient focuses on the examiner's nose. The examiner slowly rotates the patient's head to one side, roughly 30 degrees. Then, while asking the patient to continue to fixate, the head is rapidly rotated to the opposite mirror image position. In a normal subject, the eyes remain fixated on the examiner's nose throughout the entire procedure, moving equal and opposite to the head. In a patient with a poor vestibular-ocular reflex, such as in bilateral vestibular loss, a refixational eye movement is necessary after the head has stopped moving. This test can also sometimes detect unilateral vestibular lesions, because there may be a refixation saccade only when the head is rotated toward the bad side.

The *hyperventilation test* is most useful in patients with normal examinations up to this point. In this test the patient breathes deeply and forcefully for 30 breaths at a rate of roughly one breath per second. Immediately after hyperventilation, the eyes are inspected for nystagmus with the Frenzel's goggles, and the patient is asked if the procedure reproduced symptoms. A subjectively positive test result without nystagmus suggests the diagnosis of hyperventilation syndrome and is thought to be a sign of an anxiety disorder. Nystagmus induced by hyperventilation can occur in patients with tumors or irritation of the eighth nerve or in the setting of multiple sclerosis.

Associated Neurological Findings

Cerebral. Assessment of *cognitive function* does not often contribute to diagnosis of syndromes involving cranial nerve VIII. Unless there are specific issues suggested by history, this portion of the neurological examination can usually be omitted. The examination for aphasia should be undertaken if it appears that there is a discrepancy between the ability to detect sound versus the patient's ability to interpret sound. For example, an individual with cortical deafness may startle to a hand-clap but otherwise appears deaf.

Cranial Nerves. Other *cranial nerves* are rarely involved in processes that affect cranial nerve VIII. Corneal reflexes should be assessed when there are sensory complaints involving the face. Rarely, tumors of cranial nerve VIII grow larger than 3 cm and may compress cranial nerve V. Because cranial nerve VII travels with VIII in the IAC, the examiner should evaluate facial movement. Facial weakness is unusual even with large acoustical neuromas, however. In the brain stem, the nuclei of cranial nerves IX, X, and XI are close to that of VIII, and an assessment of the voice, palatal function, and gag may reveal unilateral weakness in certain patients. A careful oculomotor examination is crucial for detecting many subtypes of central vertigo.

Motor/Reflexes/Cerebellar/Gait. The motor examination should include assessment of power in the upper and lower extremities. The cerebellar examination should particularly focus on the assessment of upper extremity coordination. Reflexes should be checked, because asymmetry or a positive Babinski's sign may be a valuable clue to a brain stem disorder.

Sensory. When the history suggests a sensory disturbance, examination should be made of pinprick in the face and extremities. Position sense should be checked in all ataxic patients.

Autonomic Nervous System. The pupils should be also checked for Horner's syndrome (miosis, ptosis, and rarely anhidrosis), because the sympathetic system in the brain stem is at times affected with CN VIII dysfunction, particularly with vascular lesions (Wallenberg's syndrome). Blood pressure and pulse are taken with the patient standing, and if the blood pressure is low (110/70 or lower), it should be repeated with the patient lying flat. These procedures are intended to exclude orthostatic hypotension, which needs to be considered in patients with symptoms suggestive of postural vertigo or ataxia.

Neurovascular Examination. The carotid and subclavian arteries are examined by auscultation in all patients with symptoms that suggest cranial nerve VIII dysfunction.

Associated Medical Findings

The heart and the carotid and subclavian arteries should be auscultated. In patients with pulsatile tinnitus, the head should be auscultated for bruits. In patients with potential syncope who are younger than 70 years of age and have no carotid bruit, 10 seconds of carotid sinus massage may be undertaken. This is done with the patient in the sitting position, first on one side, then on the other, in an attempt to reproduce symptoms.

EVALUATION GUIDELINES (Tables 12-5 and 12-6)

Numerous laboratory procedures are commonly used for evaluation of patients with vertigo and dizziness. For efficiency and cost, procedures should be selected according to specific symptom complexes present in the patient.

Neuroimaging. Skull films, cervical spine films, computed tomography (CT) scans of the head, and CT scans of the sinuses are not routinely recommended in the evaluation of vertigo or hearing disturbances. Magnetic resonance imaging (MRI) of the head can be used to evaluate

TABLE 12-5 -- USEFUL STUDIES IN THE EVALUATION OF DISORDERS OF CRANIAL NERVE VIII

Syndrome	Neuroimaging	Electrophysiology	Fluid and Tissue Analysis	Neuropsychological Tests	Other Tests
Central hearing disorders	Temporal cortex lesion: MRI, CT	N/A	N/A	Abnormal	Poor word recognition on audiometry
Peripheral hearing loss	Usually normal MRI, CT	BAER ECOG MLR	N/A	N/A	Audiogram abnormal
CPA syndrome	Lesion in CPA: MRI, CT	BAER	CSF	N/A	Audiogram abnormal

Meniere's disease	Normal	BAER ECOG	N/A	N/A	Audiogram ENG
Vestibular neuritis	MRI may show enhancement of vestibular nerve	N/A	N/A	N/A	ENG
Bilateral vestibular loss	Normal	N/A	N/A	N/A	ENG Rotatory chair Audiogram

MRI, magnetic resonance imaging; CT, computed tomography; MLR, middle latency response; BAER, brain stem auditory evoked responses; ECOG, electrocochleography; N/A, not applicable; ENG, electronystagmography.

the structural integrity of the brain stem, cerebellum, periventricular white matter, eighth nerve complexes, and sinuses. The T1 MRI with gadolinium contrast is the most useful study. MRI is not routinely needed to evaluate vertigo or hearing disturbance without accompanying neurological findings. Although the MRI may show enhancement of the vestibular nerve in vestibular neuritis, the expense of this study should be considered when attempting to document the existence of this self-limited condition. MRI with contrast is preferred to brain stem auditory evoked responses (BAER) testing, when acoustic neuroma is suspected, because it detects tumors at an earlier stage. CT of the temporal bone provides higher resolution than MRI and is preferred in the evaluation of lesions involving bone, particularly when otosclerosis or cholesteatoma is suspected.

Electrophysiology. *Electroencephalography* has a low yield in most disorders related to cranial nerve VIII but is indicated when there is unexplained vertigo after head trauma or for the "quick spin" symptom complex. The BAER test, also known as *auditory brain stem response test*, assesses the auditory nerve and brain stem pathways. This test is usually ordered to rule out an acoustic neuroma, and this study has roughly a 90 percent sensitivity. Because BAER results may be inaccurate in patients who have no high-frequency hearing, audiometry is recommended before BAER testing. The presence of abnormal BAER results is an indication for a MRI evaluation of the posterior fossa (T1-weighted image with contrast). For cost efficiency, BAERs need not be obtained if an MRI is planned, and the MRI is generally the preferred test in most instances. Electrocochleography (ECOG) is a variant of the BAER in which needle electrodes are placed in the ear drum to obtain better definition of the cochlear potential. ECOG is sometimes helpful to confirm a diagnosis of Meniere's disease.

Numerous more unusual electrophysiological tests can be used to infer the integrity of central auditory pathways. The middle latency response, or MLR, is generated by thalamocortical pathways. The "mismatch" response is a test of higher order auditory discrimination. The role of these tests in clinical practice is uncertain.

Fluid and Tissue Analysis. *Blood tests* are triggered by specific symptom complexes, and there is no routine set of values obtained in every patient. In particular, chemistry panels, complete blood counts, glucose tolerance tests, and allergy tests need not be routinely ordered. Similarly, urine testing is rarely productive in disorders of cranial nerve VIII.

Cerebrospinal Fluid. Lumbar puncture has limited usefulness in disorders of cranial nerve VIII. Occasionally, it may be indicated in pursuit of the diagnosis of neurosyphilis, Lyme disease, and meningeal carcinomatosis.

Neuropsychological Tests. Neuropsychological testing of speech and language may be helpful in patients in whom the diagnosis of a central hearing disturbance is being entertained. Otherwise, these procedures have limited usefulness in the evaluation of disorders of cranial nerve VIII. The Minnesota Multiphasic Personality Inventory has some usefulness when the diagnosis of malingering is being considered. Neuropsychological testing may also be useful in determining how much anxiety is associated with the patient's symptom complex.

Other Tests. The audiogram is the single most useful test in the patient with a hearing disorder and/or vertigo. In hearing disorders, the audiogram is crucial in defining the degree and type of loss. In patients with vertigo, abnormalities in the audiogram usually narrow the differential diagnosis down to otological vertigo. Accompanying the audiogram is a battery of related measures. The *tympanogram* measures middle ear pressure, and tympanometry is helpful in identifying a perforated ear drum or middle ear infection. *Acoustical reflexes* measure the stapedius and tensor tympani reflex-generated ear drum movement in

TABLE 12-6 -- LABORATORY PROCEDURES FOR DISORDERS RELATED TO THE EIGHTH NERVE

Test	Indication
NEUROIMAGING	
MRI of head	Central vertigo or hearing loss abnormal BAER
MRA	
CT scan of temporal bone	TIA or CVA
	Suspect fistula, cholesteatoma, mastoiditis, congenital abnormality

response to intense sound, and they can be helpful in corroborating particular types of hearing loss. Reflexes that are present at abnormally low levels suggest recruitment with a cochlear site of lesion. Reflexes that decay rapidly suggest a retrocochlear lesion.

The *word recognition score (WRS)* (also called *speech discrimination*) measures the ability to repeat words presented at a comfortable loudness. Word recognition can be impaired by both auditory distortion and central abnormalities such as a nonfluent aphasia. Speech reception threshold (SRT) measures the auditory threshold of hearing for words. It should be consistent with pure-tone hearing. When they are not consistent, a nonperipheral hearing disturbance is more likely.

The short-increment sensitivity index (SISI), alternate binaural loudness balance (ABLB), and Bekesy's tests are no longer used in most clinical practices. Audiometry is particularly useful in the diagnosis of Meniere's disease. A fluctuating low-tone sensorineural hearing loss is typical of this condition ([Fig. 12-6](#)).

Otoacoustic emissions have become an added option to the hearing evaluation. A click is usually used to generate the response. The outer hair cells generate a sound in response to the stimulus, and this sound is captured by a microphone in the ear canal. The test has proven useful for infant hearing screening.

Four types of vestibular tests are selected according to the clinical situation. *Electronystagmography (ENG)* is the most useful, and it consists of a battery of procedures that can identify vestibular asymmetry (such as that caused by vestibular neuritis) and that document spontaneous or positional nystagmus (such as that caused by BPPV). Because of anatomical variability and technical difficulty, the ENG result can be misleading, most commonly suggesting an abnormality when none exists. An abnormal result that does not fit the clinical picture should be confirmed with *rotatory chair* testing. Rotatory chair testing measures vestibular function of both inner ears together and is also highly sensitive and specific for bilateral loss of vestibular function. Although rotatory chair testing does not establish the side of a unilateral vestibular lesion, there is a characteristic pattern on unilateral loss. For this reason it can also be helpful in corroborating an abnormal ENG. *Fistula testing* involves the recording of nystagmus induced by pressure in the external ear canal. Its sensitivity to a perilymph fistula is only 50 percent, but it is the only objective procedure that is available to substantiate a clinical suspicion of fistula. *Posturography* is an instrumented variant of the Romberg's test. The sole diagnostic indication for posturography at this writing is to document malingering.

Syncope is a common differential diagnosis in the evaluation of disorders of cranial nerve VIII; it is sometimes useful to check patients for arrhythmia or abnormal control

Figure 12-6 Audiogram depicting the low-tone sensorineural loss typical of Meniere's disease. The gray shaded area indicates the normal range. The *le(X marks)* is normal at all frequencies. The right *ec(circles)* has decreased hearing on both air and bone for lower frequencies.

of blood pressure. *Ambulatory event monitoring* or Holter monitoring is used to detect arrhythmia or sinus arrest. *Tilt-table testing* is sometimes advocated for the diagnosis of syncope. At present, however, this is a lack of data establishing a link between tilt-table test abnormalities and successful treatment outcomes, and thus the role of the tilt-table test in the evaluation of dizzy patients is presently unclear.

CLINICAL SYNDROMES (Table 12-7)

Syndromes Primarily Involving Hearing

Hearing loss is highly prevalent, especially in the older population, and three types are commonly encountered: conductive, sensorineural, and central hearing loss. In conductive hearing loss, sound is not transmitted into the inner ear. Diagnosis is ordinarily made via observation of an "air-bone gap" on audiometry, meaning that hearing is superior when sound is transmitted in such a way that it bypasses the middle ear ossicular chain. Causes include a buildup of ear wax, foreign body in the ear canal, otosclerosis, external or middle ear infections, allergy with serous otitis, and perforation of the tympanic membrane. Characteristically, hearing aids work well for this population.

Sensorineural hearing loss is the most common type of hearing loss, occurring in 23 percent of the population older than 65 years of age. The term *sensorineural* is used to indicate that there is either a cochlear or an eighth nerve lesion. The diagnosis of a sensorineural pattern hearing loss is made through audiometry, which shows a significant hearing loss without the air-bone gap characteristic of conductive hearing disturbances. Common causes include old age (when the hearing pattern is often somewhat confusingly called *presbycusis*), Meniere's disease, toxin exposures (such as to high-dose aspirin), and noise. Treatments are mainly aimed at preventing further damage. If the loss is minor, avoidance of noise and avoidance of ototoxic medications are appropriate "treatments." If the loss is significant, a hearing aid should be tried. Occasionally, persons with acquired deafness can be treated with a surgically implanted prosthesis that directly stimulates the spiral ganglion.

Central hearing loss is extremely rare compared with the

TABLE 12-7 -- SELECTED ETIOLOGIES ASSOCIATED WITH DISORDERS OF CRANIAL NERVE VIII

Etiological Category	Specific Etiologies	Chapter
STRUCTURAL DISORDERS		
Developmental structural disorders	Arnold-Chiari malformation Mondini malformation	28
Degenerative and compressive structural disorders	Paget's disease	
HEREDITODEGENERATIVE DISORDERS		
Storage diseases: Lipidoses, glycogen disorders and leukoencephalopathies	Hurler's, Hunter's, Sanfilippo's, Morquio's syndromes Krabbe's disease	29
Chromosomal anomalies and the neurocutaneous disorders	Waardenburg's, Usher's, Down's, Pendred's syndromes	32
ACQUIRED METABOLIC DISORDERS AND NUTRITIONAL DISORDERS		
Endogenous metabolic disorders	Kernicterus	38
Nutritional deficiencies and syndromes associated with alcoholism	Wernicke's (Central vertigo)	
INFECTIOUS DISORDERS		
Viral Infections	Vestibular neuritis Herpes zoster oticus Cytomegalovirus (infants)	41
Nonviral Infections	Chronic, acute otitis media (bacterial) Meningitis (bacterial, fungal) Syphilis	42
NEUROVASCULAR DISORDERS	AICA, PICA syndromes Subarachnoid hemorrhage	45
NEOPLASTIC DISORDERS		
Primary neurological tumors	Acoustic neuroma Cholesteatoma	46
DEMYELINATING DISORDERS		
Demyelinating disorders of the central nervous system	Multiple sclerosis	48
TRAUMATIC DISORDERS	Blunt head trauma	51
EPILEPSY	Central vertigo	52
HEADACHE AND FACIAL PAIN	Central vertigo (vertebrobasilar migraine)	53
DRUG-INDUCED AND IATROGENIC NEUROLOGICAL DISORDERS	Vestibular ototoxicity: aminoglycosides	55

AICA, anterior inferior cerebellar artery; PICA, posterior inferior cerebellar artery.

sensorineural or conductive types. The diagnosis is usually not made by the pure tone audiogram, which often yields a normal result. Rather, patients usually have an aphasia, which may be associated with disproportionately poor scores on the speech reception threshold tests or word recognition scores portions of the audiogram.

Pure word deafness is a rare subtype of central deafness. This disorder is defined as disturbed auditory comprehension without difficulties with visual comprehension. Patients characteristically have fluent verbal output, severe disturbance of spoken language comprehension and repetition, and no problems with reading or writing. Nonverbal sounds are correctly identified. The lesion is classically postulated to be a disruption in connections between the dominant Heschl's transverse gyrus and the medial geniculate as well as callosal fibers from the opposite superior temporal region. Initially, it appears commonly as a Wernicke's aphasia. With recovery, difficulties in auditory comprehension persist. Although usually caused by a stroke, pure word deafness can arise from other causes of focal cortical lesions such as tumors.

Auditory agnosia, another rare subset of central deafness, is typified by relatively normal pure tone hearing on audiometry, but inability to interpret (recognize) nonverbal sounds such as the ringing of a telephone. Inability to interpret nonverbal sounds but preserved ability to interpret speech may be a result of a right hemisphere lesion alone. Amusia is a particular type of auditory agnosia in which only the perception of music is impaired. Again, right-sided temporal lesions are thought to be the cause.

Cortical deafness is essentially the combination of word deafness and auditory agnosia. It is characterized by an inability to interpret either verbal or nonverbal sounds with preserved awareness of the occurrence of sound (for instance, by a startle reaction to a clap). In most instances, the cause is bilateral embolic strokes in the area of Heschl's gyri. Patients present with sudden deafness evolving later so that they can hear sounds but are unable to recognize their meaning. Relatively few cases of this disorder have been studied, and it is possible that bilateral lesions of the central auditory pathways, other than the speech cortex, can also result in these deficits.

Auditory hallucinations consist of an illusion of a complex sound such as music or speech. These hallucinations most commonly occur as a result of an injury to the

superior temporal auditory association areas. Penfield discovered that stimulating this area induced an auditory sensation that seemed real to patients. Auditory hallucinations can also occur as a result of temporal lobe seizure.

Syndromes Primarily Involving Vestibular Function

Conditions that involve vestibular function can be separated into peripheral (otological vertigo) and central subgroups. Patients with these syndromes present clinically with a combination of vertigo and ataxia. Practically, there are far more cases of otological vertigo than central vertigo, and for this reason, in clinical practice, a detailed understanding of otological vertigo is essential.

BENIGN PAROXYSMAL POSITIONAL VERTIGO

Benign paroxysmal positional vertigo is the cause of half of all cases of otological vertigo; it accounts for about 20 percent of all patients with vertigo. Benign paroxysmal positional vertigo is diagnosed by the history of positional vertigo with a typical nystagmus pattern (a burst of upbeating/torsional nystagmus) on Dix-Hallpike positional testing. Symptoms are precipitated by movement or a position change of the head or body. Getting out of bed or rolling over in bed are the most common "problem" motions. A burst of nystagmus can often be provoked by placing the head in positions wherein the posterior canal is made vertical in space, and ENG testing may be helpful in documenting this condition. Benign paroxysmal positional vertigo is usually a straightforward clinical diagnosis. Ordinarily there is no need to obtain neuroradiological tests, audiometric testing, or posturography.

It is currently thought that BPPV is caused by the presence of free debris, possibly otoconia, within the semicircular canals, which is dislodged from the otolith organs by trauma, infection, or degeneration ([Fig. 12-7](#)). The otoconial debris can move about by changes in head position, causing vertigo and nystagmus when the debris tumble through the semicircular canals. The duration of symptoms is brief, because dizziness occurs only while the debris shifts position. Physical treatments based on the manipulation of head are the most effective remedies for BPPV. These maneuvers reposition the otolithic debris to an insensitive location within the inner ear.

VESTIBULAR NEURITIS AND OTHER UNILATERAL VESTIBULOPATHIES

Vestibular neuritis is a self-limited otological condition. Patients present with vertigo, nausea, ataxia, and nystagmus. Most cases of vestibular neuritis are monophasic. Hearing is not impaired, and when there are similar symptoms with abnormal hearing, the syndrome is termed *labyrinthitis*. A strong nystagmus is seen acutely, and Frenzel's

Figure 12-7 Debris hypothesis of benign paroxysmal positional vertigo. Otoconia displaced from the utricle gravitate to the most dependent parts of the inner ear.

goggles are particularly useful in seeing these eye movements. Vestibular neuritis is thought to be caused by viral infections involving the vestibular portion of the eighth nerve.

Similar symptoms may be seen with other etiologies. Meniere's disease is usually recognized by the episodic pattern (see later). Herpes simplex virus infection of the vestibular nerve is recognized by a combination of ear pain and the presence of vesicles on the external canal. Acoustic neuroma (discussed later) is recognized by a slower course and the occurrence of hearing loss. Vascular disorders such as a labyrinthine artery infarction are generally impossible to exclude, and their diagnosis is suggested by an identical symptom complex combined with vascular risk factors.

No laboratory testing is needed in straightforward cases. When a central disorder is suspected in the setting of multiple cerebrovascular risk factors or neurological diseases, however, further laboratory testing may be helpful to confirm the anatomical diagnosis. Electronystagmography testing often reveals a significantly decreased caloric response on one side as well as spontaneous nystagmus. Rotational testing is not necessary, but when obtained, it typically shows reduced gain and increased phase lead. Posturography is also not necessary, but results are typically abnormal, indicating that balance is impaired.

In vestibular neuritis, severe distress associated with constant vertigo, nausea, and malaise usually lasts 2 or 3 days, and less intense symptoms ordinarily persist for 1 or 2 weeks. The treatment strategy involves the use of vestibular suppressants and antiemetics ([Tables 12-8](#) and [12-9](#)). Roughly 10 percent of patients may take as long as 2 months for the condition to improve substantially. These patients usually have a significant fixed vestibular paresis combined with central dysfunction that slows their compensation. For example, patients with alcoholic cerebellar degeneration or persons of advanced age may recover much more slowly. Such patients often benefit from visual- vestibular exercises.

Vestibular exercise instructions may be given to patients in the form of a handout. These exercises are done three times daily, moving from the easier procedures to more difficult ones, as recovery ensues. Specialized physical therapy programs are also available in which individualized therapy can be offered and supervision provided, when appropriate. It should also be noted that numerous avocational activities serve well to promote vestibular compensation, and depending on the abilities and interests of patients, clinicians may prescribe golf, bowling, racquetball, bicycling, or even t'ai chi.

CEREBELLOPONTINE ANGLE SYNDROME

Acoustic neuromas and other tumors such as meningiomas, which can appear at the cerebellopontine angle, usually display asymmetrical sensorineural hearing loss. Usually, patients in the fifth or greater decade present with mild vertigo or ataxia, accompanied by a significant asymmetrical hearing loss. Generally, there are no other physical examination abnormalities, and facial and sixth nerve functions are ordinarily normal.

If the hearing loss is minor, an audiogram may be performed within 6 months. If hearing loss progressively worsens, an MRI scan should be pursued. If a tumor is identified and is small, or the patient is reluctant to have surgery, the tumor may be followed with periodical evaluations. MRI should be repeated every year, more frequently if there is a substantial change in hearing. In many instances, lesions remain stable over many years and surgery can be avoided. Gamma knife treatment is an emerging modality and may also be used when surgery is refused or when the patient is a poor surgical risk.

MeNIERE'S DISEASE

Classic Meniere's disease presents as a quadrad of paroxysmal symptoms, including tinnitus, monaural fullness, fluctuating hearing, and episodic vertigo. This clinical picture is sometimes called the "hydrops" symptom complex, inferring that the mechanism is related to dilation and

TABLE 12-8 -- VESTIBULAR SUPPRESSANTS

Drug	Dose	Adverse Reactions	Pharmacologic Class and Precautions
Meclizine (Antivert, Bonine)	12.5-50 mg every 4-6 hours	Sedating, precautions in prostatic enlargement, glaucoma	Antihistamine Anticholinergic
Lorazepam (Ativan)	0.5 mg twice daily	Mildly sedating Drug dependency	Benzodiazepine
Clonazepam (Klonopin)	0.5 mg twice daily	Mildly sedating Drug dependency	Benzodiazepine
Scopolamine (Transderm-Scop)	0.5 mg patch every 3 days	Topical allergy with chronic use. Precautions in glaucoma, tachyarrhythmias, prostatic enlargement	Anticholinergic

Dimenhydrinate (Dramamine)	50 mg every 4-6 hours	Same as meclizine	Antihistamine Anticholinergic
Diazepam (Valium)	2-10 mg (1 dose) given acutely orally, intramuscularly, or intravenously	Sedating Respiratory depressant Drug dependency Precaution in glaucoma	Benzodiazepine

Doses listed are used in adults Drugs arranged in order of preference.

TABLE 12-9 -- ANTIEMETICS

Drug	Usual Dose (Adults)	Adverse Reactions	Pharmacological Class
Droperidol (Inapsine)	2.5 or 5 mg sublingual or intramuscularly every 12 hours	Sedating Hypotension Extrapyramidal	Dopamine antagonist
Meclizine (Antivert, Bonine)	12.5-50 mg every 4-6 hours orally	Sedating Precautions in glaucoma, prostate enlargement	Antihistamine and anticholinergic
Metoclopramide (Reglan)	10 mg orally three times daily or 10 mg intramuscularly	Restlessness or drowsiness Extrapyramidal	Dopamine antagonist
Ondansetron (Zofran)	4-8 mg po single dose	Hypotension	5-HT ₃ antagonist
Prochlorperazine (Compazine)	5 mg or 10 mg intramuscularly or orally every 6-12 hours or 25 mg rectal every 12 hours	Sedating Extrapyramidal	Phenothiazine
Promethazine (Phenergan)	12.5-25 mg orally every 6-8 hours or 12.5-25 mg rectal every 12 hours	Sedating	Phenothiazine
Trimethobenzamide (Tigan)	12.5 mg intramuscularly every 6-8 hours 250 mg orally three times daily or 200 mg intramuscularly three times daily	Extrapyramidal Sedating Extrapyramidal	Similar to phenothiazine
Thiethylperazine (Torecan)	10 mg orally, up to three times daily or 2 ml intramuscularly, up to three times daily	Sedating	Phenothiazine

Doses listed are used in adults.

rupture of the endolymphatic compartment of the inner ear. The tinnitus is characteristically of two types. Between attacks the tinnitus is characteristically a ringing noise (about 75 percent of the population has ringing tinnitus from time to time). During an attack, the tinnitus becomes a multifrequency noise such as a roar, hiss, or buzz. Patients also generally complain of monaural fullness, a sensation as if the ear were full of water, beginning a day or two before an attack. Hearing is normal at the onset of the condition, but with each attack a low-frequency sensorineural reduction in hearing appears (see [Figure 12-5](#)), and then it usually resolves a day or two later. After many attacks, hearing begins to decline and involves the high frequencies. Ultimately, many individuals with Meniere's disease develop permanent sensorineural pattern deafness.

The clinical picture of Meniere's disease varies widely, with some patients developing deafness with their first attack and others retaining normal hearing after several decades of repeated attacks. Variants of Meniere's disease include a form that follows head injury (labyrinthine concussion or delayed endolymphatic hydrops), and a bilateral form attributed to autoantibodies or genetic predisposition.

The diagnosis of classic Meniere's disease can be made purely by history, but most commonly it is made by combining a history of episodic vertigo and hearing symptoms with audiometric documentation of a fluctuating low-tone sensorineural hearing loss. Electrocochleography may be useful in cases when the history is not classic. It is conventional practice to obtain several blood tests including fluorescent treponemal antibody, antinuclear antibody, complete blood count, and fasting blood glucose after diagnosing Meniere's disease to identify specific treatable causes.

In the treatment of Meniere's disease, vestibular suppressants and antiemetics are used in a way similar to that described for vestibular neuritis (see [Tables 12-8 and 12-9](#)). Because bouts generally last only 2 hours, acute treatment is usually episodic. Often patients can anticipate an attack and can start taking an antiemetic and/or vestibular suppressant before their full-blown symptoms occur. It is presently generally accepted that reduction of salt intake with a no-added-salt diet and daily use of a salt-wasting diuretic is helpful in reducing the number and intensity of spells over the long term.

Effective surgical treatment of Meniere's disease is based on procedures that destroy vestibular function. Three procedures are commonly used today, including labyrinthectomy, selective vestibular nerve section, and transtympanic gentamicin treatment. Gentamicin treatment is presently growing rapidly in popularity.

CENTRAL VERTIGO

In neurological practice, central vertigo typically makes up only about 25 percent of diagnoses of patients presenting with vertigo, because otological vertigo and vertigo of unknown cause are much more frequent ([Table 12-10](#)). Stroke and transient ischemic attacks account for one third of cases of central vertigo. Vertigo attributed to vertebrobasilar migraine accounts for another 15 percent of cases. A large number of individual miscellaneous neurological disorders such as seizures, multiple sclerosis, and the Arnold-Chiari malformation make up the remainder.

GENERAL MANAGEMENT GOALS

General pharmacological management of conditions affecting hearing is nearly nonexistent, in spite of many attempts over the years using vasoactive agents, steroids, and agents for allergy.^[10] When a specific etiology is known,

such as Meniere's disease, treatment directed at the cause may be used, but there is no effective pharmacological management of tinnitus or hearing loss.

Hearing aids are indicated when hearing loss is significant and "aidable," meaning that improvement in word recognition scores may be obtained with amplification. Hearing aids are expensive. They are often not covered by standard insurance policies, and there are considerable performance differences between basic and "deluxe" models. For these reasons, hearing aids should ideally be fit by an experienced audiologist who offers at least a 1-month tryout period.

For tinnitus, an assortment of medications may be empirically tried, including antidepressants, minor tranquilizers, and anticonvulsants. Hearing aids or "maskers" (devices that generate white noise) are helpful in a few patients.

With respect to symptomatic management of peripheral vestibular disorders (see [Tables 12-4](#) and [12-5](#)), vestibular suppressants and antiemetics are generally used. In patients with static and significant structural vestibular lesions, vestibular rehabilitation approaches including vestibular exercises are substituted. In patients with central vestibular disorders, treatment approaches are generally eclectic. Agents used in peripheral disorders are usually tried, followed by empirical trials of other medication groups, including benzodiazepines and anticonvulsants. Vestibular rehabilitation again may be quite useful in this group.

Certain medications should be used with caution in patients with disorders of the eighth cranial nerve. A surprisingly large number of frankly ototoxic medications are in common clinical use (see [Table 12-2](#)). It is usually prudent to eliminate as many of these medications as possible in such patients. In addition, it is common practice to use potentially addictive medications, such as benzodiazepines, in the management of patients with vertigo or imbalance when other medications fail. Although these agents are indispensable in these settings, the doses should be kept low and patient use should be monitored.

Hearing protection is often indicated in patients with damage to the eighth cranial nerve, and patients need to be explicitly warned to avoid loud noises and use hearing protection devices in excessively noisy environments.

HISTORY AND DEFINITIONS

The glossopharyngeal and vagus nerves have been described since antiquity. Galen of Pergamus (131 to 201 AD) included them in his descriptions of neuroanatomy, grouping together cranial nerves IX, X, and XI as a single nerve.¹ Centuries later the anatomy of the glossopharyngeal and vagus nerves was elucidated in greater detail by the Prussian anatomist Samuel Thomas von Soemmering (1755-1830) in his treatise on the 12 cranial nerves. Although study of the glossopharyngeal nerve in isolation is impractical, the vagus nerve, with its numerous thoracic and abdominal visceral innervations, has long held the attention of physiologists, including the Russian Nobel Laureate Ivan Petrovich Pavlov (1849-1936), who, with E.O. Schumov-Simanovskaja, published in 1895 their prominent paper describing vagus nerve innervation for gastric secretion in dogs. The clinical consequences of pathology, particularly trauma and tumors, upon the glossopharyngeal or vagus nerves have been described by a number of authors who have attached their names to syndromes of the lower cranial nerves, beginning with John Hughlings Jackson in 1883.

Cranial nerves IX and X, the glossopharyngeal and vagus nerves, respectively, have their nuclei in the medulla, and they serve motor, sensory, and autonomic functions. Both nerves are formed by the joining of rootlets that emerge from the lateral medulla in a groove formed between the olive and the inferior cerebellar peduncle. The two nerves travel closely in their proximal courses, both exiting the skull at the jugular foramen, and consequently they are typically affected together by intracranial pathology. The name of the glossopharyngeal nerve refers in Latin to its targets of function, *glosso* referring to tongue and *pharyngea* to the beginning of the alimentary canal. The vagus nerve is aptly named as well, with its numerous afferent and efferent functions in the head, neck, chest, and abdomen; *vagus* is a Latin adjective meaning wandering or roving.

Both the ninth and tenth nerves have components of branchial motor fibers (special visceral efferent) providing innervation of striated muscle, visceral motor fibers (general visceral efferent) to secretory glands, and both visceral and general sensory functions (general visceral and general somatic afferent). Additionally, the glossopharyngeal nerve has special afferent fibers receiving taste sensation from the posterior third of the tongue. Together the ninth and tenth cranial nerves provide sensory and motor innervation of the larynx and pharynx, including the afferent and efferent limbs of the gag reflex, and exteroceptive information for these structures, the tongue, the auditory meatus and tympanic membrane, and parts of the ear. The glossopharyngeal nerve also provides afferent input from the baroreceptors of the carotid sinus and the chemoreceptors of

202

the carotid body. The vagus nerve subserves esophageal peristalsis, heart rate and blood pressure modulation, gastric secretion, and bowel motility.

[PreviousNext](#)

CLINICAL HISTORY

The primary clinical symptom of cranial nerve IX dysfunction is dysphagia or choking, and the most readily identified sign of vagal nerve damage is hoarseness. The clinical histories of patients with symptoms referable to the glossopharyngeal and vagus nerves necessarily reflect the location of the nerve dysfunction and the process producing it. Dependent upon these two factors the temporal appearance of symptoms may vary widely, ranging, for example, from the acute onset of hoarseness and dysphagia due to brain stem infarction involving the vagus nerve nuclei to the insidious appearance of hoarseness without dysphagia produced by the encroachment of a pulmonary neoplasm upon the intrathoracic recurrent laryngeal branch of the vagus nerve.

Intraparenchymal brain lesions of the medulla at the level of the glossopharyngeal and vagus nerves typically affect the nuclei of both, and possibly also of the eighth cranial nerve, resulting in symptoms of vertigo, hoarseness of speech, and dysphagia. Because cranial nerves IX, X, and XI pass together through the jugular foramen at the base of the skull, a lesion at this location can cause added neck muscle weakness.^[1] Rarely, throat pain occurs, specifically in the syndrome of idiopathic glossopharyngeal neuralgia, in which fleeting pain at the base of the tongue is sometimes triggered by chewing or swallowing. An intramedullary lesion of the vagal motor nucleus producing vocal cord weakness and hoarseness of speech likely also affects adjacent structures, such as the spinal tract and nucleus of cranial nerve V, the spinothalamic tract, and cerebellar fibers. Hence, associated symptoms include a crossed sensory disturbance (ipsilateral face and contralateral limbs) and ataxia. An ipsilateral Horner's syndrome may be present from involvement of descending sympathetic fibers, although the patient is unlikely to describe accompanying symptoms, because an intracranial but extramedullary lesion of the vagus nerve involves also the ninth and eleventh cranial nerves. The presence or absence of dysphagia, with hoarseness of speech, is an important clue to the localization of the lesion of the vagus nerve. Hoarse speech without dysphagia occurs when the lesion site of the vagus nerve is below the upper cervical levels where the pharyngeal branches exit. This lesion most commonly occurs at the level of the recurrent laryngeal nerve branch. Possible mechanisms include an expanding aneurysm at the aortic arch, mediastinal adenopathy, and pulmonary neoplasms.^[2],^[3]

Head, neck, or oral trauma, and surgery of these structures may result in damage of the ninth and tenth cranial nerves. Head injury with basilar skull fracture may compromise both nerves at the jugular foramen.^[4] Vocal cord paralysis is a recognized complication of neck surgery, including thyroidectomy and carotid endarterectomy.^[5],^[6] Both procedures may injure laryngeal branches of the vagus nerve by manipulation or transection. The recurrent laryngeal nerve is injured by thyroidectomy at a rate of approximately 7 percent, producing ipsilateral paralysis of all the laryngeal muscles except for the cricothyroid. This injury may result in breathiness of speech and aspiration.^[7]

Underlying medical conditions or their treatment may cause injury to the glossopharyngeal and vagus nerves. Patients with neoplasms that involve the head or neck, either primary tumors or metastases, may experience impaired swallowing as a consequence of nerve compression at the jugular foramen or other sites.^[8] Infectious or inflammatory processes involving the central nervous system (CNS) at the level of the brain stem can produce cranial neuropathies. Although the ninth and tenth cranial nerves may be involved, they generally do not produce prominent symptoms or signs. Neurological manifestations of sarcoidosis typically involve cranial nerves, particularly the facial nerve, yet involvement of cranial nerves IX and X can occur in conjunction with facial weakness, and their function should be assessed.^[9] The ninth and tenth nerves may also be damaged as a consequence of diabetes, syphilis, or alcoholism.^[10],^[11],^[12]

Patients may have respiratory complaints, because abnormalities of ventilatory drive by hypoxic stimulation can occur with involvement of carotid body chemoreceptor afferent fibers from the glossopharyngeal nerve.^[13] Patients may also have symptoms of lightheadedness and orthostatic dizziness from involvement of baroreceptor afferent fibers from the carotid sinus.^[14] The Guillain-Barre(c) syndrome may have associated autonomic dysfunction resulting from demyelination of glossopharyngeal afferents from the carotid sinus and vagal fibers, producing instability of blood pressure and heart rhythm, and bowel motility disturbance such as ileus.^[15],^[16] A history of all medications and toxin exposures is important, because cranial nerve neuropathy due to exposure to known neurotoxins may involve the glossopharyngeal and vagus nerves. Patients undergoing cancer treatment with the chemotherapeutic agent vincristine may rapidly develop jaw pain due to peripheral injury of the glossopharyngeal nerve.^[17]

ANATOMY OF CRANIAL NERVE IX (Table 13-1)

Motor Fibers

NUCLEUS

The nucleus ambiguus runs in a rostral to caudal direction in the medulla and is located in the ventrolateral reticular formation, posterior to the inferior olivary nuclear complex and anteromedial to the spinal trigeminal nucleus (Fig. 13-1).^[18],^[19] The rostral portion of the nucleus ambiguus gives rise to special visceral efferent fibers of the glossopharyngeal nerve, which innervate the stylopharyngeus muscle. This muscle originates from the styloid process and descends between the internal and external carotid arteries to the upper wall of the pharynx. Contraction of the stylopharyngeus muscle aids in raising the larynx and elevating and expanding the pharynx during swallowing. The nucleus ambiguus is also the source of special

TABLE 13-1 -- USEFUL STUDIES IN THE EVALUATION OF THE TRIGEMINAL NERVE

Anatomical Site of Damage	CN IX or X Finding	Medical Findings	Common Etiologies	Comments
IntraCranial, intra- or extramedullary at the level of the medulla, involving CN X, XI, and XII	Ipsilateral paralysis of the soft palate, pharynx, and larynx producing hoarseness and dysphagia	Ipsilateral weakness of the sternocleidomastoid and trapezius muscles, and atrophy and weakness of the ipsilateral tongue	Infarction, neoplasm	Jackson's syndrome
Nucleus ambiguus, CN XI Nuclei and Extramedullary fibers	Ipsilateral paralysis of the soft palate, pharynx, and larynx producing hoarseness and dysphagia	Ipsilateral weakness of the sternocleidomastoid and trapezius muscles	Infarction, neoplasm, Idiopathic neuropathy	Schmidt's syndrome
Extramedullary fibers of CN X and XII	Ipsilateral paralysis of the soft palate, pharynx, and larynx producing hoarseness and dysphagia	Atrophy and weakness of the ipsilateral tongue	Trauma, neurofibroma of the CN X and XII nerves, parotid tumor	Tapia's syndrome
Jugular foramen involving CN IX, X, XI	Ipsilateral paralysis of the soft palate, pharynx, and larynx producing hoarseness and dysphagia	Ipsilateral paralysis of the Sternocleidomastoid and trapezius muscles	Trauma, neoplasm, jugular bulb thrombosis, internal carotid artery aneurysm	Vernet's syndrome
Retropharyngeal space, Involving CN IX to XII	Ipsilateral paralysis of the soft palate, pharynx, and larynx producing hoarseness and dysphagia	Ipsilateral weakness of the sternocleidomastoid and trapezius muscles, and atrophy and weakness of the ipsilateral tongue	Neoplasm, trauma, internal carotid artery dissection, coiling of the internal carotid artery	Collet-Sicard syndrome
Retropharyngeal space, involving CN IX to XII, and cervical sympathetic fibers	Ipsilateral paralysis of the soft palate, pharynx, and larynx producing hoarseness and dysphagia	Ipsilateral weakness of the sternocleidomastoid and trapezius muscles, atrophy and weakness of the ipsilateral tongue, and ipsilateral Horner's syndrome	Cervical internal carotid artery dissection, lung apex neoplasm	Villaret's syndrome
Vagus nerve below higher cervical levels where branches to the pharynx exit	Ipsilateral paralysis of the larynx producing hoarseness without dysphagia		Neoplasm, trauma	
Lateral medulla	Ipsilateral vocal cord paralysis producing hoarseness, ipsilateral weakness of the palate and pharynx the uvula will be drawn to the intact side, dysphagia	Ipsilateral pain around the eye, face or ear, vertigo, nausea and vomiting, impaired pain and temperature sensation of the ipsilateral face and contralateral limbs, unsteady gait and ataxia of ipsilateral limbs	Thrombosis or dissection of the vertebral artery occluding the opening to the posterior inferior cerebellar artery	Wallenberg's syndrome (lateral medullary syndrome)

CN, Cranial nerve

visceral efferent fibers of cranial nerves X and XI, which together with cranial nerve IX innervate the muscles of the pharynx and larynx.

UPPER MOTOR NEURON, SUPRANUCLEAR CONTROL

The nucleus ambiguus receives bilateral input primarily from the precentral gyrus of the cerebral cortex. These corticobulbar fibers travel through the internal capsule and brain stem in association with the corticospinal tract and terminate on reticular formation neurons, which transmit signals to the nucleus ambiguus.

LOWER MOTOR NEURON, PERIPHERAL PATHWAYS

The motor fibers emerge from the medulla in a groove between the inferior cerebellar peduncle and the olive as part of the rootlets comprising the glossopharyngeal nerve. The nerve travels laterally through the posterior fossa and exits the skull through the jugular foramen together with cranial nerves X and XI. The fibers to the stylopharyngeus muscle travel downward in the neck deep to the styloid process and reach the muscle around its posterior margin.

Sensory Fibers

SENSORY ORGANS AND FIRST ORDER NEURONS

First order neurons for sensory functions of the glossopharyngeal nerve have their cell bodies located in either the superior or inferior glossopharyngeal ganglia, which are found at the jugular foramen. Taste from the posterior third of the tongue is detected by chemical stimulation of cells within taste buds and then is conveyed by the special afferent fibers. The first order neuron for taste has its cell

Figure 13-1 Cross section of the medulla. The ninth and tenth cranial nerve nuclei lie in the lateral portion of the medulla, in close juxtaposition with the eighth cranial nerve nucleus, the spinal nucleus of cranial nerve V, and the inferior cerebellar peduncles.

body located in the inferior glossopharyngeal ganglion. The central processes of these neurons project to the rostral nucleus solitarius. The specific means for detection of pain, temperature, and tactile sensation in areas served by the glossopharyngeal nerve are presumably similar to those elsewhere in the body. Pain, temperature, and tactile sensation from the posterior third of the tongue, upper pharynx, tonsils, skin behind the external ear, inner aspect of the tympanic membrane, and eustachian tube are conveyed by general somatic afferent fibers of the glossopharyngeal nerve. Cell bodies for these first order neurons lie in both the superior and inferior glossopharyngeal ganglia. The central processes of these neurons enter the medulla and descend in the spinal trigeminal tract and synapse within the

caudal part of the spinal trigeminal nucleus.

NUCLEAR AND SUPRANUCLEAR CONTROL

The axons of cells in the nucleus solitarius conveying taste from the posterior third of the tongue ascend and terminate at the ventral posterior nuclei of the thalamus. These neurons in turn project to the inferior third of the postcentral gyrus for taste perception. The secondary neuron cell bodies for pain, temperature, and tactile sensation are located in the spinal trigeminal nucleus. Their processes cross the midline in the medulla and ascend to terminate at the contralateral ventral posterior nucleus of the thalamus. From this point the third order neurons project to the postcentral, sensory cortex region.

Autonomic Fibers

NUCLEUS

The inferior salivatory nucleus gives rise to general visceral efferent fibers that provide input for parotid gland secretion. The afferent limb for autonomic reflexive control of respiration and cardiac output is provided by general visceral afferent fibers of the glossopharyngeal nerve. These fibers convey impulses to the nucleus solitarius from chemoreceptors of the carotid body and baroreceptors from the carotid sinus regarding blood oxygen tension and blood pressure, respectively.

SUPRANUCLEAR CONTROL

The salivatory nucleus receives input from the hypothalamus. The output influencing parotid gland secretion may be modulated by emotional stimuli, such as fear causing dryness of mouth, or by sensory input, such as pleasant odors of food producing increased secretion (mouth watering).

PERIPHERAL PATHWAYS

The glossopharyngeal general visceral efferent fibers reach the otic ganglion, which lies below the foramen ovale. Postganglionic fibers from the otic ganglion then provide input to the parotid gland.

ANATOMY OF CRANIAL NERVE X

Motor Fibers

NUCLEUS

The nucleus ambiguus is the origin of special visceral efferent fibers of the vagus nerve, which supply striated muscles of the tongue and larynx, and all of the striated muscles of the soft palate and the pharynx except for the tensor veli palatini and the stylopharyngeus (which are innervated by branches of cranial nerves V and IX, respectively) (see [Table 13-1](#)). The palatoglossus is the only tongue muscle supplied by the vagus nerve; the remainder are supplied by cranial nerve XII. The palatoglossus muscle originates in the soft palate and passes through the tongue in a transverse fashion. Together with the styloglossus muscle, it acts to elevate the posterior tongue.

UPPER MOTOR NEURON, SUPRANUCLEAR CONTROL

The nucleus ambiguus receives input from motor areas of the cerebral cortex, particularly the precentral gyrus. The cortical input is bilateral and indirect. The corticobulbar fibers terminate first on adjacent reticular formation fibers, which in turn transmit signals to the nucleus ambiguus. The nucleus also receives sensory input from the larynx, pharynx, and airways, which mediate reflexive actions such as coughing, swallowing, and vomiting.

LOWER MOTOR NEURON, PERIPHERAL PATHWAYS

The special visceral efferent fibers exit the skull through the jugular foramen with the vagus nerve and then divide into three major branches: the pharyngeal nerve, superior laryngeal nerve, and recurrent laryngeal nerve. The pharyngeal

Figure 13-2 Diagram of the vagus nerve (cranial nerve X), specifically, its branch, the recurrent laryngeal nerve, and its relationship to the large vessels of the neck. The right and left nerves are not identical, and the recurrent laryngeal nerve branches at the base of the neck on the right and in the thorax on the left.

and superior laryngeal nerves branch from the vagus high in the neck. The recurrent laryngeal nerve branches at the base of the neck on the right and in the thorax on the left ([Fig. 13-2](#)). The pharyngeal nerve enters the pharynx and divides into the pharyngeal plexus to supply the muscles noted earlier. The superior laryngeal nerve descends and divides to reach the cricothyroid and the inferior constrictor muscles. The right and left recurrent laryngeal nerves take different paths to reach their destination, supplying all of the intrinsic muscles of the larynx except the cricothyroid. On the right, the recurrent laryngeal nerve descends anterior to the subclavian artery, loops posteriorly beneath it, and then turns upward again, running along the right side of the trachea to the larynx. The left recurrent laryngeal nerve passes under the aortic arch and travels upward in a groove between the left trachea and esophagus to the larynx.

Sensory Fibers

SENSORY ORGANS AND FIRST ORDER NEURONS

General somatic efferent fibers of the vagus nerve convey sensations of pain, temperature, and touch from the meninges of the posterior fossa, the back of the ear, the external auditory canal, the external tympanic membrane, the larynx, and the pharynx. Sensation from the vocal cords and the larynx below this level is carried by sensory fibers of the recurrent laryngeal nerve. Sensation above the vocal folds is conveyed by the internal laryngeal nerve, which is a branch of the superior laryngeal nerve. The cell bodies for sensation of the ear, external auditory meatus, and tympanic membrane are in the superior vagal ganglion (jugular ganglion); the remaining fibers have their cell

bodies in the inferior vagal ganglion (nodose ganglion). Both the superior and inferior vagal ganglia are located on the proximal vagus nerve intracranially at the jugular fossa near the jugular foramen. The central processes of both ganglia enter the medulla and descend in the spinal trigeminal tract to the trigeminal nucleus.

Visceral afferent fibers of the vagus nerve carry visceral sensation from the intestines, stomach, esophagus, tongue, part of the pharynx, lungs, bronchi, trachea, and larynx. These fibers also convey signals from chemoreceptors detecting blood oxygen tension located in the aortic body, and baroreceptors for blood pressure in the aortic arch. Cell bodies for all visceral afferent fibers are in the inferior vagal ganglion. Their central processes descend in the tractus solitarius in the medulla to reach the nucleus of the tractus solitarius.

NUCLEAR AND SUPRANUCLEAR CONTROL

After reaching the spinal trigeminal nucleus, impulses for pain, temperature, and tactile sensation are carried by second order neuron fibers, crossing in the medulla, to the contralateral ventral posterior nucleus of the thalamus. The third order neurons in the thalamus project to the sensory cortex via the internal capsule. The nucleus of the tractus solitarius, along with the reticular formation and hypothalamus, has connections to the dorsal vagal motor nucleus for reflexive control of cardiac, respiratory, and gastrointestinal functions.

Autonomic Fibers

NUCLEUS

The dorsal vagal motor nucleus is the origin of the preganglionic, parasympathetic fibers (general visceral efferent) of the vagus nerve. This nucleus is a column of cells located in the floor of the fourth ventricle medial to the nucleus ambiguus. These parasympathetic fibers of the vagus control secretion of glands in the mucosa of the larynx, pharynx, gut from the esophagus to the colon at the splenic flexure, pancreas, liver, and lungs. Fibers to the stomach are responsible for acid secretion. Activation of the parasympathetic fibers to the heart results in slowing of the heart rate; such activation also produces a negative inotropic effect on heart muscle contraction. The vagus parasympathetic fibers also innervate smooth muscle of the airway and gut. These fibers carry signals to open the airway during breathing, to produce bronchoconstriction, and also to coordinate peristalsis of the esophagus and intestine.

SUPRANUCLEAR CONTROL

The dorsal motor nucleus of the vagus receives input from the hypothalamus, the nucleus of the tractus solitarius, the reticular formation, and the olfactory system.

PERIPHERAL PATHWAYS

The parasympathetic fibers affect numerous body functions in structures within the neck, thorax, and abdomen. They leave the cranium with the vagus nerve through the jugular foramen. These preganglionic fibers terminate near their target sites on ganglia associated with plexuses at several locations, including the esophagus, pharynx, lungs, heart, and intestines. The parasympathetic functions of the vagus nerve are addressed in the chapter on the autonomic nervous system.

EXAMINATION OF CRANIAL NERVES IX AND X

Directed Neurological Examination

CRANIAL NERVE IX

The functions of the glossopharyngeal nerve overlap with those of other cranial nerves, making it difficult to test in isolation.

Motor. The sole skeletal muscle innervation of cranial nerve IX is the stylopharyngeus, which aids in elevation of the pharynx. The oral cavity should be inspected visually at rest to ascertain whether asymmetrical lowering of the pharynx is present. The pharynx is elevated also by the palatopharyngeus and salpingopharyngeus muscles, both of which derive their nerve supply from the vagus nerve. Lesions of the glossopharyngeal nerve therefore may not produce any noticeable clinical motor effect.

Autonomic. The activity of parotid gland salivary secretion through Stensen's duct reflects autonomic functioning of the glossopharyngeal nerve. The duct is located on the inside of the cheek opposite the crown of the second upper molar tooth. Secretion from the parotid glands should be symmetrical, although the amount of saliva normally produced may vary. This quantity may be tested by having the patient suck on a lemon wedge, or by injecting pilocarpine intravenously, and then assessing saliva volume from the duct. Reduced volume of one side suggests glossopharyngeal autonomic dysfunction on that side. Saliva volume measurements for this purpose are impractical and are virtually never done.

Sensory. The sensory function of the glossopharyngeal nerve most accessible to testing is general visceral sensation (tactile, pain, temperature) of the posterior and lateral aspects of the pharynx, and the posterior third of the tongue and the tonsils. Testing is done by touching the soft tip of a cotton applicator to either side of these areas and asking the patient about asymmetry of sensation. Tactile sensation in these areas also serves to trigger the gag, or pharyngeal, reflex. Testing taste sensation of the posterior third of the tongue cannot be done reliably in the clinic. Testing may be accomplished in a laboratory setting by stimulating this area of the tongue with an electrical current.

Reflexes. The gag, or pharyngeal, reflex is centered in the medulla and consists of the reflexive motor response of pharyngeal elevation and constriction with tongue retraction in response to sensory stimulation of the pharyngeal wall, posterior tongue, tonsils, or faucial pillars. This reflex is examined by touching the posterior pharynx with the soft tip of a cotton applicator and visually inspecting for

elevation of the pharynx. Both sides of the pharynx should be examined for both the afferent and efferent limbs of the reflex by touching one side first and then the other, while watching for symmetry of pharyngeal movement. The normal reflex response varies, and it may be reduced in the elderly or in smokers. Asymmetry of the reflex is the feature most indicative of pathology.

CRANIAL NERVE X

Motor innervations of the vagus nerve to the soft palate, larynx, and pharynx are readily available for testing.

Motor. Inspection of the palate on phonation shows deviation of the uvula to the intact side with a unilateral vagus nerve lesion. The unaffected muscles contract normally, drawing the uvula upward and pulling it laterally away from the side of the lesion. A lesion involving the branches of the vagus nerve to the larynx produces vocal cord paresis on that side. The affected cord lies between abduction and adduction. The patient may demonstrate a mild hoarseness, or speech may be unaffected because of compensatory movement of the intact vocal cord. A lesion affecting innervation to the palate produces speech with a nasal quality. This quality is due to inability to close the nasal passage by palate elevation during phonation, allowing air to escape into and resonate within the nasal cavity. The patient may also have dysphagia due to involvement of pharyngeal muscles, with liquids escaping into the nasal cavity during swallow. Vocal cord function can be assessed by listening to the patient's speech to detect a hoarse or breathy voice with reduced volume. Cord function is best examined by visualization using indirect or direct laryngoscopy. Videostroboscopy recording using the fiberoptic direct laryngoscope may also be helpful to assess vocal cord movement.

Sensory. Sensory testing of the vagus nerve cannot be reliably accomplished in the routine neurological examination. Regions of the body that have vagus sensory innervation are either inaccessible or also have sensory input from the fifth and ninth cranial nerves.

Autonomic. The carotid sinus baroreceptors are innervated by the carotid sinus nerve branch of the glossopharyngeal nerve. Their stimulation results in heart rate reduction mediated by the vagus nerve. Testing the integrity of these fibers by carotid artery massage is not only impractical and unreliable but also is potentially dangerous. This maneuver may produce asystole or ventricular arrhythmia and should be done only where resuscitative means are immediately available, and not as part of a neurological examination. The vagus nerve is the efferent limb also of the oculocardiac reflex, where heart rate is decreased by pressure upon the eyeball. The afferent impulses for this reflex are conveyed by the trigeminal nerve. The heart rate may slow slightly when the reflex is intact. Heart rate is influenced by numerous factors, however, and this reflex is not a reliable test for vagus nerve integrity. Testing of autonomic functions related to the vagus nerve is addressed in the chapter on the autonomic nervous system.

Reflexes. The vagus nerve participates in several reflexes, including coughing, swallowing, sneezing, yawning, and hiccups, but only the gag reflex lends itself to routine testing in the neurological exam. The gag reflex involves afferent fibers provided by the glossopharyngeal nerve (and, in some people, also the vagus nerve) and motor efferents to the pharynx, soft palate, and tongue from the vagus. The reflex is elicited by tactile stimulation of the walls of the pharynx or the posterior tongue. The reflex consists of symmetrical contraction and elevation of the pharynx and retraction of the tongue. This process is described earlier in the section on reflex testing of the glossopharyngeal nerve.

Associated Neurological Findings

Cerebral. Dysphagia and changes in speech similar to that which is produced by a lesion of the cranial nerves or their nuclei may occur with interruption of the corticobulbar fibers, which provide the brain stem nuclei with innervation from the frontal cerebral cortex. This condition is referred to as *pseudobulbar palsy*. The brain stem nuclei receive bilateral input; consequently, a unilateral lesion does not result in bulbar symptoms. Speech and swallowing disorders are due to bilateral injury of these pathways. The interruption may occur at any point from the cortex to the brain stem, but most commonly the interruption is due to ischemic injury.^[20] Clinical findings indicative of cerebral lesions producing these pseudobulbar symptoms may include aphasia, sensory changes, or corticospinal tract findings such as limb spasticity, increased tendon and jaw jerk reflexes, and an extensor plantar response. Patients with pseudobulbar palsy also may have impaired emotional control with unprovoked laughter or crying, and emergence of primitive reflexes such as suck and snout.

Cranial Nerves. Lesions of the ninth or tenth cranial nerve nuclei usually affect adjacent brain stem structures, producing ipsilateral sensory disturbance of the face from involvement of the fibers of the descending tract and nucleus of cranial nerve V, vertigo from vestibular nuclei, contralateral limb sensory changes from the lateral spinothalamic, and ipsilateral limb ataxia caused by involvement of the inferior cerebellar peduncle. The ninth and tenth cranial nerves travel closely together between the brain stem and the jugular foramen and consequently are rarely affected independently of one another in their intracranial locations. More peripherally, a lesion at the jugular foramen also affects the spinal accessory nerve, which passes through this opening with the glossopharyngeal and vagus nerves. In addition to disturbance of speech, swallow, and gag, the patient demonstrates weakness of the sternocleidomastoid and trapezius muscles. The twelfth cranial nerve may be involved together with the ninth, tenth, and eleventh nerves by trauma, infection, or neoplasm at the retroparotid space. A lesion of cranial nerve XII produces deviation of the tongue to the side of the lesion when the tongue is protruded.

Motor/Reflexes/Cerebellar/Gait. Changes in muscle tone can be indicative of neurological disease involving cranial nerves IX and X. Cerebral lesions causing pseudobulbar palsy with alteration of speech and dysphagia may be associated with limb spasticity due to corticospinal tract injury. Parkinsonism caused by various etiologies frequently

is associated with difficulties in speech and swallowing. No specific lesions exist of the cranial nerves, but rather the subcortical control is affected bilaterally. Patients with progressive supranuclear palsy particularly have prominent difficulty with speech and dysphagia. In patients with suspected cranial nerve IX or X lesions the presence of abnormal reflexes, such as an extensor plantar response, or the emergence of rudimentary reflexes like the suck or snout, are indicators of CNS pathology. Disorders of the neuromuscular junction also produce dysarthria and dysphagia. Repetitive testing of ocular or limb muscle power may produce an inordinate amount of fatigue and weakness pointing to a diagnosis of myasthenia.

A brain stem lesion producing impairment of speech and swallow may also include ataxia of ipsilateral limbs and gait by injury to the inferior cerebellar peduncle that lies adjacent to the nuclei of nerves IX and X.

Sensory. Alteration of pain and temperature sensation of the ipsilateral face with sensory changes of contralateral limbs in association with dysphagia and dysarthric or hoarse speech indicate a brain stem lesion. Sensory changes of the limbs and face on the same side may be produced by a cerebral lesion that contributes to a pseudobulbar state.

Autonomic Nervous System. Disorders of vagal nerve autonomic function may result in symptoms relating to cardiopulmonary and gastrointestinal functions, none of which are testable in the neurological examination. These may be assessed by specialized tests such as the tilt-table cardiac examination or studies of gastrointestinal motility.

Neurovascular. The precise mechanism of neurally mediated syncope (vasovagal vasomotor syncope) remains undetermined. These fainting spells are often provoked by unpleasant sensory stimuli and are accompanied by bradycardia, peripheral vasodilation, and hypotension. Blockage of the vagally mediated bradycardia with atropine does not eliminate the vasodilation and hypotension or the syncope. Vascular function is not a means of assessing glossopharyngeal or vagal status in a setting other than a research environment.

EVALUATION GUIDELINES ([Table 13-2](#))

Neuroimaging. Lesions of the medulla such as infarction or neoplasm, or extramedullary, intracranial lesions, are better visualized by magnetic resonance imaging (MRI) than by computer-assisted tomography (CT). Some lesions that involve bone, especially the skull base, may be detected by CT or radiographs, the latter usually requiring the neurologist to request special views of the base of the skull. Imaging should be employed to assist in defining lesion type when the clinical examination indicates an intracranial process.

Electrophysiology. Disorders of speech and swallow suspected to be due to neuromuscular disorders such as motor neuron disease or myasthenia gravis may be evident on electrophysiological testing. Repetitive stimulation on nerve conduction studies, and single fiber assessment of jitter may aid in the diagnosis of myasthenia. Electromyography (EMG) of the tongue or limb muscles may demonstrate denervation indicative of motor neuron disease. The location of a nerve lesion producing vocal cord paralysis may be established by EMG testing of the thyroarytenoid

TABLE 13-2 -- USEFUL TESTS IN THE EVALUATION OF DISORDERS OF CRANIAL NERVES IX AND X*

	Neuroimaging	Electrophysiology	Fluid and Tissue Analysis	Neuropsychology Tests	Other Tests
Seven supranuclear lesions unilateral or bilateral	CT or MRI evidence of structural lesion, most commonly ischemic infarction of the frontal lobe.	EEG may demonstrate nonspecific abnormalities	Not applicable	Evidence of cognitive impairment	None
Nuclear lesions: lateral medulla	MRI evidence of ischemic infarction. CT is not optimal imaging modality in this region. Angiographic evidence of impaired flow in the vertebral or basilar arteries	No findings	Not applicable	No abnormal findings	None
Proximal peripheral nerves: Cerebellopontine angle lesion	MRI or CT evidence of contrast enhancing mass lesion	Abnormal interwave separation (waves I-III, I-V) on brain stem auditory evoked potential	Not applicable	None	None
Middle peripheral nerve lesion at base of skull or nasopharynx	MRI or CT evidence of neoplasm or trauma	None	Not applicable	None	None
Far distal peripheral nerve lesions	MRI or CT evidence of neoplasm or trauma	Not applicable	Not applicable	None	None

* With cross-references to chapters on neuroimaging, electrodiagnostics, tissue analyses, neuropsychology testing, and other tests. MRI, magnetic resonance imaging; CT, computed tomography; EEG, electroencephalogram.

and cricothyroid laryngeal muscles.^[21] Evidence of denervation restricted to the cricothyroid or thyroarytenoid muscle alone indicates neuropathy of the superior laryngeal or recurrent laryngeal nerves, respectively. Denervation of both muscles places the lesion proximally in the laryngeal nerve or the vagus. Laryngeal EMG has also been useful in discriminating laryngeal dystonia (spasmodic dysphonia) from voice tremor and other disorders producing speech problems.^[22]

Fluid and Tissue Analysis. Occasionally, biopsy of tissue outside the CNS may be productive in establishing a diagnosis involving the ninth and tenth cranial nerves. Amyloid neuropathy involving the cranial nerves may be demonstrated on peripheral nerve biopsy. Sarcoidosis with basilar meningitis and cranial neuropathies may be evident on lung or lymph node biopsy.

Cerebral Spinal Fluid and Intracranial Pressure. Lumbar puncture should be accomplished in cases of suspected CNS infectious or inflammatory disorders.

Neuropsychological Testing. Patients with pseudobulbar palsy may have findings of cognitive impairment on formal neuropsychological testing.

Other Tests. Patients with voice disorders should undergo careful otolaryngological evaluation of the neck and pharynx, and visualization of the vocal cords by either indirect or direct laryngoscopy. Paresis of the left vocal cord may result from disease processes in the chest involving the recurrent laryngeal nerve, such as an expanding aortic aneurysm, mediastinal adenopathy, or lung neoplasm. Chest radiographs, and possibly CT, should be employed to evaluate patients with suspected thoracic disease. Intravenous administration of edrophonium (Tensilon test) may be helpful in diagnosis of suspected myasthenia gravis.

CLINICAL SYNDROMES (Table 13-3)

Supranuclear Lesions

Interruption of the corticobulbar tracts providing innervation of cranial nerve motor nuclei from the cerebral precentral motor cortex produces disturbances of speech, swallowing, chewing, and occasionally breathing known as *pseudobulbar palsy*. Patients with this disorder may also have emotional lability with exaggerated crying or laughter in response to minimal provocation. Because the ninth and tenth cranial nerve nuclei receive bilateral innervation, a unilateral lesion may be silent or may produce only mild symptoms. Supranuclear lesions are responsible for weakness of speech, chewing, and swallowing; the muscles do not also produce prominent atrophy because the lower motor neuron and its trophic effect on the muscle remain

TABLE 13-3 -- SELECTED ETIOLOGIES ASSOCIATED WITH DISORDERS OF CRANIAL NERVE XI AND CRANIAL NERVE XII

Etiological Category	Selected Specific Etiologies	Chapter
STRUCTURAL DISORDERS		
Developmental	Immaturity of cervical vagus nerve fibers	28
Degenerative compressive	Paget's disease	29
HEREDITARY AND DEGENERATIVE DISORDERS		
The degenerative dementias	Bifrontal pathology, especially Alzheimers, Picks disease	33
Movement disorders	Adductor spasmodic dysphonia Abductor spasmodic dysphonia Parkinsonism	34
Degenerative motor, sensory and autonomic disorders	Amyotrophic lateral sclerosis	36
ACQUIRED METABOLIC AND NUTRITIONAL DISORDERS		
Endogenous metabolic disorders	Neuropathy of glossopharyngeal afferent and vagus efferent fibers of circulatory reflexes especially diabetes	38
Nutritional deficiencies and syndromes associated with acoholism	Neuropathy of glossopharyngeal afferent and vagus efferent fibers of circulatory reflexes,poor nutrition, alcoholism	40
INFECTIOUS DISORDERS		
Nonviral infections	Syphilis	42
NEUROVASCULAR DISORDERS		
	Strokes with bifrontal pathology (pseudobulbar paresis) Lateral medullary syndrome, postenor fossa, artenovenous malformation	45
NEOPLASTIC DISORDERS		
Primary neurological tumors	Schwannoma	46
Metastatic neoplasms and paraneoplastic syndromes	Tumor to base of skull, nasopharynx, chest	47
DEMYELINATING DISORDERS OF THE PERIPHERAL NERVOUS SYSTEM	Guillain-Barre syndrome	49
AUTOIMMUNE AND INFLAMMATORY DISORDERS	Sarcoidosis	50
TRAUMATIC DISORDERS	Compromise of jugular foramen contents by basilar skull fracture	51
EPILEPSY	Intractable epilepsy	52
HEADACHE AND FACIAL PAIN	Glossopharyngeal neuralgia	53
DRUG-INDUCED AND IATROGENIC DISORDERS	Vincnstine	55

210

intact. Palate and gag reflexes remain intact, even heightened, and abnormal reflexes such as the snout and suck may be present, along with an increased jaw jerk reflex. Patients with pseudobulbar palsy may have dementia due to cerebral pathology involving bilateral frontal areas.

Acute onset of pseudobulbar palsy in one series of 13 patients was associated with infarction in the operculum, the internal capsule or corona radiata, or hemorrhage in lenticular nuclei.^[23] Six of these patients had no prior history of stroke. Only one of these patients was described as having neuropsychological deficits, and all improved or recovered from the pseudobulbar symptoms within a few weeks.

Supranuclear innervation of speech is also derived from extrapyramidal pathways. Basal ganglia dysfunction is believed to be the source of focal dystonias involving the larynx causing adductor and abductor spasmodic dysphonia.^[24] The former type is the far more common of the two. Involuntary adduction of the cords during phonation produces speech that has an interrupted, strangulated quality that is often effortful for the patient. In the less common abductor type of spasmodic dysphonia the patient has a breathy voice. As in other forms of focal dystonia, the patient may employ certain "tricks" to briefly overcome the dystonia, presumably by using other motor pathways to accomplish the desired movement. Some patients with spasmodic dysphonia may find their voice nearly normal when singing or shouting. These fluctuations of symptoms and ability to speak have in the past resulted in psychiatric diagnoses, leading to inappropriate and unproductive therapies and, when the correct diagnosis is established, a lingering resentment and hostility on the part of the patients toward physicians.

Symptomatic treatment of adductor dysphonia has been quite successful by injection of small amounts of botulinum toxin into the thyroarytenoid muscle of the larynx.^[25]^[26]^[27] This technique is regarded by many as the treatment of choice for this disorder. Treatment of the abductor type of spasmodic dysphonia by botulinum toxin injection has been technically more difficult and has produced less satisfactory results, although some investigators have reported success targeting the posterior cricoarytenoid or the cricothyroid muscles.^[28]^[29]

Unilateral stimulation of the vagal nerve has been studied as an adjunctive means to treat intractable partial epilepsy.^[30] Electrodes from an implantable pacemaker device are attached to the left vagus nerve, and they provide intermittent stimulation. The mechanism of reducing seizures is believed to be by activating cortical and subcortical connections to the vagal nuclei.

Nuclear Lesions

The lateral medullary syndrome, known also as Wallenberg's syndrome, is the prototype lesion involving the nuclei of the ninth and tenth cranial nerves. The syndrome results from infarction of the medulla by vertebral artery thrombosis or dissection that may also produce occlusion of the opening to the posterior inferior cerebellar artery.^[31]

Presenting symptoms often include a stabbing pain in the eye, face, or ear ipsilateral to the side of infarction, presumably as a result of involvement of the nucleus of the descending tract of cranial nerve V. Vertigo or a sense of dysequilibrium occurs commonly because of injury of the vestibular nuclei. Nausea and vomiting are often accompanying symptoms, and they may also arise from vestibular nuclei involvement. Intractable hiccups are rarely caused by lesions of the medulla but may

be present in lateral medullary infarction.^[32] Involvement of the nucleus ambiguus causes ipsilateral vocal cord paralysis and a hoarse voice, as well as ipsilateral weakness of the palate and pharynx. Palate elevation on phonation is asymmetrical, with the uvula drawn to the intact side, and the patient experiences dysphagia. Impaired sensation to pain and temperature occurs in a crossed fashion involving the ipsilateral face and contralateral limbs caused by, respectively, involvement of the descending tract of the cranial nerve V and the spinothalamic tract. Injury of spinocerebellar fibers and of the inferior cerebellar peduncle results in an unsteady gait and ataxia of the ipsilateral limbs. An ipsilateral Horner's syndrome occurs from involvement of the descending sympathetic fibers from the hypothalamus. Limb weakness, tendon reflex changes, and extensor plantar responses do not occur because the corticospinal fibers are ventrally located at this level of the medulla and are outside of the area of injury. Ipsilateral facial weakness may be present even though the infarction does not extend beyond the lateral medulla. The triad of Horner's syndrome, ipsilateral limb ataxia, and contralateral limb numbness reliably indicates lateral medullary infarction.^[33]

Unless cerebellar infarction is also present, cranial CT often does not identify the infarction.^[33],^[34] Imaging by MRI is clearly superior to CT to visualize lesions in the medulla. The prognosis for recovery from a lateral medullary CVA is generally good, although in some cases the infarction may be fatal because of secondary edema and herniation or obstructive hydrocephalus and increased pressure in the posterior fossa. The area of infarction may also be extended by propagation of clot into the basilar artery, or by vessel-to-vessel embolism from the vertebral artery to the basilar artery.^[35]

Proximal Peripheral Lesions

The glossopharyngeal and vagus nerves pass through the area of the cerebellopontine angle, formed by the junction of the pons, medulla, and cerebellum, before exiting the skull through the jugular foramen. In this area, both nerves may be compromised by an expanding mass lesion, most commonly a schwannoma originating from the vestibular portion of the eighth cranial nerve within the internal auditory canal. The syndrome of a cerebellopontine angle tumor generally begins as tinnitus with hearing loss, and dysequilibrium or frank vertigo, which may be episodic. As the tumor expands, the fifth cranial nerve becomes involved, resulting in ipsilateral facial pain and numbness and loss of the corneal reflex. The cerebellum or cerebellar peduncles may become compressed, producing ataxia. Unilateral impingement upon the vagus nerve causes mild

hoarseness and asymmetrical elevation of the soft palate. Schwannoma arising from the glossopharyngeal nerve is a rare occurrence, but, interestingly, the presenting symptom of patients with this tumor is most commonly hearing loss.^[36] This occurs because the mass emanating from the glossopharyngeal nerve is clinically silent until it has enlarged to the point that it is impinging upon adjacent structures.

Middle Peripheral Lesions

Lesions at the jugular foramen, retropharyngeal space, or other peripheral locations produce syndromes involving the ninth and tenth nerves, and sometimes also the eleventh and twelfth cranial nerves. The lesions may be due to various potential etiologies, including neoplasm, infection, and trauma. The syndromes are associated with the names of authors describing them and are listed in [Table 13-1](#). The jugular foramen syndrome, also known as *Vernet's syndrome*, involves the ninth, tenth, and eleventh cranial nerves. The syndrome is comprised of weakness of the ipsilateral vocal cord, palate, and pharynx and the trapezius and sternocleidomastoid muscles. A lesion in the retropharyngeal space is responsible for Villaret's syndrome, which involves cranial nerves IX, X, XI, and XII and produces anesthesia of the palate, larynx, and pharynx; weakness of the trapezius and sternocleidomastoid muscles; atrophy and weakness of the tongue; and a Horner's syndrome. This last feature is due to involvement of cervical sympathetic fibers.

Far Distal Peripheral Lesions

Isolated lesions of either the glossopharyngeal or vagus nerves are unusual. As noted earlier, glossopharyngeal nerve abnormalities may be clinically undetectable unless adjacent structures are also involved. Perhaps the most common vagus nerve lesion is that involving the recurrent laryngeal nerve, resulting in ipsilateral vocal cord paresis and hoarseness of voice. The left nerve has a longer course, with its looped recurrence in the chest rather than in the neck, as on the right. The nerve passes around the aorta before returning rostrally to the larynx. The left recurrent laryngeal nerve may be compromised by an expanding aortic arch aneurysm or other intrathoracic processes, such as enlargement of the left atrium of the heart, pulmonary neoplasm, or mediastinal adenopathy. Both right and left superior or recurrent laryngeal nerves may be injured during the course of neck surgery such as thyroidectomy. Vocal cord paralysis has been described with vagal neuropathy attributed to diabetes or alcohol consumption, and with vagal neuritis in association with herpes simplex and herpes zoster.^[37] Superior laryngeal branch neuralgia produces pain in the area of the thyroid cartilage radiating to the ear, and it is triggered by talking or swallowing. This is a rare disorder; treatment is with carbamazepine. Immaturity of the cervical vagus fibers may play a role in sudden infant death syndrome.^[38]

Glossopharyngeal Neuralgia

This is an uncommon disorder, occurring with an annual crude incidence of 0.7 per 100,000 population.^[39] The pain of glossopharyngeal neuralgia is located at the base of the tongue, tonsils, ear, or angle of the jaw and is triggered by talking, swallowing, and coughing. Glossopharyngeal neuralgia produces symptoms similar in character to those of trigeminal neuralgia: brief, recurrent, stabbing pains lasting seconds to a couple of minutes. Of these two cranial nerve disorders glossopharyngeal neuralgia is less common; the ratio of trigeminal to glossopharyngeal neuralgia is 5.9:1.^[40] The attacks of glossopharyngeal neuralgia are comparatively more mild, and in contrast to trigeminal neuralgia bilateral symptoms frequently occur.^[39] The course tends to be relapsing and remitting.

Epidemiological data from a population in Minnesota found men and women equally affected with rates of incidence highest in the sixth through eighth decades.^[39] Syncope is an unusual accompaniment of glossopharyngeal neuralgia.^[41] Spontaneous discharges of the glossopharyngeal nerve to the medulla may cause bradycardia or even asystole by reflexive vagal nerve cardiac inhibitory output.^[42] The syncopal episode is produced by this bradycardia together with hypotension caused by reduced sympathetic output. Clonic jerking mimicking seizure may accompany the syncopal spells, although electroencephalographic recording during spells has demonstrated slowing and suppression of activity rather than seizure activity.^[43]

Glossopharyngeal neuralgia is divided into idiopathic and symptomatic forms, with the latter due to identifiable pathology such as oropharyngeal or neck carcinoma or a posterior fossa arteriovenous malformation.^[44]^[45]^[46] Although results of the neurological examination are normal in idiopathic glossopharyngeal neuralgia, patients with symptoms of this disorder should have careful examination of the oral cavity and neck and brain imaging with attention to the posterior fossa to exclude underlying pathology. Treatment for the symptoms of glossopharyngeal neuralgia includes the medications used for trigeminal neuralgia, including carbamazepine, baclofen, phenytoin, or combinations of these.

Surgical treatment is an option for patients with symptoms refractory to medical therapy. Sectioning of the rootlets of the glossopharyngeal nerve effectively terminates symptoms but obviously sacrifices the nerve. Alternatively, microvascular decompression has also been successful in treating this disorder and spares the function of the glossopharyngeal nerve. This technique is based upon the idea that the neuralgia is due, at least partly, to an adjacent blood vessel producing mechanical irritation to the glossopharyngeal nerve. In one series of 40 patients, the most common offending blood vessel was the posterior inferior cerebellar artery, followed by an artery and vein combination.^[47] In this surgery the glossopharyngeal nerve is identified along with the offending vessels and they are separated. A piece of Teflon felt may be placed between the nerve and an artery. Successful treatment of the neuralgia, by medical or surgical means, should also eliminate any associated syncopal episodes.

GENERAL MANAGEMENT GOALS

During the initial evaluation of a patient with disorders attributable to the ninth and tenth cranial nerves, few specific precautions for management are indicated. Bilateral vagus nerve lesions, regardless of the pathological process, occlude the airway by opposition of the vocal cords in the midline. This condition is an emergency and requires endotracheal intubation to maintain airway patency. Patients with bradycardia or asystole due to increased vagal output are treated initially with atropine or cardiac pacing until the causative process is addressed. It should be kept in mind that the condition of patients with lateral medullary syndrome by infarction may be unstable. Status may decline clinically by pressure effects in the posterior fossa or by extension of the area of infarction by propagation of clot or embolization from the vertebral artery into the basilar artery. It is not clear that the risks of intravenous heparin are justified to attempt to prevent stroke extension.

HISTORY AND DEFINITIONS

The assignment of numbers to the cranial nerves may be traced back to Galen (circa 130-201 AD) and perhaps even to Marinus of Tyre (circa 100 AD).^[1] Galen recognized 11 of the 12 structures that we now designate as cranial nerves, lumping several of these together such that there were seven paired cranial nerves. Galen combined what we now know as the ninth through eleventh cranial nerves, calling these structures the sixth cranial nerve. In his system, the hypoglossal nerve was the seventh and final cranial nerve. The Galenic system for numbering the cranial nerves persisted for one and a half millennia.^[2] It was still used by Andreas Vesalius, the Italian anatomist, in his text *De Fabrica* in 1543.^[3] Thomas Willis, the English physician and anatomist, numbered the cranial nerves at eight rather than seven. In his celebrated text of 1664, *Cerebri Anatome*,^[4] he provided the first thorough description of the spinal accessory nerve. It is said that he used the word "accessory" because the nerve was accessory to the vagus nerve.^[5] Samuel von Soemmering, the Prussian artist, inventor, paleontologist, and clinical investigator, has been credited with the first modern enumeration of the 12 cranial nerves in 1778.^[6]

The spinal accessory nerve (cranial nerve [CN] XI) and hypoglossal nerve (CN XII) share a number of features. These nerves, along with cranial nerves IV and VI, are pure motor nerves, meaning that they subservise only motor functions, and they do not carry sensory or autonomic fibers.^[7] Nuclei of the spinal accessory and hypoglossal nerves lie in the medulla, along with the nuclei of the glossopharyngeal (CN IX) and vagus nerves (CN X).^[8]

This chapter focuses on those disturbances of the spinal accessory and hypoglossal nerves that result in weakness rather than overactivity of innervated muscles, because the latter is discussed in other chapters on involuntary movements (see [Chapter 16](#) and [Chapter 34](#)).

[PreviousNext](#)

CLINICAL HISTORY

Patients with dysfunction of structures innervated by CN XI or XII or their supranuclear input may present to the physician with various complaints. The more common complaints when CN XI is involved are difficulty rotating the head, complaint that the head "droops" forward, or complaint that the shoulders seem asymmetrical or misshapen. The more common complaints when CN XII is involved are slurred speech, garbled speech, speaking with "marbles in my mouth," difficulty chewing, complaints that "my tongue gets in the way," or difficulty swallowing. Occasionally, a patient notices that the tongue is asymmetrical, appearing small and wrinkled on one side with protrusion. These complaints may be associated with neurological signs, including weakness of the sternocleidomastoid

215

(SCM) and trapezius muscles (with or without atrophy), winging of the scapula, deviation and weakness of the tongue (with or without atrophy), dysarthria, and dysphagia.^[9] ^[11]

Patients may present with complaints of acute, subacute, and chronic onset. Acute presentations, characterized by the rapid onset of symptoms and signs, include the medial medullary syndrome (i.e., an acute cerebrovascular event involving the posterior circulation), basal skull fracture, shoulder trauma, and dislocation of upper cervical vertebra. Subacute presentations include lesions due to multiple sclerosis, brain stem abscesses, and tuberculous meningitis. Chronic presentations are typically seen in motor neuron disease, acoustic neuroma, meningioma, and other tumors of the central and peripheral nervous system. ^[10]

Dysfunction of the eleventh and twelfth cranial nerves may be the result of various precipitating events or underlying etiologies, and several of these were alluded to earlier. These include trauma to the head, neck, or shoulder region (basal skull fracture, stab wound, or gunshot wound of the neck; dislocation of upper cervical vertebra; shoulder trauma), various infectious etiologies including bacterial (tuberculosis, brain abscess, syphilis) and viral (acute poliomyelitis), inflammatory or granulomatous processes (multiple sclerosis, Guillain-Barre syndrome, neurosarcoidosis), metabolic disorders (Paget's disease), structural disorders (platybasia, syringobulbia), exogenous toxins (botulism), acute cerebrovascular events (medial medullary syndrome), neoplasms (glomus cell tumor, neurofibroma, meningioma, acoustic neuroma, metastatic carcinoma), and iatrogenic events (radiation therapy involving the neck, neck surgery). ^[10], ^[12]

Lesions of these cranial nerves may be accompanied by any of a large number of associated diseases, symptoms, or signs, including the several systemic illnesses (systemic sarcoidosis, tuberculosis, carcinoma, syphilis), other neurological disorders (multiple sclerosis, Guillain-Barre syndrome, motor neuron disease), and other associated symptoms and signs referable to involvement of regional anatomy, particularly long tracts passing through the brain stem (resulting in weakness with spasticity, dysautonomia, sensory disturbances, gait instability, and incoordination) and other cranial nerves (resulting in facial numbness, nystagmus, dysphagia). ^[10], ^[11]

ANATOMY (Table 14-1)

Cranial Nerve XI

NUCLEUS

The spinal accessory nerve (CN XI) is classified as a special visceral efferent (SVE) nerve because it innervates striated muscles that arise embryologically from the branchial arches.^[1] CN XI consists of two distinct portions, the cranial (or accessory) portion and the spinal portion (Fig. 14-1).^[2] These are sometimes referred to as the *ramus internus* and *ramus externus*, respectively,^[11] each with distinctive embryological development.^[13]

The cranial and spinal portions of CN XI arise from separate nuclei. The nucleus for the cranial portion of the

Figure 14-1 Schematic of the cranial and spinal portions of CN XI.

nerve is the most caudal part of the nucleus ambiguus, which is the longitudinal column of cells that is dorsal to the inferior olivary nucleus in the medulla.^[14] The nucleus ambiguus is composed of cells controlling several functions outside of the domain of CN XI: (1) motor neurons supplying the muscles of the soft palate, pharynx, and larynx; (2) preganglionic parasympathetic neurons involved with control of heart rate; and (3) afferent input from brain stem sensory nuclei, especially the nucleus of the spinal tract of the trigeminal nerve and the nucleus of the tractus solitarius. The nucleus for the spinal portion of CN XI is the accessory nucleus, which is a longitudinal column of cells in the anterior horn of the upper five cervical segments of the spinal cord.^[7]^[14] As is too often the case in the biological sciences, nomenclature is somewhat muddled, and it is important not to confuse (1) the *accessory nucleus* in the cervical spinal cord, which gives rise to the spinal portion of CN XI; and (2) the cranial or *accessory portion of CN XI*, arising from the nucleus ambiguus in the medulla.

LOWER MOTOR NEURON: PERIPHERAL PATHWAYS

The eleventh cranial nerve fibers extend peripherally from two distinct nuclei: the caudal portion of the nucleus ambiguus in the medulla and the accessory nucleus in the cervical spinal cord. Fibers from the caudal portion of the nucleus ambiguus leave the brain stem caudal to the vagus nerve, as the cranial root of CN XI.^[7]^[14] Fibers from the accessory nucleus exit the cervical spinal cord as a series of rootlets. These unite to form a common trunk. They then ascend as the spinal root of CN XI, passing upward through the foramen magnum, and uniting with the cranial root of CN XI near the medulla. The united cranial and spinal roots of the accessory nerve exit the cranium through the jugular foramen.^[7]^[12]^[14]^[15] At this point, the spinal accessory nerve lies within the same dural sheath as the vagus nerve, separated from it by a fold of arachnoid.^[11]

After exiting the cranium through the jugular foramen,

TABLE 14-1 -- CLINICO-ANATOMICAL CORRELATION OF DISORDERS OF CRANIAL NERVES XI AND XII

Anatomical Site of Damage	CN XI or XII Finding	Other Neurological and Medical Findings	Common Etiologies
Supranuclear (cerebral hemisphere)	Neck weakness, tongue deviation	Hemiparesis with spasticity and extensor plantar responses, pseudobulbar palsy, cognitive deficits, personality changes, urinary incontinence, gait apraxia, primitive reflexes (e.g., suck, snout, glabellar), paratonic rigidity (gegenhalten)	Stroke, brain tumor, multiple sclerosis, brain abscess
Supranuclear (pontine)	Dissociated weakness (ipsilateral SCM and contralateral trapezius), contralateral weakness with spasticity, and deviation of the eyes toward the weakness	Facial numbness (CN V), weakness of the palate (CN X), or autonomic dysfunction. Contralateral loss of pain and temperature in the body and ipsilateral loss of pain and temperature in the face	Stroke, multiple sclerosis, brain abscess, brain tumor
Nuclear	Bilateral lesions may result in diminished ability to rotate the neck, inability to protrude the tongue, slurred and indistinct speech, impaired swallowing, and possibly some respiratory difficulty. The medial medullary syndrome results in ipsilateral tongue weakness, and contralateral weakness and impaired tactile and proprioceptive sense of the arm and leg	With vascular lesions, bilateral pyramidal signs, and diminished vibration and position sensation can occur	Motor neuron disease, poliomyelitis, brain stem abscess, syringobulbia, strokes
Within the cranium or in the region of the foramen magnum	Neck and tongue weakness	Cranial nerve IX and X involvement (depressed gag, palatal paresis, and vocal cord paralysis)	Platybasia, Paget's disease, glomus tumors, acoustic neuromas, meningiomas, metastases to the skull base, syphilis, tubercular meningitis, sarcoidosis
Within the region of the jugular foramen	Vernet's syndrome (ipsilateral weakness of the SCM and trapezius)	Vernet's syndrome (ipsilateral loss of taste and depressed sensation over the posterior one third of the tongue, ipsilateral depressed gag reflex and palatal weakness, ipsilateral vocal cord paralysis, and ipsilateral weakness of the SCM and trapezius muscles)	Tumor, basal skull fracture
In the retroparotid or retropharyngeal spaces, and distal peripheral nerve lesions	Collet-Sicard syndrome (ipsilateral weakness of the SCM, trapezius, and tongue)	Collet-Sicard syndrome (same as Vernet's syndrome, with the addition of weakness of the ipsilateral tongue)	Surgical trauma, local infections, neck irradiation or local tumors

the spinal accessory nerve divides into two portions: (1) the fibers from the nucleus ambiguus join the vagus nerve to form the inferior laryngeal nerve; this nerve innervates the intrinsic muscles of the larynx; (2) the fibers from the accessory nucleus first innervate the SCM muscle and then innervate the rostral portion of the trapezius muscle. The middle and lower portions of the trapezius muscle are innervated by cervical roots.^[1]^[14]^[16]

A number of connections exist between the eleventh cranial and other nerves. In particular, in the neck, the eleventh cranial nerve unites at several points with the first through fourth cervical nerves.^[11]

Some investigators have soundly suggested that the cranial portion of CN XI is actually no more than a mislabeled inferior branch of CN X.^[9] First, the cranial portion of CN XI innervates the intrinsic muscles of the larynx rather than the SCM or trapezeii. Second, the cranial portion of CN XI only travels with the spinal portion for a short distance before joining CN X.^[9] When the function of CN XI is assessed in the standard neurological examination, only the spinal portion is tested.^[10]

UPPER MOTOR NEURON: SUPRANUCLEAR CONTROL

The nature of the supranuclear input to each of the paired eleventh cranial nerve nuclei is not well understood. It is generally believed that these nuclei receive bilateral supranuclear input, and that this input arises from the lower portion of the precentral gyrus. Although the input for the trapezius muscle is believed to be derived primarily from the contralateral hemisphere,^[12] the input for the SCM is less well understood but is thought to be derived predominantly from the ipsilateral hemisphere. Although a minority have argued that the supranuclear fibers for the SCM do not decussate, there is a body of evidence, from isolated case reports, that there is a double decussation.^[12],^[17],^[20] The precise location of these decussations is not entirely known, although the first decussation may occur in the midbrain or pons, and the second may occur in the medulla or cervical spinal cord below the level of the first cervical root. Not surprisingly, the supranuclear input for the trapezius muscle travels separately in the brain stem

27

from the supranuclear input for the SCM muscle, and there have been a number of reports of the pathological dissociation of the two.^[21],^[22]

The primary supranuclear input for the trapezius muscle is located ventrally in the brain stem and crosses the brain stem in either the midbrain or pons. The supranuclear input for the SCM muscle is located in the brain stem tegmentum, and it decussates twice. Some investigators have suggested that the sternal head of the SCM (responsible for rotation of the head in the contralateral direction) is innervated by the ipsilateral hemisphere, but the clavicular head of the SCM (responsible for tilting the head to the ipsilateral side) is innervated by the contralateral hemisphere.^[23] Teleologically, this may be understood as an example of the concept that each cerebral hemisphere controls movement in the contralateral hemisphere rather than just in contralateral muscle groups.^[23]

Cranial Nerve XII

NUCLEUS

The hypoglossal nerve is classified as a general somatic efferent (GSE) nerve because it innervates striated muscle that arises embryologically from the somites.^[6],^[7] The nucleus of CN XII is located in the medulla, ventral to the floor of the fourth ventricle. The hypoglossal triangle or trigonum hypoglossi, in the floor of the fourth ventricle, serves as an external landmark for the rostral portion of the hypoglossal nucleus.^[14] As with some of the other pure motor cranial nerves, the nucleus is situated medially in the brain stem, which is a result of embryological anatomical relationships. The hypoglossal nucleus, formed by a column of large cells, is approximately 1.8 cm in length. It transverses much of the length of the medulla.^[7],^[19] Numerous fibers cross the midline of the medulla to connect the paired hypoglossal nuclei.^[11] Several discrete smaller nuclear groups surround the hypoglossal nucleus in the medulla, including the nucleus intercalatus, nucleus prepositus, and the nucleus of Roller.^[7]

LOWER MOTOR NEURON: PERIPHERAL PATHWAYS

Upon exiting the hypoglossal nucleus, the hypoglossal nerve travels ventrolaterally, passing through the medullary reticular formation, just lateral to the lateral margin of the medial longitudinal fasciculus and the medial lemniscus, and through the medial segments of the inferior olivary nucleus.^[11] The nerve exits the ventral aspect of the medulla in the pre-olivary or ventrolateral sulcus, between the medullary pyramid and the inferior olive, and medial to the ninth, tenth, and eleventh cranial nerves.^[6],^[14] When the nerve exits the medulla, it is comprised of 10 to 15 separate rootlets on each side.^[12] These rootlets coalesce to form two larger bundles, and these perforate the dura mater separately, uniting after their passage through it.^[15]

The hypoglossal nerve exits the posterior fossa through the hypoglossal canal.^[14] It descends in the neck close to the angle of the mandible. It passes beneath the internal carotid artery and the internal jugular vein, then travels forward between these two blood vessels and crosses the external carotid artery.^[11] The branches of the hypoglossal nerve are the meningeal (sending branches to the dura mater in the posterior cranial fossa), descending (sending branches to the omohyoid, sternohyoid, and sternothyroid muscles), thyrohyoid (sending branches to the thyrohyoid muscle), and muscular (sending branches to the extrinsic and intrinsic muscles of the tongue) (Fig. 14-2).^[14],^[15] The extrinsic muscles of the tongue include the genioglossus, styloglossus, hyoglossus, and chondroglossus muscles, whereas the intrinsic muscles of the tongue include the superior and inferior longitudinales, transversus, and verticalis muscles.^[11] The emphasis in the standard neurological examination, with regard to hypoglossal nerve function, is on the function of the extrinsic muscles of the tongue.^[6],^[11]

UPPER MOTOR NEURON: SUPRANUCLEAR CONTROL

The supranuclear input for the hypoglossal nerve is better understood than that for the spinal accessory nerve. As with the latter, the supranuclear input is derived from the lowest portion of the precentral gyrus.^[6] The corticobulbar afferents, which travel by way of the genu of the internal capsule and the middle of the cerebral peduncle, are predominantly contralateral, although some are also ipsilateral.^[6],^[14] The supranuclear input for the genioglossus muscle may be strictly contralateral.^[12],^[21]

EXAMINATION OF CRANIAL NERVES XI AND XII

Directed Neurological Examination

CRANIAL NERVE XI

The examination of cranial nerve (CN) XI consists of two parts: observation (at rest and during action) and palpation. Abnormal findings include atrophy; fasciculations; neck or shoulder deviation; and limitations in range, strength, or speed of motion.

Examiners should observe the neck and back while the patient is seated or standing, paying particular attention to the SCM muscle and the upper portion of the trapezius muscle. Atrophy or asymmetry should be noted. Fasciculations may be present with nuclear or lower motor neuron lesions. A unilateral paralysis of the SCM muscle causes little if any change in the position of the head while in the resting state. Bilateral paralysis may cause the neck to fall backward. Paralysis of the upper or middle portion of the trapezius muscle may alter the position of the scapula ([Fig. 14-3](#)). The upper part of the scapula may fall laterally away from the shoulder and vertebral column, and the inferior part may be drawn inward. ^[1], ^[11]

The speed, strength, and range of motion should be assessed. The major action of the SCM muscle, through its sternal head, is to turn the head to the opposite side. ^[9], ^[22] Additionally, through its clavicular head, the SCM tilts the

Figure 14-2 The origin and innervation of CN XII.

head to the ipsilateral side. To examine the right SCM muscle, the patient should turn the chin completely toward the left shoulder, and the examiner should attempt to overcome the movement. During this maneuver, it is important for the examiner to press against the patient's cheek rather than the mandible, because with the latter maneuver, one is testing not only the SCM but also the lateral pterygoid muscle (CN V) as well. ^[11] The SCM muscle is also involved in neck flexion, and when both SCM muscles act simultaneously, the result is to bring the head forward and downward. This movement may be tested by asking the patient to flex the neck while the examiner exerts firm pressure on the forehead. ^[11]

To assess the strength of the rostral portion of the trapezius muscle, the patient should elevate or shrug the shoulders and maintain this movement against resistance. ^[9] The rostral portion of the trapezius muscle also retracts the head and draws it to the ipsilateral side, ^[11] and this movement may be tested as well. The rostral and middle portions of the trapezius muscle normally stabilize the scapula, and a lesion of CN XI may cause winging of this structure. This muscle action is tested by asking the patient to extend the arms forward and horizontally. CN XI lesions cause winging of the scapula, although to a milder degree than that seen with dysfunction of the serratus anterior muscle. ^[9]

The SCM and the trapezius muscles should be palpated for the presence of atrophy or hypertrophy. Proper palpation of the sternal head of the SCM muscle is aided by asking the patient to turn the head to the opposite side against resistance. When activated, the right SCM turns the chin to the left. ^[9], ^[16]

A unilateral hemispherical lesion does not usually cause marked deviation of the head, although some weakness may be present. In cortical or subcortical strokes, the head can deviate to the side of the lesion, away from the hemiparetic body, making rehabilitation efforts frustrating. Atrophy and fasciculations are not present in an upper motor neuron lesion. ^[11] Irritative cortical foci may result in seizures accompanied by forced deviation of the head to the contralateral side. ^[16] A unilateral supranuclear lesion in the upper brain stem may produce dissociated weakness, with ipsilateral weakness of the sternal head of the SCM and contralateral weakness of the trapezius. ^[11] Nuclear lesions of CN XI are rare. These lesions result in muscle weakness as well as atrophy and fasciculations. Unilateral nerve lesions produce weakness of the involved muscles as well as some deviation and possibly winging of the scapula. Bilateral nerve lesions result in diminished ability to rotate the neck, and the neck may fall either backward or forward, depending on whether the SCMs or trapezii muscles are more involved. Because other cervical muscles such as the scaleni and splenii play a major role in neck deviation, flexion, and extension, a complete paralysis of neck muscles does not occur even with bilateral lesions of CN XI. ^[11]

Figure 14-3 Lesion of the right spinal accessory nerve resulting in displacement of the right scapula.

CRANIAL NERVE XII

The examination of CN XII consists of three parts: observation, palpation, and percussion. The examiner should assess the tongue for atrophy; fasciculations; deviation; limitations in the range, strength, or speed of motion; and involuntary movements.

The tongue is observed as it rests in the mouth, with attention to atrophy, fasciculations, deviation, tremor, myoclonus, or chorea (see [Chapter 34](#)). ^[9] Atrophy, if present, may be particularly noticeable at the tip or borders of the tongue, resulting in a scalloped appearance with multiple small folds ([Fig. 14-4](#)). ^[9], ^[11] A fine rippling of the tongue due to incomplete relaxation should not be confused with fasciculations. ^[16] Even while the tongue is "resting" in the floor of the mouth, there is some activity of the styloglossus muscles. These muscles pull the tongue upward and backward. When there is a unilateral hypoglossal nerve lesion, the resting tongue may deviate slightly away from the side of the lesion because of unopposed action of the styloglossus muscles. ^[11]

The tongue should be observed during protrusion. The examiner should note atrophy, tremor, chorea, or deviation. The genioglossus muscle causes protrusion of the apex of the tongue. When there is a unilateral lesion of the hypoglossal nerve, the protruding tongue deviates toward the side of the lesion owing to the unopposed action of the normal genioglossus muscle. ^[9], ^[9] When there are complete bilateral nuclear or hypoglossal nerve lesions, the patient is unable to protrude the tongue at all. In general, when examining the protruding tongue for deviation, it is very important to choose appropriate landmarks. ^[9], ^[12] For example, if the lips are used as a landmark, in the setting of unilateral facial weakness, the tongue may falsely appear to deviate toward the weak side. A more appropriate landmark in this and most other settings is the space between the two upper central incisors. This space should be aligned with the median raphe of the tongue. ^[9], ^[16]

The tongue is observed during movements other than protrusion. First, the speed and range of motion should be assessed by asking the patient to wiggle the tongue rapidly from side to side, and to point the tip upward and downward. Second, the strength of tongue motion should be assessed by asking the patient to press the tip of the tongue sideways against the inside of the cheek, while the examiner exerts opposing pressure by placing an index finger on the outer aspect of the cheek. ^[9] Third, speech, and particularly lingual sounds, should be assessed for the presence of dysarthria.

Palpation and percussion comprise the final aspects of the examination of the tongue. Palpation of the tongue between the examiner's thumb and index finger sometimes confirms the presence of atrophy. ^[9], ^[16] When a diagnosis of myotonia is being considered, the tongue should be tapped with a percussion hammer. A myotonic response is characterized by a contraction that is very slow to disappear. ^[9]

In a unilateral supranuclear lesion, the tongue may deviate toward the contralateral side; however, atrophy and fasciculations are not present. In a unilateral nuclear or hypoglossal nerve lesion, the tongue is atrophic on the ipsilateral side. On protrusion, it clearly deviates toward the side of the nuclear or nerve lesion. ^[9] In this setting, speech, swallowing, and respirations should be unaffected. If there are bilateral nuclear or nerve lesions, the tongue is diffusely atrophic, and the patient is unable to protrude the tongue at all. Additionally, articulation (especially lingual sounds) may be impaired, with slurred and indistinct speech. Swallowing and respiration may be impaired as the tongue falls back into the pharynx. ^[11] Fasciculations may

be present either unilaterally or bilaterally in progressive disorders that involve the nucleus (e.g., amyotrophic lateral sclerosis or syringobulbia). Forced deviation of the tongue may be a manifestation of a seizure, and involuntary movements of the tongue may be a feature of myoclonus, or rarely Parkinson's disease (tremor), Huntington's disease (chorea), or tardive dyskinesia or tardive dystonia (oral-buccal-lingual movements).^[11]

Associated Neurological Findings

Cerebral. With regard to CN XI or XII, bihemispherical lesions may result in significant weakness of the SCM, trapezeii, or extrinsic tongue muscles. Other features that confirm the presence of bihemispherical lesions are urinary incontinence, gait apraxia, pseudobulbar palsy (i.e., dysarthria, dysphagia, and emotional incontinence), cognitive deficits, and alterations in personality.

Cranial Nerves. Dysfunction of neck or tongue musculature may be the result of lesions in the brain stem affecting supranuclear, nuclear, or nerve fibers of CN XI or CN XII. Other features of a brain stem lesion are facial numbness (CN V), weakness of the palate (CN X), or autonomic dysfunction, indicating involvement of cranial nerve nuclei or sympathetic fibers in close proximity to the nuclei of CN XI or XII. Additionally, although supranuclear lesions may result in both head and eye deviation (due to connections between the accessory nucleus and the medial longitudinal fasciculus), a peripheral lesion of the spinal accessory nerve should not be accompanied by eye deviation.

Motor/Reflexes/Cerebellar/Gait. When examining a patient with a suspected lesion of CN XI or XII, it is important to perform a thorough motor examination. The examiner should note any primitive reflexes (e.g., suck, snout, glabellar) or paratonic rigidity (gegenhalten). These signs, along with pseudobulbar palsy, may be indicative of bilateral frontal lobe lesions. In addition, weakness in other ipsilateral muscles in the face, arm or leg, accompanied by hypertonia, hyperreflexia, or extensor plantar responses, are suggestive of an upper motor neuron lesion,^[24] whereas weakness with atrophy, loss of reflexes, or fasciculations are signs of either a lower motor neuron lesion or neuronopathy. The supranuclear fibers for the sternal head of the SCM muscle probably decussate twice: once in the midbrain or pons and a second time in the medulla or cervical spinal cord.^[18] Hence, a lesion in the right side of the pons may result in (1) left-sided weakness (involvement of corticospinal tract fibers before their decussation in the medulla); and (2) weakness of the left SCM muscle and deviation of the head to the left (i.e., the same side as the hemiparesis) because of involvement of the supranuclear input to the left SCM muscle after the first but before the second decussation. In contrast, a lesion in the right cerebral hemisphere or right internal capsule or high in the right midbrain, before the initial decussation of the supranuclear fibers to the SCM, may result in (1) left-sided weakness due to involvement of the corticospinal tract fibers before their decussation; and (2) weakness of the right SCM muscle and deviation of the head to the right (i.e., the side opposite the hemiparesis).^[12]

When dysfunction of CN XI or XII is present, it is also important to perform a thorough examination of coordination and gait. The presence of cerebellar signs ipsilateral to CN XI or XII deficits may be indicative of involvement of the inferior cerebellar peduncle, which is consistent with a lesion in the region of the medulla.

Sensory. The sensory examination is especially important in assessing brain stem dysfunction because of the distinctive pattern of findings seen only with damage to this structure. The nucleus ambiguus is situated just medial to the spinothalamic and trigeminothalamic tracts in the medulla. Contralateral loss of pain and temperature in the body and ipsilateral loss of pain and temperature in the face confirm a lesion in the medulla in the region of the nucleus ambiguus. The medial lemniscus is located in the medial medulla, ventral to the hypoglossal nucleus, and tongue weakness with simultaneous loss of position and vibratory sense implies a lesion in this area (i.e., Dejerine's syndrome or anterior spinal artery syndrome of the medulla).^[7],^[12]

Autonomic Nervous System. Lesions of the brain stem may sometimes involve autonomic pathways. An examination of the autonomic nervous system involves assessment of: pulse rate, blood pressure in different positions (lying, seated, and standing), changes in skin color and texture, changes in hair and nails, decreased or excessive perspiration (e.g., anhidrosis in Horner's syndrome), and reflexes (e.g., pupillary, oculocardiac).

Neurovascular. Carotid dissection as well as brain stem stroke are etiologies of lower cranial nerve dysfunction, and the patency of the carotid artery may be preliminarily assessed at the bedside. Auscultation may reveal a bruit (i.e., partial occlusion). Palpation of the carotid pulse may reveal unilateral or even bilateral diminished pulsation, indicative of partial or complete occlusion of this blood vessel.

EVALUATION GUIDELINES ([Table 14-2](#))

The following tests may aid in the diagnosis of problems affecting the eleventh and twelfth cranial nerves.

Neuroimaging. Various neuroimaging studies may be useful.^{[25][27]} *Plain films of the skull* may provide diagnostic information in platybasia (flattening of the base of the skull so that the angle formed by an imaginary line connecting the anterior margin of the foramen magnum, the tuberculum sella, and the nasion is greater than 143 degrees), Paget's disease (areas of increased and decreased bone density, giving the bones a cotton-wool appearance), and basal skull fracture. *Head computed tomography (CT)* may be diagnostic in meningioma (homogeneous contrast-enhancing lesions with well-defined borders), acoustic neuroma (a well-defined uniformly enhancing tumor in the cerebellopontine angle, along with widening of the internal auditory canal), and skull fracture. *Head magnetic resonance imaging (MRI)* is useful in the diagnosis of a multitude of lesions including syringobulbia (a syringobulbar cavity), multiple sclerosis (plaques), tuberculous or carcinomatous meningitis (meningeal enhancement), brain abscess (a thin rim of contrast enhancement that surrounds a central

TABLE 14-2 -- USEFUL STUDIES IN EVALUATING LESIONS OF CRANIAL NERVES XI AND XII

	Neuroimaging	Electrophysiology	Fluid and tissue Analysis	Other Tests

EMG/NVC , electromyogram/nerve conduction velocity; CSF, cerebrospinal fluid; CBC, complete blood count; BAER, brain stem auditory evoked response; PPD, purified protein derivative; N/A, not applicable

zone of low attenuation), medial medullary syndrome (infarction in the medial medulla), and metastatic cancer. *Doppler studies* or an *angiogram* may be useful with regard to the workup of the medial medullary syndrome resulting from vascular occlusion in the posterior circulation.

Electrophysiology. A number of electrophysiological studies may provide valuable diagnostic clues. *Electromyography (EMG)* with nerve conduction studies may be useful to diagnose Guillain-Barre syndrome (reduction in conduction velocity, slowing of F wave conduction velocity, nerve conduction block), and motor neuron disease (widespread fibrillations and positive sharp waves). *Evoked potentials* (visual, brain stem auditory, somatosensory) may be useful in the diagnosis of multiple sclerosis.

Cerebrospinal Fluid. Cerebrospinal fluid (CSF) analysis may aid in the diagnosis of lesions of CN XI and XII. Elevated CSF protein level is a feature of multiple sclerosis, neurosarcoidosis, tuberculous meningitis, and poliomyelitis. A low CSF glucose level may be present in tuberculous meningitis, carcinomatous meningitis, and neurosarcoidosis. CSF leukocytosis may be found in neurosarcoidosis and tuberculous meningitis. Albuminocytological dissociation (elevated CSF protein level in the relative absence of CSF leukocytosis) is a feature of Guillain-Barre syndrome. CSF oligoclonal bands are a feature of multiple sclerosis. Cytological examination of cellular material in the CSF may be diagnostic in carcinomatous meningitis. CSF cultures along with analysis of genetic material by polymerase chain reaction may be diagnostic in infections of the CSF. CSF pressure may be elevated in a number of processes including abscesses, neurosarcoidosis, and tuberculous meningitis.

Fluid and Tissue Analysis. Blood work may also be of diagnostic value (e.g., alkaline phosphatase levels in Paget's disease, angiotensin converting enzyme levels in sarcoidosis, Venereal Disease Research Laboratory test [VDRL] in syphilis, viral cultures in poliomyelitis, genetic testing in neurofibromatosis). Purified protein derivative (PPD) is helpful in diagnosing tuberculosis, as is lymph node biopsy in sarcoidosis.

Neuropsychological Tests. This technique has limited value in diagnosis of processes involving CN XI and XII.

Other Tests. Plain films of the chest are of diagnostic value in evaluating pulmonary disorders that extend beyond the pleura to involve CN XI, including tuberculosis, lung carcinoma, and pulmonary sarcoidosis.

CLINICAL SYNDROMES

Supranuclear Hemispherical Lesions ([Table 14-3](#))

The supranuclear input to CN XI and XII is not fully understood. Although input is thought to be bihemispherical in general, some muscles probably receive predominantly ipsilateral input (SCM), whereas others receive predominantly contralateral input (trapezius, genioglossus). A destructive unilateral supranuclear lesion (e.g., infarction,

hemorrhage, tumor, multiple sclerosis, brain abscess) may result in some weakness of neck and tongue musculature so that the chin deviates toward the lesion. Atrophy and fasciculations are not present in an upper motor neuron lesion. ^[10], ^[11] An irritative unilateral supranuclear lesion (e.g., a seizure focus) may result in forced deviation of the head or tongue away from the lesion. ^[11]

Pontine Lesions

A unilateral lesion in the brain stem (e.g., stroke, multiple sclerosis, abscess, tumor) may produce dissociated weakness, with ipsilateral weakness of the SCM and contralateral weakness of the trapezius. ^[11] In addition, the supranuclear fibers for the SCM muscle probably decussate twice. A lesion in the right side of the pons may result in left-sided weakness (i.e., involvement of the corticospinal tract fibers before their decussation in the medulla) and possible deviation of the head to the left (i.e., involvement of supranuclear input to the left SCM muscle after the first but before the second decussation). Involvement of the paramedian pontine reticular formation may also result in deviation of the eyes toward the weakness.

Nuclear Lesions at the Level of the Medulla (CN XI and XII) and Cervical Cord (CN XI)

The nuclei of CN XI or XII may be involved in a number of disease processes including motor neuron disease, poliomyelitis, brain stem abscess, and syringobulbia. ^[28] In addition to muscle weakness, these lesions may result in atrophy and fasciculations. Bilateral involvement of these nuclei may result in diminished ability to rotate the neck, inability to protrude the tongue, slurred and indistinct speech, impaired swallowing, and possibly some respiratory difficulty. The medial medullary syndrome, which is caused by occlusion of the vertebral artery, results in paralysis and atrophy of the tongue on the side of the lesion (due to involvement of the twelfth cranial nerve or nerve nucleus), weakness of the arm and leg on the side opposite the lesion (due to involvement of the pyramidal tracts before their decussation), and impaired tactile and proprioceptive sense of the side of the body opposite to the lesion (due to involvement of the medial lemniscus). ^[12], ^[29]

Lesions Within the Cranium or in the Region of the Foramen Magnum

A large number of different pathological processes in this region may impinge upon either the eleventh or twelfth cranial nerves. Additionally, other cranial nerves in the posterior fossa may be involved (CN IX and X). Platybasia and Paget's disease, indirectly through their effects on the bony structures in this region, may impinge upon these cranial nerves. Tumors, including glomus tumors, acoustic neuromas, meningiomas, and metastases to the skull base, may impinge on the eleventh or twelfth cranial nerves. A number of infectious processes, including syphilis and tuberculosis, ^[30] may result in dysfunction of CN XI and XII. Combined dysfunction of CN IX through XII may result in neck and tongue weakness, depressed gag, palatal paresis, and vocal cord paralysis.

Lesions Within the Region of the Jugular Foramen

These lesions may affect CN IX, X, and XI, which exit the skull through this foramen. The resultant syndrome, Vernet's syndrome, is characterized by the following features: ipsilateral loss of taste and depressed sensation over the posterior one third of the tongue, ipsilateral depressed gag reflex and palatal weakness, ipsilateral vocal cord paralysis, and ipsilateral weakness of the SCM and trapezius muscles. ^[10], ^[12], ^[31]

Lesions in the Retroparotid or Retropharyngeal Spaces, and Distal Peripheral Nerve Lesions

CN XI and XII may be affected by a number of distal peripheral nerve lesions resulting from surgical trauma, ^[32] ^[38] local infections, stretch, ^[39], ^[40] neck irradiation, ^[41] or local tumors. ^[42] ^[46] A dissecting carotid aneurysm may result in hypoglossal nerve palsy. ^[47] A self-limited idiopathic hypoglossal nerve palsy also has been reported. ^[48], ^[49] The resultant findings (i.e., weakness and atrophy) in peripheral nerve lesions have been described earlier. Occasionally, a lesion may affect CN IX through XII, with a resultant Collet-Sicard syndrome, characterized by the same features as Vernet's syndrome described earlier, with the addition of weakness of the ipsilateral tongue. ^[10], ^[12]

GENERAL MANAGEMENT GOALS

Patients with dysfunction of either CN XI or CN XII may exhibit a number of problems with communication, swallowing, and well as difficulty resulting from weakness of the neck or trapezius muscle. Difficulty with swallowing may be amenable to swallowing therapy, including oral exercises and methods of postural facilitation. A soft mechanical diet with thickened liquids may decrease the likelihood of tracheal aspiration; however, a nasogastric tube or even a percutaneous gastrostomy device may be required.

Difficulty with articulation and communication may be amenable to speech therapy; however, augmentive and alternative communication devices may be required. Devices vary from the simple (e.g., boards with letters, words, or symbols), to the more complex (e.g., electronic communicators).

Weakness of the neck may be aided by a cervical orthotic device, and that, as well as weakness of the trapezius, may be aided by conventional physical therapy techniques such as range of motion and strengthening exercises, compensatory

TABLE 14-3 -- SELECTED ETIOLOGIES ASSOCIATED WITH DISORDERS OF CRANIAL NERVE XI AND CRANIAL NERVE XII

Etiological Category	Specific Etiologies	Chapter
STRUCTURAL DISORDERS		
Developmental	Platybasia (CN XII) Syringobulbia (CNs XI, XII)	28
Degenerative and compressive	Paget's disease	29
HEREDITARY AND DEGENERATIVE DISORDERS		
Chromosomal abnormalities and neurocutaneous disorders	Neurofibromatosis (CN XII)	32
Movement disorders	Dystonia (CNs XI, XII) Huntingtons disease (CN XI) Myoclonus (CN XII)	34
Degenerative motor, sensory and autonomic disorders	Amyotrophic lateral selerosis (CNs XI, XII)	36
ACQUIRED METABOLIC AND NUTRITIONAL DISORDERS		
Endogenous metabolic disorders	Paget's disease (CN XII)	38
Exogenous acquired metabolic disorders of the nervous system: Toxins and illicit drugs	Botulism (CN XII)	39
INFECTIOUS DISORDERS		
Viral infections	Acute poliomyelitis (CNs XI, XII)	41
Nonviral infections	Tubercular meningitis (CN XII) Neurosyphilis (CN XII) Brain stem abscess (CN XII)	42

HISTORY AND DEFINITIONS

Recognition that paralysis resulted from injuries to the nervous system was described in the Hippocratic writings, but it was the work of three men Galen of Pergamon (130-200 AD), Andreas Vesalius (1514-1564), and Thomas Willis (1621-1675) that established the foundation of our current knowledge of the functional anatomy of weakness.^{1,2} Galen, who was also physician to the Roman emperor, Marcus Aurelius, was the first experimental physiologist. His vivisection studies on the brain established that cutting into the brain produced paralysis, but he gave undue attention to the ventricles as the source of the weakness rather than the substance of the hemispheres. Galen's experiments on the spinal cord were more definitive; he showed different levels of paralysis by sectioning different regions of the cord, including hemisections that caused paralysis on the same side of the body. Little more was added to our knowledge of the nervous system until the Renaissance anatomist Vesalius refined Galen's anatomical observations of the central nervous system (CNS) and corrected Galen's misconceptions about the function of muscles and the anatomy of nerves. Galen thought that muscles were mere protective flesh for the tendons, which produced movement when excited by the animal spirits flowing from the ventricle through hollow nerves. Vesalius recognized that Galen's "flesh" was the "particular organ of motion and not merely the stuffing and support of the fibers." He also recognized that nerves were solid, not hollow, and when ligated, produced paralysis according to which nerve was divided.

The English physician Thomas Willis recognized that weakness could result from lesions at all levels of the nervous system and that the distribution of the paralysis was determined by the site of the lesion. Charles Bell (1774-1842), and Brown-Sequard (1817-1894) further refined our understanding of the functional anatomy of paralysis, and Robert Bentley Todd (1809-1860) described epileptic hemiplegia. In more modern times, John Hughlings

Jackson contributed the concept of the hierarchical nature of the motor system, and Wilder Penfield refined the localization of motor function in the motor cortex by defining the now familiar motor homunculus by direct stimulation of the cortex in patients undergoing surgery for epilepsy.

Willis and Descartes introduced the notion of reflexes and reflex action, but until the latter half of the nineteenth century, tendon jerks and cutaneous reflexes were not appreciated as valuable aids in localizing lesions and diagnosing diseases of the nervous system. In his paper of 1875, Erb was the first to describe systematically the tendon reflexes and their exaggeration in patients with hemiplegia and paraplegia, although he acknowledged that his observations were not new to his neurological colleagues. Erb also described ankle clonus. A few years later, William Gowers noted that knee jerks were diminished or lost in diseases of the nerve roots or the muscle itself. Although the cutaneous flexor withdrawal reflex had already been described, Babinski pointed out in 1876 the diagnostic importance of the extensor response of the great toe when the sole of the foot is scratched. A few years later the brilliant English experimental neurophysiologist, Sir Charles Sherrington, defined the nature of reflex arcs and the importance of reciprocal inhibition in his landmark book, *The Integrative Action of the Nervous System*.³ Other late nineteenth century neurologists also contributed important observations to help localize and diagnose diseases causing weakness. Charcot described the atrophy and fasciculations of muscle in amyotrophic lateral sclerosis, and Duchenne described the features of muscular dystrophy, including pseudohypertrophy.

Degrees and location of muscular weakness and changes in muscle tone are described by more or less precise terms. Paralysis refers to a complete loss of voluntary movement, whereas paresis is a reduced but not complete abolition of voluntary movement. Palsy is an older term that has been used interchangeably with either paralysis or paresis; currently, its use is confined to historical diagnoses that have been retained in conventional use such as Bell's palsy and cerebral palsy. The distribution of the paralysis or paresis is modified by the prefixes mono (for involvement of one limb), para (for involvement of both legs), hemi (for the limbs on one side of the body), and quadra or tetra (for all four limbs). A brachial paresis (or paralysis) refers to a monoparesis of an arm, and crural refers to involvement of one leg.

Changes in muscle tone that are elicited by passive movements of the limbs are described by the following terms. *Flaccidity* is the absence of normal muscle tone, while *spasticity* and *rigidity* are abnormal increases in muscle tone. Spasticity differs from rigidity in that it selectively increases the tone in the flexor muscles of the arm and the extensors of the leg, whereas rigidity affects flexors and extensors equally. The *gegenhalten* (German "hold against") phenomenon is felt as an increase in tone but is the result of resistance with an equal and opposite force by the patient to the examiner's attempt to move the limb passively.

The terms *lower motor neuron* and *upper motor neuron* are often used to differentiate two basic types of weakness: the first, due to a lesion of the motor neuron in the anterior spinal gray and its axon coursing to the muscle through the spinal roots and peripheral nerves and the second, due to a lesion that interrupts the descending motor pathways from supraspinal neurons that converge on the lower motor neuron pool. These very useful terms in clinical neurology derive from the concept that pools of upper motor neurons exist in a hierarchical order in the brain stem and motor cortex and converge via several different pathways on the lower motor neuron pool consisting of alpha and gamma motor neurons.

The *neuromuscular junction* is the specialized anatomical connection between the motor nerve endings and the skeletal muscle. The muscles that convert the electrical impulse into the force that produces movement is striated muscle, which is often referred to as skeletal muscle; this muscle type contrasts with smooth muscle, which responds to activation of the autonomic nervous system.

The term *fatigability* is used in a general sense to describe the feeling of being tired and not being able to put out full effort. It is also used more precisely to define a change in force-generating capacity of the neuromuscular apparatus brought about by muscular activity. Normal fatigue results from intense muscular contraction. When one or more muscles used in a specific task become weaker and weaker with repetitive but normal use, the phenomenon is referred to as fatigability and implies dysfunction at the neuromuscular junction.

Finally, *weakness* should be differentiated from *dyspraxia* (see [Chapter 4](#)). Weakness is an inability to carry out a desired movement with normal force because of a reduction in strength of the muscles necessary to carry out the movement. In dyspraxia, strength is normal, and the inability to perform a movement results from a failure in the motor centers in the cortex that plan and provide the proper commands to execute the movement.

CLINICAL HISTORY

For disorders of strength, as for other disorders of the nervous system, the clinical history is primarily important in defining the location and cause of the disorder. The onset (sudden or insidious), rate of progression (gradual or rapid), and temporal profile (intermittent, step-wise, or stable and chronic) help narrow the diagnostic possibilities. Precipitating elements associated with onset of the disorder, such as trauma, exposure to toxins, recent infections, or travel, provide important clues. Because the molecular and genetic natures of more and more neurological disorders are being defined, it is most important to take a careful family history. Other medical illnesses and the medications taken for them may be important determinants of the cause. Life style and habits, and drugs, both prescribed and illicit, including alcohol, vitamins, and special diets, are potential causes of weakness. Other neurological illnesses or features may also help in localizing the lesion and defining the cause of the weakness. For example, dementia or a speech and language disorder may localize the problem to the cortex; the distribution of numbness, pain, and other sensory symptoms helps to localize the lesion causing weakness. The phenomenon of fatigability typifies a lesion of the neuromuscular junction.

ANATOMY OF STRENGTH AND REFLEXES

Overview of Voluntary Motor Function

The motor systems are responsible for initiating and coordinating all movements that are part of the normal and abnormal behavioral repertoires. The motor systems generate three general types of movements. *Reflex responses* are rapid, stereotyped involuntary movements elicited by a stimulus that requires a quick reaction at an involuntary level—for example, withdrawal of a bare foot that has touched a sharp or hot object. *Rhythmical movements* such as walking and running require a stereotyped sequence of muscle activation (see [Chapter 18](#)). *Voluntary movements* are the most complex. They are goal-directed and initially require conscious direction. Through practice, skilled movements such as playing a piano become more automatic and require less conscious direction.

The three types of movements correlate with the overall organization of the motor system, which is *hierarchical* and contains three major components: local reflex networks in the spinal cord; motor integration areas of the brain stem; and motor integration areas of the cerebral cortex. The spinal cord contains the circuitry for the reflex responses and some rhythmical motor patterns, whereas the brain stem system contains circuits for more complex patterns of motor movements including rhythm generators. The cortex is the command center that plans and initiates movements and uses the reflex and patterned responses of the brain stem and spinal cord to generate the details of the movement.^[1]

The motor systems do not function in isolation and require a constant flow of sensory information to produce the appropriate movement. The sensory system is also organized in a hierarchical fashion and provides appropriate sensory information to each level of the motor system. In addition to these three hierarchical levels, two other parts of the motor system regulate movement, the cerebellum (see [Chapter 17](#)) and the basal ganglia (see [Chapter 16](#)). The cerebellum improves the coordination and accuracy of movement by comparing sensory feedback from the periphery with the descending motor commands, and the basal ganglia receive inputs from both motor and sensory cortical regions and project principally to areas of the frontal cortex that are involved in motor planning.

In addition to this hierarchical organization, many pathways operate in *parallel* and can act independently to control motor output. Thus, higher centers can adjust the operation of different spinal circuits independently to produce combinations of movements required for complex tasks. For example, postural reflexes residing in the brain stem maintain the ballet dancer's body position and balance while the cortex initiates a reaching movement of the arms.

Ultimately, all of these descending hierarchical and parallel pathways converge on a set of motor neurons in the spinal cord that give rise to the motor nerves that innervate skeletal muscle and produce movement. These are the *lower motor neurons* of the ventral gray matter of the spinal cord. Sometimes they are referred to as the final common pathway. In contrast, the motor neurons that generate voluntary, rhythmical, and reflex responses are the *upper motor neurons*. Most of the control signals coming from the upper motor neuron do not act directly on the lower motor neuron but use networks of interposed neurons known as *interneurons*, or the internuncial pool of neurons. These neurons are very important in integrating the reflex and rhythmical patterns of movement. The final effector of movement, skeletal muscle, responds in two modes, tonic and phasic contractions. For example, muscles involved in posture contract tonically, whereas those involved in voluntary limb movements contract in a phasic pull and push of joints. Phasic movements require coordinated contractions of agonists and antagonists. In the sections that follow, these elements of the motor system are discussed in more detail, starting with the muscle and the neuromuscular junction and then proceeding with the lowest level of hierarchical organization, the spinal cord, and progressing through the brain stem to the cortex. The parallel processing of motor control is discussed for each of these levels.

Muscle

Skeletal muscle is the effector of all motor commands from the CNS. The degree of movement, or force, depends on the magnitude of neural excitation of skeletal muscle. Striated muscle is composed of bundles of *myofibers*, which are the multinucleated cells of muscle. Muscles are composed of two types of myofibers that are distinguished by their energy metabolism. *Type I* fibers correspond to the slow-contracting fibers that rely primarily on aerobic oxidative metabolism and are involved in more sustained contractions such as maintenance of posture. *Type IIA* fibers are fast-contracting but are also capable of sustained activity. These fibers are both aerobic and anaerobic; although oxidative enzymes are present, their activity is slightly less than that of type I fibers. *Type IIB* fibers are characterized by anaerobic or glycolytic metabolism and correspond to the fast-contracting fibers that are recruited for short periods of vigorous exercise.^[1] The differences in the predominant metabolic enzymes used by these two types of muscle fibers can be readily seen by histochemical stains specific for the enzymes of either type.

Each myofiber contains many bundles of slender filaments called *myofibrils* ([Fig. 15-1](#)). Under the electron microscope myofibrils are seen to contain dark bands alternating with light bands bisected by a narrow dark line called the Z line, which gives a regular striated appearance to the muscle. The segment from one Z line to another is called a *sarcomere*; this is the unit of contraction because it contains the contractile proteins responsible for transforming chemical energy into mechanical force. Each sarcomere consists of thick filaments, primarily composed of the protein *myosin*, and thin filaments, which contain *actin*. *Actin* interacts with myosin to produce contraction of the muscle. The thin filaments also contain regulatory proteins including tropomyosin and troponin.^[1]

Two other ultrastructural elements are important in the process of contraction^[1] ([Fig. 15-2](#)). The *transverse tubule* (T-tubule) is a specialized invagination of the plasma membrane of the myofiber, the sarcolemma. The T-tubule is responsible for propagation of the action potential into the

Figure 15-1 Histological and molecular structure of skeletal muscle. E represents a longitudinal section of a sarcomere showing the arrangement of the myofilaments actin (thin filaments) and myosin with projecting bridges (thick filaments). F, G, H, I are cross sections through the sarcomere showing the arrangements of the thin and thick filaments at the sites indica (From Bloom W, and Fawcett DW: *A Textbook of Histology*. Philadelphia, W. B. Saunders, 1968.)

interior of the myofiber in response to depolarization of the sarcolemma. The other important structure involved in contraction is the *sarcoplasmic reticulum*, which is a set of tubules and cisterns surrounding the myofibrils. The sarcoplasmic reticulum stores calcium, which is released or taken up again in the process of *excitation-contraction coupling* and relaxation. In response to neurally initiated depolarization of the sarcolemma, calcium is released from the sarcoplasmic reticulum. The sudden increase in calcium concentration changes the conformation of the regulatory proteins on the thin filament, allowing interaction between myosin and actin to form cross-bridges and contraction. Contraction is terminated by the reuptake of calcium into the sarcoplasmic reticulum. This active transport of calcium requires energy. If energy is not available to reduce the calcium accumulation in sarcoplasm, the actin and myosin cross-bridges persist and relaxation does not occur. When this occurs after death it is known as rigor mortis.

A variety of metabolic disorders of muscle are possible if defects occur at any step in this orderly sequence of excitation-contraction coupling and relaxation. Disturbances in sodium channels in the sarcolemma membrane result in episodic weakness, giving rise to the disorder known as *periodic paralysis* (see [Chapter 37](#)). Muscle weakness can result from a shortage of fuel when defective glycolytic enzymes cannot convert glycogen to glucose (*glycogen storage diseases*) or when the machinery that converts glucose to energy is defective (*mitochondrial disorders*) (see [Chapter 31](#)). Defects in the uptake of calcium into the sarcoplasmic reticulum disrupt relaxation and also result in weakness (*myotonia, myotonic dystrophy*) (see [Chapter 36](#)).

All of these defects in the contraction and relaxation of muscle are genetic in origin. Recently, work in molecular genetics has shown that the muscular dystrophies, in particular *Duchenne's and Becker's dystrophies*, result from a defective gene that codes for a major structural protein in the sarcolemmal membrane known as *dystrophin* (see [Chapter 36](#)).^[1] Immunohistochemical studies show that dystrophin is completely absent in Duchenne's dystrophy, whereas in Becker's dystrophy the dystrophin protein is either smaller than normal or is present in low levels.

Neuromuscular Junction

The transfer of information from the axon potentials of motor nerves to the muscle occurs at a specialized synapse, the neuromuscular junction. After entering muscle, the axon of a motor neuron divides into many thin branches or twigs. Each of these twigs makes contact with only one myofiber, approximately midway between its ends. At this

Figure 15-2 The transverse tubule system, showing the relationship of the sarcoplasmic reticulum and transverse tubular system to the myofibril (From Bloom W, and Fawcett DW: A Textbook of Histology. Philadelphia, W. B. Saunders, 1970.)

motor endplate, the axonal twig divides further and forms a complex of approximately 50 boutons, each making synaptic contact with the muscle cell. The lower motor neuron uses *acetylcholine* as its chemical transmitter. When an action potential from the lower motor neuron reaches the neuromuscular junction, normally enough acetylcholine is released to produce a suprathreshold *excitatory endplate potential*, which produces a propagated *muscle action potential* and a twitch in the fiber innervated by that alpha motor neuron. This involves two major events, presynaptic release of the acetylcholine and interaction with the postsynaptic receptor.

In the presynaptic terminal, acetylcholine is synthesized from acetyl CoA and choline and is catalyzed by *choline acetyltransferase*. The acetylcholine is packaged in synaptic vesicles and is released into the synaptic cleft after a nerve action potential arrives by a process that requires calcium and is called *stimulus-secretion coupling*. The entry of calcium in the presynaptic terminal through voltage-gated channels triggers the fusion of the synaptic vesicles with the presynaptic cell membrane.^[1] This fusion of the vesicular and plasma membrane opens the vesicle to the synaptic cleft, releasing its contents in a process known as *exocytosis*. Synapsin I, a phosphoprotein localized in vesicles, may mediate translocation of vesicles to the membrane. The subsequent steps have not yet been deciphered, but after acetylcholine has been released, the presynaptic membrane is pinocytotically recaptured, and the vesicles are remade and repleted with acetylcholine. ^[2] The acetylcholine binds to a receptor on the postsynaptic membrane. If sufficient acetylcholine is released, the postsynaptic membrane is depolarized, resulting in the *endplate potential*. The probability that an interaction will occur between the released acetylcholine and its receptor on the postsynaptic membrane is increased by concentration of the *cholinergic receptors* along postjunctional folds at the neuromuscular junction. The cholinergic receptor is of the *nicotinic type*. The action of acetylcholine is terminated by *acetylcholine esterase*, which catabolizes it into its two constituents, and the choline is recaptured for reuse by low-affinity transport in the nerve terminal.

Lower Motor Neuron Pool

Contraction of skeletal muscle can occur only when a nervous impulse is conducted down the axons of the motor

neuron. The motor neurons lie in the ventral horn of the spinal cord and are known as *lower motor neurons*. There are two types of motor neurons that provide a parallel system of innervation of the muscle. The larger *alpha motor neurons* innervate the extrafusal muscle fibers, and the smaller *gamma motor neurons* innervate the intrafusal muscle fibers of the *muscle spindle* (Fig. 15-3 (Figure Not Available)). The axons of the motor neurons leave the spinal cord through the ventral roots and continue into the ventral and dorsal branches (rami) of the spinal nerves. The dorsal rami innervate the paravertebral muscles of the neck and trunk, and the ventral rami innervate the rest of the trunk and the extremities. In the brain stem, the motor neurons in the cranial nerve motor nuclei send axons to innervate the muscles of the tongue, pharynx, larynx, palate, face, and extraocular muscles. Because signals to skeletal muscle from any part of the motor system rely on activation of the lower motor neuron pool, Sir Charles Sherrington coined the term *final common pathway* to describe the function of the lower motor neurons. The activation of different numbers and combinations of alpha motor neurons by other motor centers determines the force and speed of the resulting movement. The accuracy of a movement depends on sensory feedback. The parallel gamma motor neuron system provides a way for the motor system to ensure the accuracy of the sensory information it is receiving.

ALPHA MOTOR NEURON

Nerve impulses generated by the alpha motor neuron cause contraction of extrafusal muscle fibers, resulting in the generation of force and movement. The axon of the alpha motor neuron divides into numerous branches when it enters the muscle, and each terminal branch makes synaptic contact with one muscle cell. The number of terminal branches and muscle cells innervated by an individual alpha motor neuron may vary greatly but generally corresponds to the size of the motor neuron. An alpha motor neuron and all the muscle cells innervated by it are called a *motor unit*, another term introduced by Sherrington. Therefore, all muscle cells innervated by that alpha motor neuron contract simultaneously when an *action potential* is generated by that motor neuron. The size of a motor unit may range from as few as ten muscle cells innervated by one motor neuron to more than 1000. The smallest motor units are found in muscles that are used for delicate precise movements such as the extraocular muscles, the larynx, and the intrinsic muscles of the hand. The largest motor units are found in large powerful muscles involved in more forceful movements that require less precise control like the back and thigh muscles.^[1]

The myofibers belonging to the same motor unit may be scattered throughout the muscle, but they are all of the same fiber type. Therefore, all of the myofibers in a given motor unit have the same characteristics with regard to maximal force, velocity of contraction, and endurance. Also, there is a correlation between the size of the motor units and the fiber type. The smallest motor units consist of type I fibers, whereas the largest ones consist of type IIB fibers.

The difference in fiber types amplifies the difference in the maximal force that can be generated by the large and small motor units. Therefore, in the largest motor units, where type II fibers predominate, not only are there more myofibers but each one can also generate more force.

Figure 15-3 (Figure Not Available) The parallel organization of the alpha and gamma lower motor neurons (black cell bodies). The alpha motor neurons innervate extrafusal skeletal muscle, the gamma motor neuron innervates the intrafusal muscle fibers to ensure proper sensory feedback from the muscle spindle. The activity of both motor neurons is modulated by multiple segmental and suprasegmental input (From Snell RS: Clinical Neuroanatomy for Medical Students. Boston, Little, Brown & Co., Inc., 1987.)

Smaller motor units made up of type I fibers are found in muscles used for finely graded changes of force needed for more precise control.

The force of a muscle contraction can be increased in a graded manner by two means. One is a gradual increase in the number of alpha motor neurons activated, which results in the *recruitment* of more and more motor units and thus more myofibers. When a muscle contraction is initiated, the smallest, most fatigue-resistant, and slowest motor units are recruited first; as the force is increased, larger and faster-contracting motor units that are more susceptible to fatigue are recruited successively. This concept was demonstrated by Henneman and colleagues,^[1] who referred to it as the "size" principle. They also described the relationship between the size of a motor unit (i.e., the number of myofibers innervated) and the size of its motor neuron. The smallest motor neurons are more excitable and thus are activated first. The largest motor neurons are not as easily excited but have the highest maximum firing frequencies and can generate the quickest forceful movements. Therefore, the *size principle* ensures selection of the motor units that are best suited for a particular kind of movement.

The other method of increasing the force of muscle contraction and movement is to increase the firing frequency of the alpha motor neurons already recruited, thereby increasing the force developed by each motor unit. A single action potential from a motor neuron produces only a very brief contraction of the myofiber, or twitch. If no other action potentials arrive within a tenth of a second, no movement is produced. However, if action potentials arrive at closer and closer intervals, the individual twitches become a sustained contraction. As the firing frequency of the motor neuron increases, the tension and force generated increase also; this is referred to as summation. The maximum muscle contraction at the maximum firing frequency is known as *fused tetanus*. Unfused tetanus occurs at submaximum firing frequencies.

Motor neurons are *somatotopically organized* in the ventral gray matter of the spinal cord. Within the ventral gray, the motor neurons are grouped in longitudinally oriented columns (Fig. 15-4). Each column contains the alpha and gamma motor neurons to one or a few functionally similar muscles. Generally, each column extends through more than one segment of the cord. Therefore, each muscle receives motor fibers through more than one ventral root and spinal nerve. This explains why destruction of one root or spinal nerve by a lumbar disc protrusion, for example, produces weakness but not complete paralysis of a muscle.

Another level of organization is seen in the distribution of the neurons supplying the axial muscles versus those supplying the extremities. The motor neurons innervating the paravertebral muscles are located most medially in the ventral gray, whereas those supplying the muscles of the extremities are located more laterally. This arrangement can be seen most dramatically on cross-sections of segments of the cord that send fibers to the extremities; the ventral horn is much larger and extends more laterally in the cervical and lumbar enlargements. There is also a dorsal-ventral organization in which the motor neurons supplying the proximal muscles of the extremities lie more ventrally in the ventral gray than those supplying the distal muscles of the hand and foot.

The spinal cord is divided into *segments*, each giving rise to a dorsal and ventral root, which combine to form a spinal nerve. The axons of all the motor neurons located in one spinal segment leave the spinal cord through one ventral root and continue into the spinal nerves.

These spinal nerves conform to the embryological *myotomes*. This myotomal organization can still be seen in the rostral caudal distribution of innervation from the cervical and lumbar cord segments innervating the upper and lower extremities, respectively. The proximal muscles of the shoulder and hip girdle are innervated by the more rostral segments of the cervical cord (C5-C6) and the lumbar cord (L2-L4), whereas the intrinsic muscles of the hand and the more distal leg and foot muscles are innervated by the lowermost segments of the cervical (C8-T1) and lumbar (L5-S1) segments. There are the same number of thoracic (12), lumbar (5), and sacral (5) spinal roots as vertebral bodies. However, there are eight cervical spinal roots, whereas there are only seven cervical vertebral bodies. The first pair of cervical nerves exits from the vertebral column between the atlas and the skull. Each of the remaining cervical nerves from C2 to C7 leaves the spinal column *above* the vertebra of the corresponding number. Because there are eight pairs of cervical nerves and only seven cervical vertebrae, the eighth cervical nerve leaves the spinal column between C7 and T1. The first thoracic nerve and all the remaining spinal nerves pass out from the vertebral column *below* the vertebra of like number.

After leaving the spinal column, the cervical and lumbar nerves combine to form the brachial plexus and the lumbosacral plexus from which the peripheral nerves to the arm and leg are formed. As a result, motor axons from one spinal segment are distributed to several peripheral nerves. Looking at it from the standpoint of the muscle, each limb muscle receives motor axons from more than one spinal segment. As noted earlier, destruction of one spinal nerve therefore produces only a weakness rather than a paralysis of a muscle. Destruction of the peripheral nerve innervating the muscle, however, interrupts all of the motor innervation for that muscle, resulting in paralysis and atrophy of the muscle. Knowledge of the peripheral nerves, the spinal nerves contained in them, and the muscles innervated by them is crucial in localizing lesions in the subdivisions of the lower motor neuron, whether in the spinal nerve, plexus, or peripheral nerve. Diagrams of the important relationships are contained in [Figures 15-5 15-6 15-7](#).

The cervical, brachial, and lumbosacral plexuses are formed by the anterior primary rami of the spinal nerve roots (the posterior rami innervate the paravertebral muscles). In the plexuses the roots become reorganized into peripheral nerves, which then contain contributions from two or more spinal roots. Therefore, to accurately localize a lesion to a specific part of a plexus, one has to know the motor and sensory supply of all peripheral nerve components supplied by that division.

The *cervical plexus* is formed by the anterior primary rami of C1 through C4 behind the sternocleidomastoid and in front of the scalenus medius and levator scapulae muscles. The motor branches of the plexus supply the muscles of the neck. Injuries to the cervical plexus are infrequent,

222

Figure 15-4 Functional organization of the lower motor neurons in the spinal cord (From Bossy: Atlas of Neuroanatomy and Special Sense Organs. Philadelphia, W. B. Saunders, 1970.)

but any of its branches can be injured by penetrating wounds, surgery, or enlarged lymph nodes (see [Fig. 15-6 A](#)). Involvement of the cervical plexus may also compromise the closely associated cranial nerves XI and XII. In patients with lesions of the cervical plexus, sensory symptoms in the form of head and neck dysesthesia and pain may predominate over motor signs.

Injuries are more common to the *brachial plexus*, which is formed from the anterior primary rami of C5 through T1. It extends from the spinal column to the axilla and is divided into five major components starting proximally and proceeding distally. The first components are the roots, which recombine to form trunks, and then divisions, cords, and finally branches. [Figure 15-6](#) shows a diagram of the anatomy of the brachial plexus.

The *lumbosacral plexus* is derived from the anterior primary rami of the twelfth thoracic through the fourth sacral levels and is contained within the psoas major muscle. Although many more roots contribute to the lumbosacral plexus, it is somewhat simpler than the brachial plexus. Two major nerves, the femoral nerve and the sciatic nerve, are formed from the plexus (see [Fig. 15-7](#)).

GAMMA MOTOR NEURON

Like the alpha motor neurons, the gamma motor neurons lie in the ventral horn of the spinal cord interspersed among the alpha motor neurons innervating the same muscle. Gamma motor neurons innervate the *intrafusal* muscle fibers of a specialized sensory organ, the *muscle spindle*.¹⁰ The muscle spindle consists of a small bag of muscle fibers that lie in parallel with the extrafusal skeletal muscle fibers. Therefore, when the muscle lengthens or shortens, the intrafusal muscle spindle fibers are stretched or relaxed correspondingly. The intrafusal fibers are surrounded by

223

Figure 15-5 The axons of the lower motor neurons form the spinal roots, one for each spinal segment (A). The spinal roots (containing both sensory and motor axons) recombine to form the brachial plexus (B), from which the major peripheral nerves are formed (C). (Adapted from Patton HD, Sundsten JW, Crill W, Swanson PD: Introduction to Basic Neurology. Philadelphia, W. B. Saunders, 1976.)

sensory nerve endings that become 1a afferents to the dorsal root ganglion. When the intrafusal fibers are stretched as the muscle is lengthened, the sensory fibers are activated, providing sensory feedback about the degree of lengthening that has occurred. When the muscle contracts and shortens, the intrafusal spindle fibers also shorten. If this were a completely passive system, the intrafusal fibers would relax and the sensory endings would become silent, providing no helpful feedback information about the state of the muscle. To prevent this inefficient circumstance, gamma motor neurons are activated, maintaining tension in the intrafusal fibers to continue to provide precise sensory information.

This phenomenon can be observed experimentally if alpha motor neurons are excited in isolation. When the muscle contracts, there is a pause in volleys from the 1a afferent. When the gamma motor neuron is excited at the same time, the afferent volleys do not pause. This simultaneous activation of alpha and gamma motor neurons during muscle contraction is called *alpha-gamma co-activation*; it is an excellent example of sensory motor integration in the nervous system. By this means, innervation of the muscle spindle by an independent system of gamma motor neurons allows the central nervous system to adjust the sensitivity of the spindle and fine-tune the information it receives ([Fig. 15-8](#)).

Another sensory organ, the *Golgi tendon organ*, also conveys information about the state of the muscle. The Golgi tendon organs lie in the muscle tendon and, unlike the muscle spindle, are coupled in series with the extrafusal muscle fibers. Therefore, both passive stretch and active contraction of the muscle increase the tension of the tendon and activate the tendon organ receptor. In contrast to

the activity of the muscle spindle, which depends on muscle length, the Golgi tendon organ conveys information about muscle tension. Together they convey precise information about the length, tension, velocity, and force of the muscle contraction, thus allowing greater precision of movement. [11]

Changes in muscle tone, defined as resistance to passive stretch of muscle, are an important feature of diseases of the motor system. At one time, an important component of normal resting muscle tone was thought to be the result of low-level background alpha-gamma co-activation. However, more recent studies in fully relaxed individuals indicate that the viscoelastic properties of muscle and tendons account for normal resting tone. [12] Common experience indicates that resting muscle tone can vary considerably depending on the state of relaxation of the muscle as well as its viscoelastic properties. Some studies have shown that the passive viscoelastic properties of muscle may contribute to increased tone in patients with chronic spasticity and rigidity, but the most important determinants of pathological alterations in tone are the result of alterations in stretch reflexes.

ALPHA AND GAMMA MOTOR NEURONS AND REFLEX ARCS

Reflex actions are the simplest form of coordinated movement. A reflex action is a stereotyped response to a specific sensory stimulus. The reflex elicited depends on the site of the stimulus, and the strength of the stimulus determines the amplitude of the response. Reflex responses are used by higher motor centers to generate more complex movements and behaviors. The neural circuitry responsible for reflex actions is present at different levels of the motor system, and disturbances in these reflexes are important for localizing lesions in the motor system. Some reflexes, especially spinal and brain stem reflexes, are normally observed or elicited only in the developing nervous system. As the nervous system and higher motor centers mature, these reflexes are suppressed, only to reemerge if damage to the higher motor centers modulates the reflex. The unmasking of spinal reflexes in particular is a good example of the hierarchical organization of the motor system.

The *monosynaptic stretch reflex* is the simplest spinal reflex. As the name implies, the reflex muscle contraction is elicited by lengthening or stretching the muscle. To evoke this reflex, the muscle must be stretched rapidly, which produces a short phasic contraction. Thus, this reflex is termed a *phasic stretch reflex*. [13] In the human subject, sudden stretch is produced by tapping a tendon with a reflex hammer.

Sherrington demonstrated that this reflex could be eliminated by cutting either the dorsal or the ventral root, thus establishing that this reflex requires both sensory input from the muscle to the spinal cord and motor output from the motor neurons to the muscle. [2] The sensory receptor for the afferent limb of the reflex is the muscle spindle. [10] Sudden lengthening of the muscle by the tap on the tendon causes an increase in the discharge rate of type 1a nerve fibers from the muscle spindle. The 1a afferents entering the spinal cord excite motor neurons to both agonist and

Figure 15-9 (Figure Not Available) The two neuron monosynaptic phasic stretch reflex. A rapid stretch of a muscle increases the discharge rate of the 1a afferent fibers from the muscle spindle. The 1a afferent entering the spinal cord directly excites the alpha motor neuron, causing contraction of agonist muscles to oppose the lengthening. (From Gardner E: *Fundamentals of Neurology*. Philadelphia, W. B. Saunders, 1968.)

synergist muscles, causing contractions that oppose the lengthening (Fig. 15-9 (Figure Not Available)). Branches from the 1a afferents also excite interneurons that inhibit antagonist motor neurons, causing the antagonist muscles to relax. Thus, this reflex can be seen as a negative feedback loop that resists changes in muscle length. Note that although contraction of the agonist muscles results from a simple monosynaptic connection between the 1a afferent and the alpha motor neuron, relaxation of the antagonist muscles requires an *inhibitory interneuron* and a phenomenon called *reciprocal inhibition*. (Fig. 15-10 (Figure Not Available)).

Internuncial Pool

More complex reflexes use even more of these inhibitory interneurons, sometimes referred to as the *internuncial pool*. One of these inhibitory interneurons with a special action was described by Birdsie Renshaw and is known by his name. [14] The *Renshaw cell* receives a recurrent collateral, i.e., a branch of the axon of the alpha motor neuron before it leaves the ventral horn (Fig. 15-11). The axons of the Renshaw cells contact the alpha motor neuron. An action potential down the axon of the alpha motor neuron also excites the Renshaw cell through the recurrent collateral. The Renshaw cell in turn inhibits the same alpha motor neuron and other alpha motor neurons that innervate agonists. The Renshaw cell also inhibits the inhibitory interneuron mediating the reciprocal inhibition. In this way, the Renshaw cell shortens the reflex contraction of

Figure 15-10 (Figure Not Available) Reciprocal inhibition. When the agonist muscle is activated by the monosynaptic phasic stretch reflex, a branch from the 1a afferent of the muscle spindle, also excites interneurons that inhibit the antagonist motor neurons causing relaxation of the opposing antagonist muscle. (From Gardner E: *Fundamentals of Neurology*. Philadelphia, W. B. Saunders, 1968.)

Figure 15-11 The internuncial pool of inhibitory interneurons. White cells and synapses are excitatory; the black cells are inhibitory. 1 and 2 are anterior horn cells; 3 is the Renshaw cell; 4, 5, and 6 are interneurons. Note the spinal and supraspinal inputs to the inhibitory interneurons. Note also the recurrent collateral from the alpha motor neuron contacting the Renshaw cell, which in turn makes contact with the anterior horn cell and sends a recurrent collateral to inhibit the inhibitory interneuron mediating reciprocal inhibition. (From Curtis BA, Jacobson S, Marcus EM: *Introduction to the Neurosciences*. Philadelphia, W. B. Saunders, 1972.)

the agonist and, at the same time, shortens the reciprocal inhibition of the antagonist. Through this mechanism, the motor neurons can inhibit their own activity. This seems to be important in preventing alpha motor neurons from sending long trains of action potentials in response to a brief stimulus. The Renshaw cell and other internuncial neurons receive input from the higher motor centers, which can modulate the activity of these neurons and fine-tune the reflex movements. This means that the spinal reflexes provide the nervous system with elementary and automatic motor patterns that can be activated either by sensory stimuli or by descending signals from higher motor centers. Supraspinal input can therefore modify or suppress the expression of the reflex through the internuncial pool of inhibitory interneurons.

Clearly, most spinal reflexes are mediated by polysynaptic circuits that allow the reflex to be modified and the movement to be more finely coordinated. The most important of the *polysynaptic* spinal reflexes is the *flexor reflex* (Fig. 15-12 (Figure Not Available)). It is stimulated by a noxious *cutaneous stimulus* to the leg. The response is a withdrawal of the leg from the source of the painful stimulus. Teleologically, this reflex is important in preventing injury to the foot from stepping on a sharp or hot object. As with other reflexes, the strength of the response corresponds to the strength of the stimulus. In a normal individual only a painful stimulus elicits the reflex. When descending motor pathways that suppress and modulate the reflex are damaged, a lighter, nonpainful stimulus may elicit the reflex. This was discovered by Babinski when he scratched the sole of the foot of a patient with central nervous system lesions. With the light nonpainful stimulus, the strength of the response parallels the extent to which the upper motor

Figure 15-12 (Figure Not Available) The polysynaptic flexor reflex. The impulses from a cutaneous receptor excite the alpha motor neuron to the effector muscles through an intermediate neuron. Additional impulses also reach the cerebral hemisphere by way of an ascending tract. (From Gardner E: *Fundamentals of Neurology*. Philadelphia, W. B. Saunders, 1968.)

neuron lesion has allowed upregulation of the reflex. In a patient with a small hemispherical lesion, only a small fragment of the reflex may be elicited, i.e., extension of the great toe, known as the *Babinski sign* (Fig. 15-13 (Figure Not Available)). With complete transection of the spinal cord, the entire withdrawal reflex with flexion at the hip, knee, and ankle may occur.

The sensory limb of this reflex arc is mediated by cutaneous receptors of fast-conducting 1a afferents that converge on the internuncial pool of inhibitory interneurons. While the motor neurons to the flexor muscles are excited, the extensor muscles are inhibited through reciprocal inhibition. At the same time, motor neurons to the extensors of the contralateral leg are activated and the flexors are relaxed to compensate for the shift of weight to the contralateral leg while the ipsilateral leg is withdrawn from the painful stimulus. This *crossed extensor reflex* maintains postural support during withdrawal from a painful stimulus.

One can readily appreciate that the spinal circuits responsible for flexion withdrawal and crossed extension do more than mediate protective reflexes. They also serve to coordinate limb movements and voluntary movements. The

Figure 15-13 (Figure Not Available) Babinski sign. Top, The normal adult response to stimulation of the lateral plantar surface of the foot. Bottom, The normal infant and abnormal adult responses. (From Gardner E: *Fundamentals of Neurology*. Philadelphia, W. B. Saunders, 1968.)

interneurons in these pathways receive convergent inputs from different types of afferent fibers, not just pain fibers, as well as from descending pathways. Therefore, this convergence combines inputs from many different sensory sources including commands for voluntary movement through the descending pathway. This integration of sensory input is necessary for the regulation of precise movements because voluntary movements also produce excitation of cutaneous and joint receptors as well as muscle receptors.

Another cutaneous reflex of clinical significance is the *superficial abdominal reflex* (Fig. 15-14). This reflex is elicited by stroking the skin of the abdomen, which causes a reflex contraction of the abdominal muscles beneath the stimulus. Thus, stroking the upper abdomen causes contraction of the upper abdominal muscles, whereas stimulation of the lower abdomen causes contraction of the lower abdominal muscles. This relationship between the location of the stimulus and the muscles that contract is called a *local sign*. Other examples are contraction of the *cremasteric* muscles of the scrotum in response to stroking the skin of the inner thigh and the reflex contraction of the external anal sphincter when the perianal skin is stroked.

The normal function of the short-latency phasic stretch reflex is hard to define. In a fully relaxed individual who can exert total voluntary control over the excitability of the motor neurons, the stretch reflex does not appear to contribute to muscle tone. However, when these descending influences are interrupted, the excitability of the motor neurons involved in the stretch reflex is enhanced. This can be seen in the alteration of muscle tone called *spasticity*.

The pathophysiology of spasticity may involve several mechanisms. Hyperexcitability of the alpha motor neurons

Figure 15-14 The superficial abdominal reflex. The examiner strokes the skin with a stick as diagrammed. Stroking the upper quadrant tests thoracic segments 7 to 9 and the lower quadrants for T10-12.

from a primary intrinsic change in membrane properties may account for certain elements of spasticity, but most of the changes in lower motor neuron function are thought to be secondary to alterations in suprasegmental synaptic input. With regard to the 1a afferent pool, there are several types of suprasegmental inhibition that may be altered in spasticity. Presynaptic inhibition mediated by axo-axonic synapses on 1a terminals is reduced by suprasegmental disease, causing normal stimuli to 1a afferents to induce an exaggerated response. In addition, the 1a system on paired flexor and extensor muscles normally functions in a coordinated fashion to reduce the likelihood that antagonistic muscle groups will be co-activated during a muscle contraction. In the condition of spasticity, this type of 1a inhibition is lost, resulting in inefficient co-contractions that can compromise motor function. In addition, 1a inhibitory interneurons are also affected by descending excitatory pathways, and when these latter paths are damaged, the interneurons from flexors to extensors and from extensors to flexors are affected differently. In addition to the changes in the 1a system, nonreciprocal 1b inhibition is also reduced or even replaced by facilitation in spastic patients, suggesting that important physiological alterations occur in this system as well. In fundamental contrast to all of these mechanisms, recurrent inhibition via Renshaw cell activity is actually increased in patients with spinal cord lesions and spastic paresis. The specific descending pathways of influence are discussed subsequently.

In addition to the short-latency monosynaptic stretch reflex, a second reflex contraction of muscle occurs at a longer latency. This *long-latency stretch reflex* (sometimes referred to as the long-loop stretch reflex) is mediated by a polysynaptic reflex pathway and has different properties from the short-latency monosynaptic stretch reflex.^[15] The strength of the long-latency reflex depends on whether the muscle is relaxed or active at the time of stretching and whether the subject is instructed to resist the stretch or to let go. The strength of the reflex may also change during learning of a motor task. Therefore, this reflex can adapt quite readily to voluntary descending control from the higher motor centers. This kind of control appears to be mediated through the internuncial pool of interneurons, which can regulate the excitability of the motor neurons and therefore the degree of muscle contraction.

The function of the long-latency stretch reflex is as hard to define as that of the short-latency reflex, but based on the elegant experiments of Marsden and associates,^[16] it appears to compensate for changes in resistance during slow precision movements. In these experiments, while the subject flexed the thumb with a constant speed against a force of constant magnitude, the force was suddenly changed at unpredictable times. The change in compensatory force by the subject occurred at a latency that was faster than that of voluntary contraction and consistent with a polysynaptic long-latency reflex. The stretch reflex appeared to function to keep the sensitivity of the muscle spindles at a high level so that the slightest perturbations could be detected and the activity of the alpha motor neurons could be adjusted appropriately.

A disturbance in the long-latency stretch reflexes may be responsible for the characteristic increased muscle tone seen in patients with Parkinson's disease and known as

rigidity. In contrast to spasticity, rigidity is felt as a constant resistance to stretch that occurs in both flexion and extension of a joint; it may be felt during passive stretching of muscles that are too slow to elicit the spastic catch.

Delwaide's studies on spinal interneuron activity provide the best explanation for the pathophysiology of rigidity. The magnitude of rigidity correlates well with a reduction in short-latency autogenic 1b inhibition and simultaneous 1a interneuron facilitation. Activation of the descending reticulospinal tract from the nucleus reticularis gigantocellularis in experimental animals elicits this same pattern of 1b inhibition and 1a facilitation, suggesting that this system is involved in rigidity. Studies in monkeys who are rigid and parkinsonian due to exposure to the toxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) in fact show excessive activation of this pathway.

Upper Motor Neuron Pool

There are many neurons in the cerebral cortex and brain stem that initiate and modify movement through their connections with the lower motor neurons in the anterior spinal gray. These projections also synapse on the internuncial pool of interneurons, which in turn make contact with the alpha and gamma motor neurons. These are known as the *upper motor neurons*. These supraspinal motor neurons in the cerebral cortex and brain stem are interconnected with each other and participate to various degrees in all automatic and voluntary movements. Descending tracts from the motor centers in the brain stem are primarily involved with posture and automatic movements, whereas the motor areas of the cerebral cortex are required for voluntary movement.

CORTICOSPINAL TRACT

The corticospinal tract is composed of axons of *pyramidal neurons* located in lamina 5 of the cerebral cortex. Most of the axons of the corticospinal tract come from neurons in the precentral gyrus (Brodmann area 4),^[17] although significant contributions come from many other areas of the cortex, especially premotor area 6 and supplementary motor area. This is the only motor tract that passes directly from the cerebral cortex to the spinal cord without making any intermediate synaptic connections. The cytoarchitecture of the primary motor area, supplementary motor area, and premotor cortex is distinct from that of the adjacent sensory and prefrontal regions. Layer 4, the major afferent layer for the sensory cortex, is absent in the motor areas, and hence these motor regions are often termed agranular.

Layer 5 in the primary motor cortex contains the distinctive giant pyramidal neurons known as *Betz cells*. The axons of these cells become the corticospinal or pyramidal tract and represent one of several descending influences on the motor neurons of the brain stem and spinal cord. The remaining cells mostly come from the supplementary motor and premotor cortex. Most of the axons terminate on interneurons in the internuncial pool of the ventral gray of the spinal cord. Axons that connect monosynaptically with the lower motor neurons are involved in control of the distal muscles of the extremities, especially the intrinsic muscles of the hand that control finger movements.^[18] Upper motor neurons in the cerebral cortex also send axons to the motor nuclei of the cranial nerves and form the *corticobulbar tract*. The motor neurons in the primary motor area have a somatotopic organization. The *homunculus* was mapped by Penfield and colleagues^[19] by electrically stimulating the surface of the cortex during epilepsy surgery in humans. Stimulation of most of the lateral surface of the primary motor area produced movement in the mouth, tongue, face, and hand muscles, which is consistent with the importance of fine voluntary control of these structures (Fig. 15-15 (Figure Not Available) A).

The axons of the corticospinal tract gather together, forming the corona radiata, and descend through the posterior limb of the *internal capsule* into the middle

two-thirds of the *cerebral peduncles of the midbrain*. In this descent, the fibers shift position, and those representing the face become most medial, while those of the legs become most lateral. The corticospinal fibers become less recognizable as a tract as they course through the ventral two-thirds of the pons. They form bundles interspersed with a variety of other descending and crossing white matter tracts. When the fibers enter the medulla, they form a very discrete, easily recognizable bundle on the ventral aspect of the medulla known as the *pyramids*. Because it is such an easily recognizable bundle of nerve fibers, the corticospinal tract is often referred to as the *pyramidal tract*, although the pyramids also contain fibers other than those in the corticospinal system.^[19] Half to three-fourths of the fibers of the pyramidal tract originate in areas 4 and 6 anterior to the central sulcus, and the rest come from areas posterior to the central sulcus in the parietal lobe.

At the caudalmost level of the medulla, most of the corticospinal fibers cross the midline in the decussation of the cervical medullary junction and continue in the lateral funiculus of the spinal cord as the *lateral corticospinal tract*. A much smaller number of fibers continue uncrossed in the ventral funiculus as the *ventral corticospinal tract*. The lateral corticospinal axons terminate in internuncial pools and motor neurons involved in movement of the contralateral extremities, whereas the ventral corticospinal axons terminate in the medial and ventral portions of the anterior gray in which are found neurons innervating the paravertebral muscles involved in posture (see Fig. 15-15 (Figure Not Available) B). The corticospinal tracts and their relationship to other descending pathways in the spinal cord are shown in [Figure 15-16](#).

Corticobulbar fibers destined for the motor nuclei of the cranial nerves leave the corticospinal tract in the brain stem. Muscles of the head, except for the lower facial muscles, receive both crossed and uncrossed corticobulbar fibers. Therefore, as a rule, in a patient with a lesion of the corticobulbar tract on one side, one seldom sees significant weakness of the jaw, tongue, pharynx, or larynx.

Because the corticospinal tract extends from the cerebral cortex to the spinal cord, its considerable length makes it vulnerable to lesions at many different sites along its path. One of the most common lesions is ischemia resulting from occlusion of an artery. Therefore, it is helpful to know the

220

vascular supply of the corticospinal tract as it courses through the brain and spinal cord (see [Chapter 22](#)).

BRAIN STEM MOTOR TRACTS

Whereas the corticospinal tracts direct voluntary movements of the distal extremities, the brain stem motor tracts are responsible for the automatic reflexes involved in posture.^[20] The one exception is the *rubrospinal tract*, which forms a *lateral pathway* that terminates in the same part of the ventral gray as the pyramidal tract and is involved in distal limb movements.^[21] The *medial pathways* include the reticulospinal, vestibulospinal, and tectospinal tracts. The medial pathways travel in the ventral columns of the spinal white matter and terminate in medial ventral motor neurons innervating the axial and proximal limb muscles.

The *reticulospinal tract* originates from several nuclear groups in the reticular formation in the pons and medulla (Fig. 15-17 (Figure Not Available)). The reticulospinal system also receives input from a variety of other sources, including the cerebral cortex and the vestibular nuclei, and integrates this information in maintaining posture. Crude voluntary proximal movements of the extremities seen in monkeys with a pyramidal tract lesion probably result from the corticoreticular portion of the reticulospinal input.

The *vestibulospinal tracts* originate in the vestibular nuclei and convey information from the vestibular labyrinth ([Fig. 15-18](#)). The vestibulospinal tract has two parts. The largest is the lateral vestibulospinal tract, which originates in the lateral vestibular (Deiters') nucleus and reaches all levels of the spinal cord. Its input to both alpha and gamma motor neurons is excitatory, and maintains contraction of antigravity muscles to maintain posture. The medial vestibulospinal tract reaches only the cervical and upper thoracic segments of the cord; it mediates reflex head movements in response to vestibular stimuli.

The *tectospinal tract* arises in the superior colliculus and is involved in coordination of head and eye movements.

The *rubrospinal tract* that forms the lateral pathway arises in the magnocellular portion of the *red nucleus* (Fig. 15-19 (Figure Not Available)). In the cat it is an important pathway for controlling movements of the distal extremities, but in humans it has become a vestigial pathway whose function has been taken over by the corticospinal tract.^[21] Most of the red nucleus in the human, the parvocellular portion, contains smaller neurons whose major connections are with the cerebellum and inferior olive.

Reflex Integration of Motor Pathways

POSTURAL REFLEXES

Because postural reflexes are difficult to study without special techniques^[22] in normally functioning animals and humans, and because the pathways involved are intermingled with many other neural systems in the brain stem, postural reflexes abnormalities are detected primarily in

Figure 15-17 (Figure Not Available) The reticulospinal tracts. Note the multiple inputs including cerebral cortex and vestibular nuclei. (From Snell RS: *Clinical Neuroanatomy for Medical Students*. Boston, Little, Brown & Co., Inc., 1987.)

222

Figure 15-18 The vestibulospinal tract. The inputs from the lateral vestibulospinal tract to the alpha and gamma motor neurons excite antigravity axial muscles. The medial vestibulospinal tract terminates in the cervical and upper thoracic segments to mediate reflex head movements in response to vestibular stimuli. (From Kandel ER, Schwartz JH, Jessell TM: *Principles of Neural Science*. Norwalk, CT, Appleton & Lange, 1991.)

animals with large lesions of the brain stem. Experimentally, this was demonstrated most vividly when Sherrington transected the brain stem below the red nucleus in a cat. By interrupting the descending tracts from the cerebral cortex, the postural reflexes mediated by the brain stem systems were greatly exaggerated. This produced increased tone in the antigravity muscles, allowing the cat to be stood on all four legs. This is called *decerebrate rigidity*. Decerebrate rigidity with tonic extension of all four limbs is also seen in humans with lesions of the midbrain and upper pons.^[23] In humans with brain stem lesions, the rigid extension of the limbs is not persistently maintained but may be paroxysmal, often in response to external stimuli, and is then referred to as *decerebrate posturing* (Fig. 15-20 (Figure Not Available)).

Decorticate rigidity is a posture in which the arms are flexed and adducted and the legs are extended due to lesions above the midbrain in the cerebral hemispheres. The posture is usually bilateral and is essentially the same as a bilateral spastic hemiplegia.

TONIC NECK REFLEXES

Reflex changes in muscle tone and posture, especially in the extremities when the relationship of the head to the body is changed, are known as neck reflexes. Neck reflexes are not usually seen in normally functioning humans and animals. Stimulation of the labyrinths (labyrinthine reflexes) produces effects on muscle tone and posture that are exactly the opposite of the neck reflexes, thereby holding these in balance in the normal individual. However, in decerebrate animals, human infants,

and children with cerebral palsy, the neck reflexes may be unmasked and can be demonstrated by turning the head from side to side. For example, when the head is rotated to the right, an increase in extensor tone occurs in the ipsilateral extremities and an increase in flexor tone is seen in the contralateral extremities, producing the so-called fencer's posture.

LOCOMOTOR REFLEXES

Pattern generators for locomotion reside in these brain stem systems. Pattern generators for locomotion also exist at a spinal level, although in humans the brain stem generators are more important. Locomotion is examined in more detail in [Chapter 18](#).

Pharmacology of the Motor System

The lower motor neuron uses *acetylcholine* as its neurotransmitter. The internuncial pool of neurons in the spinal cord are all inhibitory neurons that use the amino acid neurotransmitters *gamma-aminobutyric acid (GABA)* and *glycine*. Whereas glutamate is the most important excitatory neurotransmitter in the brain as well as the motor system, GABA is the most widely distributed and major chemical neurotransmitter used in the inhibitory systems. Some output neurons in the basal ganglia and cerebellum use GABA as their transmitter, but most GABA is contained and utilized by local circuit inhibitory interneurons including the internuncial pool in the spinal cord. GABA is synthesized from glutamate by the enzyme *glutamic acid decarboxylase (GAD)* and is catabolized by the enzyme *GABA-transaminase (GABA-t)*. Drugs that inhibit GABA-t such as some newly developed antiepileptic drugs increase the concentrations of GABA and inhibitory tone. Drugs can also act as agonists at GABA receptors. Clinically useful drugs such as the benzodiazepines and baclofen presumably reduce spasticity by stimulating GABA receptors at inhibitory synapses in the spinal cord.^[24] Toxins and poisons like *tetanus toxin* and the drugs picrotoxin and bicuculline block GABA receptors, thereby producing excessive

242

243

excitation and leading to tetanic muscle spasms or convulsions.

Glycine is the principal neurotransmitter of the Renshaw cell. Strychnine is a specific antagonist at the glycine receptor. In small doses *strychnine* has been used as part of herbal or homeopathic preparations as an "energizer." In higher concentrations it causes convulsions by blocking normal inhibitory feedback on the motor neurons.

The motor neurons of the cerebral cortex use *glutamate* as their transmitter. This includes all motor outputs from the cerebral cortex including the corticospinal and corticobulbar tracts as well as inputs to the rubrospinal and tectospinal systems. Aspartate has also been proposed as a neurotransmitter at some of the synapses, but evidence favoring it is much less compelling than favoring glutamate.

EXAMINATION OF STRENGTH AND REFLEXES

Directed Neurological Examination

ASSESSMENT OF MUSCLE BULK

The patient should be in a state of sufficient undress for the physician to be able to appreciate his or her general bodily habitus and especially the muscle bulk of the extremities. Before actual testing of muscle strength begins, simple observation may disclose asymmetries in muscle bulk of the extremities or more focal atrophy of specific muscles or muscle groups. The upper extremities should be inspected in both the pronated and supinated positions, which is especially important to appreciate differences in the extensor and flexor compartments of the forearm. The lower extremities should be observed from the front and the back while the patient is standing.

If a significant asymmetry or focal atrophy is apparent, the bulk of the muscle groups in the arm, forearm, thigh, and leg can be measured objectively by measuring the girth and comparing sides. The point at which the circumference is to be measured is marked with a ballpoint pen, usually at the point of greatest estimated girth. To find the same site on the opposite limb, the distance to the closest bony landmark is measured, and that measurement is used on the opposite limb to obtain precise symmetrical measurements. Muscle bulk is usually greater in the dominant limb; a difference of 1.0 cm is accepted as within the range of normal in the leg and thigh, and 0.5 cm is acceptable in the forearm and arm.

In most cases, a significant difference indicates hypotrophy of the smaller side. However, in some cases the difference may be the result of an unusual hypertrophy or pseudohypertrophy in patients with muscular dystrophy. Pseudohypertrophy in a patient with muscular dystrophy is generally symmetrical and most commonly involves the calves. Therefore, any disparity in muscle bulk between the upper and lower extremities should also be sought. During the inspection of muscle bulk, one should also look for fasciculations. The ease with which fasciculations may be seen depends on how much subcutaneous tissue is present. In thin elderly men with suspected amyotrophic lateral sclerosis, the shoulder girdle and pectoral muscles are often a good place to look for fasciculations. In patients with more subcutaneous adipose tissue, the first dorsal interosseous muscle of the hand is better. forcible contraction or percussion of the muscle may increase the frequency of the fasciculations.

Fasciculations are a feature of disorders of the anterior horn cell or root compression. Therefore, fasciculations are often viewed as an ominous sign. They need not be because they are commonly experienced as a benign phenomenon in the absence of any disorder of the motor neuron or spinal nerve roots.^[22] Fasciculations of a benign nature can generally be distinguished from fasciculations secondary to lower motor neuron disease by several features. They have a predilection for males and for certain muscle groups, especially the calves and thighs. When they occur in the arm muscles they tend to be seen as a repetitive twitch in the same muscle fascicle as opposed to the random nonstereotyped twitches of many parts of the muscle seen in patients with anterior horn cell disease. Benign fasciculations in the calves are more difficult to distinguish clinically because they may be frequent and multiple and have a more malignant appearance. However, there is no associated weakness or atrophy of the affected muscles with benign fasciculations. Electrophysiologically, a benign fasciculation appears like a normal motor unit; there are no other features of denervation in the muscle. A malignant fasciculation in a patient with motor neuron disease is more complex and has a longer duration and a higher amplitude.^[23] The predilection toward benign fasciculations in males tends to be familial and increases progressively with age.

ASSESSMENT OF TONE

Muscle tone is assessed by asking the patient to relax completely while the examiner moves each joint through the full range of flexion and extension. Patients vary in their ability to relax. Generally it is easier for them to relax the lower extremities in the sitting position, whereas the upper limbs can be examined in either the sitting or lying position. Some patients, especially mildly demented elderly people, find it difficult not to voluntarily help move the limb in the desired direction. In a completely relaxed patient, no resistance should be felt at the wrist and elbow, and minimal resistance at the shoulder, knee, and ankle. It is very important to compare sides because a minimal but pathological increase in tone may initially be considered normal until one compares it with the normal side. The degree of relaxation varies from patient to patient, and any change from normal is necessarily somewhat subjective. In assessing tone, it is also important to recognize that patients with non-neurological disease, specifically pain or bone or joint abnormalities, may demonstrate resistance to passive movement, thus confounding the examination.

Flaccidity, in particular, may be difficult to judge.^[24] Certain maneuvers may be helpful in showing a difference from one side to the other. For example, flexion of the wrist can be compared by noting the distance the thumb can be brought to the flexor aspect of the forearm. Another maneuver is to shake the forearm and observe the floppiness of the movements of the hand at the wrist, or, with

244

the arms raised overhead, compare the degree of flexion or limpness of the wrist on each side. The lower extremities can be tested by rapidly flexing the thigh after instructing the patient to let the leg flop. The sudden flexion of the thigh raises the knee. In a patient with normal tone, the heel may come off the bed slightly and transiently and then drag along the sheet as the thigh is flexed. The heel of the flaccid leg will be dragged across the bed from the very beginning, while the spastic leg will jerk upward and the heel may never fall back to the bed.

In assessing *hypertonus*, one must differentiate between spasticity and rigidity. In *spasticity* the distribution of increased tone is very specific for the upper and lower extremities. The flexors of the arm (primarily the biceps) and the extensors and adductors of the leg display a greater increase in tone. This can be vividly seen in the classic hemiplegic posture in which the arm is flexed at the elbow and wrist and adducted against the chest while the leg is stiffly extended and the foot is inverted and flexed in a plantar direction. One can see spasticity in the adductors of the leg in the tendency of the hemiplegic leg to "scissor" over the good leg; this scissoring is most easily seen in a patient with spastic paraplegia. When the patient is lying down, the increase in tone in the adductors of the thigh can be felt by rapidly rotating the thigh back and forth to detect the increase in tone when the thigh is rotated externally.

The difference in tone in the flexors of the arm and the extensors of the leg can also give rise to the *spastic catch*, or the clasped knife phenomenon. This is a manifestation of the heightened stretch reflex that occurs in patients with lesions of the upper motor neuron pathways. By rapidly flexing and extending the elbow or knee, a sudden stretch is put on the muscle by lengthening it. The reflex contraction resists this lengthening and is sometimes referred to as the *lengthening reaction*. It is felt as a catch or interruption in the velocity of extension at the elbow or flexion at the knee. It is important to extend the elbow or flex the knee rapidly because the rate of stretch is important in eliciting the maximum response. The muscle spindles are maximally activated with a rapid stretch. Even with a very rapid stretch, a free interval occurs at the start of the movement, followed by the resistance. As the muscle is lengthened further, the resistance gives way, a process that has been compared to opening the blade of a clasped knife.

In contrast to spasticity, *rigidity* involves an equal increase in tone occurs in the flexors and extensors. The increase in tone is felt throughout the range of movement, and has been compared to bending a lead pipe. As the rigidity increases, it becomes more difficult to rapidly flex and extend the joint. In fact, it may be easier to feel the rigidity with slower movements. It is important, however, to flex and extend the joint repetitively because the rigidity may gradually build up in intensity with repeated motion. Often the rigidity is not felt as a continuous smooth change, as implied by the terms plastic or lead pipe. Instead, a rapid and rhythmical succession of catches and releases occurs that has been compared to a lever jumping from one cog to another in the turning of a cog wheel, hence the term cog wheel rigidity. The physiological explanation for cog wheeling and rigidity is still being debated; current evidence favors a disturbance in the long loop stretch reflex (see earlier discussion of muscle tone in the section, Gamma Motor Neuron). It is important to note that the phenomenon of cog wheeling can occur in patients with *essential or familial tremor* in the presence of normal tone and may be confused with parkinsonism. In these instances, the clinician feels the alternate activation of the flexors and extensors that produce the tremor, but does not feel the hypertonicity.

The *gegenhalten phenomenon* is not a true increase in muscle tone but a pseudovoluntary resistance by the patient against any passive movement of the limb. Each attempt at moving the limb by the examiner is met with an equal and opposing force. This can give rise to the appearance of increased tone. It is involuntary to the extent that the patient has great difficulty in voluntarily suppressing the urge to resist. *Gegenhalten* is usually associated with diffuse cerebral disease and dementia.

ASSESSMENT OF STRENGTH

The strength of a movement can be measured according to certain criteria; the most commonly used scale is that devised by the Medical Research Council^[25] ([Table 15-1](#)). The grade assigned to the muscle is the maximum force generated by an effort to move the involved body area. Judgment of the presence of mild weakness depends on making appropriate comparisons, one arm versus the other, or the arms versus the legs, or extension versus flexion. The examiner should always look for

patterns of weakness and compare the weak limb or muscle against the normal one in the same individual. Of course, if the weakness is generalized, judgment must be based on an estimate of the power normally generated by the age and bulk of the muscle.

More objective measurements can be made with the use of specially designed instruments to measure force. The only one widely used in clinical practice measures grip strength. Recently an electronic strain-gauge that measures maximum isometric force has also been used in clinical research trials for the treatment of amyotrophic lateral sclerosis.^[29] Some degree of objective measurement can also be obtained through formal assessment by a specially trained physical therapist. These semiquantitative methods (semiquantitative because they require the full cooperation of the patient being examined) are not primarily used for diagnostic purposes but rather for measuring changes that occur over time in response to some disease or treatment.

The most important purpose of strength testing is to

TABLE 15-1 -- THE MEDICAL RESEARCH COUNCIL RATING OF MUSCLE STRENGTH

Scale	Muscle strength
1	No contraction
2	Flicker or trace of contraction
2	Active movement, with gravity eliminated
3	Active movement against gravity
4	Active movement against gravity and resistance
5	Normal power

From Medical Research Council: Aids to the Examination of the Peripheral Nervous System Memorandum No. 45. London, Crown Publishing, 1976

discover whether there is a particular pattern of weakness that can be used to localize the lesion. Is it a hemiparesis, suggesting a hemispheric lesion, a paraparesis, which is consistent with a spinal cord lesion, or a proximal pattern of weakness compatible with a myopathic process versus a distal pattern that is consistent with neuropathy? ([Table 15-2](#)).

Even more important than tests of the strength of individual movements are tests of the ability of the patient to perform functional movements that bring out more subtle deficits escaping detection when muscle strength is tested against resistance. For example, a very subtle weakness of the leg may be noticed if the patient has some difficulty in hopping in one place. Because the leg and thigh muscles are so powerful, the patient's ability to walk, hop on either foot, and walk on the heels and toes is important. A mild upper motor neuron weakness may be betrayed by a slight circumduction or external rotation of the leg or even by an occasional scuffing of the sole against the floor. One may be able to differentiate an L5 from an S1 radiculopathy due to a herniated disc if weakness of dorsiflexion of the foot reduces the ability to walk on the heels (L5 lesion), whereas a weakness of the gastrocnemius diminishes the ability to rise on the toes (S1 lesion). Walking may demonstrate a decrease in arm swing that is consistent with an upper motor neuron or basal ganglia lesion of one hemisphere.

A variety of functional tests of the upper extremities can be used to bring out subtle weakness or spasticity. Probably the most widely used test is the one in which the patient is asked to extend the arms in the fully supinated position while keeping the eyes closed. A mildly paretic arm gradually

TABLE 15-2 -- PATTERNS OF WEAKNESS THAT AID IN LOCALIZATION

Distribution of Weakness, UMN or LMN Signs	Location of Lesion
Limbs and lower face on same side (spastic hemiparesis, UMN)	Contralateral cerebral hemisphere
All four limbs (spastic tetraparesis, UMN), speech (spastic dysarthria), swallowing with hyperactive jaw and facial jerks (pseudobulbar palsy, UMN)	Bilateral cerebral hemispheres
Hemiparesis (UMN) plus cranial nerve signs (LMN)	Brain stem
Tetraparesis (UMN) plus cranial nerve signs (LMN)	Brain stem
All four limbs (spastic tetraparesis, UMN)	Mid or upper cervical cord
Lower limbs (UMN) and hands (LMN)	Low cervical cord
Lower limbs (spastic paraparesis, UMN)	Thoracic spinal cord
	Bilateral, medial motor cortex
All limbs, proximal > distal (LMN)	Muscle (myopathy or dystrophy)
Legs, distal > proximal (LMN)	Nerve (polyneuropathy)
Ocular muscles, eyelids, jaw, face, pharynx, tongue (LMN)	Neuromuscular junction (NMJ)
Jaw, face, pharynx, tongue; sparing ocular muscles, eyelids (UMN and LMN)	Motor neuron disease
Specific muscle groups in one limb (LMN)	Nerve root, plexus or peripheral nerve

UMN, Upper motor neuron; LMN, lower motor neuron.

becomes pronated and sometimes flexed and drifts downward, showing the "*pronator drift*." Other tests not as well validated by widespread use are the *digiti quinti minimi* sign (hyperabduction of the outstretched fifth finger on the paretic side) and the forearm rotator sign (the patient rotates the forearms around each other; the paretic arm tends to stay fixed while the good arm rotates around it). Because paretic muscles move more slowly with reduced amplitude, some repetitive tasks, such as finger tapping or the forearm rotator test, are used to look for asymmetrical movements. However, interpretation of these tests may be more difficult because it may be hard to differentiate an abnormality from the bradykinesia of Parkinson's disease or even from problems with coordination secondary to cerebellar disease.

Because walking requires not just strength but the interplay of all the motor and sensory systems that are necessary for balance and the execution of motor programs, it is one of the most important parts of the neurological examination. A normal gait excludes a wide variety of neurological disorders (see [Chapter 18](#)). Abnormal gait patterns may provide powerful clues to the localization of a lesion. Upper motor neuron weakness is generally accompanied by spasticity, which produces a gait with a stiff jerky quality. The classic example of a lower motor neuron weakness is the steppage gait typical of a motor neuropathy in which weakness of dorsiflexion of the feet requires the patient to lift the legs higher to prevent the toes from scuffing the pavement. This appearance is accompanied by an excessive slapping of the forefoot against the floor. It may occur unilaterally in a patient with a pressure palsy of the peroneal nerve. The incomplete dorsiflexion of the foot combined with the slapping of the forefoot on the ground gives rise to the appearance of the "*drop foot*." The foot may also be inverted because of the unopposed action of the posterior tibial muscle. However, one must be careful to differentiate this condition from dystonia of the foot, which commonly produces a posture of flexion and inversion of the foot. The ability to dorsiflex the foot should be carefully examined in such patients; in patients with dystonia it will be normal, whereas in those with a peroneal palsy it will not.

A characteristic gait and posture are apparent in patients with myopathic weakness, in which the proximal muscles are much weaker than the distal ones. The weakness of the lumbar paraspinal muscles results in a hyperlordosis, and failure of the myopathic girdle muscles to fix the pelvis on one side when the other leg is being advanced gives rise to a ducklike waddling appearance. When a proximal myopathic weakness is suspected, other important functional tests include tests of the ability to rise from a squat or out of a chair, or to step up onto a stool or chair. Another helpful test in children with suspected muscular dystrophy is rising from a supine to a standing position. They cannot simply sit up and then push themselves to a standing position because truncal and hip girdle weakness prevents it. Instead, they roll to a prone position, push themselves up on all fours, and then quickly grab their thighs and walk up the thighs to a standing position (*Gower's sign*).

FATIGABILITY

Normal fatigue associated with intense muscular contraction is accompanied by a reduction in the motor-unit firing

rate, which is thought to be the result of a reduction in the excitatory drive to the motor neurons, which is a central mechanism. ¹³⁰ The phenomenon of fatigability with normal levels of muscle activity is a specific characteristic of disorders of the neuromuscular junction and is accompanied by a decrement in amplitude, not frequency, of the muscle action potential. This phenomenon is demonstrated most easily with electrophysiological techniques in the clinical neurophysiology laboratory. However, there are methods for bedside testing of the ability to produce a repetitive forceful movement or tonic muscle contraction. Jolly devised a grip ergometer connected to a smoke drum that could demonstrate the classic decrement in force produced by each attempt by the patient to produce a maximum grip. The *Jolly test* has subsequently been modified, depending on the availability of material at the bedside and the ingenuity of the examiner. One readily available method is to inflate a blood pressure cuff, which the patient can grip and squeeze repetitively. The height of the excursions of the mercury manometer can be readily monitored, and the decrement in pressure produced by each squeeze is readily appreciated.

Such methods of quantitating fatigability are especially important when one is assessing the patient's response to the acetylcholinesterase inhibitor *edrophonium chloride* (Tensilon) as a test for myasthenia gravis. For example, one may test how many squats can be performed before and after the injection of Tensilon. The muscles or movements to be tested depend to a great extent on the patient's symptoms, but whenever possible a movement should be chosen that can be quantitated as accurately as possible. Another quantifiable method is the length of time a posture can be held. For example, if the patient complains of ptosis or double vision, the length of time the patient can maintain upward vision before ptosis or diplopia occurs can be estimated. Another is the length of time a patient can hold the arms out before they fall below a horizontal 90 degrees. Sometimes the fatigability of the muscles involved in myasthenia gravis cannot be readily quantified. For example, weakness of the face has to be judged on a more subjective basis. Usually the weakness is bilateral and symmetrical, and milder examples may escape notice until after Tensilon clearly produces a change in facial movements and expression. Reading a standard passage can help in measuring the time it takes for the speech to become mushy and dysarthric.

The Tensilon test is performed by giving incremental intravenous injections of 10 mg (1 ml) of the drug. A test dose of 2 mg (0.2 ml) is given first to monitor the heart rate (preferably with electrocardiography [ECG]) to avoid bradycardia and vasodepressor syncope, which occasionally occur with higher doses. If this dose is tolerated and no definite improvement in strength occurs, another 3 to 4 mg is given. If there is still no response, the final 4 to 5 mg is given.

ASSESSMENT OF REFLEXES

Tendon jerks are conventionally graded on a scale of zero to 4, with zero representing absent jerks and 4 representing hyperactivity with clonus. A commonly used scale with accompanying definitions is shown in [Table 15-3](#). Superficial

TABLE 15-3 -- SCALE FOR AMPLITUDE OF TENDON REFLEXES

Scale	Tendon Reflex Amplitude
0	Absent with reinforcement
1	Present but decreased in amplitude and velocity from the normal range and elicited with reinforcement
2	Normal amplitude and velocity without reinforcement
3	Increased in amplitude and/or velocity with spread to adjacent site
4	Increased in amplitude and/or velocity with spread to adjacent site and duplication of the jerk or clonus

cutaneous reflexes are noted as present or absent. Tendon reflexes are elicited with a percussion hammer, of which many types are available. The two most commonly used are the hammer developed at the National Hospital for Nervous Diseases at Queen Square in London, and the tomahawk-shaped hammer used most often by American neurologists. The "Queen Square" hammer comes in a variety of sizes. The mallet should have sufficient weight and the handle should be long enough to easily create enough momentum to produce a sharp but nonpainful tap on the desired tendon. The sites at which the tendon reflexes are most commonly tested are listed in [Table 15-4](#), which notes the myotome level of innervation involved in the reflex arc.

Finger flexor jerks may be obtained in two different ways. The more common method is the one described by Hoffman. The middle finger is held between the second and third fingers of the examiner and the distal phalanx is flicked downward by the examiner's thumb. A positive *Hoffman sign* is a reflex flexion of the fingers, most easily seen in the thumb. A more reliable way of obtaining this flexion reflex of the fingers was described by *Troomner*. The examiner lays the fingers of the patient's hand on his own and taps his own fingers. The sudden stretch on all of the patient's fingers elicits a more reliable response, which is a reflex flexion of the fingers that can be felt by the examiner and also observed in the thumb as in the Hoffman's reflex. Like the tendon jerk, the reflex is most apt to be obtained in patients with hyperactive reflexes. However, the reflexes need not be pathologically hyperactive because this reflex can be seen in normal individuals. The reflex has clinical significance when it is asymmetrical and confirms a suspected asymmetry in the tendon jerks. The presence of a Hoffman sign by itself is not necessarily pathological and must be interpreted in the context of other tendon jerks and other signs of an upper motor neuron lesion such as ankle clonus and a Babinski sign.

TABLE 15-4 -- MYOTOMAL INNERVATION OF TENDON REFLEXES

Reflex	Spinal Segment	Peripheral Nerve
Biceps jerk	C5-C6	Musculocutaneous
Brachioradialis	C5-C6	Radial
Triceps jerk	C6-C7	Radial
Flexor finger jerk	C7-C8	Median and ulnar
Knee jerk	L2-L4	Femoral
Ankle jerk	L5,S1-S2	Sciatic

Reflex clonus, the repetitive contraction of a muscle or muscle group, is also obtained by putting a sudden stretch on a muscle. It is most commonly and easily elicited at the ankle. The Achilles tendon is stretched by rapidly dorsiflexing the foot and holding it in the dorsiflexed position. This can be done with the patient in either a sitting or lying position but is generally obtained most reliably in the supine position with the examiner holding the leg flexed at the knee and rapidly dorsiflexing the foot with an upward and outward motion. In the sitting position it may be more readily elicited using a combination of a tap on the tendon with the hammer followed by holding the foot in a dorsiflexed position. In a patient with fully developed ankle clonus, repetitive plantar flexion of the foot can be maintained virtually indefinitely as long as an upward pressure is maintained on the foot. Patellar (quadriceps) clonus can be obtained by producing a quick forcible downward displacement of the patella, which puts a stretch on the patellar or quadriceps tendon. In patients with severe spasticity one may also obtain clonus in the fingers, elicited by the Hoffman or Troomner maneuver, or in the jaw by tapping it with a hammer. Occasionally, one to two beats of clonus can be obtained at the ankle in normal individuals with naturally brisk reflexes. Generally speaking, however, clonus cannot be obtained at any site in the normal individual. The severity of clonus parallels the severity of spasticity and hyperreflexia.

The presence of the flexor reflex in the form of extension or dorsiflexion of the great toe (i.e., the sign described by Babinski) is referred to in many ways. Some report it as the presence or absence of the *Babinski sign* (see Fig. 15-13 (Figure Not Available)). To avoid confusion, some prefer to describe the response of the great toe to stimulation of the plantar surface of the outer sole. Thus, the plantar (or toe) response is described as flexor or extensor. Another colloquial way to refer to the

presence of a Babinski sign is to describe it as an "up going toe." The preference of the author is to refer to it as a flexor or extensor plantar response.

The extensor plantar response is most reliably obtained with the method of stimulation described by Babinski. Others have described additional methods of stimulation that also produce the extensor toe response.¹³¹ This reflects an expansion of the reflexogenous zone or receptive field when the upper motor neuron lesion is more complete and/or mature, especially in patients with spinal cord lesions. The most commonly used alternative to the Babinski method is the Chaddock maneuver, which consists of rubbing the lateral surface of the foot with the edge of a tongue blade or key from the heel to the little toe. The Oppenheim maneuver involves applying heavy pressure with the thumb and forefinger to the anterior surface of the tibia and stroking downward from the infrapatellar region toward the ankle. Bing obtained the extensor toe response by pricking the dorsum of the foot or great toe with a pin, and Gordon obtained it by squeezing the calf muscles. These other maneuvers are mainly useful in the patient who is very ticklish in whom it is difficult to differentiate spontaneous withdrawal from reflex responses. Another sign of upper motor neuron disease is the crossed adductor reflex.

Diffuse cerebral disease can unmask reflexes normally present only in the infant. These are generally referred to as *primitive reflexes*. They are sometimes referred to as frontal release signs because they are most commonly seen in demented individuals with frontal lobe disease. The *snout reflex* is a component of the suck reflex in which there is a puckering movement of the lips in response to pressure or light tapping on the lips. The facial jerks are usually increased in this situation, and it may not be possible to differentiate between the two. The most convincing demonstration that this is a primitive reflex occurs when stroking the cheek elicits the same response it would in an infant or if visual presentation of an object moving toward the mouth produces the response ("visual suck"). The *grasp reflex* may also be unilateral or asymmetrical and reflects unilateral or asymmetrical frontal lobe disease. It is elicited by diverting the patient's attention and casually stroking the palm of the hand with two or three fingers. If the reflex is present, the examiner's fingers will be grasped with increasing force; the harder the examiner tries to extricate his fingers, the harder the patient grips. Patients may literally be lifted off the bed and the fingers pried open only with great difficulty after the examiner has put the arm back in a resting position. The *palmomental reflex* is obtained by scratching the palm of the hand and observing the reflex contraction of the mentalis muscle of the chin. This reflex is seen more often in demented individuals but may also be seen in normals and is too unreliable to be used as a diagnostic sign of dementia.

Stretch reflexes can also be obtained by putting a sudden stretch on muscles that lack a tendon. This is done by directly tapping the muscle with the aid of the examiner's fingers and the reflex hammer. The two best examples are the facial jerk and the jaw jerk. To obtain the *facial jerk*, the examiner first stretches the skin of the patient's nasolabial fold with the index and middle finger of one hand and then taps these fingers with the reflex hammer, producing a reflex contraction in the underlying facial muscles. A reflex contraction in the muscles of mastication, the *jaw jerk*, is more easily obtained by simply tapping the point of the chin with the reflex hammer. Usually the examiner's fingers are put on the point of the chin and interposed between the blow of the hammer and the patient's chin.

As in the detection of weakness, it is the pattern of changes in the reflexes that is sought as an aid in localization. For upper motor neuron lesions, the distribution of hyperreflexia is the most valuable aid. The most common pattern is one of asymmetry between the sides because of a lesion in one cerebral hemisphere. The presence of symmetrical hyperreflexia, spasticity, clonus, and Babinski signs indicates an interruption of the corticospinal tracts bilaterally, which could be a result of bilateral hemispherical disease or a brain stem or spinal cord lesion. The differentiation between these possible sites can usually be determined by associated signs (Table 15-5). If the disease is hemispherical, the corticobulbar tracts are also interrupted, producing a pseudobulbar palsy with spastic dysarthria, dysphagia, and increased facial and jaw jerks. Other signs of diffuse cerebral dysfunction may also be present such as dementia. If the lesion is in the brain stem, bilateral corticospinal dysfunction is often associated with disturbances of consciousness or cranial nerve dysfunction. A cervical cord lesion produces hyperreflexia and spasticity

TABLE 15-5 -- CLINICO-ANATOMICAL CORRELATIONS FOR DISORDERS AFFECTING STRENGTH AND REFLEXES

Anatomic Site of Damage	Strength and Reflex Findings	Other Neurological and Medical Findings	Common Etiologies	Comments
UPPER MOTOR NEURON SYNDROMES				
Pyramidal lesions Cortex and subcortex	Contralateral hemiparesis, hyperreflexia, spasticity, Babinski's sign	<i>Cortex:</i> Left: aphasia, apraxia Right: constructional apraxia Homonymous hemianopia on paretic side <i>Subcortex:</i> No aphasia or sensory loss	Stroke, neoplasm	If parietal sensory cortex is affected primary sensory modalities are reduced but not lost Integration of sensory information is affected, causing graphesthesia, extinction of sensory stimuli, and
Brain stem	Large bilateral lesion: tetraparesis, bilateral hyperreflexia, Babinski's sign Small lesions: contralateral hemiparesis, hyperreflexia, Babinski's sign	Coma, decerebrate posturing Ipsilateral cranial nerve palsy	Stroke, trauma	Basis pontis lesions cause "locked in syndrome: tetraparesis with paralysis of horizontal eye movements and jaw, face, and bulbar muscles, but consciousness and vertical eye preserved
Spinal cord	Tetraparesis or paraparesis, bilateral hyperreflexia, Babinski's sign, normal jaw jerk	Sensory level, no cranial nerve signs	Trauma, multiple sclerosis	See Table 15-13 for other spinal cord syndromes
Diffuse excitation of internuncial pool	Weakness of ocular, facial, or bulbar muscles (cephalic tetanus), diffuse hyperreflexia	Rigidity, tetanic seizures	Tetanus, stiff-person syndrome	
LOWER MOTOR NEURON SYNDROMES				
Progressive spinal atrophy syndrome	Progressive weakness, muscular atrophy, loss of tendon reflexes	No sensory symptoms or loss	Genetic	Classification based on hereditary pattern, age of onset, rate of progression and muscles affected--e.g., generalized infantile-onset lethal form: Werdnig-Hoffman disease; proximal childhood onset: Wohlfart-Kugelberg-Welander disease
Radiculopathy	Weakness of individual or combinations of muscles in one limb, reduction or loss of reflexes in myotomal pattern	Dermatomal sensory loss	Herniated intervertebral disc	
Plexopathy	Weakness and loss of tendon reflexes of muscles supplied by more than one spinal or peripheral nerve	Pain and sensory change in distribution of more than one spinal or peripheral nerve	Autoimmune, inflammatory, trauma, tumor	
Peripheral neuropathy, mononeuropathy	Weakness of muscles supplied by single peripheral nerve	Sensory change in peripheral nerve	Entrapment, trauma, diabetes	See Table 15-13 for most common examples

Polyneuropathy	Symmetrical weakness and loss of tendon reflexes, distal before proximal; legs before arms	Symmetrical distal sensory loss; legs before arms	Diabetes mellitus, alcoholism, uremia	
COMBINED UPPER AND LOWER SYNDROMES				
Motor neuron disease	Weakness, atrophy, and fasciculations of jaw, facial, bulbar, and limb muscles, hyperreflexia	No sensory abnormalities; no weakness of eyelids or ocular muscles	Amyotrophic lateral sclerosis (ALS)	Tendon reflexes are especially quick and "snappy" Despite hyperreflexia Babinski's signs may not be present early in the disease
Myelopathy	Weakness, atrophy, fasciculations, loss of reflex at level of lesion (cervical cord); weakness, hyperreflexia below level of lesion; bilateral Babinski's signs	Sensory loss below level of lesion	Multiple sclerosis, trauma	See Table 15-13 for various myelopathic syndromes
NEUROMUSCULAR JUNCTION SYNDROMES				
Neuromuscular junction	Weakness of ocular, jaw, facial, and bulbar muscles and limbs; normal reflexes	No sensory abnormalities fatigability (MG)	Autoimmune (MG); exogenous toxin (botulism)	Note that myasthenia gravis commonly affects ocular muscles (diplopia) and eyelids (ptosis), whereas ALS does not
Presynaptic cholinergic cell	Limb weakness, dysphagia, loss of knee jerks	Dry mouth, loss of taste, impotence	Association with neoplasia (paraneoplastic syndrome)	Autoantibodies against calcium channel
MYOPATHIC SYNDROMES				
Muscle	Bilateral symmetrical, proximal weakness; reflexes are retained until weakness is severe	Skin rash (dermatomyositis)	Autoimmune or inflammatory (polymyositis); muscular dystrophy	

MG, Myasthenia gravis.

in the limbs with normal function in the cranial muscles and a normal jaw jerk. In the presence of diffuse hyperreflexia of the tendon jerks, normal cerebral function and normal speech increase the probability that the lesion is at the level of the cervical cord. A normal jaw jerk therefore is helpful in confirming the localization. If the reflexes are normal in the upper extremities but abnormal in the lower extremities, the lesion is at the thoracic cord level. In contrast to exaggerated tendon reflexes in the presence of an upper motor neuron lesion, the superficial abdominal reflexes are absent. These reflexes also may be helpful in localizing lesions to the midthoracic cord if they are present in the upper quadrants and absent in the lower.

Lower motor neuron lesions are accompanied by a reduction or loss of both the tendon jerks and the superficial cutaneous reflexes. Once again, the distribution of the absent reflexes can define the localization of the lesion. For example, loss of one ankle jerk indicates a lesion of the S1 nerve root. A symmetrical absence of ankle jerks and a reduction in knee jerks indicate a neuropathy. A mild reduction in knee jerks with normal ankle jerks suggests a myopathy. Absence of cremasteric and anal reflexes reflects disease of the lumbosacral cord or roots.

OTHER OBSERVATIONS

Comparison of the contraction of the upper and lower abdominal muscles yields another sign that is valuable in localizing thoracic cord lesions. This comparison is made by palpating the muscles while the patient lifts the head off the pillow, causing contraction over the abdominal muscles. In a patient with a mid to lower thoracic cord lesion, the upper abdominal muscles may contract while the lower ones remain flaccid. This maneuver may also result in an upward movement of the umbilicus, as noted by *Lord Beevor*, for whom this sign is named.

The presence of *atrophy* and *fasciculations* is further evidence of a lower motor neuron lesion. A focal or segmental distribution suggests a root lesion. Fasciculations are seldom seen with peripheral nerve lesions; therefore, atrophy without fasciculations is more compatible with a peripheral nerve lesion. If fasciculations are confined to the upper extremities, it is very important to check the tongue. Atrophy and fasciculations of the tongue suggest the presence of diffuse lower neuron disease, i.e., amyotrophic lateral sclerosis, whereas atrophy and fasciculations confined to the arms, especially the intrinsic muscles of the hands, could indicate cervical cord pathology such as a tumor, spondylitic myelopathy, or syringomyelia.

Myotonia, which is impaired relaxation of muscle from its contracted state, can be demonstrated in two ways. The first is direct percussion of the muscle. In the normal muscle, the tap produces such a brief contraction and relaxation to the normal resting state that it is not seen. In a myotonic muscle the contraction remains as a dimple for a few seconds before the contraction subsides. In a smaller muscle such as the thenar eminence, the contraction is strong enough to produce adduction of the thumb. Impaired relaxation can also be readily demonstrated after a forceful grip; the patient with myotonia has marked difficulty in relaxing and opening the fingers. Myotonia in the eyelids can be demonstrated by asking the patient to look upward and then rapidly look down; this produces a pronounced lid lag. The impaired relaxation of muscle in patients with myotonia is the result of impaired uptake of calcium by the sarcoplasmic reticulum.

Mirror movements are most often seen in children with cerebral palsy or as a rare inherited disorder. These movements are most readily demonstrated by asking the patient to produce a rapid alternating movement of the hand; when he does so, it will be mirrored by the same movement in the opposite hand. This phenomenon is also sometimes referred to as *synkinesis*.

Though the level of the patient's relaxation (or nervousness) can sometimes influence the state of the tendon reflexes, both the tendon and the superficial reflexes are the only truly objective attributes of the neurological examination, since the patient cannot voluntarily alter them in most cases. A sophisticated patient may be able to fake a Babinski sign, but an experienced observer can usually

detect the fakery, which occurs very rarely. In contrast, estimation of muscle strength depends on the patient's cooperation and effort. Therefore, it is possible for the patient to voluntarily change the level of effort, thus producing the impression of weakness. It is important to recognize when the patient is not putting out a full effort or is intentionally trying to deceive the examiner for whatever reason.

The most common pattern of feigned weakness is a sudden collapse of the limb after an initial, often normal effort. It may be a phasic ratchet-like collapse as the muscle is tested, most commonly the biceps. Another pattern is seen when the arm is in the abducted position. When the arm is pushed downward, the patient bends his trunk to that side, giving the impression that his arm is being pushed downward when in fact the relationship with the trunk remains the same. If the adventitious nature of the weakness is not obvious, one can usually bring it out by testing the muscle strength rapidly and simultaneously in the arms starting at the shoulders and proceeding distally as rapidly as possible so the patient does not have time to think about what his response should be. As a result, the good side may collapse in unison with the bad side after an initial symmetrical effort. This is usually most easily demonstrated when testing abduction of the fingers.

With the patient lying supine, one can judge the effort put forth in the lower extremities by placing one hand between the heel and the examining table while testing the ability of the patient to raise the other leg off the table. With full effort the heel on the table is forced downward to support the raising of the opposite leg. When full effort is used to raise the good leg, one can feel the normal downward pressure of the "weak" leg. When the weak leg is supposed to be raised, one may feel very little if any pressure under the leg with presumably normal strength, indicating that the patient is not trying to raise the weak leg. In fact, the pressure under the heel of the good leg may decrease. When this pattern of effort is present, it is referred to as a *Hoover's sign*.

It is important to identify *psychogenic paralysis* of a limb or a paraplegia, and certain observations and tests are helpful in revealing the true nature of such a weakness. A paralyzed arm that is held limply at the side will flail back and forth when the patient's shoulders are shaken back and forth. If, instead, the arm is observed to remain tightly held against the body, it has normal strength and tone. Hysterical paraplegia may be suspected by the ease with which the patient is able to roll over and move in bed and can be confirmed by the presence of normal reflexes. If the patient can walk, he exhibits behavior that indicates that he is markedly exaggerating the effort to take a step and in the process displays extraordinary strength and coordination.

Associated Neurological Findings (see [Table 15-5](#))

In addition to patterns of weakness and reflex changes, clinical findings in other neural systems will confirm or further help in localizing the source of the weakness.

Cerebral. A command center for conjugate gaze is located in each frontal lobe. When one is damaged, the unopposed action of the other causes deviation of the eyes to the side of the lesion and away from the hemiplegia. The motor cortex is very close to Broca's area, and a nonfluent or Broca's aphasia often accompanies a right hemiplegia of cortical origin. The sensory cortex is across the Rolandic fissure, and a cortical sensory loss often accompanies hemiplegia. Lesions in the hemispherical visual pathways will result in a contralateral homonymous hemianopia.

Cranial Nerves. Cranial nerve dysfunction and the pattern of involvement define the brain stem as the source of the lesion causing the weakness. Since the pyramidal tract is a midline structure in the brain stem, midline damage causes weakness and hyperreflexia, usually bilaterally, and affects cranial nerves III and IV (midbrain), VI and VII (pons), and XII (medulla).

Cerebellar/Gait. Brain stem lesions causing weakness also commonly affect connections with the cerebellum, producing ataxia and dysynergia. These components of cerebellar motor dysfunction may be difficult to see depending on the severity of the weakness. Proximal weakness can produce wavering when the patient puts a finger to the nose, which is very reminiscent of a cerebellar intention tremor. In this situation one must examine the patient's coordination in finger and hand movements. One helpful test is repetitive tapping of the forefinger against the flexor crease of the thumb. Pyramidal and extrapyramidal lesions slow the rate of movement, but accuracy in hitting the target is unaffected, whereas in patients with cerebellar disease, the rate may be normal, but the accuracy is impaired and the rhythm of tapping is erratic. Rapid alternating movements of the hands are slow and regular in pyramidal and extrapyramidal disease; in cerebellar disease the rate and rhythm are irregular and clumsy.

Walking is one of the most important tests in differentiating upper from lower motor lesions causing weakness. The spasticity caused by an upper motor neuron lesion can be seen in the very stiff jerky movements of the legs. Spasticity of the adductor muscles produces scissoring (i.e., a tendency for the legs to cross over one another from one step to the next). If the upper motor lesion is unilateral, the spastic leg is often circumducted with the leg extended at the knee while the arm is held in a flexed posture, that is, the typical hemiplegic posture. Distal weakness due to a lower motor neuron lesion produces floppy feet that slap on the floor and must be lifted high to prevent the toe from dragging and tripping the patient. Weakness of the hip girdle, most often seen in patients with myopathies, results in weakness of fixation of the pelvis and a waddling ducklike walk. Often the gait is widened to increase stability because otherwise the gait is made more unstable by the hip girdle weakness.

Sensory. The presence or absence of sensory symptoms and signs and the pattern and type of sensory change are very helpful in confirming which level of the motor system is involved in producing weakness. A relatively mild hemisensory loss affecting touch and proprioception more than pain and accompanied by impairment of stereognosis, graphesthesia, and two-point discrimination is characteristic of a lesion in the contralateral sensory cortex. A change

in touch and pain sensation in the ipsilateral face and contralateral body is characteristic of a unilateral lateral medullary lesion (Wallenberg's syndrome). Spinal cord lesions often affect sensation on both sides of the body; the upper level of the sensory loss, especially in regard to pain and temperature, help to define the level of the lesion. When half the cord is damaged, a pattern of loss of proprioception and vibration ipsilateral to the lesion and contralateral loss of pain and temperature sensation is characteristic of the Brown-Sequard syndrome. Central cord lesions produce a suspended sensory loss affecting pain and temperature sensation with sparing of the sacral dermatomes, and vibration and proprioception (see [Chapter 19](#) and [Chapter 20](#)). Lesions of the conus medullaris or cauda equina produce loss of sensation in the perineum. Careful mapping of a more localized area of sensory loss in a limb can differentiate a dermatomal pattern of loss consistent with a spinal root lesion from a peripheral nerve distribution. An absence of sensory symptoms or signs indicates that the weakness results from disease in the motor neurons, muscle, or neuromuscular junction.

Autonomic Nervous System. At the bedside, some aspects of the autonomic nervous system can be tested. The most easily appreciated lesion is an impairment of sympathetic innervation to the cranial structures producing ipsilateral ptosis, miosis, and anhidrosis of the face (Horner's syndrome). Horner's syndrome may result from lesions of the descending sympathetic fibers in the brain stem and spinal cord in which the pattern of weakness, the presence or absence of cranial nerve signs, and sensory changes are more important in localizing the lesion. The presence of a Horner's syndrome is more helpful in localization of a lesion when a spinal root or brachial plexus lesion is suspected. The preganglionic sympathetic fibers leave the spinal cord with the C8 and T1 spinal roots, which become the lower trunk of the brachial plexus. Therefore, lesions of the C8 or T1 nerve roots (e.g., herniated disc) or lower trunk of the brachial plexus (e.g., apical lung tumor) may be associated with a Horner's syndrome. The postganglionic sympathetic fibers course along the carotid arteries into the cranium. Occasionally an occlusion of the common carotid artery produces an ipsilateral Horner's syndrome along with a contralateral hemiparesis.

The parasympathetic pupillomotor fibers from the Edinger-Westphal nucleus in the third nerve nuclear complex of the midbrain is impaired with lesions of the third nerve nucleus or nerve, which result in a paralysis of the pupillary sphincter, producing pupillary dilatation. Attention to autonomic function, especially sweating, can be helpful in defining the level of acute transverse spinal cord lesions. A loss of sweating occurs below the level of the lesion. Sometimes this can be appreciated by lightly rubbing the dorsal surface of the forefinger along the skin, starting below the expected level of the lesion and stroking upward; the finger slides easily over the smooth dry skin below the lesion but sticks momentarily as it meets the normal moist skin at the upper border of the lesion.

Orthostatic hypotension is sometimes described by the patient as weakness rather than as a presyncopal lightheaded fainting sensation. Diffuse autonomic dysfunction with orthostatic hypotension is a feature of multiple system atrophy (olivopontocerebellar atrophy and Shy-Drager syndrome). Orthostatic blood pressures are checked after 3 minutes in a recumbent posture and again after 3 minutes of standing. The pulse rates are also taken in the supine and standing positions. In patients with autonomic dysfunction the pulse rate does not rise to compensate for the fall in blood pressure, whereas in those with hypovolemic orthostasis a significant compensatory increase in pulse rate is seen.

Neurovascular. The neck vessels should be examined in patients in whom strokes are suspected. Evidence of small vessel disease in the form of poor pulses or trophic skin changes may suggest diabetes or vasculopathic causes of weakness.

Associated Medical Findings

Examination of other organ systems is most useful in finding clues that may establish the cause of the weakness. Examination of the skeletal system can help to confirm localization of the lesion in certain circumstances. For example, the presence of a scoliosis may increase suspicion of a thoracic cord lesion. An asymmetry in the length or size of the limbs on one side suggests a deficit in growth during development that is compatible with a congenital hemispherical motor lesion.

Examination of the skin may disclose the cafe-au-lait spots or axillary freckling of neurofibromatosis, a hairy patch or dimple over the lumbar spine at the site of a tethered cord, or inflammatory skin changes compatible with dermatomyositis. If a stroke or transient ischemic attack (TIA) is suspected, it is especially important to examine the heart for murmurs and arrhythmias and the carotid arteries for a bruit or pulse deficit. Inflammation or deformities of the joints may also limit the ability of the patient to exert full strength and give a false sense of weakness. The optic fundi should be examined for the presence of papilledema and lesions of the retina and macula that may be seen in patients with metabolic, developmental, or inflammatory diseases.

EVALUATION GUIDELINES (Table 15-6)

A wide variety of tests are now available to the neurological clinician. The work-up must be tailored to the situation and guided by a careful analysis of the neurological examination and history. The findings on the neurological examination localize the lesion to the nervous system and to the area where the attention should be focused. They also narrow the possible causes of the disorder. The list of possible causes is narrowed further by the history, which gives the clinician the temporal profile of the disease process.

Neuroimaging. Neuroimaging has become a powerful tool in confirming the localization of lesions. Magnetic resonance imaging (MRI) is the most powerful imaging tool available, but in some cases computed tomography (CT) is equally effective (e.g., in some tumors) or better (e.g., bony abnormalities, hemorrhage) in visualizing the lesion. Because it has a much higher resolution and is not subject to artifact from neighboring bony structures, MRI is the test of choice for imaging the posterior fossa. MRI is also the tool of choice for visualizing the spinal canal

TABLE 15-6 -- USEFUL STUDIES FOR THE EVALUATION OF DISORDERS OF MUSCLE STRENGTH AND REFLEXES

	Neuroimaging	Electrophysiology	Fluid and Tissue Analysis	Neuropsychological Tests
UPPER MOTOR NEURON SYNDROMES				
Pyramidal lesions Cortex and subcortex	MRI or CT of brain: lesion contralateral to hemiparesis	N/A	CSF pressure	Lateralized right or left hemisphere dysfunction Left: tests of language, praxis Right: tests of construction, spatial orientation
Brain stem	MRI: local lesion	N/A	N/A	N/A
Spinal cord	MRI or CT myelography: extrinsic versus intrinsic lesion	Somatosensory evoked potentials (SSEP): delayed conduction with median or tibial nerve stimulation	CSF: protein, glucose, IgG, WBC, RBC count	N/A
Decerebrate and decorticate posturing	MRI or CT scan: lesion in midbrain (decerebrate); bilateral hemisphere (decorticate)	N/A	N/A	N/A
Diffuse excitation of internuncial pool	N/A	EMG: continuous motor potentials	Blood and CSF: GABA, GAD autoantibodies (stiff-person syndrome)	N/A
LOWER MOTOR NEURON SYNDROMES				
Progressive spinal atrophy syndrome	MRI: atrophy of spinal cord (late stages)	EMG: denervation-fibrillations, fasciculations, positive sharp waves, giant MUAPs	Muscle biopsy: grouped atrophy Blood: DNA analysis	N/A
Radiculopathy	MRI or CT myelography: compression of nerve root by disc or bony spur	EMG: denervation potentials in muscles supplied by affected root	Blood: FBS	N/A
Plexopathy	MRI: infiltrating mass	EMG: denervation of muscles supplied by multiple roots	Blood: FBS, ESR, SR, ANA, SPEP	N/A
Peripheral neuropathy Mononeuropathy	N/A	EMG/NCV: abnormal nerve conduction of affected nerve results in denervation of muscle supplied by that nerve	Nerve biopsy: inflammation, demyelination Blood: ESR, ANA, SPEP, FBS	N/A
Polyneuropathy	N/A	EMG/NCV: abnormalities of all nerves; legs affected before arms	CSF: protein Nerve biopsy: inflammation, demyelination, amyloid Blood: ESR, ANA, SPEP, FBS, B ₁₂ , T4/TSH, anti-nerve antibodies	N/A
COMBINED UPPER AND LOWER SYNDROMES				
Motor neuron disease	MRI: cervical cord-may be atrophic	EMG: denervation with giant MUAPs, normal NCV	Muscle biopsy: grouped atrophy Blood: CK normal to mildly elevated	N/A
Myelopathy	MRI, CT myelography	Somatosensory evoked potentials Visual evoked potentials (if multiple sclerosis is suspected)	CSF: protein, IgG, oligoclonal bands, inflammatory cells Blood: VDRL, B ₂ , long chain fatty acids	N/A
Spinal shock	MRI, CT myelography	N/A	N/A	N/A
NEUROMUSCULAR JUNCTION SYNDROMES				
Myasthenia and botulism	Chest CT	EMG: decremental response to repetitive nerve stimulation	Blood: acetylcholine receptor antibodies Botulinum toxin	N/A
Eaton-Lambert syndrome	Chest x-ray, mammography, pelvic ultrasound	EMG: incremental response to repetitive nerve stimulation	Blood: striated muscle antibodies	N/A
MYOPATHIC SYNDROMES				
Myopathy	N/A	EMG: small-amplitude polyphasic MUAPs	Skin/muscle biopsy: inflammation, mitochondrial abnormalities, necrosis and fibrosis, histochemical analysis Blood: CK, ESR	N/A

MRI, Magnetic resonance imaging; CT, computed tomography; EMG, electromyography; CSF, cerebrospinal fluid; WBC, white blood count; RBC, red blood count; GABA, gamma aminobutyric acid; GAD, glutamic acid decarboxylase; DNA, deoxyribonucleic acid; NCV, nerve conduction velocity; MUAP, motor unit action potential; FBS, fasting blood sugar; SR, sedimentation rate; ANA, antinuclear antibodies; SPEP, serum protein electrophoresis; ESR, erythrocyte sedimentation rate; B₁₂, vitamin B₁₂; T4/TSH, thyroxine-thyroid-stimulating hormone; VDRL, Venereal Disease Research Laboratory; CK, creatine kinase; IgG, immunoglobulin G; N/A, not applicable.

except in circumstances (e.g., cervical spondylosis, vascular malformations) when myelography with CT may be superior for identifying the extent of the root or cord involvement. Conventional radiographs of the spinal column may be indicated when infectious, neoplastic, degenerative, or developmental disorders of bone are suspected.

Electrophysiology. Electromyography and measurement of nerve conduction velocities can be crucial in identifying, localizing, and determining the extent and severity of disorders in the lower motor neuron unit. The electromyographer still needs guidance from the history and neurological examination to tailor his evaluation to the appropriate region and choose the proper test to gain accurate and confirmatory observations most efficiently. With these tools, it is possible to differentiate an anterior horn cell disorder from a lesion of the spinal root or nerve or to differentiate disorders of the neuromuscular junction from primary muscle disease.

Fluid and Tissue Analysis. Examination of the cerebrospinal fluid (CSF) via a lumbar puncture has been one of the standbys in neurological diagnosis. Because it is virtually identical in composition to the extracellular fluid, changes in the chemical or cellular composition of CSF can reflect a variety of diseases. Analysis of the CSF is most useful in diagnosing subarachnoid hemorrhages or infections and inflammatory disorders that produce an excess of white cells or changes in immunoglobulin.

Tests for specific bacterial and fungal antigens are now available for diagnosing the more common bacterial (e.g., influenza, pneumococcal, meningococcal) or fungal (e.g., cryptococcal) meningitides. Polymerase chain reaction (PCR) tests for certain viruses are now available. It is no longer necessary to perform a brain biopsy to diagnose herpes simplex encephalitis.

Immunohistochemical techniques have made muscle biopsy even more useful in diagnosing any disorder affecting muscle including mitochondriopathies. Nerve biopsies are usually less informative and are generally useful only in patients with inflammatory disorders affecting the nerves or their blood supply, or in those with amyloidosis for detecting the deposition of amyloid.

Except as a tool for making a diagnosis of a tumor or abscess, brain biopsy is used sparingly to diagnose rare encephalitides (e.g., Creutzfeld-Jakob disease) or vasculopathies (e.g., granulomatous angiitis).

Neuropsychological Tests. If cerebral lesions are suspected, neuropsychological testing may identify evidence of a single, multifocal, or diffuse process. Special tests for aphasia, apraxia and spacial orientation identify and lateralize cortical lesions.

Other Tests. Edrophonium chloride (Tensilon), a short- acting cholinesterase inhibitor, is used in the diagnosis of myasthenia gravis (Tensilon test). As explained earlier in the discussion of fatigability, a symptomatic muscle that is most amenable to semiquantitative testing is chosen for the measurement of fatigability before and after the intravenous injection of edrophonium. This test is sometimes done in conjunction with injection of a saline placebo. However, because muscarinic as well as nicotinic receptors are stimulated by the accumulation of acetylcholine in the synaptic cleft, this test is difficult to perform in a blinded fashion because intestinal cramping and muscle fasciculations in the eyelids are generally produced by the edrophonium. The muscarinic effects may also cause a bradycardia that is sufficiently severe to induce fainting, and rarely asystole occurs in what appears to be an idiosyncratic reaction. Therefore, a small test dose of 0.2 ml is given first to assess for an idiosyncratic reaction before the remaining 0.8 ml is given. The effects are short lasting but are long enough to assess strength in the muscles chosen for testing. A positive test (i.e., a significant improvement in muscle strength), is consistent with myasthenia gravis.

A forearm ischemia test is used to diagnose disorders of energy production in muscle. This test is especially useful

TABLE 15-7 -- SELECTED ETIOLOGIES OF CONDITIONS THAT AFFECT STRENGTH AND REFLEXES

Etiological Category	Specific Etiologies	Chapter
STRUCTURAL DISORDERS		
Developmental	Hydrocephalus; neural tube defects; segmentation, cleavage and midline defects, neuronal migration defects	28
Degenerative and compressive	Degeneration disc disease; cervical spondylosis; ankylosing spondylitis; fibrous dysplasia; Paget's disease of bone; compressive neuropathies	29
HEREDITARY AND DEGENERATIVE DISORDERS		
Storage diseases: Lipidoses, glycogen disorders and leukoencephalopathies	Gangliosidoses; sphingomyelinoses; cerebrosidoses; mucopolysaccharidoses; mucolipidoses; glycogen storage diseases, leukodystrophies	30
Amino/organic acidopathies, mitochondrial enzyme defects and other metabolic errors	Maple syrup urine disease (MSUD), urea cycle disorders (UCD); propionic acidemia (Pa); methylmalonic acidemia (MMA); deficiency of phenylalanine hydroxylase (Pah); homocystinuria; glutaricaciduria type 1; subacute necrotizing encephalomyelopathy; Alper's disease; myoclonic epilepsy and ragged red fibers; mitochondrial encephalopathy, lactic acidosis and strokelike episodes; fatty acid oxidation disorders; Hartnup's disease; Menkes' disease; porphyrias	31
Chromosomal abnormalities and neurocutaneous disorders	Neurofibromatosis; tuberous sclerosis	32
The degenerative dementias	Progressive aphasia; progressive frontal lobe/frontotemporal syndrome; progressive perceptual motor syndrome; ALS-dementia complex, multiple system atrophy	33
Movement disorders	Multiple system atrophy, stiff-person syndrome	34
Ataxias	Friedreich's ataxia; congenital ataxias; autosomal dominant cerebellar ataxia	35
Degenerative motor, sensory and autonomic disorders	Amyotrophic lateral sclerosis; spinal muscular atrophy; hereditary spastic paraplegias; dystrophinopathies; limb girdle muscular dystrophies; fascioscapulohumeral muscular dystrophy; scapuloperoneal syndrome; myotonic dystrophy; oculopharyngeal muscular dystrophy; Emery-Dreifuss muscular dystrophy; distal myopathies; hereditary sensory and motor neuropathies; hereditary sensory and autonomic neuropathies; Shy-Drager syndrome	36
Inherited muscle, neuromuscular and neuronal disorders	Channelopathies; congenital myopathies; malignant hyperthermia; Brody's disease; congenital myasthenias; familial amyloid polyneuropathy; giant axonal neuropathy; Isaac's disease	37
ACQUIRED METABOLIC AND NUTRITIONAL DISORDERS		
Endogenous metabolic disorders	Hypocalcemia; hypercalcemia; hyperthyroidism; hypothyroidism; diabetes	38
Exogenous acquired metabolic disorders of the nervous system: Toxins and illicit drugs	Arsenic; inorganic lead; manganese; inorganic mercury; organic mercury; organophosphate insecticides; organochlorine insecticides; snake and spider venoms; tick paralysis; chickpea (lathyrism); diphtheria; tetanus; botulism, cocaine, amphetamine analogs	39
Nutritional deficiencies and syndromes associated with alcoholism	Thiamine; niacin/nicotinic acid; cobalamin (vitamin B ₁₂); pyridoxine (vitamin B ₆); Strachan's syndrome; postgastroplasty polyneuropathy; Marchiafava-Bignami disease; alcoholic myopathy; alcoholic neuropathy	40
INFECTIOUS DISORDERS		

Viral infections	Meningitis; encephalitis neuritis, myelitis	41
Nonviral infections	Acute bacterial meningitis; recurrent bacterial meningitis; abscess (bacterial, fungal, paracytic); intracranial thrombophlebitis; subdural empyema (bacterial, fungal, paracytic); extradural abscess (cranial and spinal epidural); myelitis (Lyme disease); neuritis (Lyme disease); syphilitic; dorsal root ganglion disease; cyst formation (echinococcus), myopathy (parasites) tick paralysis	42
Transmissible spongiform encephalopathies	Sporadic disease; familial disease, iatrogenic disease	43
HIV and AIDS	HIV-related neuropathies; HIV-related myopathy; progressive HIV-related encephalopathy; HIV-associated neoplasms; opportunistic infections; cerebrovascular complications	44
NEUROVASCULAR DISORDERS	Ischemic stroke; hemorrhagic stroke: subarachnoid hemorrhage; arteriovenous malformations; subdural hematomas; epidural hematomas; spinal cord strokes	45
NEOPLASTIC DISORDERS		
Primary neurological tumors	Parasagittal meningioma; infiltrative CNS tumor	46
Metastatic neoplasms and paraneoplastic syndromes	Intraparenchymal metastasis; meningeal and ventricular metastases; spinal metastases; peripheral nerve metastases; paraneoplastic encephalomyelopathies; paraneoplastic motor neuron diseases; paraneoplastic neuromuscular junction and muscle disorders; paraneoplastic peripheral neuropathies	47
DEMYELINATING DISORDERS		
Demyelinating disorders of the central nervous system	Multiple sclerosis; neuromyelitis optica; isolated inflammatory demyelinating CNS syndromes; acute disseminated encephalomyelitis	48
Demyelinating disorders of the peripheral nervous system	Acute inflammatory demyelinating polyradiculoneuropathy; chronic inflammatory demyelinating polyradiculoneuropathy; monoclonal gammopathies of undetermined significance; neuropathy with multiple myeloma; neuropathy with osteosclerotic myeloma; motor neuropathy with multifocal conduction block	49
AUTOIMMUNE AND INFLAMMATORY DISORDERS	Inflammatory vasculopathies; rheumatoid arthritis; systemic lupus erythematosus; progressive systemic sclerosis; myasthenia gravis; dermatomyositis/polymyositis; eosinophilic myositis; inclusion body myositis; Sjogren's disease; Behcet's disease; Mollaret's syndrome; sarcoid	50
TRAUMATIC DISORDERS	Acute head injury; spinal cord injury; whiplash injuries; trauma-induced brachial and lumbosacral plexopathies; mountain sickness; decompression sickness; lightning and electrical injuries	51
EPILEPSY	Todd's paresis; epilepsies related to CNS lesions	52
HEADACHE AND FACIAL PAIN	Complicated (hemiplegic) migraine	53
SLEEP DISORDERS	Narcolepsy	54
DRUG-INDUCED AND IATROGENIC DISORDERS	Anesthetics; cholinesterase inhibitors; penicillins; aminoglycosides; sulfonamides; isoniazid; rifampin; ethambutol; amphotericin B; chloroquine; alkylating agents; methotrexate; vinca alkaloids; cisplatin; thiamine; pyridoxine; penicillamine; clofibrate; lovastatin and pravastatin; coronary artery bypass graft; cardiac catheterization; percutaneous transluminal coronary angioplasty; radiation damage; vaccinations	55

HNP, Herniated nucleus pulposus; AIDS, acquired immune deficiency syndrome; CMV, cytomegalovirus; IC/MCA, internal carotid middle cerebral artery; AIDP, acute inflammatory demyelinating polyneuropathy

in patients with deficiencies of enzymes that break down and utilize glycogen. The prototypical disorder that can be diagnosed by this test is McArdle's disease, or alpha-phosphorylase deficiency. Normally, in the presence of ischemia, muscle can shift to anaerobic glycolysis to satisfy its energy needs. In alpha-phosphorylase deficiency, glycogen cannot be used, and the muscle becomes weak and then develops an electrically silent cramp identical to that seen in rigor mortis. More sophisticated tests of oxygen utilization and energy production by muscle can be done in a human performance laboratory. Magnetic resonance (MR) spectroscopy is becoming more widely available for analyzing the level and distribution of high-energy phosphate compounds.

Physical therapists trained in evaluating the strength of individual muscles can be very helpful in systematically and semiquantitatively assessing and documenting changes in muscle strength over time. Pulmonary function tests are used to assess the presence and degree of weakness in the respiratory muscles in patients with disorders of the neuromuscular junction or acute inflammatory demyelinating polyneuropathy (Guillain-Barre syndrome).

CLINICAL SYNDROMES ([Table 15-7](#))

Upper Motor Neuron Syndromes

The upper motor neuron syndrome is marked by weakness, spasticity, hyperactivity of the tendon reflexes, and the presence of the flexor reflex (Babinski sign). This pattern of motor disturbance occurs when there is an interruption of the descending projections from the motor neurons in the

cerebral cortex and brain stem that modulate excitation of the internuncial pool of inhibitory interneurons and the alpha and gamma motor neurons. The net effect is a reduction of inhibitory influences and an increase in excitatory tone, producing exaggeration of the muscle stretch reflexes (hyperreflexia), increased muscle tone (spasticity), weakness, and disinhibition of the flexor reflex (Babinski sign). Several clinical syndromes affect the upper motor neurons.

The upper motor neuron syndrome is primarily a reflection of interruption of the corticospinal (pyramidal) tract. Because the corticospinal tract extends from the cerebral cortex to the lumbosacral spinal cord, the pattern of weakness and associated reflex abnormalities depends on the site of the lesion along the considerable length of this pathway. Because there are two halves to the brain and consequently two corticospinal tracts, the pattern also depends on which side is affected or whether both sides are affected. Also, the clinical signs on the affected side depend on whether the lesion is above or below the decussation of the tracts in the cervical medullary junction. A unilateral lesion of the cerebral motor cortex will affect the other side of the body. Depending on the size of the lesion, it might affect only one limb or even a part of one limb. For example, a small stroke in the arm area could produce a brachial monoplegia. Because the leg area is on the medial side of the hemisphere at the apex of the motor strip, the leg areas from each hemisphere face each other in the interhemispheric fissure. Therefore, a *parasagittal lesion* in the interhemispheric fissure could affect both legs and produce a syndrome of paraparesis, simulating a spinal cord lesion. This is most commonly produced by a parasagittal meningioma ([Table 15-8](#)).

Hemiparesis most commonly results from a lesion in the contralateral cerebral cortex. Depending on its location in the hemisphere and the side affected, other associated signs can further localize the lesion ([Table 15-9](#)). Because of the considerable length of the corticospinal tract, hemiparesis can also result from lesions anywhere along its path (see [Table 15-9](#)). Because the axons from the motor neurons gather together in the posterior limb of the internal capsule ([Fig. 15-21](#)), a lesion in this location may be very small and still cause a complete hemiparesis (face, arm, body, and leg). Weakness that affects the entire side of the body equally without associated sensory signs (or aphasia if the lesion is in the left hemisphere) has been referred to by Fisher, in a clever redundancy, as a " *pure motor hemiplegia*." Less commonly, small strokes (lacunar infarcts)

TABLE 15-8 -- ANATOMIC LOCALIZATION OF PARAPARESIS

Location of Lesion	Pattern of Weakness, Reflexes, and Associated Signs
Bilateral medial hemispheres (leg area motor cortex)	Spastic paraparesis with no sensory level
Thoracic	Paraparesis with hyperreflexia of legs, normal reflexes in arms; thoracic sensory level
Lumbar	Paraparesis, loss of reflexes, double incontinence with flaccid bladder and sphincters

TABLE 15-9 -- ANATOMIC LOCALIZATION OF HEMIPARESIS

Location of Lesion	Characteristics of Hemiparesis and Associated Signs
Cerebral cortex	Contralateral arm is affected more than leg or face; sometimes tongue (deviates to weak side). Left hemisphere: aphasia, apraxia Right hemisphere: inattention to left half of body, visual space; constructional apraxia Homonymous hemianopia on weak side Decreased graphesthesia, extinction of sensory stimuli
Internal capsule	Contralateral arm equal to leg; face may be spared No sensory loss or aphasia
Brain stem	Contralateral arm equal to leg plus ipsilateral cranial nerve palsy
Midbrain	Third nerve palsy (Weber syndrome)
Pons	Sixth and seventh nerve palsies (peripheral); ipsilateral conjugate gaze palsy possible (Foville's syndrome)
Medulla	Twelfth nerve palsy
Cervical spinal cord (hemicord)	Ipsilateral weakness of arm and leg, sparing face; Ipsilateral loss of proprioception and vibration Contralateral loss of pain and temperature (Brown-Sequard syndrome).

can produce more focal weakness depending on the region of the internal capsule involved. Weakness in the face and arm can produce the *dysarthria-clumsy hand syndrome*.

Lesions of the corticospinal tract as it traverses the brain stem also affect other structures in the brain stem, producing recognizable syndromes depending on the location and size of the lesion. Unilateral lesions of the pyramidal tract in the cerebral peduncle of the midbrain may involve the neighboring third nerve, red nucleus, or superior cerebellar peduncle (brachium conjunctivum). Lesions in this area are generally lacunar infarcts in hypertensive individuals that result from occlusion of small paramedian arteries supplying these structures. As the pyramidal tract enters the pons, the fibers become intermingled with other ascending and descending tracts in the basis pontis. It is still possible for lacunar infarctions to involve the pyramidal tracts primarily, producing a pure motor hemiparesis with or without facial involvement that is similar to the syndrome resulting from a lacunar infarct in the posterior limb of the internal capsule. The corticobulbar and corticopontocerebellar fibers are also present, and a lacunar infarction in the basis pontis, especially one at the junction of the upper third and lower two-thirds, may result in a *dysarthria-clumsy hand syndrome* that is similar to the clinical presentation of a lacune in the genu of the internal capsule. Another lacunar infarct syndrome is a homolateral ataxia and hemiparesis, which is more severe in the lower extremity. This also may be associated with dysarthria, nystagmus, and paresthesia from a lesion in the contralateral pons. Lesions (usually strokes) that include the pontine tegmentum produce a characteristic syndrome composed of an ipsilateral cranial nerve palsy and a contralateral hemiparesis (see [Table 15-9](#)). These uncommon clinical syndromes are described in more detail in [Chapter 45](#) .

Figure 15-21 Cross section of the cortex showing the internal capsule and its fiber arrangement (From Snell RS: *Clinical Neuroanatomy for Medical Students*. Boston, Little, Brown, 1987.)

Bilateral lesions of the basis pontis (infarction, hemorrhage, central pontine myelinolysis) produce the " *locked-in syndrome*" ([Table 15-10](#)). The patient is quadriparetic due to bilateral corticospinal tract involvement and aphonic due

TABLE 15-10 -- ANATOMIC LOCALIZATION OF TETRAPARESIS

Location of Lesion	Pattern of Weakness, Reflexes, and Associated Signs
Bilateral cerebral hemispheres	Tetraparesis, spastic dysarthria, dysphagia with hyperreactive jaw and facial jerks (pseudobulbar palsy), decorticate posturing (large acute lesions)

Midbrain	Tetraparesis, coma, mid-size poorly reactive pupils, decerebrate posturing
Basis pontis	"Locked-in" syndrome; tetraparesis, paralysis of horizontal eye movements, jaw, face, pharynx, and tongue muscles; preservation of eye blink, vertical eye movements, consciousness
Cervicomedullary junction	Tetraparesis with or without weakness of pharynx and tongue
High cervical	Tetraparesis, no cranial nerve palsies, normal jaw and facial jerks
Mid cervical	Tetraparesis with preservation of shoulder movements

to involvement of the corticobulbar fibers to the lower cranial nerves, and occasionally his horizontal eye movements are impaired owing to bilateral involvement of the fascicle of the sixth cranial nerve as it exits the pons. Because the patient cannot move or speak, he may initially appear to be in a coma. However, because the tegmentum of the pons is spared, the reticular formation is intact, and the patient is awake. Vertical eye movements and blinking are still intact, and the patient is able to communicate via eye blinks.

Hemorrhages in the pons that produce tetraplegia owing to destruction of the basis pontis usually also affect the dorsal tegmentum, producing sudden coma, pinpoint pupils, ophthalmoplegia, hyperthermia, and progression to death. A more restricted hemorrhage may occur in the lateral tegmentum of the pontomesencephalic junction, producing a more restricted syndrome that includes small reactive pupils with the smaller pupil ipsilateral to the lesion, ipsilateral conjugate palsy due to involvement of the paramedian pontine reticular formation, ipsilateral ataxia due to involvement of cerebellar connections, and contralateral hemiparesis and hemisensory deficits. Occasionally, the ocular motor abnormality is an ipsilateral skew deviation or internuclear ophthalmoplegia caused by involvement of the medial longitudinal fasciculus.

Although we often refer to the corticospinal tract as the

28

pyramidal tract and to weakness from a lesion as a pyramidal weakness, weakness resulting from lesions of the pyramids in the medulla is very seldom seen. The medullary pyramids are supplied by the paramedian arteries branching off the vertebral artery and, more inferiorly, from the inferior spinal artery. Occlusion of these arteries can produce infarction of the ipsilateral pyramid, medial lemniscus, and hypoglossal nerve and nucleus, producing a contralateral hemiplegia with sparing of the face and ipsilateral paresis and atrophy of the tongue. Occasionally, there is a contralateral loss of position of vibratory sensation due to involvement of the medial lemniscus. Because the more dorsolateral spinothalamic tract is unaffected, pain and temperature sensation are spared. However, infarction of the medulla occurs much more commonly in the vascular supply of the lateral medulla, producing the *Wallenberg* or *lateral medullary syndrome*, which spares the pyramids (see [Chapters 13](#) , [14](#) , [22](#) , and [45](#)).

Developmental malformations of the brain stem such as the Chiari malformations or tumors in the foramen magnum at the cervical medullary junction more commonly produce weakness by involvement of the medullary pyramids and the upper cervical cord at the place where they decussate into the corticospinal tracts of the lateral and ventral funiculi of the spinal cord. A spastic tetraparesis (generally the legs are more involved than the arms) occurs in varying combinations with weakness of the tongue and pharynx, nystagmus (due to involvement of the inferior cerebellar peduncle), and facial hypalgesia (due to involvement of the descending tract of the trigeminal nerve) (see [Table 15-10](#)). A syringomyelic syndrome occurs if central cavitation of the cord is present. This characteristically produces a loss of pain and temperature sensation over the shoulders and a lower motor neuron syndrome of the upper extremities with weakness, atrophy, fasciculations, and loss of reflex. The distribution of the weakness and loss of reflex depends on which segments of the cervical spinal cord are involved.

The characteristic pattern of weakness seen in patients with upper motor neuron lesions of the spinal cord is weakness combined with appropriate reflex changes on both sides of the body with no signs of cerebral, cortical, or brain stem dysfunction. The level of the lesion is defined by whether the arms are involved (cervical cord) or just the legs (thoracic cord). More exact definition of the level of the lesion is made by noting the distribution of lower motor neuron involvement if the lesion is in the cervical cord or by noting the sensory level resulting from involvement of the ascending sensory tracts with lesions in either the thoracic or cervical cord. These characteristic clinical syndromes are described in more detail in the later section on combined upper and lower motor neuron lesions (see [Table 15-7](#)).

Syndrome of Diffuse Excitation of Internuncial Pool

When the inhibitory tone in gamma motor neurons provided by the inhibitory interneuron in the internuncial pool is removed, the spontaneous excitability of the lower motor neurons is unleashed. This phenomenon of unrestrained excitation of contraction of the skeletal muscles is known as *tetanus*. In the most common generalized form of tetanus, all skeletal muscle, both agonists and antagonists as well as diaphragm, paravertebral, and respiratory muscles, contract uncontrollably in paroxysms of painful muscle spasms (tetanic seizures) (see [Table 15-5](#)). In the absence of any inhibitory check, any environmental stimuli increase the intensity of the paroxysms, preventing coordinated respiratory movements. Tetanus may remain localized to the area of the wound (local, or cephalic, tetanus if wound is of the face or head). Tetanus is produced by impairment of function of the neurotransmitters employed by the inhibitory interneurons (i.e., GABA and glycine). Tetanus toxin blocks glycine receptors. Antibodies against glutamic acid decarboxylase (GAD), the GABA-synthesizing enzyme, are produced by certain cancers and diabetes mellitus, resulting in the *stiff-person syndrome*³⁴ (see [Chapter 34](#)).

Lower Motor Neuron Syndromes

Diseases of the lower motor neuron may affect the cell body itself in the anterior spinal gray or its axon as it leaves the spinal cord in the spinal root and becomes a peripheral nerve. Signs of disease of the lower motor neuron include muscular weakness, atrophy, fasciculations, and loss of tendon reflexes.

PROGRESSIVE SPINAL MUSCULAR ATROPHY SYNDROMES

There may be selective degeneration of the anterior horn cells of the spinal cord or brain stem or both. This results in a progressive weakness and wasting of muscle and loss of tendon reflexes. The upper motor neuron is not affected. The spinal muscular atrophies (SMA) are genetic diseases of childhood and adolescence and, less commonly, adulthood. Regardless of whether they are recessive or dominant, the defect is linked to the same region on chromosome 5. In addition to patterns of heredity, clinical classifications are based on age of onset, rate of progression, and the muscles affected.³⁵ The infantile-onset form (*Werdnig-Hoffman disease*) is the most severe (lethal) form and is recessive. The later-onset, more benign forms are more likely to be dominant. The variety that affects the proximal musculature and simulates muscular dystrophy is known as the *Wohlfart-Kugelberg-Welander syndrome*. The distal musculature is preferentially affected in various combinations with the ocular and bulbar muscles in *Kennedy's syndrome*.

Lower motor neuron disorders that are restricted to certain cranial nerve nuclei or combinations are much less common. The *Moobius syndrome*, which affects the sixth and seventh cranial nerves, appears to be a failure of development of the motor neurons and presents as a congenital disorder. The progressive bulbar palsy of *Fazio-Londe* is a rare fatal disease that affects all motor nuclei of the brain stem.

29

RADICULOPATHY SYNDROMES

Lesions of the spinal nerves and roots produce weakness, atrophy, and sometimes fasciculations in the muscles innervated by the affected root or, in some cases, multiple roots. Localization of the specific nerve root affected by the lesion requires a knowledge of each group of muscles supplied by a single anterior spinal root (*myotome*) and each cutaneous area supplied by the posterior spinal root (*dermatome*). Differentiation of these syndromes from peripheral nerve or plexus lesions thus depends on the distribution of the motor and sensory signs and whether the signs conform to those produced by a particular myotome or dermatome. Root lesions may interrupt the afferent or efferent arc of the phasic stretch reflex and thus affect tendon jerks. Thus, a reduction or loss of a reflex is very helpful in localizing the root involved. [Table 15-4](#) correlates the reflex in the cervical or lumbosacral root subserving that reflex.

The spinal nerve roots may be injured directly by trauma or compressed by lesions such as tumors or herniated discs. The most common radiculopathies affect the fifth and sixth cervical roots and the fifth lumbar and first sacral roots, since those are the roots most often compressed by herniated discs. Because muscles are

innervated by more than one spinal nerve root, it may be difficult to differentiate a C5 from a C6 or a C6 from a C7 root injury. For example, a C6 root lesion may depress either the biceps or triceps reflex. Differentiating a C5 from a C7 root lesion is easier because the C5 lesion reduces the biceps jerk, whereas the C7 reduces the triceps. The same muscles are also the weakest. Therefore, one must also use the distribution of pain and sensory loss as a guide to supplement the motor signs and provide a pattern of motor and sensory change that can be assigned to one spinal segment.

In the lower extremity, the differentiation of an L5 from an S1 root lesion is most readily made by watching the patient walk on the heels and toes. Weakness of dorsiflexion (difficulty in walking on the heels) is usually due to an L5 root lesion, reflecting the fact that the anterior tibial muscle receives its major innervation from that segment. Difficulty in walking on the toes due to weakness of the gastrocnemius muscles reflects the fact that its major innervation is provided by the S1 root. The ankle jerk may be affected by either lesion but is more often abolished by the S1 root lesion.

PLEXOPATHY SYNDROMES

Plexopathies are more difficult to recognize and localize than lesions of the spinal roots or peripheral nerves because the anatomy of the plexuses is so complex (see [Figs. 15-6](#) and [15-7](#)). Brachial plexopathies present with a variety of clinical syndromes that depend on the part of the plexus involved. Trauma is the most frequent cause of damage, which usually results from a traction, compression, or stretch injury of the plexus. The most common syndromes are summarized in [Table 15-11](#). The brachial plexus is also subject to injury from radiation or malignancies, compression by tumors in lymph nodes or the apex of the lung, or immunologic attack ("brachial neuritis" or *Parsonage-Turner syndrome*). The best clue to the presence of a brachial plexopathy is a motor and sensory deficit that involves more than one spinal or peripheral nerve. The motor signs (weakness, atrophy, and loss of tendon jerk) are much more prominent than the sensory changes, which are often patchy and incomplete. Diffuse aching pain, sometimes quite severe, is often present.

Lesions of the brachial plexus most commonly affect the upper and lower trunks. The upper trunk of the plexus is affected most commonly, giving rise to paralysis and atrophy in muscles supplied by the C5-C6 roots that comprise the upper trunk (*Erb-Duchenne type*). This upper trunk palsy is most often due to traumatic hyperextension of the head and shoulder but can be due to direct pressure caused by carrying heavy objects (knapsack palsy). The upper trunk is the part of the plexus most commonly affected by an idiopathic inflammatory neuritis (*Parsonage-Turner syndrome*). The *lower brachial plexopathy (Dejerine-Klumpke type)* is usually the result of trauma to the lower trunk of the plexus, which contains the eighth cervical and first thoracic roots. It is the plexus lesion most often associated with an infiltrating tumor from the apex of the lung (Pancoast tumor). Because the sympathetic fibers destined for the superior cervical ganglion exit the spinal cord with the first thoracic root, a *Horner's syndrome* (ptosis, miosis, and anhidrosis) may result; if present, it can be a helpful confirmatory sign.

Like lesions of the brachial plexus, a lumbosacral plexopathy is recognized by deficits in the distribution of multiple spinal and peripheral nerves in the lower extremity (see [Table 15-11](#)). Also like the brachial plexus, the lumbosacral plexus is affected by idiopathic inflammatory neuritis, radiation,

TABLE 15-11 -- EXAMPLES OF PLEXOPATHIES CAUSING WEAKNESS

Plexopathy	Pattern of Weakness	Causes
BRACHIAL		
Upper trunk (C5-C6)	"Porter's tip position"; biceps, brachioradialis jerks reduced or absent	Pressure on shoulder ("knapsack palsy"); brachial neuritis
Lower trunk (C8-T1)	Wrist and finger flexion, intrinsic hand muscles	Trauma, Pancoast's tumor of lung
LUMBOSACRAL		
Lumbar segments (T12-L4)	Flexion, abduction, and eversion of thigh; absent knee jerk	Tumor, surgical trauma
Sacral segments (L5-S3)	Hip extension, abduction and internal rotation of thigh, flexion of leg and all movements of foot ("flail foot"); absent ankle jerk	Tumor, surgical trauma
ENTIRE PLEXUS	Incomplete weakness of various muscles	Diabetes mellitus, idiopathic plexitis

and infiltrating neoplasms. It is less likely to be injured by trauma than the brachial plexus, but pelvic hematomas in the psoas muscle resulting from anticoagulation and surgical trauma are more common. Lesions of the lumbar segments produce weakness of all movements of the thigh with reduction or loss of the patellar tendon jerk. Lesions of the sacral portion of the plexus result in a weakness of the foot and flexion of the knee with reduction or loss of the ankle jerk. Because most of the motor output of the lumbar portion of the plexus is contained in the femoral nerve and the output of the sacral portion is found in the sciatic nerve, it may be difficult to distinguish lumbosacral plexus lesions from lesions of their respective major peripheral nerves. To distinguish a lumbar plexus lesion from a femoral neuropathy, a diligent search should be made for weakness of the adductor muscles innervated by the obturator nerve or of sensory loss in the inguinal region or over the genitalia, which are outside the distribution of the femoral nerve. Weakness of abduction and internal rotation of the thigh and of hip extension, or sensory loss on the posterior thigh in the distribution of the posterior femoral cutaneous nerve, helps to distinguish a lesion of the sacral plexus from a sciatic palsy, which lacks these signs.

PERIPHERAL NEUROPATHY AND MONONEUROPATHY SYNDROMES

Interruption of the motor fibers in a motor or mixed nerve leads to weakness or paralysis and atrophy of the muscles innervated by that nerve. Fasciculations are less likely to occur in peripheral nerve lesions than in root or anterior horn cell lesions. [Table 15-12](#) lists the peripheral nerves most often affected by lesions, the muscles they supply, and any stretch reflex subserved by that nerve. Because a muscle is generally served by only one peripheral nerve, the weakness and wasting in that muscle are generally easier to detect than in a root lesion because the same muscle is generally served by two or more myotomes. The localization is confirmed by the pattern of sensory loss, which in most cases differs from the segmental dermatomal loss secondary to a root lesion. Lesions of a single peripheral nerve are most commonly due to entrapment, trauma, or infarction of the nerve secondary to diabetes or an inflammatory vasculitis. When a single peripheral nerve is damaged, it is termed a *mononeuropathy*. *Mononeuropathy multiplex* refers to involvement of several major named nerves in more than one limb. This condition most often occurs in systemic diseases such as autoimmune vasculitis, especially polyarteritis nodosa and diabetes mellitus. ^[36]

In *polyneuropathy*, the essential feature is impairment of function of many peripheral nerves simultaneously, causing symmetrical loss of function starting in the distal extremities. The legs are almost always affected before the arms. Hyporeflexia or areflexia often precedes any overt motor or sensory symptoms. The ankle jerks are affected first and then the knee jerks before any change occurs in the reflexes of the arms.

Polyneuropathies may be mainly sensory, mixed motor and sensory, or primarily motor. The motor component begins as weakness and atrophy in the intrinsic muscles of the feet; atrophy of the extensor digitorum brevis is often the first helpful clue. If the motor impairment progresses, the leg muscles are affected next, producing weakness of dorsiflexion and plantar flexion of the foot. Only then may the intrinsic muscles of the hand be affected. Generally, the more proximal muscle groups are not affected unless a rapidly progressive disorder is present such as an *acute inflammatory demyelinating polyneuropathy (AIDP, Guillain-Barre syndrome)* or another neuropathy mimicking AIDP such as porphyria and acquired immune deficiency syndrome (AIDS). The common distal symmetrical and slowly progressive polyneuropathies are most often due to systemic disorders, especially diabetes mellitus, alcoholism, and uremia.

Combined Upper and Lower Motor Neuron Syndromes

MOTOR NEURON SYNDROMES

Motor neuron disease refers to a group of disorders in which selective degeneration of both upper and lower motor neurons occurs. ^[37] *Amyotrophic lateral sclerosis (ALS, Lou Gehrig's disease)* is the prototypical motor neuron disease. Several varieties or subtypes are recognized based on the sites at which the motor neurons are first and most prominently involved. The spinal form most commonly

TABLE 15-12 -- EXAMPLES OF COMMON NEUROPATHIES CAUSING WEAKNESS

Neuropathy	Patterns of Muscle Weakness and Reflex Changes	Common Causes
Long thoracic nerve (C5-C7)	Winged scapula (serratus anterior)	Pressure on shoulder, weight lifting
Axillary nerve (C5-C6)	Abduction of arm (deltoid)	Dislocated shoulder, brachial neuritis
Musculocutaneous nerve (C5-C7)	Flexion of forearm (biceps), biceps jerk	Infarction due to vasculopathy (DM, PAN)
Median nerve (C5-T1)	Abduction (abductor pollicis brevis, opponens pollicis) and opposition of thumb	Entrapment--pronator or carpal tunnel syndrome
Ulnar nerve (C7-T1)	Intrinsic muscles of hand except those innervated by median nerve; "claw hand"	Pressure at elbow, entrapment in cubital tunnel
Radial nerve (C5-C8)	Extensors of wrist and fingers, "wrist drop" triceps, triceps jerk (if compressed in axilla)	Pressure in axilla ("crutch palsy") or spiral groove of humerus ("Saturday night palsy")
Femoral nerve (L2-L4-)	Flexion of thigh, leg extension (psoas, quadriceps), knee jerk	Surgical trauma, DM
Common peroneal nerve (L4-5)	Dorsiflexors and everters of foot	Pressure palsy at fibular head

DM, Diabetes mellitus; PAN, polyarteritis nodosa.

affects the lumbosacral segments first, producing weakness, atrophy, and fasciculations in one leg as the initial manifestations. At the same time, the upper motor neurons are generally affected, so instead of loss of reflexes to accompany the atrophy and fasciculations, hyperreflexia occurs, producing the characteristic combination of upper and lower motor neuron involvement. Onset of disease in the brain stem affects the lower cranial nerve nuclei, producing a *progressive bulbar palsy*. Lower motor neuron degeneration becomes evident by weakness, atrophy, and fasciculations of the tongue and weakness of voluntary palatal movement, while upper motor neuron involvement is shown by the very brisk gag reflex and jaw jerk. The otolaryngologist is often the first consultant asked to see the patient because a nasal voice and dysphagia are present. Occasionally, the upper motor neurons are selectively affected at the onset, producing a slowly progressive spastic tetraparesis and pseudobulbar palsy (primary lateral sclerosis). Often an EMG can record the fibrillations, positive sharp waves, and giant action potentials typical of lower motor neuron involvement before the signs become clinically manifest. Regardless of the mode of onset, the disorder eventually involves the motor neurons of the entire neuraxis.

From a diagnostic standpoint, it is most important to differentiate ALS from potentially treatable lesions in the cervical canal that compress the nerve roots and spinal cord, producing a characteristic syndrome of lower motor neuron signs in the hands and upper motor neuron signs in the legs. Imaging of the cervical spine is important to rule out *cervical spondylosis* or tumor. ALS is confirmed by electromyographic demonstration of denervation in a combination of facial or bulbar muscles and lower extremities.

Paralytic poliomyelitis is now rare in the vaccinated western world. The neurotrophic polio virus attacks nerve cells in the hypothalamus, thalamus, brain stem, reticular formation, vestibular nuclei, and nuclei of the cerebellum, but the major hallmark of the disease is destruction of the lower motor neurons in the motor nuclei of the brain stem and anterior horn of the spinal cord. The severity and distribution of the bulbar and spinal paralysis is quite variable. The most common bulbar symptoms are weakness of the face, larynx, and pharynx. Spinal paralysis is more common than bulbar paralysis. Weakness develops rapidly, usually attaining its maximum severity in 48 hours, and is accompanied by coarse fasciculations. The tendon jerks may be hyperactive during the acute phase but then diminish and eventually are lost as the weakness of the limb muscles progresses. Limb weakness is often asymmetrical and patchy. Muscle atrophy is generally appreciated within 3 to 4 weeks of the paralysis and is permanent. In addition to the disability produced by the weakness and atrophy, progression of muscle weakness may occur many years after the acute paralytic illness (postpolio syndrome).

MYELOPATHIC SYNDROMES

The *transverse myelopathy* syndrome interrupts the ascending tracts from below the level of the lesion and all descending tracts from above this level. Therefore, all motor and sensory function below the level of the spinal cord injury is lost. Trauma is the most frequent cause of complete loss of function at the site of the injury. In practice, many lesions are incomplete, although there is evidence of involvement of the entire cross-sectional extent of the cord. Demyelinating and inflammatory processes account for most examples of incomplete lesions and are often referred to as *transverse myelitis*. All sensory modalities are lost below the level of the lesion. There is often a zone of disagreeable dysesthesia at the uppermost border of the sensory loss. Radicular pain is common at the level of the lesion. If an infectious or neoplastic process is present in the epidural space (epidural abscess) or in the vertebrae (metastatic cancer), localized vertebral pain may be elicited by percussion of the spinous processes.

The pathological processes that produce transverse myelopathy are often acute and initially produce a flaccid areflexic paralysis known as spinal shock ([Table 15-13](#)). Within days, the motor syndrome becomes characteristic of an upper motor neuron paralysis with hyperreflexia and bilateral extensor plantar responses. At the level of the lesion, segmental lower motor neuron signs may persist owing to injury to the anterior horns or the ventral roots. The lower motor neuron signs are a reliable indicator of the level of the spinal cord injury. They may be quite obvious in the cervical level but can be subtle and hard to detect at the thoracic cord level.

Marked disturbances in autonomic function can occur below the level of the lesion. Loss of sweating and trophic skin changes occur, as well as loss of temperature control and vasomotor instability, which can result in sudden changes in body temperature and blood pressure, including hypertensive crises. Initially, after an acute lesion, the bladder

TABLE 15-13 -- MYELOPATHIES OR SPINAL CORD SYNDROMES

Location of Lesion	Characteristic Signs
Complete transection (transverse)	Complete loss of motor and sensory function below level of lesion (tetraplegia or paraplegia) Acute: flaccid, areflexia (spinal shock) Chronic: spasticity, hyperreflexia, Babinski's signs, spastic bladder
Hemisection (Brown-Sequard syndrome)	Ipsilateral hemiplegia or monoplegia, ipsilateral loss of vibration, proprioception Contralateral loss of pain and temperature below level of lesion
Central	"Suspended" sensory loss: "cape" sensory loss over shoulders from cervical lesion most common Loss of pain and temperature, sparing of vibration and proprioception ("dissociated" sensory loss) Weakness, atrophy, fasciculations, loss of reflex in extremity of affected segment (usually arm or cervical)
Anterior (anterior spinal artery syndrome)	Loss of motor function below level of lesion, flaccid tetraplegia or paraplegia. Loss of pain and temperature sensation below level of lesion with preservation of vibration, proprioception. Loss of bladder and bowel control
Caudal (conus medullaris)	Hypotonic bladder and rectal sphincters. Pain and loss of sensation in saddle distribution in perineum

is atonic, and the anal sphincter is flaccid. Later they become spastic, leading to involuntary evacuation of the bladder and bowels.

The *Brown-Sequard syndrome* produces a characteristic combination of motor and sensory signs below the level of the lesion. Interruption of the descending

corticospinal tract produces an ipsilateral spastic weakness. Also, ipsilateral loss of proprioception below the level of the lesion results from interruption of the ascending fibers in the posterior columns. Loss of pain and temperature sensation occurs contralateral to the hemisection because the crossed spinothalamic tract is interrupted. The sensory level that is responsive to pain and temperature is usually located one or two segments below the level of the lesion. When the Brown-Sequard syndrome results from an extramedullary lesion, there may be segmental lower motor neuron and sensory signs at the level of the lesion due to damage to the roots and anterior horn cells, and these signs are the most reliable indication of the level of the lesion. This syndrome is most apparent in patients with traumatic hemisections of the spinal cord (e.g., due to a stab wound). Other causes are extramedullary tumors or abscesses and, less commonly, intrinsic lesions, especially vasculitis (as in systemic lupus erythematosus). The full-blown hemisection syndrome is not commonly encountered (see [Table 15-13](#)).

The *central cord* syndrome is most often caused by *syringomyelia* and intramedullary cord tumors. The pathological process starts centrally and proceeds centrifugally, producing motor and sensory signs that evolve characteristically for this syndrome. Characteristically, the syndrome presents as a combination of segmental loss of pain and temperature sensation and lower motor neuron signs. This pattern occurs because the crossing fibers of the spinothalamic tract conveying pain and temperature sensation are initially compromised but posterior column sensation is preserved (*disassociated sensory loss*). Because only the decussating spinothalamic tract fibers are affected, the loss of pain and temperature is bilateral but affects only those segments of the spinal cord involved in the pathological cavitation or by the tumor, thus producing a *suspended sensory loss* with normal sensation above and below the lesion. In patients with syringomyelia, this pattern characteristically begins in the upper cervical segments, producing a loss of pain and temperature over the shoulders in a cape distribution. The syringomyelia or tumor usually invades the anterior horns early, producing the segmental lower motor neuron syndrome with weakness, wasting, and loss of reflex. As the lesion expands centrifugally, it may compromise the lateral corticospinal tracts, producing an upper motor neuron syndrome below the level of the lesion and loss of proprioception and vibratory sensation below the level of the lesion as it extends into the posterior columns (see [Table 15-13](#)).

When the anterior horns are affected in the cervical cord, wasting occurs first in one hand and then in the other. At the thoracic level the disease affects the lower motor neurons innervating the paraspinal musculature, resulting in a scoliosis. Finally, if the lesion extends into the spinothalamic tracts themselves, pain and temperature sensation below the level of the lesion may be lost. Because the spinothalamic tracts are arranged in a laminated pattern with the sacral segments in the most lateral and ventral position, the sacral dermatomes are often preserved (*sacral sparing*).

The *anterior spinal artery* syndrome produces a distinctive combination of motor and sensory signs. Circulation to approximately the ventral two-thirds of the spinal cord is supplied by the anterior spinal artery. Occlusion of the anterior spinal artery thus produces infarction in the ventral and most of the lateral funiculi, which include the anterior horns and the lateral corticospinal and spinothalamic tracts. Infarction leads to a subacute onset of a flaccid paralysis below the level of the lesion with loss of pain and temperature sensation below the level of the lesion. Position sense, vibration, and light touch are spared because the dorsal column supplied by the posterior spinal arteries is preserved. Infarction of the spinal cord usually occurs at border zones between the major arterial systems supplying the spinal cord. These watersheds are at the T1-T4 and L1 spinal cord levels.

Neuromuscular Junction Syndromes

MYASTHENIA GRAVIS

The defect in neuromuscular transmission in myasthenia gravis (see [Chapter 50](#)) produces a pure muscular weakness without the atrophy, fasciculations, or reflex changes seen in motor neuron disease.^[38] Myasthenia gravis also causes a pattern of weakness in the ocular and cranial muscles that is different from that seen in amyotrophic lateral sclerosis. A weakness of the extraocular muscles and eyelids producing diplopia and ptosis is common in patients with myasthenia gravis but rare in those with amyotrophic lateral sclerosis (see [Table 15-2](#)). Facial weakness is also common in myasthenia gravis, and the combination of ptosis and weakness of eye closure may be duplicated only by an acute inflammatory demyelinating polyneuropathy (Guillain-Barre syndrome), which has a very different temporal profile.

The other characteristic feature of myasthenia gravis is *fatigability*. The myasthenic muscle rapidly weakens with continued or repetitive use. The physiological counterpart is the *decremental* response to repetitive stimulation of a peripheral nerve. Rest can temporarily restore the muscle to almost normal strength, but diplopia and ptosis return as the patient uses the eyes, the nasal voice and mushy dysarthric speech resumes as he speaks, and difficulty with chewing and swallowing occurs as he eats. Limb and postural muscles are generally less affected.^[39]

MYASTHENIC SYNDROME (EATON-LAMBERT SYNDROME)

Although weakness reminiscent of myasthenia gravis is the presenting complaint in most people with Eaton-Lambert syndrome,^[40] the phenomenon of fatigability is less prominent, and the distribution of weakness, which affects the limbs and spares the extraocular muscles and eyelids, is also different. Pharyngeal weakness with dysphagia is the only weakness of the cranial musculature regularly encountered. Also in contrast to myasthenia gravis, autonomic

dysfunction and reflex changes develop. Dry mouth and perversion of taste are common. Knee jerks are often reduced or absent.^[41]

Occasionally patients with the Eaton-Lambert myasthenic syndrome describe a warming-up phenomenon, which is the opposite of fatigability; as a muscle is used repetitively, it may gain in strength, although with continued use fatigability returns. The clinical warming-up phenomenon correlates with an *incremental* increase in the amplitude of the muscle action potential with repetitive stimulation. The initial low amplitude of the muscle action potential occurs because an antibody blocks a calcium channel, slowing the entry of calcium into the presynaptic terminal to initiate vesicular release of acetylcholine.^[42] Because it is only a partial blockade, however, enough calcium eventually enters with repetitive depolarizations to allow the amplitude of response to increase and strength to improve, at least temporarily.^[43] In many but not all cases, the antibody against the calcium channel is generated by a cancer; thus, the Eaton-Lambert myasthenic syndrome is often a paraneoplastic disorder.^[44]

OTHER DISORDERS OF THE NEUROMUSCULAR JUNCTION

Botulism produces a rapidly developing paralysis. Because it usually affects the ocular and cranial musculature first, and the weakness develops so rapidly, botulism can be confused with a brain stem stroke or encephalitis. It rapidly becomes generalized to include all skeletal musculature and then may be mistaken for AIDP (see [Table 15-14](#)). In typical cases, these conditions can be distinguished from each other by the fact that botulism starts in the ocular and cranial musculature and produces a descending paralysis, whereas AIDP starts as a weakness in the legs and produces an ascending paralysis that eventually includes the cranial musculature. This rule applies very well to botulism, which almost invariably begins in the ocular and cranial musculature, but may be violated by AIDP, which sometimes begins in the cranial musculature and descends. However, the early loss of pupillary reflexes in botulism and the predilection of AIDP for the facial and lower cranial nerves can clearly distinguish the two disorders. Weakness resulting from botulism is prolonged, lasting months, because the toxin permanently impairs the presynaptic release of acetylcholine from the terminals to which the toxin is bound. Neuromuscular transmission and strength return only after the nerve terminals sprout new endings.

Myopathic Syndromes

In general, diseases of muscle (myopathies) are recognized by the characteristic pattern of proximal shoulder and hip girdle weakness with relative preservation of distal strength (see [Table 15-2](#)). Myopathic syndromes also differ from symmetrical polyneuropathies in their effect on reflexes. In contrast to polyneuropathies, in which the distal reflexes are lost early, in myopathies the reflexes are reduced in proportion to the degree of weakness; only with severe weakness in the end stages of a myopathy are the reflexes lost (see [Table 15-5](#)). Myopathies can be further differentiated from neuropathies by the lack of any sensory abnormalities. Atrophy of muscle may occur in myopathies but develops very slowly over the course of several years, whereas in motor neuron disease it develops much more rapidly. Also, no fasciculations are seen in myopathies. In certain muscular dystrophies, especially *Duchenne's muscular dystrophy*, pseudohypertrophy of the calf and deltoid muscles may occur owing to infiltration of the muscle by fat. The patient with myopathy often has a typical facial expression with ptosis, open mouth, and facial immobility.

As is often the case in medicine, there are exceptions to these general rules. The distal muscles may be weaker than the proximal muscles (e.g., *myotonic dystrophy*, *inclusion body myositis*), or a motor neuron disorder may affect the proximal musculature more than the distal, mimicking a myopathy (*Kugelberg-Welander syndrome*). Some myopathies affect the cranial and ocular muscles rather than limb muscles, as in, for example, the *chronic progressive external ophthalmoplegia* (CPEO) syndrome. The abnormal eye movements can be differentiated from those in myasthenia gravis; in CPEO eye movements are restricted symmetrically and

diplopia is not a complaint, whereas in myasthenia gravis double vision is a common symptom.

If special attention is given to the distribution of muscle weakness, the age and sex of the patient, and the family history, the likely diagnosis can often be determined. Some myopathies are congenital and have a different prognosis from rapidly progressive myopathies of childhood onset

TABLE 15-14 -- "ACUTE" GENERALIZED WEAKNESS

Location of Lesion	Differentiating Features	Causes
Midbrain	Coma, mid-size poorly reactive pupils, decorticate/decerebrate posturing, hyperreflexia, bilateral Babinski's signs	Stroke, trauma, tentorial herniation secondary to mass lesion
Basis pontis	Conscious; paralysis of horizontal eye movements and of jaw, face, pharynx, and tongue with preservation of vertical eye movements, eye blink; UMN spastic tetraparesis ("locked-in" syndrome)	Stroke
Spinal cord (spinal shock)	Flaccid paraplegia (tetraplegia), sensory loss below level of lesion with absent tendon reflexes but with extensor plantar responses; hypotonic bladder and sphincters	Trauma, infarction, metastatic tumor, transverse myelitis
Polyradicular neuropathy	Limb weakness (legs before arms), areflexia, absent or flexor toe response, minimal distal sensory loss without a sensory level	Acute inflammatory demyelinating polyneuropathy, tick paralysis, poliomyelitis
Neuromuscular junction	Ocular (including loss of pupillary light reflex) and pharyngeal weakness followed by generalized weakness without sensory loss and preservation of consciousness	Botulism, organophosphates

in boys that are usually dystrophinopathies. Dominantly inherited dystrophies have a later onset and a more benign course and have a rather uniform pattern of involvement (e.g., fascioscapulohumeral dystrophy). Mitochondrial myopathies preferentially affect the ocular and cranial musculature and are often accompanied by dysfunction in other organ systems. Inflammatory and infectious myopathies generally affect older individuals. The exception is dermatomyositis, which may occur at any age but is accompanied by characteristic skin changes.

Syndrome of "Acute" Generalized Weakness

Occasionally the pace of a disease is so rapid that by the time the patient is seen in the hospital the weakness has become generalized. The history of the mode of onset and the early course of the disease may not be available or may be confused by inaccurate observations. Therefore, accurate formulation of the problem depends on the examination and on localization of the level of the motor system that is damaged and is producing the weakness (see [Table 15-14](#)). The first step in the differentiation is to determine whether the patient is in coma. The "locked-in" patient with a basis pontis lesion may initially appear comatose because he cannot move or speak and has lost the ability to make horizontal eye movements. However, the ability to blink and make vertical eye movements is preserved, and one should attempt to establish a communication code using eye blinks. In severe cases of botulism and AIDP, even ocular movements may be totally paralyzed, but no decorticate or decerebrate posturing is present or any hyperreflexia, and there are no Babinski signs to indicate the presence of an intrinsic brain stem lesion.

Another potential source of confusion is the differentiation of AIDP without cranial neuropathy from an acute transverse myelopathy with spinal shock. Interruption of the descending motor tracts due to an acute transection of the spinal cord not only produces a paralysis below the level of the lesion but also causes a loss of all reflex activity. Tendon reflexes are lost, and initially there is no Babinski sign. However, Babinski signs generally appear within a matter of hours to a few days at most, helping to differentiate between the two. Also, in patients with acute transverse myelopathy there is a well-defined sensory level, whereas in those with AIDP there is minimal if any sensory loss, which is generally distal with no sensory level.

Episodic Weakness Syndrome

There are a number of unusual syndromes in which weakness is intermittent or fleeting. These are listed in [Table 15-15](#) . Because of the phenomenon of fatigability and recovery after rest the patient with myasthenia gravis may complain of episodic weakness. Myasthenia gravis is seldom confused with these other disorders because of the features mentioned earlier and the predilection of the weakness for the ocular and cranial muscles. An episodic hemiparesis is more apt to lead to confusion. The most common cause of this is *transient ischemic attack* but the potential for confusion is greater with *partial motor seizures* or *hemiplegic migraine*. These entities can be differentiated clinically by paying careful attention to the mode of onset and the course of the weakness. Transient ischemic attack produces an abrupt and simultaneous onset of weakness in all the muscles that will be affected during the attack. A partial motor seizure may become manifest as an inhibition of motor function, producing a stepwise progression of weakness from one body part to the next ("march") over many seconds to a few minutes as the wave of excitation or inhibition spreads along the cortical motor strip. The more common clonic jerking of the limbs may be followed by a postictal weakness (*Todd's paresis*) that lasts minutes to hours. The weakness of hemiplegic migraine takes even longer to develop than the inhibitory seizure, usually requiring several minutes to reach its completion.

Psychogenic paralyses can usually be readily diagnosed by the normal state of the reflexes and the nonanatomical distribution of sensory loss. When they are distracted or think they are unobserved, patients with this form of paralysis can usually be observed to move or use the affected body part in a way that should not be possible. The *cataleptic attack* is sudden and brief and is usually triggered by emotion. The history reveals other features of the *narcolepsy* syndrome. Another feature of narcolepsy is *sleep paralysis*. The attack generally occurs when the patient is beginning to arouse and awaken early in the morning. As the patient becomes aware of his surroundings it is apparent that he is paralyzed and cannot move or talk, although respiration is unaffected. this attack can be aborted by an external stimulus, usually touch; sometimes the patient himself can abort the paralysis by imagining a touch. This phenomenon differentiates the attack of sleep paralysis from periodic paralysis (see later discussion). An attack of sleep paralysis may also be accompanied by frightening hallucinations (*hypnagogic hallucinations*).

The term *drop attack* refers to sudden falling spells without warning, loss of consciousness, or postictal symptoms. These attacks are very brief and are presumed to result from a sudden loss of muscular strength due to dysfunction of the corticospinal tracts at the level of the pyramidal tracts in the medulla or the high cervical cord. The attacks may result from brief ischemia to this region as in a vertebrobasilar ischemic attack or transient compression by excessive movement of the odontoid in a patient with an unstable atlantoaxial articulation. The ligament holding the odontoid in place may be destroyed by rheumatoid arthritis or trauma, and certain movements of the head, especially extension, can cause the odontoid to transiently compress the cervicomedullary junction. Similar attacks of tetraparesis can also occur in the chronic cerebellar tonsillar herniation characteristic of the *Chiari malformation* or in patients with severe congenital cervical spinal stenosis during Valsalva maneuvers or after falls. In the latter examples of mechanical compression, the weakness is generally more prolonged than it is in the classic drop attack, in which the person is immediately able to get to his or her feet after hitting the ground. There is also a syndrome of idiopathic drop attacks in elderly women that has a benign prognosis.

By definition, drop attacks occur without loss of consciousness,

TABLE 15-15 -- EPISODIC WEAKNESS-DIFFERENTIAL DIAGNOSIS

Disorders	Key Features	Diagnostic Tests
COMMON		
Transient ischemic attack	All symptoms begin at once	Carotid ultrasound
LESS COMMON		
Partial motor seizure with Todd's paresis	Gradual "march" of symptoms in several seconds to a few minutes	EEG

Hemiplegic migraine	Gradual development over several minutes; family history	
Myasthenia gravis	Fatigability, recovery with rest; predilection for ocular and cranial muscles	Tensilon test, repetitive stimulation test
Hystena	Normal reflexes	
Cataplexy	Triggered by emotion; association with other features of narcolepsy; episodes very brief	Sleep study
Sleep paralysis	Narcolepsy; terminated by touch	Sleep study
Drop attacks	Sudden loss of postural tone without loss of consciousness	MRI, magnetic resonance angiography (MRA), x-ray of cervical spine with flexion extension, EEG
RARE		
Periodic Paralysis	Familial	Serum K+
Hypokalemic	Nocturnal occurrence, lasts hours to days	Carbohydrate load after exercise
Hyperkalemic with myotonia	Myotonia induced by exposure to cold	KCl load
Hyperkalemic without myotonia	More frequent; provoked by rest after exercise	
Normokalemic	More severe and prolonged than hyperkalemic	KCl load

but in practice it may be difficult to differentiate these from akinetic seizures or certain varieties of syncope in which the loss of consciousness is so brief that it is difficult for the patient to decide whether he lost consciousness or not. One must probe very carefully to elicit a history of a brief warning to identify syncope or obtain an EEG to rule out an akinetic seizure.

The most interesting and rare disorders causing episodic weakness are the *periodic paralyses*, which are associated with genetic disorders of the potassium and sodium channels. In the great majority of cases these disorders are familial and autosomal dominant. Currently, they are classified according to the level of serum potassium during the attack (see [Table 15-15](#)). During an attack variable weakness of the limbs occurs, and usually the legs are affected before the arms. Then the weakness may progress to affect the trunk muscles, but the diaphragm, sphincters, and cranial and ocular musculature are generally spared. The attack usually evolves over minutes to several hours and may last a few hours if the attack is mild or several days if it is severe. These forms of paralysis can also be distinguished from each other by the factors that provoke an attack of weakness, the duration and severity of the attacks, and the presence of myotonia.

GENERAL MANAGEMENT GOALS

Treatment of Weakness

The occupational therapist and physical therapist can offer help that is of paramount importance in the rehabilitation of the patient with weakness. Strengthening and stretching exercises maintain the weak muscles in maximum tone and keep the joints from developing contractures, which further limit movement. The patient can be trained to use adaptive movements to facilitate function and to use canes and walkers, assessing which ones produce the maximum benefit. Splints and braces can be used to stabilize the joints.

Treatment of Spasticity

A number of options are now available for the treatment of spasticity that interferes with gait or produces uncomfortable spasms such as the flexor spasms typical of spinal cord lesions. It must be emphasized, however, that spasticity may be helpful in compensating for weakness, especially in gait. Overzealous treatment of spasticity may in fact cause a decrement in function, particularly gait, especially when drugs with systemic effects are used. The development of botulinum toxin injections now offers the option of targeting muscles to avoid the deleterious effects of drugs on helpful spasticity.

Drugs with systemic effects are now used primarily in patients who are confined to a wheelchair or bed. These drugs facilitate relaxation of muscles, allowing easier transfers from bed to chair and facilitating hygiene as well as alleviating painful flexor spasms. The drugs used are baclofen, diazepam, and tizanidine.

Injections of botulinum toxin into spastic leg adductors can facilitate nursing care^[45]; injections into the arm muscles can relieve painful spasms.^[46] Injections of botulinum toxin into specific muscles also can be used in ambulatory patients to facilitate normal gait patterns while preserving spasticity in muscles that are necessary for walking. Injections into the gastrocnemius-soleus muscle can facilitate a conversion from toe walking to plantigrade foot placement. Botulinum toxin injections are useful when a

266

dynamic spasticity is present but very little, if any, permanent contracture. If a fixed contracture has developed, it may be necessary to release the contracted tendons surgically. These procedures are most commonly done to release the Achilles, adductor, and hamstring tendons.

HISTORY AND DEFINITIONS

In an attempt to distinguish the class of motor disturbances resulting from lesions of the basal ganglia, Kinnier Wilson coined the term extrapyramidal in his famous 1912 article^[1] describing hepatolenticular degeneration, now known as Wilson's disease. This term was widely adopted thereafter and continues to be used today. The *extrapyramidal system* refers to the basal ganglia with their anatomical connections, and *extrapyramidal disorders* are hypokinetic and hyperkinetic states that ensue from lesions in these anatomical sites. Unfortunately, these terminologies are not absolutely accurate, and extrapyramidal is more a functional concept than a purely anatomical one. There are many other motor pathways that are anatomically extrapyramidal and yet not necessarily related to the basal ganglia, including cerebellar, reticulospinal, vestibulospinal, and rubrospinal pathways. Furthermore, most outflow from the basal ganglia goes to the cerebral cortex via the thalamus, and eventually influences the pyramidal system. In fact, a lesion of the pyramidal system that results in paralysis will eliminate the abnormal movements that originate from a basal gangliar disturbance. Another problem with the term extrapyramidal is the different ways it is used, creating ambiguity and possible misunderstanding. Although Wilson conceived of the term to refer to all types of hypokinetic and hyperkinetic disorders, psychiatrists today usually use the term extrapyramidal side effects to represent only drug-induced parkinsonism.

At present, the term movement disorder largely replaces the older term extrapyramidal disease because it is more descriptive and accurate. Almost all movement disorders stem from disturbances in the basal ganglia or their connections, but there are important exceptions. Myoclonus is one major example of a movement disorder of brain stem, cortical, or spinal cord origin, and conditions like painful legs/moving toes and the so-called jumpy stump syndrome emerge from injuries to the peripheral nervous system.

Movement disorders are clinically characterized by hypokinesia or hyperkinesia, and sometimes both. Hypokinesia technically means decreased amplitude of movement, but it is used also to represent bradykinesia (decreased speed of movement) and akinesia (absence of movement). The important element in hypokinesias is paucity of movement in the absence of weakness or paralysis. Hypokinesia is the hallmark of parkinsonism, a term that broadens hypokinesia when it is associated with tremor, rigidity, or balance problems. Hyperkinesia means excessive movement and generally refers to a wide variety of abnormal *involuntary* movements or dyskinesias. Hyperkinetic voluntary movements, which are common in attention deficit disorders and some psychiatric disorders like mania, are not generally considered as hyperkinesias in this context. The listing of the various hypokinesias and hyperkinesias along with definitions of each are presented in [Table 16-1](#).

TABLE 16-1 -- LIST OF MOVEMENT DISORDERS

HYPOKINESIA (Parkinsonism)	Poverty of movement in speed or amplitude, synonymous with akinesia and bradykinesia
Pure parkinsonism	Akinesia or rest tremor associated with rigidity and/or postural reflex deficits
Parkinsonism-plus	Parkinsonism occurring in association with other signs, such as vertical gaze paresis, hypotension and dysautonomia, apraxias
HYPERKINESIAS	Involuntary movements that occur spontaneously or during activity, synonymous with dyskinesias
Akathitic movements	Stereotypic movements (usually legs) that occur in response to internal restless feelings
Athetosis	Twisting contorsion, a form of dystonia, usually associated with birth injury or cerebrovascular accidents
Ballism	Violent chorea, involving large muscle groups
Chorea	Involuntary rapid and irregular movements
Dystonia	Twisting, sustained posture
Hemifacial spasm	Unilateral facial contractions
Hyperkplexia	Enhanced and pathological startle response
Myoclonus	Shocklike jerks, focal or generalized
Stereotypy	Repetitive movement, simple or complex
Tics	Stereotypy that typically involves face, neck and vocal apparatus more than other body parts
Tremor	To-and-fro oscillation around a joint

Important characteristics used to describe and classify hyperkinesias include regularity, velocity and duration, and anatomical distribution. In terms of regularity, tremors are generally rhythmical to-and-fro movements, and likewise, tics and stereotypies are repetitive movements that are highly predictable in quality, although intermittent in frequency. In contrast, chorea is best characterized by rapid movements flowing irregularly from one body part to another without a predictable pattern. In terms of velocity and duration, rapid movements include myoclonus, chorea, ballism, clonic tics, and some tremors. Slow movements are dystonic or athetotic, showing a sustained contraction of muscles, often with a twisting component. Finally, several hyperkinesias have a propensity to involve certain body regions, for example akathitic movements almost always affect the legs, and tics tend to be most prominent in the face, eyes, and neck. Dystonic movements occur in all body regions but are particularly common in the neck muscles (torticollis).

CLINICAL HISTORY

There are several symptoms that are suggestive of hypokinesia. Patients report difficulty getting out of chairs, especially car seats and sofas; trouble turning over in bed; and an overall reduced speed of activities of daily living. Patients and families might interpret slowness as a sign of old age or early arthritis and not suspect a neurological disorder. Some patients may misinterpret hypokinesia as weakness. Slowness and fatigue, although they are particularly prominent in hypokinesia, can be features of depression, catatonia, or hypothyroidism.

Trouble starting and stopping can also be seen with hypokinesia. Parkinsonian patients may complain of start-hesitation or freezing^[1] during turning, when they are trying to reach a target, or when they are passing through a doorway. Difficulty stopping is the complaint of patients who have festination as part of hypokinesia, and these patients have a tendency to build up speed as they walk, even to the point of running. They cannot stop until coming to a barrier, such as a wall. The mechanism is considered to be a combination of the loss of postural reflexes and the flexed posture, which brings the center of gravity in front of the feet.

Falling is an important historical feature of movement disorders, and all adults who fall without ready explanation should be evaluated neurologically. In parkinsonian disorders, patients eventually develop loss of postural reflexes, which can lead to poor balance and falling. This problem is particularly apparent to patients with freezing. Falling occurs in other movement disorders as well, especially in patients with Huntington's disease, in whom loss of postural reflexes occurs in association with a stuttering, dancing gait. Truncal ataxia due to cerebellar or proprioceptive impairment may cause a wide-based staggering stance and gait, which patients interpret as "walking like a drunk."

Falling is also a common feature of hyperekplexia or excessive startle syndrome. In this disorder, often inherited with a defect in the gene for the glycine receptor,^[2] a sudden noise or threat can trigger the patient to lose muscle tone and then fall. In this disorder, the patient has an exaggerated startle reflex,^[3] which can be measured electrophysiologically. If patients have a delayed reaction to sudden noise or threat, a psychogenic problem should be considered.^[4]

Another cause of falling is positive and negative myoclonus. The positive myoclonic jerk can result in a patient being thrown off balance. Negative myoclonus, especially of the thigh muscles when the patient is standing or walking, produces a bouncing stance, and the sudden inhibitions of the muscles leads to a fall. Posthypoxic myoclonus is the most common cause of this type of negative myoclonus,^[5] and in these cases, patients complain of sudden body jerks that cause them to lose balance control without warning.

Not knowing what to call the various forms of hyperkinesias, patients may use terms such as muscle jerks and shaking movements to describe their disorder. Only the examination can definitively differentiate the type of dyskinesia, but the history can suggest the most likely categories. Sudden muscle jerks are usually myoclonus or tics. Rhythmical movements are usually tremors, rhythmical (segmental) myoclonus, or the repetitive movements of tardive dyskinesia, such as oral-lingual-buccal dyskinesias, body rocking, and marching in place. In dystonia, movements may occur or increase with volitional activity such as writing, pouring liquids, buttoning, and walking. The timing of abnormal movements is important to document, especially with tremors. Parkinsonian tremor occurs during rest while the patient is watching television or lying in bed. Postural tremor, associated with many drugs, hyperthyroidism, or familial tremor, is seen during activity and affects handwriting, and the patient often complains of large, sloppy handwriting. Cerebellar end-point kinetic tremor is seen when patients extend their arms maximally to complete a task,

and the dyssynergia that accompanies the tremor causes extreme sloppiness, spilling, and soiling of clothes.

In most movement disorders, the onset of symptoms is insidious, although frequently patients date them to an incident such as a frightening event or trauma. An exception to this rule is hemiballismus, which often is sudden in onset and related to a cerebrovascular accident.

Sudden movement induces some special forms of dyskinesia. A history of intermittent attacks of dyskinesias that arise just as a person stands up or starts to run immediately raises the suspicion of a paroxysmal dyskinesia,^[6] such as paroxysmal kinesigenic dyskinesia. In addition to sudden movement, startle and hyperventilation can also be the precipitating factor.^[7] Prolonged exercise can induce attacks of hyperkinesia as well and leads to the diagnosis of paroxysmal exertional dyskinesia.^[8] Other types of paroxysmal dyskinesias are more commonly induced by fatigue, stress, or ingestion of caffeine and alcohol. Nonkinesigenic paroxysmal dyskinesias, however, especially those without a family history, are often psychogenic in etiology.^[9] Most psychogenic movement disorders are continual rather than intermittent and can present as any type of hyperkinesia^[10] and even hypokinesia^[11] and gait disorders. There are many historical clues to suspect the psychogenic etiology of a movement disorder,^[12] including their frequent distractibility, inconsistency of signs, and abrupt, strokelike onset.^[12]

Medication exposure requires a special place in the clinical history of a movement disorder. The most important drugs that induce movement disorders are those that are dopamine D₂-receptor antagonists, the so-called dopamine receptor blocking agents. These drugs can cause acute dystonic reactions, acute akathisia, drug-induced parkinsonism, neuroleptic malignant syndrome, and the tardive dyskinesia syndromes. The last entity presents a wide variety of dyskinesias,^[13] which are characterized by their frequent persistence even after drug withdrawal. Drugs, and certain endocrine compounds such as thyroxine, epinephrine, and insulin that alter noradrenergic tone, can exaggerate physiological tremor. Anticonvulsants can induce chorea, and valproate may even induce hypokinesia. Cocaine can induce chorea,^[14] tics,^[15] and opsoclonus-myoclonus.^[16]

Although movement disorders are primary motor conditions, a number of sensory phenomena can occur. Painful muscle cramps are most often due to neuromuscular disease^[17] but can occur with severe rigidity or stiff-person syndrome.^[18] Dystonia can sometimes be painful, particularly drug-induced forms. Painful foot cramping due to dystonic spasms can be an early sign of parkinsonism.^[19] Also in parkinsonism, pain may be focal in the oral and genital areas^[20] and have a burning quality or numbness and itching. In patients with akathisia, a movement disorder associated with a primary subjective restlessness, patients frequently describe a vague but intense discomfort in their body that is relieved by movement.

In addition to these historical elements, a careful medical and family history is important in evaluating hypokinesia and hyperkinesia. The medical history should include an evaluation of all body systems, including the mind, because dementia, psychosis, depression, and various personality traits like attention deficit disorder and hyperactivity, and obsessive-compulsive disorder can help in diagnosis and co-morbidity analyses. Several primary movement disorders are hereditary, and therefore the creation of a family tree focusing on the type of movement disorder the patient has along with other neurological and psychiatric disorders may prove pivotal to the final neurological diagnosis.

ANATOMY OF THE BASAL GANGLIA

The basal ganglia are a group of subcortical nuclei, most of which are located in proximity to the thalamus and hypothalamus. These regions and their white matter pathways connect to the cortex and indirectly to descending pyramidal and other spinal cord pathways that modulate motor and cognitive programs ([Figs. 16-1](#) and [16-2](#)). There is no dedicated basal ganglia-spinal tract, and the so-called final common pathway for basal ganglia motor function involves the corticospinal pyramidal tract and the lower motor neuron (see [Chapter 15](#)). Although they are highly complex, these anatomical connections have been schematized in block diagrams in order to test specific hypotheses related to hypokinesia and hyperkinesia ([Fig. 16-3](#)). The specific nuclei of primary focus are the caudate nucleus and putamen, collectively known as the striatum; the globus pallidus (both internal and external segments, termed GP_i and GP_e); the subthalamic nucleus; and the substantia nigra (pars compacta and pars reticulata).

Figure 16-1 Transverse section of a human brain with basal ganglia identified. CN = caudate nucleus, P = putamen, GP = globus pallidus, T = thalamus; I_aC = internal capsule anterior limb, I_pC = internal capsule posterior limb.

Figure 16-2 Cross section of a human midbrain with the black band of dark melanin-rich substantia nigra (SN) and the pyramidal tract that lies anteriorly.

Basal Ganglia Connections

Anatomical discussions of the basal ganglia usually consider structures in afferent and efferent relationship with the striatum. The caudate and putamen complex contains several different neuronal types, the most abundant population being the medium spiny neuron which uses gamma-aminobutyric acid (GABA) as its neurotransmitter. This neuron sends its axonal projection out of the striatum and also has several recurrent axon collaterals that are distributed primarily within its own intrastriatal dendritic field. In addition, the striatum contains numerous large cholinergic interneurons, known as large aspiny neurons, as well as stomatostatin-rich cells that contain nitric oxide synthase for production of the neuromodulator nitric oxide. ^[21]

Cortical afferents to the caudate and putamen are somatotopically organized and excitatory, using glutamate as the neurotransmitter. ^[22] The brain stem input is primarily from the pars compacta substantia nigra, a dopaminergic pathway. The substantia nigra is a melanin-rich structure located dorsal to the pyramidal tracts (crus cerebri) in the midbrain. Efferent pathways from the striatum are largely directed to the internal segment of the globus pallidus and the pars reticulata of the substantia nigra. There are two distinct pathways of primary importance, named conveniently the direct and the indirect pathways. The direct pathway is inhibitory and passes monosynaptically from the striatum to these nuclei. The indirect pathway reaches the same destination but synapses first in the external segment of the globus pallidus and then in the subthalamic nucleus. The direct and indirect pathways balance one another physiologically, because the indirect pathway functions in sum as an excitatory path on the GP_i, with two inhibitions and one excitation (see [Fig. 16-3](#)). Thus, activation of the direct pathway inhibits GP_i neurons, whereas activation of the indirect pathway stimulates GP_i. ^[23]

Efferent pathways directed beyond the basal ganglia to the thalamus and cortex emanate primarily from the GP_i and pars reticulata of the substantia nigra. This influence is a tonic inhibitory one via GABAergic cells that project to the ventral anterior and ventral lateral thalamic nuclei and, to a lesser extent, to other thalamic regions, as well as the brain stem. The various influences on GP_i provide phasic modulation of the tonic inhibition on the thalamus. The final part of this loop involves the thalamocortical projections, which are excitatory, probably use glutamate as the neurotransmitter, and synapse in the motor, supplementary, and premotor cortices. ^[24]

Intrastriatal Structure

Within the striatum, there is a large neuronal matrix compartment, comprising approximately 80% of the striatum, and a smaller compartment interdigitated with the matrix and known as striosomes or patches. Both the matrix and striosomal neurons receive inputs from dopamine cells coming from the pars compacta of the substantia nigra. Both cell types send efferent projections to the GP_e, and these cells all contain enkephalin. In contrast, however, the matrix population also sends efferents to the substantia nigra pars reticulata and the GP_i, whereas the striosomal cells project in large part back to the pars compacta. These projection cells contain substance P and dynorphin. ^[25]

Figure 16-3 Schema of anatomical nuclei and pathways involving the basal ganglia. Black arrows represent excitation, and speckled arrows represent inhibition. Note the two primary pathways that leave the striatum--the "direct" pathway that flows monosynaptically to the G_i and the "indirect" pathway that has intermediate synapses in the G_e and the subthalamic nucleus. G_i = globus pallidus internal segment; G_e = globus pallidus external segment; STN = Subthalamic nucleus; SNr = pars reticularis of the substantia nigra; SNc = pars compacta of the substantia nigra; thal = thalamus.

Additional Brain Stem-Cortical Loops

A series of anatomical loops have been identified that are involved in the genesis of myoclonus, presumably through transmission of aberrant electrical discharges. A cortical loop has been proposed involving diffuse areas of the cortex, but predominantly the sensorimotor area, the pyramidal tract, medial lemniscus, and thalamus, with return fibers to the cortex. Complementing and interacting with the cortical loop is the spino-bulbar-spinal reflex, which primarily involves the brain stem reticular formation. Sensory impulses entering the spinal cord ascend bilaterally within the spinoreticular pathway, project to the nucleus reticularis gigantocellularis of the medial medullary reticular formation, descend within the reticulospinal tract, and eventually terminate on interneurons at various spinal cord levels influencing alpha motor neurons. In several instances of myoclonus, involvement of nuclei and pathways involving the cerebellum has also been identified. Specifically, the network connecting the red nucleus, dentate nucleus, and the inferior olivary nucleus (triangle of Guillain and Mollaret) has been directly implicated as playing a role in rhythmical palatal myoclonus. In other clinical settings, myoclonus can be associated with damage to the dentate nucleus, superior cerebellar peduncles, and the spinocerebellar pathways, with preservation of the red nucleus and olives. Finally, a spino-spino loop with involvement of the flexor reflex afferents has been implicated in the generation of rhythmical myoclonus that occurs in a spinal segmental distribution. In contrast, repetitive, nonrhythmical jerks resulting in flexion at the trunk, hips, knees and neck may be produced by abnormal electrical activity generated within the cord and transmitted via the propriospinal system.

Neurotransmitters

Although neurotransmitters relate to all neuroanatomical discussions, they are of particular interest in relation to the basal ganglia and their function. Much of the basic understanding of neurotransmitters in clinical medicine came from studies of human basal ganglia disorders, and most medical specialists in this area of neurology have a sound foundation in neurochemistry and neuropharmacology. Additional material related to neurotransmitters was reviewed in the discussion of Emotion, Mood, and Thought (see [Chapter 3](#)). A neurotransmitter is an endogenous chemical that relays information from one neuron to another through synaptic release and receptor activation. To qualify as a neurotransmitter, five classic criteria must be demonstrated: (1) presence within neurons, (2) synthetic pathways with identified enzymes, (3) release mechanisms from the neuron into the synapse, (4) metabolic pathways to effect the removal of the chemical, and (5) mimicry of neuronal activity by iatrogenic application of the neurochemical. Few chemicals accepted as neurotransmitters actually fulfill all criteria within the central nervous system.

DOPAMINE

This simple catecholamine is synthesized in four major central nervous system pathways, and the most important and most widely understood involves the nigrostriatal pathway of the basal ganglia. The synthetic pathway for dopamine is tyrosine--1

ardopa--2

The rate-limiting enzyme is tyrosine hydroxylase (enzyme 1), and the second synthesizing step involves aromatic amino acid decarboxylase (enzyme 2). Once dopamine is produced in the nigral cell, it is transported along the axon to the striatal terminals, where it is released from vesicles into the synaptic cleft. There are receptors for dopamine on the striatal cells (postsynaptic receptors) as well as presynaptic or auto-receptors on the nigral axon. Depolarization of the autoreceptor raises the resting potential of the presynaptic neuron and makes the neuron easier to depolarize; on the other hand, the gradient between resting potential and action potential has been reduced, so that the end result is a decreased release of dopamine. This important mechanism provides for self-regulation of dopamine function. Activation of the postsynaptic receptors by dopamine can lead to depolarization or hyperpolarization, depending on the receptor site. An important concept for all neurotransmitters, including dopamine, is that the final result, hyperpolarization or depolarization, is dependent on both the transmitter and its receptor. The concept of an inhibitory transmitter should be abandoned for the more accurate concept of an inhibitory interaction between neurotransmitter and receptor.

Dopamine activity can be increased by four mechanisms: (1) increased synthesis, (2) increased release, (3) prolongation of neurotransmitter activity, and (4) direct receptor stimulation. Synthesis of the neurotransmitter can be increased by giving dopa because it is the product beyond the rate-limiting enzyme and there is ordinarily an abundant amount of aromatic amino acid decarboxylase in the central nervous system. When dopa is combined with a peripherally active decarboxylase inhibitor, more dopa is delivered across the blood-brain barrier and can be used to synthesize central dopamine. Increased release can be effected by drugs such as cocaine, amphetamine, and methylphenidate, all forcing release of presynaptic catecholamines. The normal metabolism of dopamine involves reuptake of dopamine into the presynaptic cell, with subsequent metabolism by two enzymes, monoamine oxidase (MAO) and catechol O-methyltransferase (COMT). Prolongation of dopamine activity can be effected by blocking re-uptake or altering enzyme activity. Amantadine and possibly some tricyclic antidepressant medications operate on the dopaminergic system through blockade of reuptake. MAO inhibitors and COMT inhibitors for human use also increase dopaminergic activity. Finally, direct activation of the dopamine receptors on the striatal cell can be induced by agonists like bromocriptine, pergolide, and other drugs. Importantly, orally administered dopamine itself has no place in altering the central nervous system dopamine levels, because it cannot cross the blood-brain barrier.

Dopamine function can be antagonized by three basic mechanisms: (1) decreased synthesis, (2) decreased release, and (3) blockade of dopamine receptors. Alpha-methyl para-tyrosine inhibits the synthesis of dopamine by blocking the rate-limiting enzyme tyrosine hydroxylase. Because this is also the rate-limiting enzyme for the synthesis of norepinephrine, the use of this drug had widespread effects on the autonomic nervous system. Vesicular packaging

of dopamine for proper release is blocked by reserpine and tetrabenazine, which are very potent dopamine antagonists. However, these drugs are nonspecific and also inhibit vesicular storage of norepinephrine and serotonin. Finally, receptor blockade occurs with phenothiazine neuroleptics or haloperidol. These drugs are relatively specific for the dopaminergic system, but are not specific to any one dopaminergic pathway. Hence, when one tries to block dopamine function in one region, one may also block dopaminergic function in other basal ganglial and nonbasal ganglial systems. Dopaminergic pathways include the nigrostriatal, mesolimbic, mesocortical, and hypothalamic circuit involving prolactin. Many of the side effects of these potent drugs can be explained by these overlap effects.

Dopamine receptors fall into two major categories; those associated with (D₁ group) or independent of (D₂ group) adenylyl cyclase. The D₁ group includes receptor types D₁ and D₅, and the D₂ group includes D₂, D₃, and D₄. In relationship to the striatum and its double dopaminergic input from the substantia nigra, the direct pathway involves the D₁ receptors and the indirect pathway involves D₂ systems.

ACETYLCHOLINE

Acetylcholine is synthesized from dietary choline, and acetyl coenzyme A by the enzyme choline acetyltransferase (CAT). There are two types of cholinergic receptors in basal ganglial structures, nicotinic and muscarinic. The cholinergic interneurons within the striatum are primarily muscarinic, but nicotinic receptors also populate the striatum as well as other basal ganglial nuclei. Because CAT is the rate-limiting enzyme, its function cannot easily be increased. Hence, augmentation of presynaptic acetylcholine has remained largely an unrealized dream for neuropharmacologists. The normal metabolism of acetylcholine takes place within the cholinergic synapse by the extracellular enzyme acetylcholinesterase. The centrally active acetylcholinesterase inhibitor physostigmine increases the available acetylcholine at central cholinergic receptors and increases cholinergic activity transiently. Its use in clinical medicine is limited by its short duration of action, its usual parenteral use, and its peripheral side effects. At present, cholinergic receptor agonists are being developed in order to bypass the presynaptic acetylcholine-synthesizing cells. In regard to antagonism of the cholinergic system, CAT inhibitors have not been developed and would likely be highly toxic. Cholinergic receptor antagonists are widely available for the muscarinic population and have been available since the nineteenth century. Originally called belladonna alkaloids, they block the muscarinic receptors of the pupil as well as the central nervous system and hence were used in the past by women who wanted large pupils as a sign of beauty.

GAMMA-AMINOBUTYRIC ACID

Unlike acetylcholine and dopamine, GABA is a tiny amino acid that serves both as a neurotransmitter and as an intermediate metabolite in the normal function of cells. GABA is synthesized from glutamate, another amino acid neurotransmitter, by way of the vitamin B₆-dependent enzyme, glutamate decarboxylase. The presence of this enzyme has helped investigators in deducing whether GABA is present in a cell as a neurotransmitter or as a metabolite in other cell functions. The metabolism of GABA can proceed by two paths, via GABA transaminase or via the Krebs cycle.

In basal ganglial systems, GABAergic cells have a dense representation in the striatum, co-existing in cells that also contain either substance P or enkephalins. Striatal GABAergic cells send axons to the substantia nigra pars compacta and reticulata, and to the external and internal globus pallidi. The pathways from the external globus pallidus to the subthalamic nucleus and from the internal globus pallidus to the thalamus also use GABA. In all known systems, GABA appears to interact with its receptor systems to inhibit or hyperpolarize.

GLUTAMATE

This amino acid has high depolarization potential in many neuronal populations. Like GABA, it is an intermediate in cellular metabolism, so the presence of glutamate in a cell does not necessarily suggest neurological activity. As a neurotransmitter, however, glutamate functions with its receptors in an excitatory or depolarizing system at primary afferent nerve endings, the granule cells of the cerebellum, the dentate gyrus, and the corticostriatal pathways important to basal ganglial function. The differentiation between glutamate-containing and aspartate-containing neurons is difficult with present technology. Glutamate activates receptors sensitive to either N-methyl-D-aspartate (NMDA), kainate, or quisqualate (non-NMDA).

NOREPINEPHRINE

This catecholamine neurotransmitter has its main cell populations in the hypothalamus, the lateral tegmentum, and the locus ceruleus. It is synthesized from dopamine, and therefore shares the same enzymes, including the rate-limiting tyrosine hydroxylase. Norepinephrine, however, has a unique enzyme associated with its synthesis called dopamine beta-hydroxylase that transforms dopamine into norepinephrine. The presence of this unique enzyme is the primary way that noradrenergic cells are identified in the central nervous system. Norepinephrine is released from vesicles and activates two primary receptor systems, alpha and beta. Like dopamine, norepinephrine is removed from the synapse by active reuptake into the presynaptic cell and then is metabolized by two enzymes, MAO and COMT. The final metabolic product of norepinephrine is 3-methoxy-4-hydroxymandelic acid (vanillylmandelic acid; VMA), although another metabolite, 3-methoxy-4-hydroxyphenylglycol (MHPG), is often followed as the preferred marker of central nervous system norepinephrine metabolism. The noradrenergic system is more fully discussed in [Chapter 3](#).

SEROTONIN

This indolamine neurotransmitter has its main cell bodies in the dorsal raphe nucleus of the brain stem as well as

the spinal cord, hippocampus, and cerebellum. In parallel to dopamine, it is synthesized by a two-step process, first with a rate-limiting enzyme and then a general enzyme. The first step takes tryptophan to 5-hydroxytryptophan (5-HTP) with the rate-limiting enzyme, tryptophan hydroxylase. The second step takes this

intermediate to serotonin (5-hydroxytryptamine, or 5-HT) by aromatic amino acid decarboxylase, which is the same enzyme involved in dopamine synthesis. There are several types of serotonin receptors spread throughout the brain, and they are classified by their location, enzymatic linkage, and propensity for various ligands. Serotonin is metabolized like the catecholamines, by active reuptake into the presynaptic cell and then metabolism by MAO (see also [Chapter 3](#)).

Basal Ganglia Interactions with the Cerebellum

Besides the basal ganglia, the cerebellum also has profound influences on motor function. Major cerebellar outflow paths converge on the ventral anterior and ventral lateral nuclei of the thalamus, and hence, these nuclei serve as a coordination center for the basal ganglia and cerebellar inputs to the cortex. Similar to the basal ganglia, the cerebellum influences the pyramidal system primarily through thalamocortical projections, and when cerebellar lesions occur, patients are poorly coordinated but are not weak. The cerebellar system, however, functions differently from the basal ganglia in that it has its own direct afferent paths from the entire cortex, as well as the spinal cord. The cerebellum appears to be important for rapid corrections of gross motor movements, whereas the basal ganglia affect more complex motor controls. As such, the prototype of a cerebellar lesion is sloppy execution of simple motor tasks but without the superimposition of abnormal involuntary movements (see [Chapter 17](#)).

Anatomical and Physiological Hypotheses for Hypokinesia and Hyperkinesia

Based on these data, models of hypokinetic and hyperkinetic disorders have been proposed and examined in animals as well as in humans. In monkeys treated with the toxin *N*-methyl-4-phenyl-1,2,3,6-tetrahydropyridine, profound hypokinesia develops, and pathologically, there is highly focused damage of the pars compacta substantia nigra ([Fig. 16-4](#)). Physiologically, as predicted by a resultant enhancement of the indirect pathway and a diminished influence of the direct pathway, the degenerated pars compacta and the associated loss of striatal dopamine lead to increases in the neuronal discharge of the subthalamic nucleus and tonic discharges from the GP_i. The resultant enhanced inhibition of the thalamus reduces cortical activation and correlates with reduced volitional movement in these experimental animals. In concert, there appears to be an altered phasic responsiveness by the GP_i to proprioceptive stimuli. Numbers of responding cells increase, and the receptive field becomes less specific, with loss of directional effects and responses from multiple joints. It has

Figure 16-4 Schema of hypokinesia, with reduced input from SNc, enhanced activation of the indirect pathway and reduced function of the direct pathway. Output from the GPi is enhanced with more inhibition at the level of the thalamus and less activation of the cortex. Abbreviations: seeFigure 16-3 .

been suggested that such changes account for rigidity and for altered timing and coordination of volitional movements in hypokinesia. Direct lesioning of the subthalamic nucleus, GP_i, and thalamus can relieve hypokinesia (see [Chapter 34](#)).

The same anatomo-physio-pharmacological model has been applied to hyperkinesia as well, with the disorder, Huntington's disease, serving as the prototype ([Fig. 16-5](#)). In this case, the primary driving aberration involves the indirect striatal pathway with selective loss of the GABA-enkephalin-containing cells projecting from the striatum to the GP_e. Resultant overactivation of GP_e excessively inhibits the subthalamic nucleus; the thalamus is no longer inhibited, with resultant overexcitation of cortical signals

Figure 16-5 Schema of hyperkinesia, diminished activation of the indirect pathway, and enhanced function of the direct pathway. Output from the GPi is decreased with less inhibition at the level of the thalamus and more motor activation of the cortex. Abbreviations: seeFigure 16-3 .

224

and hyperkinesia. Evidence that this model is sound for at least some forms of hyperkinesia includes the known pathological changes in Huntington's disease, the cessation of hyperkinetic drug-induced dyskinesias in Parkinson's disease patients after lesions of the GP_i, and the well-documented induction of ballistic hyperkinesias after destruction of the subthalamic nucleus. However, the large variety of dyskinesias are not explained by this model at the present time.

EXAMINATION OF HYPOKINESIA AND HYPERKINESIA (Table 16-2)

Directed Neurological Examination

In assessing hypokinesia or hyperkinesia, the directed neurological examination aims to categorize the disorder phenomenologically and to detect the activities that maximize abnormal movements. With this information and support from appropriate diagnostic tests (see Part II), the diagnosis of a movement disorder by specific name and etiology can be determined (see [Chapter 34](#)). In assessing hypokinesia or hyperkinesia, three primary testing paradigms are used: (1) rest, (2) maintenance of a static posture, and (3) volitional activity. Tone is determined at rest, with attention to changes with posture or activity. A final task that is requisite to any evaluation of hypokinesia or hyperkinesia is walking, because this activity integrates several functions, and specific patterns of gait dysfunction are particularly helpful in characterizing a movement disorder.

Patient at Rest. The patient needs to be observed sitting quietly in a comfortable position, and occasionally, it is necessary to observe the patient lying supine. In assessing the rest position, be certain that the extremities are fully relaxed and supported so that the patients are not holding a posture. When engaged in conversation, most individuals have spontaneous gestures of their hands, often cross one leg over the other, and smile when chatting. In hypokinetic disorders, there is a paucity of movement,

TABLE 16-2 -- OTOTOXIC MEDICATIONS

Antibiotics
Mainly vestibulotoxic
Gentamicin
Streptomycin
Tobramycin
Mainly cochleotoxic
Vancomycin
Kanamycin
Neomycin
Amikacin
Diuretics (mainly cochleotoxic)
Furosemide
Bumetanide
Ethacrynic acid
Quinine (cochleotoxic)
Aspirin and sodium salicylate (cochleotoxic, reversible)
Chemotherapy (mainly mixed toxicity)
Cis-platinum (mainly cochleotoxic)
Nitrogen mustard
Actinomycin
Bleomycin

including lack of normal gesturing and spontaneous movements. The face is hypomimetic, with lack of expression, and there is reduced rate of blinking. Rest tremor, if present, is elicited when the hands and feet are completely relaxed.

In hyperkinesias, key information is obtained by observing the patient at rest in complete repose without talking. Relaxing these patients and finding the best rest position can be a challenge. It is important to recognize that a sitting position is one of rest for the extremities, but one of activation for the trunk. In dystonia, in which movements are often absent during rest and activate with a maintained posture, the examiner must be particularly vigilant to correctly identify postures that are resting and active. As such, in truncal dystonia, a kyphotic posture may be present when the patient is sitting erect or standing in seeming repose, because the trunk muscles are activated in these positions. To test for resolution or diminution in the rest posture, these patients must lie supine or prone. Likewise, neck hyperkinesias must be studied with great care to achieve a rest position. Cervical dystonia may be prominent with the patient quietly sitting, but in fact, the neck muscles are very active in the sitting posture and the rest position for the neck requires head support, such as the patient resting the back of the head against a wall or high-backed chair.

Many other hyperkinesias are present at rest, such as athetosis, ballism, chorea, moving digits, myokymia, and tics. Patients with akathisia resist sitting quietly because their restlessness increases, and even when instructed to remain still, they persist with movements such as caressing the scalp, crossing and uncrossing the legs, spontaneously standing up, and even moaning. Involuntary vocalizations that occur in tic disorders or gasping choreic sounds may be audible when the patient is sitting comfortably, and voluntary phonic sensory tricks, used by dystonic patients to break sustained contractions of the eyelids, jaw, or pharynx, occur frequently when the patient is sitting quietly.

Importantly, tics are highly influenced by environment, and patients are usually able to suppress their tics at least partially in the presence of the observer. Encouraging them to sit in a restful position in a quiet room, especially in isolation with a video camera running, may permit an observer to appreciate a wide variety of tics, both motor and phonic, that otherwise would not be documented in the neurological examination.

If myoclonus or a heightened startle reflex is suspected, the investigator should suddenly clap the hands or drop a book on the floor to surprise the patient. Such a maneuver should be performed with the patient sitting and not standing, because patients can have both positive jerks and negative myoclonus, the latter associated with loss of postural tone and falling.

Maintenance of a Posture. Postural tremor is maximized when the patient assumes and attempts to maintain a posture. In the case of a patient with hand tremor, there may be no tremor at rest, but when the hands are outstretched, a fine or coarse tremor develops. Patients with myoclonus may extend their arms well and maintain them for several seconds, when suddenly a lightning-like jerk displaces their shoulder or upper arm. These myoclonic jerks may be so brisk as to cause the patient to drop objects or fling them. With postural tremors, during the finger to nose test, shaking will be seen as the patient moves from the finger to the nose, but at each endpoint, the tremor abates and the subject effectively hits the target without dyssynergia. During handwriting, as the hand assumes the writing posture, shaking occurs and a large, shaky signature develops. Dystonic patients also develop tremor often when they are forced to maintain a posture that activates their dystonia. This dystonic tremor is believed to be the patient's own compensatory movement to overcome the dystonia. Therefore the tremor can usually be maximized in the position that opposes the natural dystonic contraction and minimized or even aborted completely in the position of natural dystonic deformity. One of the clinical hallmarks of chorea is termed motor impersistence, and patients are unable to maintain a posture without the superimposition of the random choreic movements. The tongue darts involuntarily back into the mouth when the subject tries to maintain it protruded, and when the subject tries to grip the examiner's hand or finger with steady pressure, there is uncontrolled squeezing and release (milk-maid grip).

Execution of Tasks. Many tasks are interrupted by hypokinesia and hyperkinesia, and the structured neurological examination of the motor system usually includes a series of simple maneuvers of high yield. Finger tapping is slow and cramped in hypokinesia, and sloppy and overridden with additional movements in chorea or cerebellar dyssynergia. The same task may precipitate a spasm of contorted hand posture in a dystonic. Likewise, foot tapping brings out the same features in the

lower extremities. Handwriting is useful because bradykinesia causes a small and cramped parkinsonian script (micrographia); action tremor causes a large, tremulous signature; and dystonia induces irregular script and often the patient will need to adjust the pen several times because of painful spasms or involuntary dystonic movements. The finger-to-nose task helps distinguish postural tremor from kinetic or endpoint tremor, which is usually associated with cerebellar ataxia (see [Chapter 17](#)). In postural tremor, the tremor is seen through the trajectory movement but the patient's finger stabilizes at the endpoint (either the examiner's finger or the patient's nose). The kinetic tremor actually augments at the endpoint and is associated with dysynergia and poor stabilization.

Speech is a particularly valuable task to evaluate, because it allows the examiner to detect dysarthria, hypophonia, and language disorders and also presents an opportunity as a window of intelligence. Talking is a common motor act that induces overflow dystonic movements elsewhere in the body and can bring out action dystonia of the tongue, face, or jaw muscles. In many patients with blepharospasm as a form of dystonia, the forced eyelid closure may be relieved by talking.

Movement disorders of all types can affect the production and clarity of speech. In the hypokinetic disorders, decreased amplitude of speech (hypophonia) and lack of inflection (aprosody) are most common. Hypophonia can become so severe that the voice may be restricted to a bare whisper. Other speech abnormalities can also occur in parkinsonism, such as palilalia. In parkinsonism, palilalia is the repetition of the first syllables of words; in patients

with Tourette's syndrome, palilalia is manifested by a repetition of phrases. Patients with Parkinson's disease can also have transient speech arrests in the middle of talking due to the freezing phenomenon. They can also have tachyphemia, which is very rapid speech with no pausing between syllables; the words run together and the listener cannot easily distinguish them. Myoclonus can interrupt speech. Lingual dystonia results in impaired, indistinct speech because the tongue does not move normally. Some patients with oromandibular dystonia or blepharospasm may make sounds to break the dystonic contractions; these are basically sensory tricks.

In addition to palilalia, patients with Tourette's syndrome may have echolalia (repeating phrases of others) or coprolalia (uttering obscenities or fragments of obscene words), as well as a variety of vocal tics representing words, sounds, coughs, sniffs, or throat clearing. In addition, they may make sudden increased amplitude of their speech, and they can have speech blocks, which are interruptions of the patient's conversation that occur during a sequence of motor tics.

Voice tremor is usually a manifestation of vocal cord tremor and sometimes vocal cord adductor dystonia. Occasionally, voice tremor is the result of pronounced neck tremor. Tardive dyskinesia of respiratory muscles can also produce a lack of smoothness of speech.

Speech apraxia can be seen in apractic syndromes, including corticobasal ganglionic degeneration. Speech is often hesitant in this disorder, as it is in progressive supranuclear palsy.

Movement disorders by themselves do not regularly cause language difficulties unless some other neurological disorder is present, such as dementia. Importantly, although speech is a relevant aspect of disability in hypokinesia and hyperkinesia, the clinician must also consider upper motor neuron, lower motor neuron, and cerebellar disorders in evaluating speech (see [Chapter 6](#)).

Tone. Tone represents the resistance to passive movement of a joint. Unlike spasticity, which is characteristic of upper motor neuron disease (see [Chapter 15](#)), rigidity, the hallmark of hypokinesia, is increased tone of both flexor and extensor muscles. Often, in parkinsonism, there is a cogwheel character to the hypertonicity (cogwheel rigidity). Dystonic patients also have increased tone when the dystonia is active, although the tone in uninvolved groups is generally normal. In chorea, the tone is often reduced (hypotonia) and the excess movements take on a puppet-like quality as they flow from one body part to another. In patients with tics, the tone is normal.

Walking. As discussed in greater detail in [Chapter 18](#), gait integrates numerous neuroanatomical systems, including pyramidal, extrapyramidal, cerebellar, visual, vestibular and cognitive. In hypokinesia, the patient has a hunched, flexed posture, and the arms do not swing well during walking. The steps are small, and often the patient walks on the toes (marche a petits pas) with a propulsive running gait. Alternatively, the patient may fall backward, especially when pivoting. In hyperkinesias, a variety of abnormalities are seen. In chorea, there is a lilting, stuttering, dancelike quality of walking, often accompanied by hypotonic limbs that move too freely with superimposed random choreic hand or arm movements. In dystonia, walking brings out the spasms, so the patient may begin normally, but after several seconds or minutes, develop inversion of the foot, hyperextension of the large toe, and cramps. Tics may abate during walking or occur during pauses. After assessing walking, the clinician must test for postural reflexes by standing behind the patient and giving a brisk pull on the shoulders (pull test). Patients should be warned and instructed to resist this postural threat, but in several movement disorders, they will take several steps backward or even fall. The examiner must be prepared to catch the patient.

Associated Neurological Findings

Cerebrum. Because the basal ganglia circuits include the cortex and because the caudate nucleus is particularly involved with cognition, the cerebral examination can have important contributory findings in patients with hypokinesia or hyperkinesia. Bedside screening tests of dementia and depression are very useful, and an assessment of aphasia and apraxia indicates likely cortical lesions.

Cranial Nerves. Most cranial nerve functions are retained in hypokinesia and hyperkinesia. Ocular saccades can be slowed in Huntington's disease, and vertical conjugate gaze paresis should specifically suggest hypokinetic disorders like progressive supranuclear palsy. The facial nerve (cranial nerve VII) may be affected in patients with hemifacial spasm, and the patient may have a mildly flattened nasolabial fold at rest. Tongue protrusion and movements can reveal bradykinesia as a sign of parkinsonism, tremor as a sign of parkinsonism or other cause of tremor, and macroglossia as a sign of tardive dyskinesia. Independent of speech assessment (see earlier), the palate should be examined for the possibility of palatal myoclonus.

Motor/Reflexes/Cerebellar/Gait. Most of the pertinent motor findings in hypokinesia and hyperkinesia are discussed in the section entitled Directed Neurological Examination. In almost all instances, strength is preserved and deep tendon reflexes are normal.

Sensory System. Although patients may complain of pain or altered sensations in hypokinesia and hyperkinesia, the systematic sensory examination of pain or temperature and position or vibration senses is generally normal. In cases of the hypokinetic disorder, corticobasal ganglionic degeneration, cortical sensory loss and graphanesthesia may occur. In the condition painful legs/moving toes, which often is preceded by peripheral nervous system damage, the sensory examination shows signs suggestive of neuropathy or radiculopathy (see [Chapter 19](#) and [Chapter 20](#)).

Autonomic Nervous System. Several movement disorders are accompanied by dysautonomia, and furthermore, many of the drug treatments for hypokinetic and hyperkinetic disorders affect autonomic nervous function. Orthostatic hypotension in the face of hypokinesia, rigidity, and gait abnormalities suggests multiple system atrophy. In patients with this condition, the normal tachycardia that develops on standing does not regularly occur and patients may actually lose consciousness in the first few minutes on standing (see [Chapter 21](#) and [Chapter 34](#)).

Neurovascular. Most cases of movement disorders do not have a vascular etiology, but abnormal vascular findings

on examination can suggest very specific syndromes. Evidence of small vessel disease suggests systemic lupus erythematosus, a disorder associated with chorea; flushed skin and vascular evidence of hyperviscosity suggests polycythemia, associated with chorea and ballism; and vascular neck disease or evidence of cardiac embolic sources raises the possibility of multifocal strokes that can lead to parkinsonism or hyperkinesias.

Directed General Examination

The general medical examination provides useful diagnostic information in patients with hypokinesia and hyperkinesia. The skin examination in patients with Parkinson's disease shows seborrhea, scaly skin, and often patches of excessive dryness. Increased salivation and drooling are typical. The eyes should be examined in patients with movement disorders to detect the presence of Kayser-Fleischer rings or copper deposits in the cornea (Wilson's disease), and proptosis

and lid-lag suggests hyperthyroidism, which is frequently associated with chorea or postural tremors.

[PreviousNext](#)

EVALUATION GUIDELINES (Table 16-3)

Neuroimaging. Many of the primary neurodegenerative movement disorders, whether hypokinetic or hyperkinetic, show no abnormalities on magnetic resonance imaging (MRI) or computed tomography (CT) scans other than mild to moderate cerebral atrophy. However, in

TABLE 16-3 -- USEFUL STUDIES IN THE EVALUATION OF HYPOKINESIA AND HYPERKINESIA SYNDROMES

Syndrome	Neuroimaging	Electrophysiology	Fluid and Tissue Analysis	Neuropsychological Test
HYPOKINESIA				
Pure parkinsonism	In Parkinson's disease, MR and CT are normal. PET scans of F-dopa can show decreased uptake	Usually not used. Can study tremor with tremorometer	Copper, ceruloplasmin and thyroid	Can detect depression, dementia
Parkinsonism-plus syndromes	In multiple system atrophy putamen can have hyperdensity in T2-weighted images. SPECT scans can show decreased activity in frontal parietal lobe	Rectal EMG may be useful in multiple system atrophy	In multiple system atrophy catecholamines can be studied dementia patterns	Can detect evidence of dyspraxia, aphasia, cortical or subcortical
HYPERKINESIA				
Postural tremor	Normal	Tremor can be studied with tremorometer	Thyroid, drug levels esp lithium, amphetamines and tricyclic antidepressants	Not usually useful
Action-endpoint tremor	May show cerebellar white matter lesions	Evoked potentials may show evidence of widespread white matter disease as in multiple sclerosis	Lithium level. CSF can be studied for multiple sclerosis	Not usually useful. Pseudobulbar affect can be seen with multiple sclerosis
Chorea, choreoathetosis and balism	In Huntington's disease, there is reduced volume of caudate nucleus Generalized cerebral atrophy	Not usually useful	Acanthocytes by fresh red blood smear, thyroid, drug levels of anticonvulsants Genetic testing for Huntington's disease	Dementia can be detected, along with impulsive behavior and depression
Tics and stereotypies	Normal	Not usually useful	None used	Attention deficit disorder and obsessive compulsive behaviors are frequent problems in tic patients
Dystonia	Normal, can have lesion in putamen in some forms of secondary dystonia	Not usually useful except EMG is often used to guide botulinum toxin injections for therapy	Blood test now can identify gene in idiopathic torsion dystonia	Depression and pain can be important contributors to disability
Akathisia	Normal	Not useful	Not useful	Patients can be psychotic, depressed, and anxious
Myoclonus	Usually normal. In postanoxic myoclonus, there may be diffuse cortical and subcortical damage	EEG helps detect seizures. Also can show diffuse slow wave activity in encephalopathies research centers, back-averaging techniques can study origin of myoclonus	Electrolytes, calcium magnesium, thyroid function for metabolic causes of myoclonus	Dementia, difficulties concentrating

CSF, Cerebrospinal fluid; CT, computed tomography; EMG, electromyography; F-dopa, fluorodopa; MRI, magnetic resonance imaging; PET, positron-emission tomography; SPECT, single photon emission computed tomography.

Huntington's disease, there may be focal atrophy of the caudate nucleus, leading to the appearance of enlarged lateral ventricles, without a comparable increase in size of the temporal horns. Similarly, in multiple system atrophy of the olivopontocerebellar type, localized atrophy of the pons and cerebellum may be prominent. In cases of hypokinesia, when the MRI scan shows increased signal intensity in the putamen on T2-weighted images, local iron deposition and the diagnosis of multiple system atrophy are suggested. MRI and CT scans are particularly useful in disclosing nondegenerative, secondary causes of movement disorders. Cerebrovascular accidents, abscesses, and tumors can be identified, as well as calcium deposition that may suggest parathyroid disease, old hemorrhage, or infections. Hypokinesia caused by carbon monoxide intoxication likewise has a characteristic pattern of cystic degeneration of the globus pallidus. Other neuroimaging techniques may prove useful in particular situations, such as single photon emission computed tomography (SPECT) scanning in corticobasal ganglionic degeneration, in which focal parietal lobe hypoactivity can sometimes be detected. Positron-emission tomography (PET) scanning with the use of selective ligands is used extensively in research centers to monitor patients with hypokinesia and hyperkinesia, but it is not used in a regular clinical setting (see [Chapter 23](#) and [Chapter 34](#)).

Electrophysiology. Electroencephalography (EEG) is useful in studying any intermittent movement disorder, but the recording obtained must include episodes of the patient's movements in order to determine if there is a cortical event that occurs simultaneously. Cases of paroxysmal dyskinesias can sometimes be associated with epileptiform discharges in the contralateral frontal cortical region, and although they may not be detected in a standard EEG, double-density electrodes may provide the phase-reversal indicative of a seizure. In myoclonic disorders, EEG testing is important for documentation of a possible associated cortical event at the time of the myoclonic jerk detected by electromyography (EMG). Sensory evoked potentials and specialized computerized back-averaging techniques can be used with simultaneous EMG to clarify the brain stem or cortical origins. Tremors can be characterized with tremorometer recordings applied over agonist and antagonist muscle groups. In the evaluation of dystonic patients who will receive injections of botulinum toxin (see [Chapter 34](#)), the muscles maximally involved in the spasms can be identified with EMG needle recordings at the time of the injection. A variety of research electrophysiological tests are used for the study of movement disorders and their quantification, but these tests are largely restricted to specialty centers.

Fluid and Tissue Analysis. Few blood and urine tests are of primary interest in the characterization of movement disorders. Basic electrolytes, complete blood count (CBC), liver function tests, and thyroid function tests are standard tests that can be helpful screens. In cases of dystonia or tremor in which the specific condition known as Wilson's disease is considered, 24-hour urine levels of copper excretion and serum ceruloplasmin levels are useful. In specific cases, blood ammonia levels, coagulation profiles, or blood viscosity can be analyzed. In cases of chorea, unusual tics, or dystonic movement, fresh blood smear analysis for acanthocytes can be diagnostic. Childhood aminoacidopathies or other metabolic disorders with hypokinesia or hyperkinesias are diagnosed with specialized tests for enzyme levels or storage compounds found in blood, urine, or various biopsy tissues (see [Chapter 30](#) and [Chapter 31](#)). For a growing number of genetic illnesses with movement disorders that include Huntington's disease, generalized torsion dystonia, and dentatorubral-pallidolulysian atrophy, genetic tests can be diagnostic. In cases of acute onset of disorders, a toxicology screen is essential.

Cerebrospinal Fluid. Whereas alterations in various neurochemical metabolites like homovanillic acid (dopamine) and 5-hydroxyindolacetic acid (serotonin) are of research interest in various movement disorders, their levels are neither diagnostic nor useful specifically in dealing with disease progression.

Neuropsychological Tests. These tests help document cognitive and affective dysfunction that can be useful in determining diagnoses like Huntington's disease and also in guiding potential decisions regarding medical therapy. For example, when movement disorders are associated with depression or dementia, drugs that are associated with side effects like depression, confusion, or psychosis need to be avoided or used in reduced doses. Some movement disorders commonly co-exist with specific types of behavioral patterns, for example Gilles de la Tourette syndrome and attention deficit disorder or obsessive-compulsive disorder, and

neuropsychological evaluations complement the neurological examination in identifying such combinations.

[PreviousNext](#)

CLINICAL SYNDROMES

Hypokinesia Syndromes ([Table 16-4](#))

The term hypokinetic syndrome is synonymous with parkinsonism. In addition to slowness, parkinsonism, as a clinical syndrome of multiple etiologies, is manifested by combinations of several cardinal symptoms and signs ([Table 16-5](#)). At least two of the cardinal features should be present before the syndromic diagnosis of parkinsonism is made, with one of them being hypokinesia or tremor at rest. Parkinsonism can occur in isolation without other neurological signs, or can occur as part of a larger neurological syndrome, termed descriptively Parkinsonism-plus syndromes. The specific diagnosis depends on details of the clinical history, physical examination, and laboratory findings (see [Chapter 34](#)).

PARKINSONISM

Primary parkinsonism, or Parkinson's disease, is the most common type of parkinsonism encountered by the neurologist, but drug-induced parkinsonism is probably far more prevalent. Dopamine receptor antagonists, which are usually prescribed for psychotic behavior but occasionally for gastrointestinal disturbances, are the likely causative agents. In these forms of primary and secondary parkinsonism, the syndrome usually occurs in isolation, without other neurological signs. Hypokinesia is manifested cranially by masked facies (hypomimia), decreased blinking, soft speech with loss of inflection (aprosody), and drooling of saliva

TABLE 16-4 -- SELECTED ETIOLOGIES ASSOCIATED WITH HYPOKINESIA AND HYPERKINESIA SYNDROMES

Etiological Category	Specific Etiologies	Chapter
STRUCTURAL DISORDERS		
Developmental	Hemiatrophy-hemiparkinsonism Hydrocephalus causing gait dysfunction that resembles parkinsonism Pseudodystonia can occur in syringomyelia and Arnold-Chiari malformations	28
Degenerative and compressive	Pseudodystonia from atlantoaxial subluxation	29
HEREDITARY AND DEGENERATIVE DISORDERS		
Storage diseases: lipidoses, glycogenoses and leukodystrophies	Neuronal ceroid-lipofuscinosis especially type 1, 4, 6, GMI-gangliosidosis type III, GM ₂ gangliosidosis, sphingomyelinosis type C	30
Amino/organic acidopathies, mitochondrial enzyme defects and other metabolic errors	Mitochondrial disorders, Leigh's disease, glutaricacidemia, methylmalonic acidemia, homocystinuria, Hartnup's disease, Lesch-Nyhan syndrome	31
Chromosomal abnormalities and neurocutaneous disorders	Fragile X syndrome, Rett syndrome, Down's syndrome, tuberous sclerosis	32
Degenerative dementias	Huntington's disease, Alzheimer's disease, Pick's disease	33
Movement disorders	Parkinson's disease, progressive supranuclear palsy, multiple system atrophy, Huntington's disease, Gilles de la Tourette syndrome, essential myoclonus, dystonia, hemifacial spasms	34
Ataxias	Spinocerebellar ataxias	35
Degenerative motor, sensory and autonomic disorders	ALS-Parkinson-dementia complex of Guam Tremors in Charcot-Marie-Tooth and Roussy-Levy diseases	36
Inherited muscle, neuromuscular and neuronal disorders	Neuromyotonias can appear as pseudodystonias	37
ACQUIRED METABOLIC AND NUTRITIONAL DISORDERS		
Endogenous metabolic disorders	Hyperthyroidism, hypothyroidism, hypoparathyroidism, hyperparathyroidism, diabetes, hypoglycemia, hyperestrogen states including pregnancy	38
Exogenous acquired metabolic disorders of the nervous system: Toxins and illicit drugs	Lead, mercury, manganese, methyl alcohol, toluene, trichlorethane, carbon tetrachloride, carbon monoxide, MPTP, cocaine, amphetamine derivatives	39
Nutritional deficiencies and syndromes associated with alcoholism	Alcohol, thiamine deficiency, B ₁₂ deficiency	40
INFECTIOUS DISORDERS		
Viral infections	Influenza (encephalitis lethargica)	41
Nonviral infections	Abscess, encephalitis, vasculitis (Sydenham's chorea)	42
Transmissible spongiform encephalopathies	Creutzfeldt-Jakob disease, kuru	43
HIV and AIDS	AIDS encephalopathy, opportunistic infections and abscesses	44
Neurovascular disorders	Cerebrovascular accidents, AVMs	45
NEOPLASTIC DISORDERS		
Primary neurological tumors	Primary tumors affecting basal ganglia or white matter connecting pathways	46
Metastatic neoplasms and paraneoplastic syndromes	Metastatic tumors affecting basal ganglia or white matter connecting pathways. Stiff-person syndrome as perineoplastic syndrome	47
DEMYELINATING DISORDERS		
Demyelinating disorders of the central nervous system	Multiple sclerosis (especially paroxysmal dyskinesias and cerebellar tremor)	48
Demyelinating disorders of the peripheral nervous system	Distal chorea can develop in patients with peripheral neuropathy	49
AUTOIMMUNE AND INFLAMMATORY DISORDERS	Sydenham's chorea, systemic lupus erythematosus, chorea, stiff-person syndrome	50
TRAUMATIC DISORDERS	Dystonia, pugilist encephalopathy causing parkinsonism-plus, stump dyskinesia, painful legs/moving toes	51
EPILEPSY	Epilepsia-related paroxysmal dyskinesias. Tremor can be a sign of epilepsia partialis continua. Myoclonus can be part of the myoclonic epilepsias.	52
SLEEP DISORDERS	REM-behavioral disorder, restless legs	54
DRUG-INDUCED AND IATROGENIC NEUROLOGICAL DISORDERS	Anticonvulsants, lithium, tricyclic antidepressants, phenothiazine antipsychotics, narcotics, methotrexate, metoclopramide, oral contraceptive	55

AIDS, Acquired immunodeficiency syndrome; ALS, amyotrophic lateral sclerosis; AVM, arteriovenous malformation; HIV, human immunodeficiency virus; MPTP, 1-methyl-4-phenyl-1,2,3,6 tetrahydropyridine.

due to decreased spontaneous swallowing. In the arms, there is slowness in shrugging the shoulder and raising the arm, loss of spontaneous movement such as gesturing, smallness and slowness of handwriting (micrographia), and difficulty with hand dexterity for shaving, brushing teeth, and putting on make-up. In the legs, there is a short-stepped, shuffling gait with slowed foot movements, and in the trunk, there is difficulty arising from a chair, getting out of automobiles, and turning in bed. Bradykinesia thus encompasses a loss of automatic movements as well as

TABLE 16-5 -- CARDINAL FEATURES OF PARKINSONISM

Tremor at rest
Rigidity
Bradykinesia/Hypokinesia
Flexed posture of neck, trunk, and limbs
Loss of postural reflexes
Freezing

slowness in initiating movement on command and reduction in amplitude of the voluntary movement. The latter can be observed as decrementing amplitude with repetitive finger tapping or foot tapping. The ability to carrying out two activities simultaneously is affected, ^[26] and this difficulty may represent bradykinesia as well. ^[27]

Rigidity is another cardinal feature of parkinsonism. Rigidity is usually manifested by a ratchet-like tension in the range of motion, so-called cogwheel rigidity. As the disease advances, the patient begins to assume a flexed posture, particularly of the elbows, knees, thorax, and neck. Eventually, the flexion can become extreme. The patient begins to walk with the arms flexed at the elbows and the forearms placed in front of the body, and with decreased arm swing. With the knees slightly flexed, the patient tends to shuffle the feet, which stay close to the ground and are not lifted up as high as in normals; with time, there is loss of heel strike, which would normally occur when the foot moving forward is placed onto the ground.

Loss of postural reflexes occurs later in the disease. The patient has difficulty righting himself after being pulled off balance. A simple test for the righting reflex is for the examiner to stand behind the patient and give a firm tug on the patient's shoulders toward the examiner, warning the patient in advance that he or she should try to maintain balance by taking a step backward. Normally, a person can recover in one step. A mild loss of postural reflexes can be detected if the patient requires several steps to recover balance. A moderate loss is manifested by a greater degree of retropulsion. With a more severe loss, the patient would fall if not caught by the examiner, who must always be prepared for such a possibility. With a marked loss of postural reflexes, a patient cannot withstand a gentle tug on the shoulders or cannot stand unassisted without falling. In order to avoid having the patient fall to the ground, it is wise to have a wall behind the examiner, particularly if the patient is a large, bulky individual.

A combination of loss of postural reflexes with stooped posture can lead to festination, whereby the patient walks faster and faster, trying to catch up with his or her center of gravity to prevent falling.

The freezing phenomenon ^[28] usually begins with start- hesitation, that is, the feet take short, sticking, shuffling steps before the patient can begin walking. With progression, the feet seem to become glued to the ground when the patient needs to walk through a crowded space (e.g., a revolving door) or when trying to move a fixed distance in a short period of time (e.g., crossing the street at the green light or entering an elevator before the door closes). Often, patients develop destination-freezing, that is, stopping before reaching the final destination. For example, the patient may stop too soon when reaching a chair in which to sit down. With further progression, sudden transient freezing can occur when the patient is walking in an open space or when he perceives an obstacle in his walking path.

When faced with a patient with parkinsonism, the major differential diagnoses include primary Parkinson's disease and drug exposure to agents such as dopamine receptor blockers (antipsychotics, some antiemetic medications, and metoclopramide), dopamine-depleting drugs (alpha-methyl-dopa, reserpine, and tetrabenazine), and some illicit drugs. Cerebrovascular accidents, infections, toxins, and other neurodegenerative diseases usually cause parkinsonism in the context of additional neurological signs (see later).

PARKINSONISM-PLUS SYNDROMES

The same constellation of features can occur in patients who have additional signs of neurodegenerative lesions, and these syndromes are termed parkinsonism-plus. This heterogeneous group of disorders has a large variety of supplementary signs, but some diagnoses have particularly typical ones: supranuclear vertical gaze palsy is typical of progressive supranuclear palsy; apraxias and cortical sensory loss are typical of corticobasal ganglionic degeneration; and dysautonomia, ataxia, and endpoint kinetic tremors are typical of multiple system atrophy. There is considerable overlap among these syndromes and primary parkinsonism. In defining a patient with a hypokinetic syndrome, these additional signs must be systematically evaluated in order to differentiate to the maximal degree possible parkinsonism from parkinsonism-plus (see [Chapter 34](#)). Secondary causes such as trauma, cerebrovascular accidents, and infection cause parkinsonism-plus syndromes that lack the particular constellation of signs distinctive of the neurodegenerative disorders.

Hyperkinesia Syndromes (see [Table 16-4](#))

TREMORS

Tremor is an oscillating movement affecting one or more body parts, such as the limbs, neck, tongue, chin, or vocal cords. It is usually rhythmical and regular. Tremor can be due to alternate or simultaneous contractions of agonists and antagonists. The rate, location, amplitude, and constancy varies, depending on the specific type of tremor and its severity. It is helpful to determine whether or not the tremor is present at rest (with the patient sitting or lying in repose), with posture-holding (with the arms extending in front of the body), with action (such as writing), or with intention maneuvers (such as bringing the finger to touch the nose). Etiologies and treatment differ according to these types. Postural tremors are seen in familial tremor, in hyperthyroidism, and with some prescribed medications including lithium carbonate, tricyclic antidepressants, and theophylline. Action and intention tremors are discussed in the chapter on ataxia ([Chapter 35](#)) and other tremors are examined in the chapter on movement disorders ([Chapter 34](#)).

CHOREA, CHOREOATHETOSIS, AND BALLISM

Chorea refers to involuntary, irregular, purposeless, nonrhythmical, abrupt, rapid, unsustained movements that flow from one body part to another. Although many neurologists erroneously label almost all nonrhythmical, rapid involuntary movements as choreic, many in fact are not. Nonchoreic rapid movements can be tics, myoclonus, and dystonia. The prototypical choreic movements are those seen in Huntington's disease, in which the brief and rapid movements are irregular and occur randomly as a function of time.

When choreic movements are infrequent, they appear as isolated, small amplitude, brief movements, somewhat slower than myoclonus but sometimes difficult to distinguish from it. When chorea is more pronounced, the movements occur almost continually, presenting as a pattern of involuntary movements flowing from one site to another on the body.

Random choreic movements can be partially suppressed, and the patient with this type of chorea can often hide some of the movements by incorporating them into semipurposive movements, known as parakinesia. Random chorea is usually accompanied by the inability to maintain a sustained contraction, often medically

termed motor impersistence. A common symptom of motor impersistence is the dropping of objects. Motor impersistence is detected by examining for an inability to keep the tongue protruded and by the presence of milk-maid grips due to an inability to keep the fist in a sustained tight grip.

Athetosis refers to slow, writhing, continuous movements. These movements are more commonly appendicular but can also involve axial musculature, including the neck, the face, and the tongue. When athetosis is not present in certain body parts at rest, it can often be brought out by having the patient carry out voluntary motor activity elsewhere on the body. This phenomenon is known as overflow. For example, speaking can induce increased athetosis in the limbs, neck, trunk, face, and tongue. The speed of these involuntary movements can sometimes be faster and blend with those of chorea, and the term choreoathetosis is used. Sometimes athetosis is associated with sustained contractions, producing abnormal posturing. In this regard, athetosis blends with dystonia.

Athetosis most commonly occurs as a result of injury to the basal ganglia in the neonatal period or during infancy. When athetosis occurs in infants, the movements are slow and twisting; it should be considered a form of dystonia. In adults, athetosis is usually unaccompanied by posturing and its speed approaches that of chorea. This form of choreoathetosis can be considered a form of chorea.

Ballism refers to very large amplitude choreic movements. Because of the speed of choreic movements, these large-amplitude excursions of the limbs are expressed by flinging and flailing movements when they involve proximal musculature. Ballism is most frequently unilateral, and this form is referred to as hemiballism. This disorder is usually the result of a lesion of the contralateral subthalamic nucleus or multiple small infarcts (lacunes) in the contralateral striatum. In rare instances, ballism occurs bilaterally (biballism) due to bilateral lacunes in the basal ganglia. Like chorea, ballism sometimes occurs as a result of overdosage of levodopa.

TICS AND STEREOTYPIES

Tics can be divided into abnormal movements (motor tics), abnormal sounds (vocal tics), and combinations of the two. When motor and vocal tics are present and are of childhood onset and chronic duration, the designation of Gilles de la Tourette syndrome is commonly applied. Motor and vocal tics can be simple or complex, and burst forth for brief moments from a background of normal motor activity.^[29] Thus, they are paroxysmal in occurrence unless they are so severe as to be continual. Simple motor tics may be impossible to distinguish from a myoclonic or choreic jerk; basically, they are abrupt, sudden, single, isolated movements. Examples include a shoulder shrug, head jerk, dart of the eyes, and twitch of the nose. Most of the time, simple tics are repetitive, such as a run of eye blinking. When multiple simple tics occur in a sequence that is repeated over and over, the tics change from simple to complex. It is reasonable to view simple tics as formes frustes of complex tics. Even when tics are simple jerks, more complex forms of tics may also be present, allowing one to establish the diagnosis by associated tics. Tics frequently vary in severity over time and can have remissions and exacerbations.

Complex motor tics are very distinct, consisting of coordinated patterns of sequential movements that can appear in different parts of the body and are not necessarily identical from occurrence to occurrence in the same body part. Examples of complex tics include such acts as touching the nose, touching other people, head shaking with shoulder shrugging, kicking of legs, and jumping. Obscene gesturing (copropraxia) is another example.

Tics are usually preceded by an uncomfortable feeling that is relieved by carrying out the movement. Unless they are very severe, tics can be suppressed voluntarily for various periods of time. But when they are suppressed, inner tension builds up and is only relieved by an increased burst of more tics.

In addition to being as rapid as myoclonic jerks, tics can also be sustained contractions, resembling dystonic movements. The complex sequential pattern of muscular contractions in dystonic tics makes the diagnosis obvious in most cases. Moreover, torsion dystonia is a continual hyperkinesia, whereas tics are paroxysmal bursts of varying duration.

Involuntary ocular movements can be an important feature for differentiation of tics from other dyskinesias. Whether a brief jerk of the eyes or more sustained eye deviation, ocular movements can occur as a manifestation of tics. Very few other dyskinesias involve ocular movements. The exceptions are (1) opsoclonus (dancing eyes), which is a form of myoclonus; (2) ocular myoclonus (rhythmical vertical oscillations at a rate of 2 Hz) that often accompanies palatal myoclonus; and (3) oculogyric spasms (a sustained deviation of the eyes, thus a dystonia) associated with dopamine receptor blocking drugs or as a consequence of encephalitis lethargica.

Vocal tics can range from simple throat-clearing sounds or grunts to verbalizations and the utterance of obscenities

(coprolalia). Sniffing can also be a phonic tic, involving nasal passages rather than the vocal apparatus. Like motor tics, phonic tics can also be divided into simple and complex tics. Throat-clearing and sniffing represent simple phonic tics, whereas barking and verbalizations are considered complex phonic tics.

Involuntary phonations occur in only a few other neurological disorders besides tics. These include the moaning in akathisia and in parkinsonism from levodopa toxicity; the brief sounds in oromandibular dystonia and Huntington's disease; and the sniffing and spitting occasionally encountered in Huntington's disease.

Stereotypy refers to simple or complex movements that repeat themselves continually and identically. There may be long periods of minutes between movements,^[30] or they may be very frequent. When they occur at irregular intervals, stereotypies may not always be easily distinguished from motor tics, compulsions, gestures, and mannerisms. In their classic monograph on tics, Meige and Feindel^[31] distinguished between motor tics and stereotypies by describing tics as acts that are impelling but not impossible to resist, whereas stereotypies, although illogical, are without an irresistible urge. The odd, complex movements seen in patients with schizophrenia, mental retardation, and autism are considered to be those of stereotypy. Involuntary movements that are continuous (uninterrupted) and repeat themselves over and over again unceasingly are a continuous stereotypy. This pattern is the hallmark of abnormal movements in patients with classic tardive dyskinesia due to neuroleptic drugs (see [Chapter 55](#)).

DYSTONIA

Dystonia refers to twisting movements that are sustained at their peak, are frequently repetitive, and often progress to prolonged abnormal postures. Agonist and antagonist muscles contract simultaneously to cause dystonic movements. The speed of the movement varies widely from slow (athetotic dystonia) to shocklike (myoclonic dystonia). When the contractions are very brief, for example, less than a second, they are referred to as dystonic spasms or myoclonic dystonia. When they are sustained for several seconds, they are called dystonic movements. And when they last minutes to hours, they are known as dystonic postures. When they are present for weeks or longer, the postures could lead to permanent fixed contractures.

In primary dystonia, the movements typically occur when the affected body part is carrying out a voluntary action (action dystonia) and are not present when that body part is at rest. With progression of the disorder, dystonic movements can appear at distal sites when other parts of the body are voluntarily moving (overflow), such as occurs also in athetosis; with further progression, dystonic movements become present when the body is at rest. Even at this stage, dystonic movements are usually made more severe with voluntary activity. Whereas idiopathic dystonia often begins as action dystonia and may persist as the kinetic (clonic) form, symptomatic dystonia often begins as fixed postures (tonic form).

When a single body part is affected, the condition is referred to as focal dystonia. Common forms of focal dystonia are spasmodic torticollis (cervical dystonia), blepharospasm (upper facial dystonia), and writer's cramp (hand dystonia). Involvement of two or more contiguous regions of the body is referred to as segmental dystonia. Generalized dystonia indicates involvement of one or both legs, the trunk, and some other part of the body.

Although classic torsion dystonia may appear in the beginning stages only as an action dystonia, it usually progresses to manifest as continual contractions. In contrast to this continual type of classic torsion dystonia, a variant of dystonia also exists in which the movements are sudden in onset and transient, known as paroxysmal dyskinesias. Besides occurring in hereditary forms, dystonia is a component of a number of other neurodegenerative disorders (Wilson's disease, Hallervorden-Spatz disease) and several metabolic disorders. Additionally, perinatal cerebral injury, encephalitis, strokes, tumors, and trauma have been implicated as causes of dystonia (see [Chapter 34](#)). Among other disorders to be differentiated from dystonia are tonic tics (also called dystonic tics), which also appear as sustained contractions.

AKATHISIA

Akathisia (from the Greek, meaning unable to sit still) refers to a feeling of inner restlessness, which is relieved by moving about. The typical akathitic patient, when sitting, may stroke the scalp, cross and uncross the legs, rock the trunk, squirm in the chair, and get out of the chair often to pace back and forth, and even make noises such as moaning. The characteristic feature is that akathitic movements are complex movements and usually stereotypic; the other major disorders showing complex movements are tics, compulsions, and mannerisms. Carrying out these motor acts brings relief from akathisia. If a specific body part is affected, it may give a sensation of burning or pain, which, again, is relieved by moving that body part. A somewhat common expression of akathisia is the vocalization of continual moaning or groaning. Akathitic movements and vocalizations can be transiently suppressed by the patient if he or she is asked to do so.

The most common cause of akathisia is iatrogenic. It is a frequent complication of drugs that block dopamine receptors, such as the antipsychotic drugs. It can occur when drug therapy is initiated (acute akathisia) or after chronic treatment (tardive akathisia). Acute akathisia is eliminated on withdrawal of the medication. Tardive akathisia is associated with the syndrome of tardive dyskinesia and is usually made worse on sudden discontinuation of the medication. The exact mechanism of akathisia is not known, but heightened dopaminergic activity or supersensitive dopaminergic receptors, possibly in the limbic system, may be involved (see [Chapter 55](#)).

Tardive akathisia commonly accompanies tardive dyskinesia and, like tardive dyskinesia, is aggravated by discontinuing the neuroleptic agent; it is usually relieved by increasing the dose of the offending drug, which masks the movement disorder. When they are associated with tardive dyskinesia, the akathitic movements can be rhythmical, such as body rocking or marching in place. In this situation, it is difficult to be certain whether such rhythmic movements are due to akathisia or tardive dyskinesia.

20

MYOCLONUS

Myoclonus refers to motor jerks that are sudden, brief, shocklike involuntary movements caused by muscular contractions (positive myoclonus) or inhibitions (negative myoclonus). The most common form of negative myoclonus is asterixis, which is commonly seen accompanying various metabolic encephalopathies. In asterixis, the brief flapping of the limbs is due to transient inhibition of the muscles that maintain posture of those extremities.

Myoclonus can appear as irregular jerks, rhythmical jerks (such as palatal myoclonus and ocular myoclonus, with a rate of approximately 2 Hz), or oscillatory jerks that occur in a burst and then fade. Rhythmical myoclonus is typically due to a structural lesion of the brain stem or spinal cord (segmental myoclonus), but not all cases of segmental myoclonus are rhythmical. Myoclonic jerks occurring in different body parts are often synchronized, a feature that may be specific for myoclonus. The jerks can often be triggered by sudden stimuli such as sound, light, visual threat, or movement. Myoclonus has a relationship to seizures in that both seem to be the result of hyperexcitable neurons.

Cortical reflex myoclonus usually presents as a focal myoclonus and is triggered by active or passive muscle movements of the affected body part. It is associated with high-amplitude somatosensory evoked potentials and with cortical spikes observed by computerized back-averaging, which is time-locked to the stimulus. Reticular reflex myoclonus is more often generalized or spreads along the body away from the source in a timed-related sequential fashion.

The fact that rhythmical myoclonic jerks of one body part are synchronized with contractions elsewhere is a strong argument for categorizing such movements as myoclonus and not as tremor. Furthermore, oculopalatal myoclonus persists during sleep. As a general rule, all movement disorders except myoclonus disappear during sleep.

Often, myoclonic jerks appear with the body at rest, but action myoclonus, in which myoclonic jerks appear when the affected body part is in voluntary activity, also occurs. Action or intention myoclonus is more often encountered after cerebral hypoxia and with certain degenerative disorders, such as the Ramsay Hunt syndrome. Usually, action myoclonus is more disabling than rest myoclonus.

HEMIFACIAL SPASMS

Hemifacial spasm, as the name indicates, refers to unilateral facial muscle contractions. Generally, these spasms are continual, although there are periods of quiescence. Often the movements can be brought out by having the patient forcefully contract the facial muscles; then when the patient relaxes, the involuntary movements often appear. The disorder is believed to involve the facial nerve, and sometimes it is due to compression of the nerve by a blood vessel.^[32] As the name implies, hemifacial spasm involves only one side of the face. It usually affects both upper and lower parts of the face, but patients are commonly more concerned about closure of the eyelid than of the contractions of the cheek or at the corner of the mouth. It can be easily distinguished from blepharospasm, because blepharospasm involves the face bilaterally and often the dystonic contractions spread to contiguous structures, such as oromandibular and nuchal muscles. Blepharospasm is rarely due to unilateral dystonia. In such a circumstance, it would be difficult clinically to distinguish it from hemifacial spasm. EMG may be of assistance because hemifacial spasm may be associated with some facial nerve denervation and ephaptic transmission may be detected. The contractions in both hemifacial spasm and blepharospasm are intermittent but tend to be sustained when they appear.

GENERAL MANAGEMENT GOALS

Management of hypokinesia and immobility includes medical and physical therapies. Whereas the specific drug or surgical intervention depends on the etiology and the type of hypokinesia, all forms may benefit from careful attention to proper support tools in the home and walking aids. Sometimes, a visit to the home by a physical or occupational therapist is useful for an assessment of needs. Because freezing episodes can be precipitated by low-lying objects and crowded conditions, many families remove all unnecessary furnishings from the patient's walking area. Visual cues like striped lines on the floor may also help patients with prominent freezing akinesia to overcome the blockage and initiate movement. The patient who falls may need to wear knee, elbow, and hip padding. If the patient is highly immobilized, venous stasis and pulmonary emboli are risks, especially if the patient remains in bed.

The hyperkinetic patient likewise may need protective clothing if he bumps himself from flinging movements. Braces and splints should generally be avoided, because the movements persist and the braced extremity or trunk will be injured. Attention to weight and nutrition is important in hyperkinetic patients because hyperkinetic patients may be hypermetabolic and use unexpectedly high calories and fluids. If swallowing is affected by either hypokinesia or hyperkinesia, attention must be directed to proper nutrition, and some patients with advanced diseases require feeding tubes.

HISTORY AND DEFINITIONS

The most important sign of cerebellar disease is ataxia [Greek, a (negative article) + taxi (order)]. Cerebellar ataxia is defined as lack of accuracy or coordination of movement that is not due to paresis, alteration in tone, loss of postural sense, or the presence of involuntary movements. The classic concepts and terminology of asynergia as the cardinal symptom of cerebellar disease were first introduced by Babinski. In the recent literature the term ataxia has come to overturn asynergia/dyssynergia as the broader term, usually being synonymous with incoordination.

Cerebellar ataxia relates to motor (dys-)functions of the limbs, trunk, eyes, and bulbar musculature. *Ataxia of gait* refers to incoordination of walking that might be so severe that the patient cannot walk (*abasia*). Postural ataxia refers to *ataxia of stance* and *sitting*, and includes *truncal ataxia*. The patient may be unable to sit or stand without support (*astasia*). *Limb ataxia* refers to incoordination of limb movements and ataxia of speech to cerebellar *dysarthria*.

Different terms are commonly used to describe different aspects of *ataxia*. *Dysmetria* refers to disturbance of the trajectory or placement of a body part during active movement, both in range and direction. *Hypometria* refers to a movement undershooting its target, and *hypermetria* indicates a movement in which the limb overshoots its goal. *Bradyteleokinesia* describes terminal slowing before reaching the target. *Decomposition of movement (asynergia or dyssynergia)* refers to errors in the sequence and speed of the component parts of a movement, i.e., a breakdown of a multijoint movement into its constituent parts. Movements previously fluid and accurate become erratic and jerky. *Dysdiadochokinesia* refers to decomposition of alternating or fine repetitive movements. Deficits appear in the rate of alternation as well as the completeness of the sequence.

Cerebellar disease results in *postural* and *limb tremor*. There may be a rhythmic tremor of the body that can evolve into a severe *tibulation*. Limb tremor occurs as a kinetic and, to a lesser extent, static tremor. *Kinetic tremor* occurs as an oscillatory movement when the subject initiates a movement of the limb or during the course of moving the limb. The tremor becomes more prominent as the moving limb approaches a target. It has commonly been described as *intention tremor*, but the term kinetic tremor better describes the clinical appearance. *Static tremor* develops if the patient attempts to maintain a limb in a fixed position. Usually the position can be sustained steadily for several seconds, but then the limbs develop a rhythmical oscillation generated at the proximal limb muscles.

A variety of eye movement abnormalities are seen in cerebellar disease. Gaze-evoked *nystagmus* is a common finding. Other frequent abnormalities are impairment of smooth pursuit and saccadic (*ocular dysmetria*) eye movements, inability to suppress the vestibulo-ocular reflex

(VOR) by fixation, and abnormalities of optokinetic nystagmus.

Hypotonia, *hyporeflexia*, and *asthenia* were described as typical symptoms of a cerebellar lesion by Holmes. They can be seen only in acute lesions. Hypotonia refers to a decrease in the resistance to passive movements of the limbs, associated with *pendular tendon reflexes*, typified by the lower leg swinging back and forth several times after the knee tendon is tapped with the reflex hammer.

CLINICAL HISTORY

A positive family history suggests a form of inherited ataxia. Different ataxic disorders start in infancy, childhood, or adulthood. Patients and relatives should be asked about delayed motor milestones or poor athletic performance at school. The course of the disease might be of acute (over minutes or hours) or subacute (over days or weeks) onset, nonprogressive from birth, and episodic or slowly progressive (over month or years). By definition, congenital ataxias are nonprogressive since birth. ^[4] The acute onset of severe headache in association with ataxia suggests a diagnosis of cerebellar hematoma or ischemia. A recent history of trauma, such as a fall on the back of the head, suggests hematoma or craniocerebral injury. Subacute onset is found in viral cerebellitis, multiple sclerosis, paraneoplastic cerebellar syndromes, posterior fossa tumors or abscesses, and alcoholic cerebellar degeneration. Episodic ataxia in adults might be caused by drug ingestions, multiple sclerosis, transient vertebrobasilar ischemic attacks, foramen magnum compression, intermittent obstruction of the ventricular system, and dominantly inherited periodic ataxia. In children and young adults, a metabolic disorder should be expected. Chronic progressive ataxia suggests an inherited or idiopathic degenerative ataxia.

Patients should be asked if symptoms are worse in the dark. Ataxia largely due to sensory loss or vestibular disease is typically enhanced by lack of visual feedback compared with cerebellar ataxia. Facial droop, vertigo, hearing loss, numbness, or diplopia associated with ataxia suggest a disorder in the brain stem. The history of previous subacute monocular visual loss suggests a diagnosis of multiple sclerosis. Some degenerative ataxias are associated with gradual visual loss. Occipital headache and projectile vomiting in conjunction with ataxia are associated with raised intracranial pressure in the presence of a posterior fossa lesion. Headache and vomiting are commonly worse on coughing, bending, and walking and in the morning. Incontinence associated with dementia and gait ataxia suggests normal pressure hydrocephalus. Postural hypotension and extrapyramidal signs are associated with multiple system atrophy. Skeletal abnormalities like scoliosis and pes cavus, as well as diabetes and cardiac symptoms, are associated with Friedreich's ataxia. Repeated infections are associated with ataxia telangiectasia.

Patients should be asked whether they are receiving antiepileptic (phenytoin, carbamazepine) or cytotoxic drugs (fluorouracil, cytarabine), lithium, or alcohol, and whether they have been exposed to any toxins (heavy metals, solvents). Ataxia might be associated with primary nervous system tumors such as astrocytomas and medulloblastomas and malignant disorders (bronchial and ovarian carcinoma, Hodgkin's disease), infections (varicella, Epstein-Barr virus), or hypothyroidism.

ANATOMY OF COORDINATION (Tables 17-1 and 17-2)

Overview

The cerebellum is located behind and below the cerebral hemispheres, overlying the brain stem. It is separated from the cerebral hemispheres by the tentorium cerebelli, a membranous structure. The cerebellum consists of two large hemispheres and a midline structure, the vermis. Midline structures are involved in the control of motor execution, balance, and eye movements, and the lateral parts of the hemispheres are involved in motor planning. Lesions of the midline structures result in disturbances of stance, gait, and ocular movements, whereas lesions of the cerebellar hemispheres primarily affect limb movements. [1]

Several classifications have been used to subdivide the cerebellum based on anatomical, phylogenetic, and functional (i.e., termination of cerebellar afferents and efferents) findings. [1] Anatomically, the cerebellum is subdivided into three major components, the flocculonodular, anterior, and posterior lobes, the latter two forming the corpus cerebelli. The anterior lobe is separated from the posterior lobe by the primary fissure, and the flocculonodular lobe is separated from the posterior lobe by the posterolateral fissure. The three lobes are subdivided into several lobules. For example, the cerebellar tonsil is the most caudal lobule of the hemispherical part of the posterior lobe (Fig. 17-1). In the past, the lobules carried individual names, which have been replaced by Larsell's numbering system, which consists of Roman numerals in the vermis and the prefix H in the hemispheres.

The terms archicerebellum, paleocerebellum, and neocerebellum originate from phylogenetic and embryological studies. The neocerebellum refers to the youngest and the archicerebellum to the oldest parts of the cerebellum. The neocerebellum corresponds to the cerebellar hemispheres and the middle part of the vermis. The paleocerebellum consists of the vermal parts of the anterior lobes, and the archicerebellum corresponds to the flocculonodular lobe.

The terms vestibulocerebellum, spinocerebellum, and pontocerebellum originate from termination sides of cerebellar afferent projections. These subdivisions match well with the subdivisions based on phylogenetic studies. The flocculonodular lobe (archicerebellum) has been named vestibulocerebellum because of heavily projecting vestibular afferents; the vermis and paravermal parts of the cerebellar hemispheres (paleocerebellum) were called spinocerebellum because of its spinal afferents, and the cerebellar hemispheres (neocerebellum) were called pontocerebellum based on their pontine afferents (see Figs. 17-1 and 17-2 (Figure Not Available)).

On the basis of the efferent projections from the cerebellar cortex to the cerebellar nuclei, Jansen and Brodal, [2] and

TABLE 17-1 -- CEREBELLAR SYSTEMS: ANATOMY AND CLINICAL CORRELATIONS

Origin of Afferent Input	Afferent Cerebellar Peduncle	Projection Area of Cerebellar Cortex (Where Afferents Synapse on Purkinje Cells)	Cerebellar Nucleus (Where Purkinje Cell Axons Terminate)	Efferent Cerebellar Peduncle	Efferent Destination	Function	Syndrome* (Which Results When System Is Diseased)
Vestibular nerve and nuclei	Inferior <i>Restiform body</i>	Flocculo-nodular lobe; Caudal vermis	Fastigial; Direct projections to vestibular nuclei	Inferior	Vestibular nuclei	Balance and eye movements	Truncal ataxia: Cannot sit up without falling over
<i>Vestibulocerebellum</i>		<i>Archicerebellum</i>					
Dorsal spinocerebellar tract	Inferior <i>Restiform body</i>	Anterior lobe (rostral vermis; intermediate cerebellum)	Interposed (emboliform and globose)	Superior (to opposite red nucleus)	Rubralspinal tract	Ongoing execution of movement: Gait	Anterior lobe syndrome: Difficulty walking with little incoordination of other tasks
Ventral spinocerebellar tract	Superior <i>Brachium conjunctum</i>						
<i>Spinocerebellum</i>		<i>Paleocerebellum</i>					
Contralateral hemisphere	Middle <i>Brachium pontis</i>	Cerebellar hemispheres and middle part of vermis	Dentate	Superior (to opposite red nucleus)	Rubral-thalamic tract (going back up to cortex where the afferents originated)	Motor planning: Coordination of arms and legs	Poor limb coordination
<i>Pontocerebellum</i>		<i>Neocerebellum</i>					

*Unilateral lesions of the cerebellum cause ipsilateral limb ataxia because the major output pathway of the cerebellum is crossed (superior cerebellar peduncle) and disturbs the action of the corticospinal and rubrospinal tracts, which are also crossed.

TABLE 17-2 -- CLINICO-ANATOMICAL CORRELATION OF DISORDERS OF COORDINATION

Anatomical Location	Cerebellar Signs/Symptoms	Associated Neurological Findings
ROSTRAL VERMIS	Ataxia of stance and gait Anteroposterior body sway (3 Hz) Romberg's sign Dysarthria Dysmetric saccades	Peripheral neuropathy
CAUDAL VERMIS	Truncal, postural and gait ataxia Omnidirectional body sway (1 Hz) Absence of Romberg's sign Tendency to fall Dysarthria Saccadic slow pursuit Inability to suppress vestibuloocular reflex	Headache Vomiting Change in consciousness

CEREBELLAR HEMISPHERE	Ipsilateral limb ataxia Hypotonia Asynergia Dysdiadochokinesis Kinetic tremor Past-pointing Deviation of gait Dysarthria	Headache Vomiting Change in consciousness
PANCEREBELLUM	Truncal and bilateral limb ataxia Ataxia of gait and stance Dysarthria Oculomotor disturbances	Pyramidal signs Extrapyramidal signs Peripheral neuropathy Cranial neuropathy Dementia
POSTERIOR INFERIOR CEREBELLAR ARTERY	Ipsilateral limb ataxia Kinetic tremor Dysarthria Nystagmus Gait ataxia	Nausea, vomiting Ipsilateral Horner's syndrome, impaired facial pain and temperature sensation Contralateral impaired body pain and temperature sensation
ANTERIOR INFERIOR CEREBELLAR ARTERY	Ipsilateral limb ataxia Nystagmus Dysarthria	Nausea, vomiting Vertigo Ipsilateral Horner's syndrome, deafness, facial paralysis, impaired facial pain and temperature sensation Contralateral impaired body pain and temperature sensation
SUPERIOR CEREBELLAR ARTERY	Ipsilateral limb ataxia Dysarthria	Nausea, vomiting Ipsilateral Homer's syndrome Partial deafness Contralateral loss of facial and body pain and temperature sensation Contralateral hemifacial weakness

later Chambers and Sprague,^[9] ^[10] suggested a subdivision into three longitudinal (eq sagittal) zones: a medial zone (vermis) projecting to the fastigial nucleus, an intermediate (paravermal part of cerebellar hemisphere) zone projecting to the interposed nuclei, and a lateral (lateral part of cerebellar hemisphere) zone projecting to the dentate nucleus. Voogd^[11] showed that the longitudinal subdivision was more detailed by using a special method to stain myelin. He found seven longitudinal zones termed A and B (medial zone), C1-C3 (intermediate zone), D1 and D2 (lateral zone). Hawkes and colleagues^[12] described at least 32 parasagittal cerebellar compartments as defined by using molecular markers, so-called zebrins.

The cerebellum is connected with the brain stem by afferent and efferent fibers passing through three pairs of tracts, called the inferior, middle, and superior cerebellar peduncle (or restiform body, brachium pontis, and brachium conjunctivum). The middle cerebellar peduncle contains only afferent fibers. In the inferior peduncle, most fibers are afferent, whereas in the superior cerebellar peduncle most fibers are efferent.

Cerebellar Afferents

The cerebellar cortex receives afferent input from most parts of the peripheral (proprioceptive, cutaneous, vestibular, and visual, except olfactory) and central nervous system. The afferent fibers consist of mossy fibers, the climbing fibers, and monoaminergic fibers.

The two most important types of excitatory cerebellar afferents, mossy and climbing fibers, have been defined based on the morphology of their terminal fibers. Mossy

* The term "interposed nucleus" refers to the cerebellum in the cat, rabbit, and monkey. The corresponding nuclei in the human cerebellum are called emboliform and globose nucleus.

Figure 17-1 The cerebellar cortex, unfolded into one plane, showing the fields of termination of cerebellar afferent projections (= mossy fiber system): pontocerebellar (open contours), spinocerebellar fibers (dotted areas), and vestibulocerebellar fibers (hatched areas). LOB POST = Posterior lobe; LOB ANT = anterior lobe; lobl simplex = lobulus simplex; lobl semilun sup = superior semilunar lobule; lobl semilun inf = inferior semilunar lobule; lobl grac = gracile lobule; lobl biventer = biventer lobule; tons cbl = cerebellar tonsil; fiss I = primary fissure; fiss postlat = posterolateral fissure; Li = lingula; Ce = central lobe; Cu = culmen; De = declive; Fo = folium vermis; Tu = tuber vermis; Py = pyramis; No = nodulus; Uv = (With permission from Nieuwenhuys R, Voogd J, van Huijzen C: *The Human Central Nervous System. A Synopsis and Atlas. Berlin, Springer, 1988, p 162.*)

fiber terminals are characterized by their mosslike appearance on histological examination, whereas climbing fibers climb in a characteristic way along the cell body and dendrites of the Purkinje cell. Mossy fibers terminate at numerous granular cells in the cerebellar cortex. Climbing fibers directly contact Purkinje cells in an one-to-one relationship. Climbing fibers originate solely from the inferior olive in the brain stem.^[13] Mossy fibers form the major cerebellar input. They originate from different brain stem nuclei (pontine, vestibular, trigeminal and reticular nuclei), deep cerebellar nuclei, and neurons in the spinal cord.^[14]

Some vestibular and spinal cord afferents send fibers more or less directly to the cerebellum. From the trunk and legs, the dorsal and ventral spinocerebellar tract enter the cerebellum through the ipsilateral inferior and contralateral superior cerebellar peduncle, respectively. From the arms and neck, the cuneocerebellar and rostral spinocerebellar tracts enter the cerebellum through the inferior

Figure 17-2 (Figure Not Available) The cerebellum has three functional components based on different inputs; the vestibulocerebellum, the spinocerebellum and the cerebrocerebellum or pontocerebellum, and based on different outputs, a medial zone (vermis) projecting to the fastigial nucleus, an intermediate (paravermal parts of hemispheres) zone projecting to the interposed nucleus and a lateral zone (lateral part of hemisphere) projecting to the dentate nucleus. The main efferents from the flocculonodular lobe project directly to the vestibular n (From Ghez C: *The cerebellum. In Kandel ER, Schwartz JH, Jessell TM (eds.): Principles of neural science, 3rd ed. Norwalk: Appleton & Lange, 1991, Fig. 41-7, p 633.*)

and superior cerebellar peduncles. Many afferent pathways have additional relay stations (pontine nuclei, inferior olives) before they enter the cerebellum. The pontine nuclei represent the most important relay for corticocerebellar pathways. From the pontine nuclei, corticopontine projections enter the cerebellum mainly through the contralateral middle cerebellar peduncle. The inferior olives receive afferents mainly from the spinal cord and also from several other cortical and brain stem areas. From the inferior olive, climbing fibers enter the cerebellum through the contralateral inferior cerebellar peduncle.

The primary destination of afferent fibers is the Purkinje cell located in the Purkinje cell layer of each lobe of the cerebellar cortex.

Cerebellar Nuclei

The cerebellar cortex of the vermis and the intermediate and lateral parts of each hemisphere are connected to different deep cerebellar nuclei. Each half of the cerebellum contains four distinct nuclei. The vermis projects to the fastigial nucleus, the intermediate part of the cerebellar hemisphere to the emboliform and globose nuclei, and the lateral part of the hemisphere to the dentate nucleus (see Figs. 17-2 (Figure Not Available) and [17-3](#)). The fastigial nucleus is located most medially, followed by the emboliform and globose nucleus and, most laterally, the dentate nucleus. The Purkinje cells are the principal projections from the cerebellar cortex to the deep cerebellar nuclei. The cerebellar nuclei transmit the main output of the cerebellum. The efferents of the flocculonodular lobe (archicerebellum) project directly only to the vestibular nuclei in the brain stem, which are functionally analogous to the cerebellar nuclei.

Cerebellar Efferents

The cerebellar nuclei are the principal source of cerebellar efferent fibers. The efferent fibers from the cerebellum are distributed to several parts of the central nervous system (see [Fig. 17-3](#)). Cerebellar output is essentially ipsilateral. Most of the efferents leave the cerebellum via the superior cerebellar peduncle and a few via the inferior cerebellar peduncle. Efferent cerebellar pathways descend to the brain stem and spinal cord, and ascend to the cerebral cortex. Efferents from the flocculonodular lobe project mainly to the vestibular nuclei in the brain stem directly and indirectly via the fastigial nuclei. Efferents from the globose and emboliform nuclei descend in the contralateral superior cerebellar peduncle and ipsilateral inferior peduncle. These fibers end mainly in the reticular formation and the vestibular nuclei in the brain stem. Output from the dentate nuclei ascends in the ipsilateral superior peduncle. These fibers end in the contralateral thalamus (ventral lateral thalamic nucleus), the contralateral red nucleus, and some nuclei in the brain stem. The main efferent output from the red nucleus goes to the spinal cord (rubrospinal tract). The main projection from the thalamus goes to motor and premotor cortices. In unilateral cerebellar lesions, symptoms of limb ataxia occur

Figure 17-3 The efferent connections of the cerebellum. 1, Premotor cortex. 2, Motor cortex. 3, Pyramidal tract. 4, Ventral lateral thalamic nucleus. 5, Ventral anterior thalamic nucleus. 6, Griseum centralis mesencephali. 7, Red nucleus (parvocellular part). 8, Red nucleus (magnocellular part). 9, Uncinate cerebellar fasciculus (ascending ramus). 10, Central tegmental tract. 11, Rubrospinal tract. 12, Superior cerebellar peduncle. 13, Vermis. 14, Intermediate part of cerebellar hemisphere. 15, Cerebellar hemisphere. 16, Uncinate cerebellar fasciculus. 17, Fastigial nucleus. 18, Interposed nucleus. 19, Dentate nucleus. 20, Nodulus (flocculonodular lobe). 21, Flocculus (flocculonodular lobe). 22, Vestibular nuclei. 23, Reticular formation. 24, Medial longitudinal fasciculus. (From Nieuwenhuys R, Voogd J, van Huijzen C: *The Human Central Nervous System. A Synopsis and Atlas*. Berlin, Springer, 1988, p 166.)

ipsilaterally because the major parts of both the corticospinal and rubrospinal tract cross within the brain stem (double-crossing). In addition, the dentate nucleus sends projections to cognitive areas of the contralateral frontal cortex. ^[15]

Internal Structure

The cerebellar cortex is a uniform structure. It is divided into three distinct layers, the molecular layer, the Purkinje

cell layer, and the granular layer. The cerebellar cortex contains five types of neurons: (1) the Purkinje, (2) granule, (3) Golgi, (4) stellate, and (5) basket cell. The molecular layer is the outermost layer and contains primarily the axons of the granule cells, termed parallel fibers, as well as dendrites of the Purkinje and Golgi cells and two types of interneurons (stellate and basket cells). The large pear-shaped cell bodies of the Purkinje cells are aligned side by side in a single layer, known as the Purkinje cell layer. The extensive dendritic tree of the Purkinje cell extends into the molecular layer in a single plane. The granular layer is the innermost layer and contains primarily densely packed, small granule cells as well as a few larger interneurons (Golgi cells).

The mossy fiber afferents terminate in the granular cell layer. Mossy fiber contacts with dendrites of the granule and Golgi cell are known as cerebellar glomeruli. The mossy fibers alter the activity of the Purkinje cell via the parallel fibers, which are the axons of the granule cells. Each Purkinje cell receives inputs from numerous granule cells, and each granule cell collects inputs from several mossy fibers. The climbing fibers connect directly with the dendrites of the Purkinje cell. Each Purkinje cell receives input from a single climbing fiber, and one climbing fiber contacts 1 to 10 Purkinje cells.

The Purkinje cell is the only output neuron of the cerebellar cortex. Purkinje cells have an inhibitory action on the cerebellar nuclear neurons. Both mossy and climbing fiber afferents have an excitatory action on the Purkinje cell. The excitatory input is modulated by inhibitory interneurons (stellate and basket cells in the molecular layer, and Golgi cells in the granular layer).

Oscarsson^[16] proposed that the cerebellar cortex consists of numerous structural-functional units with distinct efferent and climbing fiber afferent connections, known as *microzones*.^[17] Ito introduced the concept of *corticonuclear microcomplexes*. He defined a microcomplex as a cortical microzone and an associated group of nuclear cells that regulates a single function of motor control.

Pharmacology of the Cerebellum

Ito discovered that all Purkinje cells are inhibitory and use the inhibitory amino acid gamma-aminobutyric acid (GABA) as their neurotransmitter. Granule cells are excitatory and use the excitatory amino acid glutamate as their neurotransmitter. The inhibitory interneurons (stellate, basket, and Golgi cells) use the inhibitory amino acid GABA as their neurotransmitter. The efferent fibers from the cerebellar nuclei are generally thought to be excitatory, and glutamate is a likely candidate. The neurotransmitter of the excitatory mossy and climbing fibers are thought to include the excitatory amino acids glutamate and aspartate. Monoaminergic fibers originate in different afferent systems and are distributed equally throughout the cerebellum. The origin of most noradrenergic fibers lies within the locus coeruleus, of serotonergic afferents within many dorsal raphe nuclei, and of histaminergic fibers within the hypothalamus. The cerebellum has a low content of identified neuropeptides (for example calcitonin gene-related peptide and corticotropin-releasing factor), which are of unknown functional importance. ^[18]

Vascular Anatomy of the Cerebellum

The blood supply of the cerebellum is provided by the vertebrobasilar arterial system. The three major branches are the posterior inferior cerebellar artery (PICA), the anterior inferior cerebellar artery (AICA), and the superior cerebellar artery (SCA). The PICA usually arises from the vertebral artery, the AICA from the basilar artery, and the SCA from the basilar artery before its bifurcation into the posterior cerebral arteries. Variations in the size and distribution of these vessels are frequent, and all major branches are highly anastomotic. All cerebellar arteries supply cerebellar as well as brain stem structures. Therefore, vascular disorders usually damage the cerebellum and brain stem together.

Branches of the PICA supply the inferior aspect of the cerebellar hemispheres extending up to the primary fissure, the cortex of the inferior vermis, the deep cerebellar nuclei as well as the inferior cerebellar peduncle, the lateral medulla oblongata, and the choroid plexus of the fourth ventricle. Branches of the AICA supply the flocculus and adjacent lobules of the inferior and anterior cerebellum, the inferior and middle cerebellar peduncles as well as the nuclei of cranial nerves VII to IX and XII in the brain stem and the inner ear (the internal auditory artery and the labyrinthine artery). The SCA supplies the superior parts of the cerebellar hemispheres, major parts of the vermis, all deep cerebellar nuclei, and all cerebellar peduncles, as well as the pons ([Fig. 17-4](#)). ^[19]

EXAMINATION OF COORDINATION

Directed Neurological Examination

Clinical signs and symptoms were comprehensively described and summarized by Holmes,^[1] Goldstein,^[20] and later by Gilman and associates^[21] and Harding.^[22]

POSTURE AND GAIT

Evaluation of posture and gait is critical in cerebellar disorders. Ataxia of gait might be the only abnormal sign in certain cases of cerebellar degeneration. Walking capacities are observed during a 10 meter test including a half turn. Patients with cerebellar disorders walk with a wide-based, staggering gait and consequently take a zigzag course, making it seem as if they were intoxicated by alcohol.^[3] Steps are short, unequal in length, and irregular. The legs often are lifted too high and brought down with undue force. The arms do not swing synchronously with the movement of the opposite leg. Gait ataxia might be visible only when the patient walks on tandem, backwards, or without visual feedback. However, cerebellar ataxia may be so severe that the patient cannot walk (abasia). Supporting

Figure 17-4 Vascular anatomy of the cerebellum. (Top: lateral view; bottom: ventral view.) 1, Posterior cerebral artery. 2, Superior cerebellar artery (SCA). 3, Basilar artery. 4, Posterior inferior cerebellar artery (PICA). 5, Anterior spinal artery, vertebral artery. 6, Anterior inferior cerebellar artery (AICA). 7, Posterior spinal artery (Adapted from Ganshirt H: Zerebrale Zirkulationsstörungen. In Hopf HC, Poeck K, Schliack H (eds). Neurologie in Klinik und Praxis. Fig. 9 b and c, p 2.9. Stuttgart, Thieme, 1983.)

a severely ataxic patient, the examination of gait reveals decomposition of truncal and leg movements, with the legs preceding while the trunk remains behind.^[4] Symptoms are more prominent during sudden changes of direction, for example, turning or stopping suddenly, or rising quickly from a chair. A tendency to fall or deviate to one side suggests a unilateral cerebellar lesion on the same side. Patients may compensate by shortening their steps and shuffling, that is, keeping both feet on the ground simultaneously.^[5]

Standing and sitting capacities are observed. The stance usually is on a broad base, with the feet several inches apart. In the mildest form, patients have difficulties standing with their feet together, in tandem position, or on one foot. However, the patient may be unable to sit or stand without support (astasia), with a tendency to fall backward or toward the side of the lesion. There may be a rhythmical tremor of the body, appearing usually as a rocking of the trunk forward and backward, from side to side, or in a rotatory movement that can evolve into a severe titubation. Romberg's sign might be present or absent in cerebellar disorders, depending on the site of the lesion. Lesions of the anterior lobe lead to anteroposterior body sway with a frequency of about 3 Hz. This form of postural tremor is provoked by eye closure (presence of Romberg's sign). Patients rarely fall because the body tremor is opposite in phase in head, trunk, and legs, resulting in a minimal shift of the center of gravity. Lesions of the lower vermis cause omnidirectional postural tremor of head and trunk, with frequency components below 1 Hz. This kind of postural tremor is not enhanced by eye closure (Romberg's sign is not present).^[23]

VOLUNTARY MOTOR ACTS

Upper Limb Ataxia. Limb ataxia is generally more marked in upper limbs than in lower limbs, in complex movements than in simple movements, and in fast movements than in slow movements. Several aspects of upper limb ataxia might be observed using the finger-nose test. Patients are asked to move an arm from an outstretched horizontal position to touch the tip of the nose or to alternatively touch the examiner's finger and the patient's own nose. Visual control is required. Initiation of movement is delayed (Fig. 17-5 (Figure Not Available) A). The arm often first flexes and then swings about till the finger reaches the nose. Thus, the arm movement is decomposed in time into its constituent parts (decomposition of movement). Defective postural stabilization of the limb and trunk might be present during the arm movement, with increased sway of proximal arm muscles and movement of the trunk in opposite direction. The movement path of the finger is erratic and jerky, and the nose is rarely touched at once (dysmetria; see Fig. 17-5 (Figure Not Available) B). Subjects more frequently overshoot the target (hypermetria) and rarely stop the movement too soon (hypometria). Errors in initiation, direction, and range become more prominent when a change of direction is required. The patient is instructed to follow with the finger the abruptly initiated horizontal arm movements of the examiner as fast as possible (finger-chase test). Kinetic cerebellar tremor occurs as an oscillatory movement that becomes more prominent as the moving limb approaches a target (see Fig. 17-5 (Figure Not Available) B). Tremor on action is a prominent symptom in diseases involving the dentate nucleus or superior cerebellar peduncle. Kinetic tremor is greatest when patients use visual cues to guide the movement.^[24] Past-pointing is examined in Barany's pointing test. The patient is asked to hold both arms extended horizontally in front. The examiner's forefinger touches the patient's extended forefinger. The patient is asked to bring the arm downward and up again (or upward and down again) to reach the examiner's finger. After a few practice trials with preserved vision, the patient is asked to close the eyes. In addition of overshooting its target (dysmetria), the forefinger of the affected deviates almost constantly outward, away from the examiner's finger position.^[5]

The ability to execute rapidly alternating movements is tested by raising the forearm vertically and making alternative movements of the hand^[6] or by patting with one hand, rapidly alternating between palm up and palm down. In cerebellar subjects, movements are irregular (dysdiadochokinesis)

Figure 17-5 (Figure Not Available) Typical defects in upper limb ataxia. A, Initiation of movement is delayed. B, Dysmetria (inaccuracy in range and direction) and kinetic tremor. C, Dysdiadochokinesis, an irregular pattern of alternating movements, can be seen in the abnormal position trace (From Ghez C: The cerebellum. In Kandel ER, Schwartz JH, Jessell TM (eds). Principles of neural science, 3rd ed., Fig. 41-16, p 643. Norwalk: Appleton & Lange, 1991; Adapted from Thach WT, Montgomery EB. Motor system. In Peariman AL, Collins RC, eds. Neurobiology of Disease, 3rd ed., pp 168-196. New York: Oxford University Press, 1990.)

and slow (bradydiadochokinesis) (see Fig. 17-5 (Figure Not Available) C). Slowness at the turning points could result from delays in movement initiation or dysmetria, or both, at the end of the movement.

Impaired execution of fine finger movements is tested by bringing each finger of one hand separately in succession to the tip of the thumb. All fingers tend to flex simultaneously, and the ability of the thumb to keep a correct posture is impaired. Investigating a variety of more complex tasks, like buttoning or handling objects, may demonstrate disturbance of activities of everyday life. Prehension involves moving the hand to an object, a coincident shaping of the hand in anticipation of the object, and a finally closing of the fingers to formulate the grasp.^[25] Cerebellar subjects open their fingers excessively wide in anticipation of the object and close their fingers with undue force grasping the object (signe de la prehension). Writing is often affected. Maintaining a low isometric force between thumb and index finger, for example, when holding a pen while writing, is impaired.^[26] The pencil is held incorrectly and is pressed too firmly on the paper. Writing becomes labored and slow. The letters are irregular in size and enlarged (megalographia).

Lower Limb Ataxia. The disturbances of lower limb ataxia are usually less severe compared with disturbances of gait. Several aspects of lower limb ataxia might be observed using the heel-to-shin test. The test is performed in the supine position, and the head is tilted so that visual control is possible. The patient is asked to raise one leg, place that heel on the knee, and then slide the heel down the anterior surface of the leg toward the ankle. On reaching the ankle joint, the leg is again raised in the air to a height of approximately 40 cm, and the action is repeated. Similar to upper limb ataxia, initiation of movement is delayed. The thigh might be bent on the trunk before the knee is adequately flexed, or the knee might flex first (decomposition of movement). The movement path of the heel is erratic and jerky, and the knee is rarely touched at once (dysmetria). Kinetic tremor is specifically observed when the patient holds the heel on the knee for a few seconds before sliding down the anterior tibial surface. Another example of decomposition of trunk and leg movements has been described by Babinski^[7]: In attempting to sit up from the supine position by flexion of the trunk, the heel of the affected side often rises from the bed.

SPEECH

Fluency and clarity of speech are tested by asking the patient to repeat several times a standard phrase, for instance, "A mischievous spectacle in Czechoslovakia." Articulation and the melodic aspects of the speech (dysprosody) are abnormal, whereas comprehension and expression of meanings via words remain intact. Cerebellar speech may be slow and becomes more labored. Signs of cerebellar dysarthria include slurred, monotonous, and irregular speech with increased variability of pitch and loudness and articulatory impreciseness. So-called scanning dysarthria with increased separation of syllables is more typical of combined pyramidal-cerebellar lesions.

OCULOMOTOR SYSTEM

A variety of eye movement abnormalities are seen in cerebellar disease, particularly in midline cerebellar lesions. Not all oculomotor abnormalities have been localized to specific parts of the cerebellum. Gaze-evoked nystagmus is a common finding, with the slow phase of the nystagmus being toward the primary eye position. The subject is asked to look laterally at the finger of the examiner. The movements assessed are mainly horizontal, but they may be oblique, rotatory, or vertical. It may be associated with slow- and fast-phase reversal on return to the primary position (rebound nystagmus). Rebound nystagmus appears to be specific for cerebellar lesions. Downbeat or upbeat

nystagmus and sustained horizontal nystagmus may also be present.

Another frequent abnormality is impairment of smooth pursuit eye movements, which are slower than normal and cause the patient to make catch-up saccades in an attempt to keep the moving target near the fovea (saccadic pursuit or jerkiness of smooth pursuit). The subject is asked to follow the slow lateral finger movement of the examiner. Dysmetria of saccades are examined using the following procedure: The two index fingers of the examiner are placed in each temporal visual field of the patient, whose eyes are in the primary position. The patient is then asked to look laterally at the finger on the right and on the left, and the average overshoot or undershoot is estimated. On attempted fixation, the eyes may overshoot the target and then may oscillate through several cycles until precise fixation is attained (ocular dysmetria). Square wave jerks (Gegenrucken) refer to inappropriate saccades disrupting fixation, which are immediately followed by a corrective saccade.

An inability to suppress the VOR and abnormalities of optokinetic nystagmus are frequently found. The ability to suppress VOR is tested by asking the patient to elevate the arms in front of him and fixate one thumb while rotating slowly the upper body. Normal subjects can maintain fixation.

Ocular flutter occurs when, without any attempt to move the eyes, brief bursts of oscillations of the eyes in neutral position are observed. Opsoclonus is the description given when the eyes conjugately, spontaneously, and continuously oscillate in a variety of directions.

OTHER CEREBELLAR SIGNS

Patients with chronic cerebellar lesions usually have normal muscle tone and normal tendon reflexes. Hypotonia refers to a decrease in the resistance to passive movements of the limbs in acute cerebellar damage, which usually disappears within a few days or weeks. As a result of hypotonia, Holmes¹³ described an increased swinging of the affected limbs in rapid passive movements. Furthermore, when the forearms are held vertically in a patient with an unilateral lesion, the affected wrist flexes more than the unaffected one. Also, if the arms are held outstretched and gently tapped, the affected arm moves in wider excursions. In patients with acute cerebellar lesions due to hypotonia, tendon reflexes have been described as being less brisk, with the involved limb continuing to swing inertly like a pendulum (pendular reflexes).¹⁴

The rebound phenomenon can be used to examine the inability to stop an ongoing movement. Excessive rebound is tested by pulling forcefully on the patient's forearm while the patient flexes the elbow. When the forearm is unexpectedly released, the hand of the affected side flies unchecked to the patient's shoulder (Stewart-Holmes sign).

Associated Neurological Findings

Pure cerebellar syndromes are rare. Cerebellar symptoms are frequently associated with brain stem dysfunction because of the cerebellum's close neighborhood to the brain stem. Vascular disorders frequently damage the cerebellum and brain stem together because all cerebellar arteries supply cerebellar as well as brain stem structures. Degenerative cerebellar disorders are frequently accompanied by pyramidal and extrapyramidal symptoms. Cerebellar symptoms might be mimicked by frontal lobe lesions.

Cerebral. Frontal signs include motor abnormalities, impairment of cognitive function, and changes in personality. There are important anatomical connections between the contralateral frontal lobe and ipsilateral cerebellum. Therefore, frontal lobe disorders might cause cerebellar-like symptoms with walking difficulties and clumsiness. However, frontal lobe tumors commonly start with mental symptoms. Cognitive dysfunction accompanies some degenerative ataxic disorders. Incontinence associated with dementia and gait ataxia suggests normal pressure hydrocephalus.

Cranial Nerves. The history of previous subacute monocular visual loss suggests a diagnosis of multiple sclerosis. Some degenerative ataxias are associated with gradual visual loss due to retinitis pigmentosa. Diplopia, facial numbness, facial droop, vertigo, or hearing loss resulting from associated cranial neuropathies (cranial nerves III, IV, V, VI, VII, and VIII) associated with ataxia suggest a disorder in the brain stem. Tumors of the cerebellopontine angle, such as acoustical neurinomas, are frequently associated with nerve palsies of cranial nerves V, VII, and VIII.

Motor/Reflexes/Gait. A slight loss of muscular power and increased fatigability of muscles may occur with acute cerebellar disorders. However, paresis associated with increased muscular tone, hyperreflexia, and extensor plantar reflexes (Babinski's sign) suggest an additional involvement of upper motor neurons (corticospinal or pyramidal syndrome). Paresis accompanied with atrophy, hypotonia, and loss of tendon reflexes (areflexia) suggests the involvement of the lower motor neuron and is usually associated with polyneuropathy, for example in Friedreich's ataxia. Several demyelinating neuropathies may give rise to prominent tremor and sensory ataxia, which might be confused with cerebellar ataxia, such as the demyelinating type of hereditary motor and sensory neuropathy, chronic inflammatory and paraproteinemic neuropathies, and Refsum's disease. In these cases, ataxia is improved by visual feedback. The Miller-Fisher variant of Guillain-Barre syndrome may present with cerebellar ataxia of subacute onset, usually associated with areflexia, ophthalmoplegia, and facial weakness.

Rigidity, akinesia, and static tremor suggest parkinsonism and are associated with multiple system atrophy. Abnormal involuntary movements might occur in cerebellar disorders. Powerful but brief involuntary movements at the beginning of the movement are due to intention myoclonus, not tremor, and occur in diseases involving the dentate nucleus or the superior cerebellar peduncle. Palatal tremor occurs in lesions of the inferior olive in the brain stem or dentatoolivary pathway. Hemiballism and chorea are associated with basal ganglia disorders.

Sensory. Pure cerebellar lesions do not cause disturbances in sensation. Hemianesthesia involving one side of the body suggests an additional lesion of the contralateral parietal lobe. Crossed sensory disturbances with a loss of pain on one side of the face and on the opposite side of

the body are common in patients with a brain stem lesion. Symmetrical sensory impairment over the feet, legs, and hands associated with reflex loss and various degrees of paresis suggests peripheral neuropathy. Peripheral neuropathies are frequently associated with degenerative cerebellar disorders.

Autonomic Nervous System. Horner's syndrome (miosis, ptosis, and retraction of the eyeball) and ipsilateral dysautonomia (increased skin temperature due to vasomotor paralysis and anhidrosis due to impaired sudomotor function) associated with cerebellar ataxia suggest an additional brain stem lesion. Postural hypotension is associated with multiple system atrophy. Urgency of micturition is common in multiple sclerosis and might be present in degenerative ataxic disorders.

Neurovascular. Fundal examination may disclose diabetic, hypertensive, or atherosclerotic retinal changes. Auscultation of the mastoid may reveal a bruit in a patient with stenosis of a vertebralbasilar artery or vascular malformation. A carotid or subclavian bruit might be heard in a patient with symptomatic atherosclerotic disease of the vertebralbasilar arteries. A reduced radial pulse and blood pressure suggests subclavian stenosis and might be associated with subclavian steal syndrome.

Associated Medical Findings

Skeletal abnormalities like kyphoscoliosis and pes cavus, as well as diabetes and cardiac symptoms, are associated with Friedreich's ataxia. Cold intolerance, dry skin, and hair loss indicate hypothyroidism. Pulmonary and gynecological examination might show signs of bronchial or ovarian carcinoma, respectively. Cervical adenopathy might reveal Hodgkin's disease. Subacute, reversible ataxia associated with pyrexia suggests viral cerebellitis. Repeated bronchopulmonary infections suggest ataxia-telangiectasia. Examination of the cardiovascular system might disclose a structural cardiac lesion or rhythm disturbances, which indicate a possible

cardiac cause of emboli.

EVALUATION GUIDELINES (Table 17-3)

Neuroimaging. Immediate computerized tomography (CT) scanning or magnetic resonance imaging (MRI) has to be performed in the setting of acute and subacute cerebellar ataxia. Posterior fossa lesions (hemorrhage, ischemia, hydrocephalus, neoplasms, abscess, or parasitic infections) carry the risk of increased intracranial pressure and death because of the cerebellar tonsils moving downward and compressing the brain stem within the foramen magnum. Angiography of the vertebrobasilar vascular system should be performed if the diagnosis of an aneurysm, vascular malformation, or basilar artery thrombosis is suspected based on the findings of the CT or MRI scan.

Compared with CT scanning, MRI offers an increased capacity for demonstrating cerebellar (and brain stem) lesions because of a lack of bone artifact. MRI demonstrates cerebellar atrophy as well as spinal and brain stem involvement in degenerative cerebellar disorders. In addition, MRI is much more sensitive to white matter lesions, particularly demyelination. Therefore, MRI should be performed when multiple sclerosis is suspected.

Electrophysiology. Electrophysiological tests are applied to confirm extracerebellar lesions. Nerve conduction studies are performed when lesions of the peripheral nervous system are expected. Evoked potentials show lesions of the visual (visual evoked potentials), auditory (auditory evoked potentials), and somatosensory (somatosensory evoked potentials) systems. Involvement of the corticospinal tract is demonstrated using magnetic evoked potentials.

Fluid and Tissue Analysis. Intermittent ataxia associated with mental retardation and onset in infancy or early childhood suggests a metabolic disorder: for example, urea cycle deficiencies, aminoacidurias, and disorders of pyruvate and lactate metabolism. Screening investigations include blood ammonia, amino acids, urinary amino acids, pyruvate, and lactate.^[6] Investigations of early-onset, chronic progressive ataxia associated with dementia should include blood ammonia, hexosaminidase, arylsulfatase A, galacto-cerebrosidase, amino acids, and bone marrow biopsy.

Metabolic disorders (e.g., lipid, mitochondrial and storage disorders, Refsum's and Wilson's diseases, hypothyroidism) should be excluded in early-onset chronic progressive ataxia and in adult-onset forms of the disorder, which are not dominantly inherited. Lipids, vitamin E, lactate, very long-chain fatty acids, adrenocorticotrophic hormone (in males), phytanic acid, ceruloplasmin, and thyroxine should be analyzed. Alpha-fetoprotein is increased and immunoglobulins are decreased in ataxia-telangiectasia. A muscle biopsy should be performed in cases of suspected mitochondrial myopathy. Poisoning or drug intoxication has to be excluded. Anemia, macrocytosis, and raised gamma-glutamyltranspeptidase suggest alcoholic cerebellar degeneration. In children, neuroblastoma may be associated with paraneoplastic cerebellar degeneration leading to opsoclonus. Urinary catecholamine levels are increased. Diabetes mellitus should be excluded in Friedreich's ataxia. Genetic testing is available for an increasing number of inherited ataxias, particularly for autosomal dominant cerebellar ataxias with onset usually after the age of 20 years.^[27] To date, direct DNA testing is available for spinocerebellar ataxia type 1 (SCA1) and type 3 (SCA3; Machado-Joseph disease), type 6 (SCA6), dentatorubral-pallidoluysian atrophy, and Friedreich's ataxia.

Cerebrospinal Fluid. Lumbar puncture and examination of the cerebrospinal fluid are applied when inflammatory or infectious disorders are expected. Pleocytosis, increased total protein content, and oligoclonal bands are found in patients with multiple sclerosis, viral cerebellitis, and paraneoplastic cerebellar disorders. In addition, serum and cerebrospinal fluid anti-Purkinje cell antibodies (anti-Yo, anti-Hu, and anti-Ri) are useful in the diagnosis of paraneoplastic cerebellar degeneration.^[28]

Neuropsychological Tests. Degenerative forms of ataxia might be associated with dementia. Neuropsychological testing might be useful to confirm and quantify existing cognitive deficits.

Other Tests. Electronystagmography is a useful laboratory tool to confirm and quantify cerebellar oculomotor disorders. Posturography is applied to quantify ataxia of stance and to distinguish spinocerebellar, vestibulocerebellar, and spinal ataxias. Lesions of the anterior lobe lead to

TABLE 17-3 -- USEFUL STUDIES IN THE EVALUATION OF DISORDERS OF COORDINATION

anteroposterior body sway with a frequency of about 3 Hz. Lesions of the lower vermis cause omnidirectional postural tremor of head and trunk with frequency components below 1 Hz. Spinal ataxia leads to predominantly lateral body sway. ^[23]

In subacute-onset ataxia, a thoracic x-ray study and pelvic imaging are required to exclude malignancies (small cell lung cancer, ovarian or breast cancer, or Hodgkin's disease) causing paraneoplastic cerebellar degeneration. Abdominal and thoracic CT scan as well as bronchoscopy might be required. An electrocardiogram should be performed in Friedreich's ataxia, which might be associated with heart disease.

[PreviousNext](#)

CLINICAL SYNDROMES (see Tables 17-3 and 17-4)

Pure cerebellar syndromes are rare. Cerebellar disorders often affect more than one of the functionally different subdivisions of the cerebellum and involve the medulla and pons early either directly or indirectly by pressure or obliteration of vessels. Pressure effects are common in the posterior fossa, where expansion is anatomically limited. There is no difference between the symptoms of ataxia that result from lesions of the cerebellar peduncles and those that result from damage to the cerebellum itself. A remarkable degree of compensation occurs in lesions of the cerebellum, which are particularly marked in children and slowly progressive disorders. On clinical grounds, the cerebellum might be divided into three functional divisions. Disturbances of gait result from lesions in all three divisions, the flocculonodular, the anterior, and posterior lobes of the corpus cerebelli. Ataxia of voluntary movements are disturbances resulting exclusively from lesions of the lateral parts of the posterior lobe.

Truncal, Gait, and Stance Ataxia (Absence of Romberg's Sign)

Lesions of the lower vermis (vestibulocerebellum or archicerebellum; so-called flocculonodular syndrome) mainly

ADCA, autosomal dominant cerebellar ataxia; CNS, central nervous system; GsS, Guillain-Barre syndrome; PNS, peripheral nervous system; SCA, spinocerebellar ataxia.

due to tumors or hemorrhage cause postural ataxia of head and trunk during sitting, standing, and walking. Patients frequently fall already during sitting. The classic example is medulloblastoma, which occurs most often in the cerebellum in children between 5 and 10 years of age. Cerebellar symptoms are first limited to unsteadiness of gait and stance. As a rule, there is no incoordination of the extremities when the patient is lying in bed. Postural sway is omnidirectional and contains frequency components of less than 1 Hz. In patients with such lesions, visual stabilization of posture, as evaluated by comparing sway with eyes closed and sway with eyes open, is impaired (absence of Romberg's sign). Severe postural sway is present with eyes open and is essentially unchanged with eyes closed. Fine coordinated movements of the limbs are relatively preserved. Dysarthria is frequently present, as well as saccadic slow pursuit and an inability to suppress the VOR. Transection of the restiform body gives rise to symptoms that are reminiscent of the flocculonodular syndrome.

Stance and Gait Ataxia (Presence of Romberg's Sign)

Damage to the anterior lobe (spinocerebellum or paleocerebellum) result in ataxia of stance and gait. Patients with this disorder develop a severe disturbance of standing and walking with relatively preserved fine coordinated movements of the upper limbs. Lesions of the spinocerebellar part of the anterior lobe are mainly observed in chronic alcoholics and lead to anteroposterior body sway with a frequency of about 3 Hz. Visual stabilization of posture is preserved and the tremor is provoked by eye closure (presence of Romberg's sign). Patients rarely fall because the body tremor is opposite in phase in head, trunk, and legs, resulting in a minimal shift of the center of gravity. Dysarthria and dysmetric saccades are frequently associated cerebellar signs.

Unilateral Limb Ataxia

Holmes fully described symptoms of the lateral parts of the posterior lobe in his classic studies of injuries of the cerebellum. In unilateral lesions, the symptoms occur on the side of the lesion. Diseases of the cerebellar hemisphere (neocerebellum or pontocerebellum) due to hemorrhage, infarction, or neoplasms are correlated with severe disturbances of limb movements, including hypotonia in acute lesions, asynergia, dysdiadochokinesis, and if the dentate nucleus is involved, kinetic tremor. Occlusion of the SCA is likely to affect the fibers in the brachium conjunctivum with resultant ipsilateral limb ataxia. Past-pointing and deviation of gait to the affected side are associated

symptoms. Unilateral ataxia is present in the homolateral upper and lower extremity.

Truncal and Bilateral Limb Ataxia

Symmetrical involvement of both hemispheres and vermis produces bilateral limb ataxia and ataxia of stance and gait, as happens in most forms of cerebellar degeneration. Dysarthria and oculomotor disturbances are also frequently present. Extracerebellar signs are often associated, such as pyramidal and extrapyramidal signs, ophthalmoplegia, and peripheral neuropathy.

Paroxysmal Ataxia

Paroxysmal ataxia with onset in infancy or early childhood is usually associated with mental retardation. In children, a metabolic disorder should be expected, such as urea cycle deficiencies, aminoacidurias, and disorders of pyruvate and lactate metabolism. Episodic ataxia in adults might be caused by drug ingestion, multiple

sclerosis, transient vertebrobasilar ischemic attack, foramen magnum compression, intermittent obstruction of the ventricular system, and dominantly inherited periodic ataxia.

Autosomal dominant forms of paroxysmal cerebellar ataxia are characterized by attacks of vestibulocerebellar ataxia presenting with ataxia of gait and stance, dysarthria, vertigo, and nystagmus.^[29] In episodic ataxia type 1, attacks last for a few seconds or minutes, and patients present with interictal facial myokymia. In episodic ataxia type 2, attacks last for a few hours to several weeks. In most patients, there are mild neurological signs between attacks, such as gaze-evoked down-and-out nystagmus and mild gait ataxia. Rarely, paroxysmal cerebellar ataxia type 2 is associated with progressing and disabling permanent cerebellar deficits.^[30]

Cerebellar Speech

Hemispherical disorders are associated with cerebellar dysarthria more frequently than are vermal lesions. The paramedian regions of the superior cerebellar hemispheres are most relevant for the development of cerebellar dysarthria.^[31], ^[32] Left hemispherical cerebellar lesions appear to be more frequently associated with cerebellar dysarthria than right hemispherical or vermal lesions.^[3] Cerebellar dysarthria is frequently present in degenerative forms of cerebellar ataxias and multiple sclerosis. Cerebellar hemorrhage, infarcts (in particular of the SCA), tumors, and trauma may all cause cerebellar speech.

Cerebellar Oculomotor Signs

Three principal syndromes of cerebellar oculomotor disorders can be identified: (1) the syndrome of the dorsal vermis and underlying fastigial vermis, (2) the syndrome of the flocculus and paraflocculus, and (3) the syndrome of the nodulus.^[33], ^[34] Lesions of the dorsal vermis and fastigial nucleus cause saccadic dysmetria and mild deficits of smooth pursuit. Lesions of the nodulus are accompanied with prolongation of vestibular responses and periodic alternating nystagmus, which is a spontaneous horizontal nystagmus that changes direction every few minutes. Lesions of the flocculus and paraflocculus cause impaired smooth pursuit; gaze-evoked, rebound, and downbeat nystagmus; impaired optokinetic nystagmus; and disability to adjust the gain of the VOR. Other cerebellar oculomotor signs cannot be localized to specific cerebellar regions at present, such as square-wave jerks, upbeat nystagmus, and pendular oscillations. These three syndromes are frequently found in patients with degenerative forms of cerebellar ataxia. Cerebellar hemorrhage, tumors, and infarcts may all cause cerebellar eye signs by direct involvement of midline cerebellar structures. Medulloblastomas involving the nodulus and uvula are frequently associated with positional nystagmus. Downbeat nystagmus is frequently associated with paraneoplastic cerebellar ataxia.

GENERAL MANAGEMENT GOALS

Acquired ataxias need to be treated according to the primary disorder. However, ataxia is often associated with progressive degenerative disease, and it is rarely possible to influence the underlying cause. Only a few forms of inherited ataxias can be treated effectively, such as episodic ataxias using acetazolamide. In most cases, no pharmacological treatment is known. The pharmacological trials using various drugs--GABA agonists (baclofen, sodium valproate), choline chloride, lecithin, physostigmine, gamma-vinyl gamma-aminobutyric acid, thyrotropin-releasing hormone, and 5-hydroxytryptophan--have been disappointing. Other drugs, like buspirone, amantadine, and a combination of sulfamethoxazole and trimethoprim, are still being investigated in clinical trials. Physical therapy is the most important treatment of disorders of coordination and ataxia. Dyssynergia might be reduced by placing additional weight on an ataxic limb to increase inertia. Genetic testing is available in an increasing number of hereditary cerebellar ataxias. However, genetic counseling has to be carefully approached because hereditary cerebellar ataxias are not treatable. Genetic counseling should agree with the guidelines for predictive and prenatal DNA analysis published by the International Huntington's Association and the World Federation of Neurologists. Drugs such as lithium and phenytoin, which are associated with cerebellar dysfunction, should be avoided. Additional neurological symptoms, like spasticity, and physical signs, like diabetes, heart disease, and skeletal deformity, are treated in a common fashion.

HISTORY AND DEFINITIONS

Walking is a product of three interrelated nervous system functions: locomotion, balance, and adaptation. Locomotion comprises the stereotyped patterns of muscle activation (synergies) of limbs and trunk that produce repetitive stepping. The nervous system must be able both to initiate and arrest stepping and to alter stepping patterns for turns, different speeds, and different support surfaces. Balance or equilibrium synergies include a number of postural responses that enable an individual to arise and remain erect during standing and locomotion. Standing is an active process (static postural response) in which the sway of the body is kept within the limits of the base of support provided by the feet. Anticipatory postural responses are changes in postural muscle groups that precede voluntary movements made to offset disturbances in balance that would result from the voluntary movement. For example, paraspinal and leg muscle activation precedes voluntary movements of the arm in a standing person to protect the person's upright stability. Anticipatory postural responses are feed-forward responses. They anticipate the perturbation of balance caused by the voluntary action. Reactive postural responses are feedback responses. They protect against unexpected external perturbations and are triggered by sensory cues indicating that the body is outside the limits of stability.

Adaptation refers to the adjustment of locomotor and balance synergies to the constraints produced by the environment, the body, and the ongoing voluntary activities. The gait pattern of normal individuals at any point in time depends on the person's perception of the environment, the condition of the body (clothes, shoes, disease), and the individual's personal goals. In addition to locomotor and balance synergies, a secure gait depends on the following: (1) information about the environment and the position of the body in the environment as relayed by proprioceptive, vestibular, and visual pathways; (2) ability to interpret and integrate the afferent information; (3) ability to produce force through the bones, joints, and muscles; (4) ability to modulate force for optimum performance; and (5) ability to select and adapt locomotor and balance synergies to the environmental requirements and the individual's capabilities.

[PreviousNext](#)

CLINICAL HISTORY

Gait and balance difficulties generally present as complaints of slow or unsteady walking and of falls. Questions about the speed of walking, the length of the steps taken, the width between the feet, and any difficulties experienced with initiating walking provide clues to the gait disorder. Additionally, the ability to turn and a tendency to trip or bump into things or appear drunk are important clues. The environment or conditions in which the person finds it difficult to walk also offer clues to the gait pattern and guide the physical examination. The clinician should specifically inquire about difficulties in turning over in bed, getting in or out of a car, and arising from a chair because these can be indicators of imbalance.

Falls require a detailed history because they are unlikely to be observed during the examination. Several recent falls that are clearly remembered by the patient or a family member should be explored in detail. Details of the exact location and activity of the patient when the fall occurred may indicate environmental or patient-related precipitants. Had the patient just arisen from a lying or sitting position, suggesting orthostatic hypotension? Or did the feet "get tangled" while turning around, suggesting incoordination?

Did the patient trip, suggesting weakness of the dorsiflexors of the ankle, increased tone characteristic of spasticity, or the shuffling of parkinsonism? Was there lightheadedness, vertigo, or loss of consciousness, suggesting orthostatic hypotension, a labyrinthine disorder, or syncope? How exactly did the patient fall? Crumpling (breaking at the knees) suggests a loss of consciousness (syncope, seizure) or of strength (transient ischemic attack). Falling backward like a log is particularly common in patients with extrapyramidal disorders. Was falling related in any way to meals, suggesting postprandial hypotension, or to drug intake, suggesting drug-induced hypotension or impairment of attention and coordination?

In other aspects of the history, the physician should probe for evidence of proprioceptive, vestibular, and visual disturbances and for signs of pain or deformity of the bones and joints that could affect gait. Weakness sufficient to disturb balance and gait is generally recognized by the patient. Slowness and clumsiness in other motor activities and dysarthria may offer clues to cerebellar and extrapyramidal disorders. Urinary urgency and incontinence are common in multi-infarct states and normal pressure hydrocephalus. The process of taking the history usually reveals whether the patient's judgment or attention span might contribute to falls.

The mode of onset of gait difficulties gives clues to the disease process producing them. Sudden onset suggests vascular disease; gradual onset suggests a degenerative disorder. The medication history is also very important because some drugs can affect the sensory-motor systems, thereby causing balance and gait disturbances. Examples of such drugs include the benzodiazepines, which affect the vestibular system; phenytoin, which affects the cerebellum; and neuroleptics, which involve the basal ganglia. Falls are associated with sedative-hypnotics, which may affect attention and judgment, and with drugs that produce orthostatic hypotension.

TABLE 18-1 -- CLINICO-ANATOMICAL CORRELATION OF DISORDERS OF GAIT AND BALANCE

Anatomic Location	Gait Abnormality	Associated Findings
Cerebral cortex	Freezing	Dementia
	Disequilibrium	Grasp reflex
	Falls	Hyperreflexia
Brain stem		Urinary urgency and incontinence
	Disequilibrium	Eye movement and pupillary abnormalities
Basal ganglia	Astasia	
	Freezing	Rigidity, tremor
	Hypokinetic gait	Bradykinesia
	Hyperkinetic gait	Chorea and dystonia
Cerebellum	Astasia	
	Ataxia	Dysmetric limbs Dysmetric eye movements
Vestibular system	Ataxia	Nystagmus Difficulty with tandem walking
Spinal cord	Spastic gait	Sensory level/loss
	Sensory ataxia	Increased DTRs Babinski's sign
Peripheral nerve	Foot drop	Reduced or absent DTRs
	Sensory ataxia	Peripheral weakness Peripheral sensory loss
Muscle and neuromuscular junction	Waddle	Hip and shoulder weakness
DTRs, Deep tendon reflexes		

ANATOMY OF GAIT AND BALANCE (Table 18-1)

Normal gait and posture depend on the normal function of various structures along the entire neuroaxis. This includes the cortical, subcortical, and spinal cord regions as well as the final common pathway of motor neurons, the neuromuscular junctions and the muscles they innervate. The anatomy and neurological examination of the motor, sensory, cerebellar, and basal ganglia components of normal gait and posture are addressed in specific chapters. This chapter integrates the function of those regions with the important spinal, subcortical, and cortical structures involved in gait and posture.

Spinal Cord

Locomotor synergies are present in the spinal cord. Spinally transected vertebrates, including humans, can produce coordinated stepping movements without any input from supraspinal neural structures. The spinal networks that produce patterned muscle activation, termed central pattern generators, are distributed throughout the spinal cord. The rhythmical muscle activation that is a part of coordinated stepping can be generated from even a few isolated segments of the hemitranssected spinal cord. The central pattern generator has been deduced to consist of excitatory and inhibitory interneurons using glycine, glutamate, and acetylcholine as neurotransmitters. Interneurons and collaterals connect the ipsilateral and contralateral central pattern generators to produce reciprocal movements of the limbs. Proprioceptive neurons connect different levels to produce coordination between the hind limbs and axial muscles and the arms or front legs. The pattern of central pattern generator activation can determine the speed of

locomotion and the direction of locomotion (forward or backward). The output of the central pattern generator is the motoneuron. Coordinated, sequential activation of the limbs and axial muscles involved in stepping is produced by the rhythmical excitation and inhibition of the motoneurons of various muscles.

Input to central pattern generators includes local sensory input and descending input from the brain stem via the reticulospinal pathways. Locomotion in spinal animals or fictive locomotion (rhythmical firing of motor neurons innervating limbs in the isolated spinal cord in vitro) can be induced by brain stem stimulation, sensory input, and treatment with monoamines (L-dopa and clonidine) in vivo and by treatment with excitatory amino acids in vitro. Spinal locomotion can be modified by sensory input and level of electrical or chemical stimulation. For example, progression from a slow walk to a trot to a gallop can be induced by increasing the speed of the treadmill on which the animal stands or by increasing the amount of electrical excitation of brain stem locomotor regions. In the isolated spinal cord, central pattern generators are adaptable to a limited degree based on peripheral sensory input. The limb that encounters an obstacle is reflexly lifted higher to clear the obstacle. However, the locomotor pattern is stereotyped and does not anticipate environmental constraints on locomotion or the needs of the animal. Nor does the spinal cord have the balance synergies that are essential for successful locomotion. The important point is that the actual programming of the muscle activation required for gait is present at the spinal level. Higher centers initiate gait and adapt it to individual needs. For straightforward walking, the higher centers need not specify the individual muscle activations necessary to produce locomotion but instead activate the central pattern generators. This arrangement does not preclude supraspinal control of individual muscles during locomotion when precise foot placement is necessary.

Brain Stem

The brain stem has three important functions in balance and locomotion: (1) setting the activity of the spinal central pattern generators to determine the initiation and speed of locomotion; (2) setting postural tone; and (3) modulating the force generated by the muscles activated by the central pattern generators.

Control of the spinal cord central pattern generators is exerted by the subthalamic and midbrain locomotor regions and relayed to the spinal cord by the reticulospinal tracts. The subthalamic locomotor region is defined physiologically as an area in the posterior lateral hypothalamus from which locomotion can be evoked by stimulation in the decerebrate animal (an animal whose brain stem has been transected just below the thalamus). The subthalamic locomotor region is not in the subthalamic nucleus but is medial and dorsal to it. This region is not associated with any particular cell group, and stimulation of it may excite axons passing through the area. A cat with an intact thalamus and basal ganglia but with the cortex removed walks continuously in a nondirected manner, termed obstinate progression. This behavior has been interpreted as disinhibition of the subthalamic locomotor region or of the influences that pass through the area. Stimulation of the subthalamic locomotor region in an intact cat induces locomotion and searching behavior.

The midbrain locomotor region is also defined physiologically but appears to overlap at least partially the pedunculopontine nucleus. This fact is important because the pedunculopontine nucleus receives a major input from the basal ganglia and from the sensorimotor and limbic cortex. This area may represent one way in which the cortex and basal ganglia affect the initiation of locomotion. Progressive increases in electrical stimulation of the midbrain locomotor region of decerebrate monkeys induce stepping first in the contralateral limb, then in both limbs, and finally in a gallop. The midbrain locomotor region can also be stimulated by injections of gamma-aminobutyric acid (GABA) antagonists that are thought to disinhibit the midbrain locomotor region from tonic GABAergic input from the basal ganglia. Stimulation of the midbrain locomotor region in the neurologically intact cat induces locomotion that appears to be initiated to avoid a painful or frightening stimulus.

Output for the locomotor regions descends by way of the medullary reticulospinal tract, which arises from the ventral medial reticularis gigantocellularis and magnocellularis nuclei. This tract traverses the ventral medial spinal cord, and lesions of the tract prevent locomotion and impair balance.

The role of the brain stem in postural control is evident by the postural responses that can be elicited in decerebrate animals. Vestibular, neck, and righting reflexes are present in decerebrate animals that have an intact brain stem. Stimulation in the dorsal tegmental fields of the pons causes an intact cat to cease walking and reduces postural tone, so that the cat sits and then lies down. Conversely, more inferior stimulation in the ventral tegmental fields of the pons increases postural tone and induces locomotion, so that a supine cat rises and then begins to walk. These stimulation sites indicate that postural and locomotor responses may be mediated, at least partially, by the same brain stem structures.

Brain stem systems do not simply turn on the spinal central pattern generators, as is done experimentally by electrical stimulation of the locomotor regions. Recordings from reticulospinal neurons that activate the central pattern generators as well as from vestibulospinal and rubrospinal neurons demonstrate that activity in these pathways is phase-locked to the step cycle. This phasic activity is largely abolished if the cerebellum is ablated. The phasic activity in these descending tracts does not determine the frequency of stepping but enhances its force and rhythmicity. The tectospinal tract influences the posture of the head and neck and its orientation to visual targets. This tract arises from the superior colliculus, a structure that receives a major input from the substantia nigra pars reticulata, hence providing another connection between the basal ganglia and the postural and locomotor systems.

Cerebellum

The cerebellum is not the origin of postural or locomotor responses because total ablation of the cerebellum does

not abolish these responses. The cerebellum, however, refines the force and timing of locomotor and postural responses. Thus, the execution of these responses in an animal with cerebellar ablation is uncoordinated and dysmetric. The cerebellum receives information about each step cycle through the spinocerebellar pathways (see Chapter 17). Many Purkinje cells fire in synchrony with various parts of the step cycle. The cerebellum partially exerts its influence on locomotion by affecting the activity of the reticulospinal, vestibulospinal, and rubrospinal pathways, which are phasically active during stepping and contribute to coordinated rhythmic stepping. Rhythmical firing in these descending bulbospinal pathways is largely abolished by cerebellar ablation. The cerebellar projections to the thalamus and thence to the frontal cortex may also affect gait and balance, although this possibility has not been explored.

Basal Ganglia

The basal ganglia may have direct input to the brain stem nuclei controlling posture and balance via the pedunculopontine nucleus (midbrain locomotor region) and the superior colliculus (tectospinal tract). The majority of the basal ganglia output is directed back to the frontal cortex, and this influence is presumably responsible for the hallmarks of disease of the basal ganglia, hypokinesia and hyperkinesia (see Chapter 16). The execution of locomotor and postural responses, like other

movements, may also be hypokinetic (parkinsonian) or hyperkinetic (choreic, dystonic).

Cortex

The cortex is completely unnecessary for routine walking in the cat, as evidenced by the performance of decorticate cats (animals in which the cortex has been removed but the basal ganglia and thalamus are left intact). However, the cat with frontal cortex or medullary pyramid lesions cannot perform stepping that requires precise placement of the feet, for example, walking on the rungs of a horizontal ladder. This indicates that "skilled walking" requires input from the motor cortex. The motor cortex has neurons that fire in phase with stepping and, therefore, like the reticulospinal, vestibulospinal, and rubrospinal systems, it probably facilitates stepping. Stimulation of the medullary pyramid can reset the step cycle. This indicates that the corticospinal tract can affect the central pattern generators and may have a role in initiating and modifying the locomotor pattern produced by the central pattern generators. ^[1] The sensorimotor cortex also has connections to the midbrain locomotor region and may affect the central pattern generators through this link. Stimulation of the motor cortex can induce discrete movements of a limb, preceded by the appropriate anticipatory postural responses, indicating that the cortex has a role in anticipatory postural responses. Lesions of the frontal cortex may also affect anticipatory reflexes. ^[11]

Other anatomical areas are undoubtedly important in balance and locomotion. The areas reviewed here are responsible for the proper mechanical execution of balance and locomotion in a relatively stereotyped fashion. They do not explain the adaptation of gait to the individual's goals, the perception of the environmental dangers to balance and upright position, and the development of appropriate strategies to cope with environmental hazards. It is important to realize that the posture and gait observed in an individual are a product of the more or less hard-wired locomotor and postural responses modified by the individual at conscious and subconscious levels to adapt these responses to his or her needs. Posture and gait patterns are not fixed and stereotyped neurological signs as are deep tendon reflexes.

[Previous](#)[Next](#)

EXAMINATION OF GAIT AND POSTURE

Directed Neurological Examination

In examining a patient with complaints regarding gait and balance, sitting balance is first evaluated. If an inability to sit upright is found, profound imbalance or weakness is suggested. The examiner should check to see whether titubation (rhythmical tremor or shaking of the trunk and head) is present, suggesting cerebellar disease, or whether there is a tendency to lean progressively in one direction, suggesting hemiparesis or basal ganglia disease. To make sitting balance more challenging and to bring out subtle abnormalities, the clinician should ask the subject to sit on the examining table with the arms and legs not touching any support surface.

Next, the ability to arise from a chair should be tested. This maneuver tests the patient's strength and anticipatory postural responses. The physician should check to see whether the patient can arise and if he or she can organize rising appropriately (brings the feet under the body, leans forward, and uses the arms to push). If the patient is unable to rise without pushing himself off the chair, proximal muscle weakness or impaired central recruitment of force is suggested, as in Parkinson's disease.

Standing unaided, which tests static balance, should then be evaluated. The examiner should determine whether the patient can stand without assistance or whether titubation or excessive sway is present, indicating cerebellar disease. The distance between the feet should be noted, because feet placed wide apart suggest problems with lateral stability (seen in patients with cerebellar disease, multi-infarct state, or proprioceptive loss). Furthermore, the presence of any discrepancy between standing with the eyes open and with the eyes closed (Romberg's sign) should be determined because this finding may indicate defective proprioception. Balancing on one foot is a more stringent test of static balance, and all healthy individuals should generally be able to manage this task for 10 seconds.

Finally, the gait should be examined. Gait initiation reveals the integrity of locomotor synergies. Abnormalities that should be sought include delays of seconds (freezing) and delays with a series of small steps (start hesitation) on the initiation of gait. These are common signs of frontal lobe, subcortical white matter, and basal ganglia lesions.

Once gait has started, the examiner should check to see whether the maintenance of stepping is disturbed by passage through narrow spaces, distractions, or turns. Changes in gait speed and stride length are nonspecific indicators of gait and balance disturbances. Speed slows and steps shorten in most disorders of gait and balance or in patients with perceived postural insecurity.^[12] Occasionally, gait is not slowed in proportion to postural instability, for example, in those with progressive supranuclear palsy, indicating difficulties with perception, attention, or judgment. The distance between the feet while walking (gait base) is an indicator of lateral stability. Typically, the base narrows as a patient changes from standing to walking. As with the standing base, a widened base during walking generally indicates sensory, cerebellar, or frontal lobe dysfunction. Head movements during walking may offer a clue to vestibular function. Patients with diminished or absent vestibular function often try to minimize head movements while walking, giving them a stiff appearance. Asking the patient with a vestibular disorder to rotate the head while walking causes the gait to become ataxic.

The cadence of gait is important because it is an indicator of motor coordination. Steps should be regular and symmetrical. In certain disorders, they may be dysmetric, choreic, dystonic, parkinsonian, hemiparetic, or spastic, thereby disturbing the normal free movements of stepping and altering gait cadence. Observation of arm swing can identify a variety of motor function problems. Involuntary movements often appear in the arms during walking, particularly dystonia, chorea, and rest tremor. Unilaterally decreased arm swing is common in early parkinsonism and mild hemiparesis. Decreased arm swing does not always have a neurological explanation because musculoskeletal disorders can induce changes as well.

Turning or pivoting while walking is more posturally demanding than walking straight ahead, and abnormalities may emerge during turning that are inapparent during straight walking. Widening of the base only during turns or taking an extra one or two short steps during turning to maintain balance may be the earliest sign of cerebellar ataxia. "En bloc" turns (in which the head, torso, and legs turn together as a rigid unit rather than in sequence beginning with the head and followed in turn by the shoulders and then the hips and legs) suggest parkinsonism or caution. With more severe imbalance, en bloc turns are associated with slow, small steps, and the patient may freeze during turning in the so-called turn hesitation that is very typical of patients with parkinsonism and frontal lobe gaits.

Tandem walking tests lateral stability and should be observed because it is a sensitive indicator of cerebellar and vestibular dysfunction. Finally, the process of pushing the patient to the side and pulling him backward (with the examiner maintaining a position to keep the patient from falling) tests reactive postural responses. These responses may be deficient in patients with basal ganglia disease or frontal or subcortical lesions.

Associated Neurological Findings

Cerebral. In the mental status examination, the physician may detect abnormalities of cognition and attention that may cause falls owing to a lack of insight or inability to interpret and adapt to the environment. Dementia is common in patients with multi-infarct state and normal pressure hydrocephalus, which may be associated with gait disturbances.

Cranial Nerves. The cranial nerve examination may reveal signs of sensory or motor dysfunction that could affect gait. Decreased visual acuity, visual field deficits, or visual neglect may cause a patient to adopt a cautious gait pattern and may contribute to falls. Likewise, extraocular muscle dysfunction causing diplopia and gaze palsies may distort and reduce visual information, thereby causing falls. Selective paresis of voluntary downgaze is a common sign in patients with progressive supranuclear palsy, a disorder that often presents with unexplained falls. Nystagmus is a marker of vestibular and brain stem pathology that may disturb balance synergies. Dysarthria is a sensitive indicator of cerebellar, basal ganglia, and corticobulbar dysfunction.

Motor/Reflexes/Cerebellar/Gait. In the motor examination, the clinician should search for weakness, particularly in the legs and hips, that may affect walking. Changes in tone may indicate corticospinal tract involvement (spasticity), parkinsonism (rigidity), and gegenhalten or paratonia (diffuse cortical dysfunction with dementia). Involuntary movements may suggest basal ganglia disease (chorea, dystonia, and rest tremor) or other cortical disease (myoclonus).

Coordination is often abnormal in patients with gait and balance problems. Finger-to-nose and heel-to-shin testing examines cerebellar function. Rapid alternating movements may be rapid but sloppy or dysmetric, indicating cerebellar dysfunction. Alternatively, they may be slow and hypometric, indicating parkinsonism, or slow and clumsy, indicating corticospinal tract disturbances. Finally, disorganized movements that fail to alternate may suggest apraxia and motor persistence may indicate parietal, subcortical, or frontal dysfunction. Abnormalities of repetitive finger tapping and handwriting are common in disorders that affect the cerebellum, basal ganglia, and cortical sensorimotor areas.

Deep tendon reflexes are important in differentiating various causes of weakness and altered tone that might influence posture and gait. Hyperreflexia is common in patients with corticospinal tract disorders; hyporeflexia is common in those with peripheral nerve diseases that produce weakness and proprioceptive sensory loss.

Sensory. Sensory testing emphasizes proprioception in the toes, ankles, and knees that is particularly important in balance and walking.

Autonomic Nervous System. Orthostatic hypotension may cause falls. It is important to recognize that the presence of orthostatic hypotension may vary during the day; it is most prominent after meals and after taking some medications. Therefore, the absence of orthostatic changes in blood pressure in the clinic does not exclude orthostatic hypotension as a cause of falls.

Neurovascular. Auscultation and palpation of the carotid and other superficial cranial vessels may suggest a vascular cause of gait dysfunction. Poor distal pulses are associated with atherosclerotic vascular disease and embolic disease. Retinal vessels also offer clues to the presence of systemic vascular disease.

Associated Medical Findings

If falls cannot be explained by neurological abnormalities, cardiac syncope must be considered, and the cardiac examination may be informative. The spine, joints, and limbs should be inspected for abnormalities or pain that might affect walking.

[PreviousNext](#)

EVALUATION GUIDELINES [Table 18-2](#)

Laboratory evaluation of patients with gait and balance abnormalities is largely determined by the findings derived from the history and physical examination that point to dysfunction in specific neural structures, and these tests are covered in other chapters. For example, a gait disturbance associated with proprioceptive sensory loss should trigger a workup for peripheral neuropathy or spinal cord (posterior column) disease depending on the accompanying signs. General guidelines pertaining specifically to gait and balance disturbances are indicated here.

Neuroimaging. Magnetic resonance imaging (MRI) of the head is indicated for patients in whom the cause of a gait disturbance is not apparent from the history and neurological examination or in whom start hesitation or disequilibrium is evident. Hydrocephalus, frontal lesions, subcortical gray and white matter lesions, and brain stem lesions may be found that were not suspected from the history or physical examination. Computed tomography (CT) of the head reveals less information about white matter and subcortical structures but excludes hydrocephalus, frontal lesions, and large subcortical abnormalities. The presence of spasticity and posterior column signs will direct imaging toward the spine, particularly the cervical region, if no explanation is apparent from brain imaging.

Electrophysiology. Nerve conduction velocities and electromyography are useful in differentiating muscle, nerve, and motoneuron causes of weakness. Brain stem and visual evoked responses may help in assessing pathology in the brain stem and visual pathways. Electroencephalography (EEG) may help in detecting encephalopathy as a cause of inattention and falls, and, combined with a Holter monitor, it may be useful in patients with unexplained crumpling falls (collapsing) to exclude seizures or cardiogenic syncope.

Fluid and Tissue Analysis. Pernicious anemia sometimes causes gait disorders that are out of proportion to the peripheral neuropathy or myelopathy that is present; vitamin B₁₂ is indicated for patients with no obvious cause of their gait and balance difficulties. A urine drug screening test may reveal drug use that explains ataxia or inattention and falls.

Cerebrospinal Fluid. Large-volume lumbar spinal taps (30 to 50 ml of cerebrospinal fluid [CSF] removed) sometimes cause a transient improvement in gait, cognitive functioning, and urinary continence in patients with normal pressure hydrocephalus.^[13] The sensitivity and accuracy of this test are not known.

Other Tests. Electronystagmography and rotational tests are used to examine peripheral labyrinthine and central vestibular function. Posturography is used to examine a standing patient's ability to maintain balance as proprioceptive and visual sensory information is reduced or distorted. Posturography can also be used to differentiate the contributions of the visual, vestibular, and proprioceptive systems to a patient's balance. Gait analysis, which measures gait speed, cadence, foot clearance, single support time (when one foot is in the swing phase of stepping), and double support time (when both feet are in contact with the ground), and the trajectories of limbs, is rarely indicated for the diagnosis of gait disturbances. It generally quantifies the observations of an astute clinician in the examining room. For intermittent gait abnormalities, videotapes made by the family of the patient during times of difficulty may be very informative. Pulse and blood pressure recordings obtained at home in relation to falls may also yield helpful clues. Finally, a visit by a physical therapist or occupational therapist to the home of a patient with unexplained falls may reveal environmental causes of falls.

CLINICAL SYNDROMES Table 18-3

Because gait and balance disturbances are common manifestations of functional disturbances of many parts of the nervous system, alterations in gait are important physical signs in diagnosing dysfunction of these structures. Diseases affecting the proprioceptive, vestibular, or visual sensory systems commonly produce an unsteady or ataxic gait. Weakness produced by muscle and motor nerve diseases alter locomotion in characteristic patterns. Upper motor neuron disorders cause weakness and spasticity, which typically become evident during locomotion. Basal ganglia disorders produce distinctive hypokinetic and hyperkinetic gaits. Cerebellar dysfunction causes ataxia. However, many gait and balance disorders seen in the clinic are not readily explained by disturbances of a single neural structure.

As described earlier in the section on anatomy, some of the basic circuitry governing locomotion and balance is known. However, many clinical abnormalities of gait and posture are not due to disturbances of this basic circuitry but to the individual's adaptation (or failure of adaptation) of normal or slightly abnormal balance and gait synergies to day-to-day living. The neuroanatomical basis of this higher level of control and adaptation of balance and gait is less well understood. For this reason, gait and balance syndromes are arranged by systems rather than anatomically; they include disorders of (1) locomotor and balance synergies, (2) primary sensory function, (3) perception/ orientation, (4) force production, (5) force scaling, and (6) adaptation/cognition/attention.

Dyssynergy/Synergy Syndromes

Although *locomotor synergies*, the basic patterns of muscle contraction and relaxation that produce coordinated rhythmic stepping, exist in the spinal cord, dyssynergies resulting from discrete spinal lesions are not recognized clinically. This is partly because spinal lesions that would disrupt the central pattern generators would probably affect

the motor neurons, producing weakness or paralysis, and would also disrupt the ascending and descending tracts, producing other neurological dysfunction. However, release of locomotor synergies can be seen in patients with damage to the central nervous system. Automatic or spinal stepping can be elicited in humans with clinically complete cervical or thoracic cord transection by having the patients partially supported on a moving treadmill. ^[14] Automatic stepping, probably due to stimulation of the brain stem locomotor regions, also occasionally occurs in patients with brain stem lesions and with coma, such as occurs with central herniation. ^[15]

Freezing gait, or difficulty in initiating and maintaining locomotion, may represent an interruption of voluntary access to the brain stem locomotor regions or spinal central pattern generators. The feet of a patient with freezing seem to stick to the floor, and the patient may be at a loss as to how to start walking. This gait pattern has been given the graphic term gait ignition failure. Its milder form is termed start hesitation because a hesitation of several seconds

ensues before the patient can begin to walk. When gait is finally initiated, it may begin with small steps that increase in length, sometimes to normal length, a phenomenon termed slipping clutch gait. Turns are accomplished with slow, small steps and sometimes freezing, termed turn hesitation. Any distraction that interrupts the patient's concentration on walking, such as being asked a question or passing through a narrow opening, may precipitate freezing. Freezing may be overcome by tricks that convert walking from an automatic act of moving from one place to another to a cortically directed process of voluntary movements of the legs and feet. Thus, patients may initiate gait by focusing on stepping on a particular spot on the floor, pretending to kick something, or stepping over an object. A plausible but unproved interpretation of these clinical observations is that locomotion in patients with freezing is achieved by cortically directing the individual movements of the limbs until stepping is initiated; then the more automatic stepping generated from the brain stem locomotor regions and spinal central pattern generators can function, but always under the constant surveillance of the cortex. Distraction in these patients brings locomotion to a halt by interfering with the necessary cortical supervision of walking.

Freezing is most commonly seen in patients with Parkinson's disease (see Chapters 16 and 34). However, frontal cortex and deep white matter lesions sometimes produce freezing with little or no imbalance and with no other parkinsonian signs. Further localization to specific frontal regions or to specific cortical bulbar tracts has not been possible, to date. Patients with these frontal and subcortical lesions may have marked freezing, but once under way they have an almost normal or completely normal stride. Arm swing is frequently preserved, which helps to differentiate isolated gait ignition failure from the freezing characteristic of parkinsonism. The base may be normal, as in parkinsonism, but often is widened, which is atypical of parkinsonism. There may be an exaggerated side-to-side sway of the trunk in an attempt to raise the feet off the floor, another feature not found in parkinsonism. Nevertheless, this freezing gait resembles the more common parkinsonian freezing gait pattern so closely that it is often referred to as lower half parkinsonism. ^[16], ^[17]

Balance or equilibrium synergies organized in the brain stem are highly stereotyped and are not context sensitive. In day-to-day living, balance synergies are adapted to the environment, body position in space, previous experience, and expectation by the higher centers. Decerebrate and decorticate posturing and tonic neck reflexes are reflex brain stem postural synergies that are released by extensive cortical and subcortical lesions (see Chapter 1 and Chapter 15). Abnormal posturing (fencer's position) may also be produced by mesial frontal lobe epileptic discharges.

Frontal disequilibrium may be seen in patients with lesions of the frontal lobes or deep white matter. This gait abnormality is associated with an imbalance that may represent loss of access to balance synergies, inappropriate selection of synergies, or release of inappropriate brain stem synergies. Hydrocephalus, frontal infarcts, multiple lacunar infarcts in deep white matter, and frontal masses can produce frontal disequilibrium, a profound disturbance of balance that may preclude standing. ^[18], ^[19] Patients with frontal disequilibrium have difficulty in rising to stand because they do not bring their feet under themselves as they try to rise and may not even place their feet on the ground. Helped to an erect position, they cannot stand independently because they do not bring their weight over their feet. Many hyperextend the trunk and push backward in seeming disregard for their support base. Stepping may be bizarre with crossing of the legs and no coordination between the trunk and the legs. This clinical phenomenon was first described by Bruns in 1892 and is sometimes termed Bruns' ataxia or frontal ataxia. It is important to recognize that this form of ataxia is different from that produced by cerebellar lesions. Frontal disequilibrium is also sometimes termed apraxia of gait; however, this term seems inappropriate because gait is limited by balance, not by locomotor difficulties. ^[20]

Frontal gait is a combination of imbalance that does not preclude locomotion, small steps, and freezing. It is more common than the two extremes described previously, frontal disequilibrium and isolated gait ignition failure. Frequently, but not always, the base is widened. ^[20] The frontal gait pattern has also been referred to as *marche à petits pas*. Frontal disequilibrium and frontal gait disorders are often accompanied by other frontal lobe signs such as grasping, dementia, pseudobulbar palsy, and urinary urgency and incontinence.

Sensory Gait Syndrome

The adaptation of spinal and brain stem synergies to an individual's goals and limitations (i.e., context) requires a knowledge of the relations of the body segments to each other, the situation of the body in space and the gravitational field, and the presence of environmental hazards and aids to balance and locomotion. This information is largely derived from the somatosensory, vestibular, and visual senses. Generally, one sensory system is adequate to orient a person and permit normal balance and gait. Balance and gait difficulties arise if environmental information is inadequate because of reduced sensory input or if a mismatch between the sensory information provided by the three sensory systems occurs because the environmental clues are ambiguous or the information is distorted by diseased sensory systems.

Sensory ataxia arises from a proprioceptive sensory loss in the lower extremities and may be produced by diseases affecting large myelinated peripheral nerves, dorsal roots, or posterior columns. The gait disorder is often first recognized when the patient is suddenly deprived of vision, such as occurs when walking into a dark room or closing the eyes to wash the face. At this mild stage, the only abnormalities detectable on examination may be a slight unsteadiness when the person stands with the feet together and the eyes closed (Romberg's sign), walks with the eyes closed, walks backward, or makes sudden turns. With more severe sensory loss, the patient shows increased sway when standing and walks with a widened base and irregular steps. The feet may be raised too high, thrown too far forward, and brought down too quickly. At this stage, the gait resembles that of a person with cerebellar ataxia. The patient's eyes

are focused on the feet and the ground immediately in front of them. Diverting the eyes away from the feet may cause the patient to fall. Reactive or protective postural responses as induced by the pull test may be delayed because proprioceptive input to signal movement of the center of mass relative to the base of support is absent. A cane may aid in walking, perhaps through proprioceptive cues appreciated in the hands. With severe proprioceptive sensory loss, the patient may not be able to stand unaided, even though strength is retained. Neurological examination reveals a profound loss of position sense at the toes and ankles and generally also at the knees and hips in patients with ataxia on the basis of proprioceptive sensory loss. Other aspects of the neurological examination help in differentiating the peripheral nerve and spinal cord posterior column origin of the sensory loss.

Vestibular ataxia is seen in patients with vestibular dysfunction; its severity depends on the speed with which dysfunction develops, the extent of the lesion, and the degree of compensation. The person with longstanding complete loss of vestibular function, for example from aminoglycoside antibiotics, may appear completely normal under most circumstances. The effects of the vestibular deficit may emerge only when the person is in an environment in which vision and proprioceptive clues are reduced or deceptive. Subtle signs in these patients include an en bloc appearance, which restricts the movement of the head during walking. Ataxia may be elicited in these patients by asking them to rotate the head from side to side while walking. The ability to balance on one foot or to walk in tandem with the eyes open or closed may also be impaired. ^[21]

Vestibular function that is present but distorted causes more difficulty with balance and gait. Patients are very dependent on visual information, but their deficient vestibular-ocular reflexes make it difficult for them to differentiate between self and environmental movement. For example, such patients find it difficult to walk on a busy city sidewalk because of the surrounding movement of pedestrians and vehicular traffic. These patients generally describe unsteadiness but not vertigo. The gait may be characterized by staggering and veering in response to erroneous perceived self-motion. Acute vestibular lesions are generally associated with vertigo and

produce prominent difficulties with gait and balance. The sudden onset of vertigo may be associated with an inability to walk or even to stand.

Historical features suggestive of vestibular disorders include the following: (1) spontaneous vertigo, (2) vertigo induced by movement, Valsalva maneuvers, noise, exercise, and heat, (3) visual blurring induced by head and body movements, and (4) disequilibrium induced by body movements and movements in the surrounding environment. Findings on examination that suggest vestibular dysfunction include spontaneous or positional nystagmus, en bloc gait (particularly minimizing head movement), ataxia with head movement, and difficulty in balancing on one foot or on a compliant surface (e.g., foam) with the eyes closed. ^[22]

Visual ataxia is unsteadiness caused by visual deficits. Under normal circumstances, humans are very dependent on vision for balance; foveal vision appears to be most important, but peripheral vision also contributes to balance. Disturbances in visual acuity or visual fields increase body sway and predispose the person to falls. People adjusting to new bifocals may feel unsteady or even fall. Vision may also be affected by abnormalities of eye movements. Limitation of eye movements, particularly downward movement, or an imbalance between the extraocular muscles, producing diplopia, can cause balance difficulties and falls. ^[23]

Multisensory disequilibrium occurs with deficits in multiple sensory systems. No single deficit is sufficient to cause a problem, but the sum causes difficulties in orientation in space. ^[24]

Higher Sensory Processing Syndromes

PERCEPTION AND ORIENTATION DISORDERS

Patients may have normal sensory input from the proprioceptive, vestibular, and visual systems but be unable to integrate and interpret the information because of abnormalities in higher sensory processing. ^[25] Failure of sensory integration may be related to distortion of the spatial maps known to exist in the parietal cortex, putamen, ventral premotor cortex, superior colliculus, and frontal eye fields. ^[26] Faulty interpretation of the position of the body segments to each other and the position of the body in space may elicit inappropriate balance and gait synergies.

Thalamic, midbrain, and putaminal astasia may represent abnormalities of orientation. Posterolateral thalamic lesions impair an individual's ability to judge verticality and may be associated with postural instability. Infarcts and hemorrhages in the midbrain tegmentum, dorsal thalamic nuclei, and putamen produce striking problems with balance. Patients with these lesions have adequate strength, primary sensation, and coordination but cannot stand without drifting and falling to the side or backward unless corrective efforts are made. In patients with lesions of the thalamus, this clinical picture has been referred to as thalamic astasia, ^[27] and similar clinical presentations have been described in patients with midbrain ^[28] and putaminal ^[29] vascular lesions. Abnormalities of eye movements (vertical gaze palsies, skewed eye position, and counter rotation) may offer clinical clues to mischief in these subcortical regions, but more often brain imaging establishes the diagnosis.

Progressive supranuclear palsy (PSP) may be another example of disorientation caused by degeneration in the subcortical regions, particularly the midbrain tectum. Patients with PSP often present with unexplained falls, an essentially normal straight ahead gait, and minimal extrapyramidal signs. The disequilibrium appears when the subject turns while walking or is pulled backward. The patient often falls with apparently no protective responses. This presentation differs from that of idiopathic Parkinson's disease, in which imbalance appears later in the course of the disease and is generally accompanied by the classical parkinsonian gait. Other findings on examination that confirm this diagnosis are decreased or absent downgaze and pseudobulbar palsy (see Chapter 34). PSP generally progresses to an inability to stand unaided. ^[30]

Lesions in the *posterior parietal cortex* are known to produce neglect and spatial disorientation. ^[31] The effect on balance and gait is not documented, but it is easy to imagine that lesions in these areas could impair gait and balance.

MOTOR FORCE DISORDERS

The musculoskeletal system is required to execute the locomotor and balance synergies. Skeletal, joint, muscle, motor nerve, and motor neuron disorders may preclude ambulation or force the nervous system to adopt unique strategies to carry out ambulation.

Articular, bone, and connective tissue disorders of the trunk and lower extremities may alter gait because of mechanical restraints or pain. However, the extent to which a person can adapt ambulation to the presence of bony deformities and artificial limbs is remarkable if the central nervous system is undamaged. The compensated gait pattern may be bizarre but provides mobility. A slow and careful gait in which movement of some joints (particularly the hips and knees) is restricted to reduce pain is referred to as an antalgic or arthritic gait. The examination should reveal pain and limitation of movement at the joints.

Muscular dystrophies, myositis, and myopathies generally affect the proximal muscles more than the distal muscles and cause weakness of the trunk and pelvic girdle. Weakness of the medial glutei prohibits fixation of the pelvis on the support leg during walking. To prevent the pelvis from tilting toward the swing leg, the trunk flexes laterally, toward the support leg. The successive movements of the trunk from side to side during walking produce a characteristic waddling gait. Examination demonstrates rather profound weakness in the hips if the gait disturbance is due to weakness.

Peripheral motor neuropathies typically affect the distal muscles and produce weakness at the ankle, particularly dorsiflexion of the ankle. If the ankle does not dorsiflex sufficiently, hip flexion must be increased to raise the leg so that the toe will not catch on the support surface. This produces the steppage gait or foot drop. Foot drop causes patients to trip frequently because the toe does not clear some minor obstacle on the ground. Distal weakness and reflex abnormalities are present on examination.

FORCE SCALING DISORDERS

Disorders of the cerebellum, basal ganglia, and corticospinal tracts do not eliminate balance and gait synergies but disrupt their execution. These synergies are apparently inappropriately scaled—that is, they are too big or too small or are distorted by other involuntary movements. Postural disturbance is often considered a key component of *parkinsonism*. Patients with advanced disease may appear to have absolutely no response to a push or a pull, toppling over like a log if not caught. However, muscle electromyographic (EMG) activity recorded from postural muscles generally shows that such patients have appropriate reactive postural responses at normal latencies. The problem is that the postural response is hypometric and generates insufficient force to produce an effective and timely correction. Thus, the postural abnormalities seen in parkinsonism appear to be related to the same physiological abnormalities that cause bradykinesia (an inability to energize the muscles quickly and forcefully) and not to a unique postural response deficit.

A very typical progression of gait abnormalities occurs in patients with parkinsonism. Initially, the only abnormality is reduced arm swing, generally unilaterally because the disease commonly begins unilaterally. Subsequently, the steps become shorter, and the speed of walking slows. The trunk is flexed (simian posture). Turns become slower, and the head, neck, and trunk move together as a rigid unit, the en bloc turn. Later, the patient may find it difficult to start to walk, and the feet remain apparently stuck to the floor (start hesitation). Once gait is underway, it looks much more normal (although the flexed posture and reduced arm swing remain) as long as the patient walks straight ahead in an open area. Turns may again cause the feet to "stick" to the floor and may be accomplished by making small shuffling steps (turn hesitation). Walking may become slower or stop completely when the patient passes through a narrow space such as a doorway or is distracted (freezing). Because the feet slow or stop and the trunk may be leaning forward in anticipation of moving forward, hesitation and freezing at starts and turns may cause falls forward onto the knees or outstretched arms. Eventually, walking may become impossible without assistance because of the freezing and hypometric protective postural responses. Throughout this deterioration of the parkinsonian gait, the base remains narrow. If a wide base is present in a patient with other signs of parkinsonism, the clinician must consider other syndromes such as multiple system atrophy, spinocerebellar atrophies, and multi-infarct gait disorders.

Choreic gaits are largely normal locomotor and balance synergies distorted by involuntary movements. In patients with moderately severe chorea, the involuntary movements of the legs cause a characteristic gait pattern. The trajectory of the leg and the position of the foot when it makes contact with the ground vary from step to step. Choreic movements may flex and extend the trunk and otherwise interrupt the smooth forward progression of the gait. The consequence is an erratic, jerky gait pattern marked by hesitations in some steps, variable length of steps, and variable contact with the ground, so that the patient may rise on the toes for one step and then land on the side of the foot or the heel the next. This produces a stuttering or dancing gait that has been likened to a puppet on a string. With severe chorea, gait

may be precluded by the superimposed involuntary movements.

Dystonic gaits are characterized by involuntary, sustained, twisting movements of the limbs and trunk that affect locomotion. Initially, dystonia tends to occur only when the patient is engaged in specific activities (action dystonia). For example, dystonic spasms may affect a leg when the person walks forward but not backward. This characteristic of the gait is often incorrectly interpreted as suggesting hysteria. Dystonic posturing of the arms is often brought out by asking the patient to walk on the toes or heels. With time, dystonic postures may be present at rest. Dystonia may remain restricted to one group of muscles or one limb, or it may be generalized. The gait pattern reflects the distribution of dystonic spasms. Because

childhood-onset dystonia often begins in a leg, abnormalities of walking or running (described as a limp by parents) are the first signs of the disorder.

Cerebellar disorders appear to produce hypermetric anticipatory and reactive postural responses and dysmetric limb movements that have impaired timing and force. The basic synergies for balance and gait are not deranged. That is, the cerebellum modifies the execution of the synergies that are generated elsewhere in the nervous system. Mild cerebellar gait ataxia shows up as impaired ability to tandem walk and the need for an extra balancing step or two on quick turns. With increasing cerebellar dysfunction, the base widens, and the stepping cadence becomes more irregular. The response to a push is often an overreaction, but the protective response is an appropriate synergy, inappropriately scaled. Severe cerebellar dysfunction may preclude standing and walking because of the marked dysmetria of the postural responses and stepping.

Cerebellar gait ataxia is often described as three distinct syndromes. Lesions of the floccular-nodular lobe (vestibulocerebellum) produce clinical abnormalities resembling those produced by vestibular lesions. There is marked disequilibrium with falling in any direction. There may be a truncal tremor when the patient is sitting or standing (titubation). Medulloblastomas are frequently associated with this syndrome. Lesions of the anterior vermis (spino-cerebellum) produce a wide-based gait with a slow and irregular cadence and superimposed lurching. The patient may have few or no other signs of ataxia except when standing and walking. Alcoholic cerebellar degeneration primarily affects the anterior vermis and produces the same picture.^[31] Lesions of the lateral cerebellar lobes (frontocerebellum) produce ataxia of limb movements and consequently an ataxic gait. Infarcts, hemorrhages, and tumors are common causes of this syndrome. These syndromes are not reliable indicators of the anatomical location of cerebellar pathology.^[32] In clinical practice, a cerebellar ataxic gait with no other prominent cerebellar signs is attributed to midline cerebellar dysfunction. A cerebellar ataxic gait with limb ataxia, dysarthria, and ocular dysmetria is attributed to involvement of the lateral cerebellar lobes.

Spastic hemiparetic and *paraparetic gaits* result from disruption of the corticospinal tracts and produce unilateral or bilateral weakness and spasticity. The patterns of automatic postural responses, anticipatory responses, and gait are basically preserved, although less force (scaling deficit), delays in distal muscle activation, and co-contraction are present. If there is adequate strength, spasticity rarely prohibits ambulation, although it may make gait precarious.

The movements of the affected leg or legs are slow, stiff, and effortful. Most of the forward movement of the spastic leg comes from the hip. Because of the weakness of the dorsiflexors of the ankle and the increased (spastic) tone in the leg, the leg moves as a rigid pillar in a semicircle during the swing phase (circumduction) to prevent catching the toe. The toe often scrapes along the floor and may catch on small irregularities, causing falls. The toes of the shoes are scuffed and worn out of proportion to the remainder of the sole of the shoe. The person with a spastic gait, like the patient with peripheral neuropathy and foot drop, is trying to overcome the weakness of dorsiflexion of the ankle, but the stiffness of the leg prevents the spastic patient from adopting the steppage gait and requires circumduction of the leg to accomplish the swing phase (bringing the leg forward for a step). The legs may even cross the midline at the end of the swing phase because of the increased tone in the adductors of the thigh, producing the scissoring gait typical of severe spasticity. There may be a marked discrepancy between the signs of spasticity elicited when the patient is supine (hyperreflexia, spastic catch in the legs, Babinski's signs) and the degree of spasticity apparent when the patient walks.

Syndromes of Impaired Adaptation and Deployment of Strategies

The individual must be able to adapt synergies to the environment and situation. Much of this process occurs at a subconscious level and operates through the frontal lobe and possibly the basal ganglia. In addition, some adaptation takes place at a conscious level and is dependent on attention, learning, and insight, functions that are associated with frontal lobe function. A normal person's gait changes appropriately depending on whether the surface is flat, rough and uneven, or slippery (such as ice) and on the kind of footwear being worn (shoes, thongs, skis, stilts). Likewise, postural synergies are adapted to the situation. The postural response to a perturbation felt when standing at the end of a low diving board depends on whether the pool is filled with water and how the person is attired. Thus, equilibrium and gait are adapted to the situation through awareness of the body and the environment as well as through the use of insight, judgment, and past experience.

The cortex is not necessary for ordinary walking in laboratory animals such as cats. It is necessary for *skilled walking*, for example, when the cat must place its feet precisely such as when walking on the rungs of a horizontal ladder. Similarly, in humans, the frontal motor areas are presumed to be involved in precise locomotion such as walking on uneven surfaces, avoiding obstacles on the ground, and dancing.

The *cautious gait*, often inappropriately referred to as a *senile gait*, is characterized by slower, shorter steps and en bloc turns. It is not a pathological gait pattern but is a more conservative balance and gait pattern, the proper response to perceived postural insecurity in the anterior-posterior direction. A normal person assumes a cautious gait pattern on an icy surface. Older individuals assume a cautious gait pattern when they perceive that their balance or their ability to regain their balance is impaired. Widening of the base of support is an appropriate response to uncertainty about when and where the feet will make contact with the support surface and the risk of falls laterally. Just as a normal person widens the base of support on a pitching ship deck, an older individual with a cerebellar, vestibular, or somatosensory disorder widens his or her base.^[20]

Dementia is not associated with a particular gait pattern, but many epidemiological studies of falls in the elderly identify dementia as one risk factor for falls.^{[33], [34]} Some falls appear to be due to poor insight; the patient attempts

do things that are not reasonable for his or her physical capabilities and environmental situation. Demented patients do not attend to their environment. It is probable that if dementia is combined with any problems with balance and gait, the chances of falls are markedly increased because the patient will be unable to adapt to the disabilities. In conclusion, demented patients may have normal balance synergies but cannot use them effectively because of their impaired attention and insight and an inability to profit from experience. The converse is also true. Some patients with severely compromised balance and gait synergies never fall because of their insight and carefulness.

Although balance and gait are thought of as "sub-conscious" functions, it has been demonstrated that attentional demands are needed to maintain balance and locomotion. As the difficulty of balancing or walking increases, as is common in the elderly, more attention is required.^{[35], [36]} Attentional demands are increased by using a walker.^[37] Thus, inattention or distraction may impede balance and walking. The increased risk of falling associated with psychotropic drug use^[33] may be related to the drug's effects on attention and not solely to alterations in sensory-motor function. Patients with unexplained falls may be encephalopathic from medical illnesses as well as drugs.^[38]

The *post-fall syndrome* consists of a sudden inability to walk without the support of objects or the assistance of another person; it occurs after a fall, and there is no evidence of a neurological or orthopedic abnormality that explains the inability to walk.^{[39], [40]} With assistance, many of these patients can learn to walk normally. This inability to walk appears to be due to excessive fear—a perceived insecurity of balance that does not match the person's physical capacity. It might be termed an overcautious gait.

Psychogenic gait disorders can take many forms including hemiparetic and paraparetic disorders, ataxic disorders, trembling, buckling of knees, and dystonic abnormalities. Features that suggest psychogenic gait disorders include (1) variability in gait from time to time, particularly with suggestion or distraction; (2) excessive slowness and hesitation in walking; (3) tandem walking with much arm waving and swing foot wavering combined with prolonged periods of balancing on the stance foot; (4) bizarre gait patterns with no explanatory neurological findings; and (5) other historical and neurological signs suggesting a psychogenic disorder.^[41] Neurological disorders that are sometimes improperly labeled as psychogenic are (1) dystonia, because the postures may be strange and may be present only during certain specific tasks (e.g., during walking but not running); (2) thalamic astasia, because of the striking evidence of disequilibrium combined with a lack of other neurological signs; and (3) frontal gait disorders, because of balance and gait dysfunction without other neurological signs in the presence of personality

changes.

GENERAL MANAGEMENT GOALS

The first management goal is patient safety, and a number of nonspecific strategies can be used to achieve this goal. Since falls are dangerous, their prevention must be of paramount concern. Stabilizing walking aids such as walkers, canes, and other support aids may be useful in weak or unstable patients, but the patients must be specifically trained to use these objects correctly. Some patients, especially those with a gait marked by freezing, may find such aids of more hazard than benefit. Padded clothing, knee pads, and elbow guards may also be used. Physical therapists are often particularly skilled in advising on the use of medical ambulation aids.

The next management goal is to identify the neural dysfunction that contributes to the patient's gait and balance difficulties. A differential list of diseases that should be investigated in the search for treatable pathologies can be developed and a prognosis established. Characterization of balance and gait disorders in terms of systems dysfunction will help to identify correctable problems such as decreased visual acuity that is amenable to refraction or cataract removal, weakness that is amenable to bracing, and so on. It is important to recognize that balance and gait disorders may have multifactorial causes^[42] and that there need not be a unique cause for the patient's difficulties. An attempt to correct all potential contributors to gait and balance problems is worthwhile.^[43],^[44]

When these goals have been accomplished, physical therapy programs for strengthening and improved balance can be refined.^[45] Further evaluation and experimentation with various assistive devices may be useful, and therapists can instruct the patient and family in the best methods to use to assist the patient without injury to self or others. The occupational therapist can evaluate the home for safety and may suggest the use of grab bars, new lighting, floor coverings, a different furniture arrangement, and so forth to prevent falls.^[46]

HISTORY AND DEFINITIONS

The direct relation of somatic sensation to the nervous system was first put forth by Herophilus of Chalcedon in the third century BC. Through careful dissections he identified nerves as structures directly connected to the brain and spinal cord and attributed sensation and motor function to them. The concept of the subdivision of somatic sensation into modalities was solidified by the specificity theory of Muller, who proposed that the stimulation of certain primary afferent fibers yielded a specific modality of sensation and that these specific nerve fibers were tuned to respond to only certain stimuli.

The specificity theory's greatest challenge came from the experimental findings of Lele and Weddell, who noted that free nerve endings in the cornea produced sensations of more than one modality. Subsequently, many subtypes of mechanoreceptors were shown to respond to various types of stimuli. However, the elegant intraneural microstimulation studies of Ochoa and Torebjork have demonstrated that an elementary sensation can be reliably elicited by stimulation of a single mechanoreceptive unit. Most likely, modality specificity exists at the most fundamental levels of the sensory unit at threshold levels of stimulation, but suprathreshold levels of stimulation activate receptors nonspecifically.

Because the sensory modalities of proprioception, vibration, and touch share neurophysiology, clinical concurrence, and some anatomy beyond the level of the mechanoreceptors, these sensations are considered together.

Proprioception is any postural, positional, or kinetic information provided to the central nervous system by sensory receptors in muscles, tendons, joints, or skin; *touch* is the sensory modality concerned with the ability to perceive superficial, non-noxious stimulation of the skin; and *vibration*, which is sometimes referred to as *pallesthesia*, is the ability to perceive sinusoidal rhythmic stimulation on both a superficial and deep level.

Alterations in sensation are often spoken of in terms of hyperesthesia, hypesthesia, and paresthesia. *Hyperesthesia* is an exaggeration of any sensory modality response. Hyperesthesia is distinct from *hyperpilaphesie*, which represents augmentation of tactile faculties in response to other sensory deprivation (e.g., touch in the blind). *Hypesthesia* represents a diminution of any sensory modality; however, it is most frequently used in the discussion of painful and tactile stimulation. *Paresthesia* reflects a perversion of sensation, producing a perception that is abnormal in

214

character (e.g., tingling on tactile stimulation) or abnormal sensations that an individual experiences in the absence of stimulation, including feelings of tingling, burning, prickling, crawling, and so on. Paresthesia has also been applied in a general sense to refer to sensations of a purely subjective nature.

[PreviousNext](#)

CLINICAL HISTORY

Sensory complaints can be subdivided into positive and negative phenomena. Negative phenomena, hypesthesia or hypalgesia, reflect a loss of sensation on stimulation. Positive phenomena are represented by hyperesthesia and paresthesia. Examples include pain perceived with light stimulation of the skin or a sensation of ants crawling on the skin in the absence of any external stimulation. Negative phenomena generally reflect failure along sensory channels secondary to either conduction block or fiber loss at any site along the sensory axis. Paresthesia or spontaneous pain, however, is most likely due to neural hyperactivity generated ectopically from damaged fibers.^[1]

A number of descriptors may be used by the patient to indicate a sensory loss: numbness, dead weight, prickling, tingling, "pins and needles," aching, tightness, creeping, itching, and burning. It is important to clarify the symptoms with the patient. Such terms as *numbness* may be used when actually the patient is experiencing weakness or, conversely, the patient is referring to an extremity feeling weak or heavy when indeed there is diminished sensation.

Several historical factors are critical in determining the etiology of a patient's sensory complaints. Chief among these is the distribution of the perceived sensory loss. Localization is the foundation for generating an accurate and complete list of conceivable causes. Some examples of the distribution of sensory loss and typical localizations are listed in [Table 19-1](#). The patient should also be asked to describe the temporal presentation, clinical course (static, progressive, stepwise, relapsing/remitting), duration, and severity of symptoms. Any precipitating or provocative factors for the sensory complaints should be noted.

Abnormalities of touch sensation are likely readily recognized by the patient, whereas impairment of vibration is generally not noted by patients because this sensory inflow is not a part of the daily conscious experience. Proprioceptive loss is most likely recognized by the patient as a lack of coordination in the limbs or impairment in gait. An early sign of proprioceptive loss may be unmasked by asking if the patient has difficulty walking or reaching for objects in the dark.

It is important to determine if there are any associated neurological deficits to aid in localization and determination of etiology, such as motor deficits, cranial neuropathies, language deficits, sensory neglect, deep tendon reflex changes, limb or gait ataxia, or autonomic dysfunction.

The presence of any familial history of sensory complaints or conditions causing sensory dysfunction must be investigated. In particular, a determination of the pattern of inheritance of a peripheral neuropathy may greatly aid in making a diagnosis.

TABLE 19-1 -- THE PATTERN OF SENSORY LOSS SEEN IN LESIONS THROUGHOUT THE SENSORY AXIS

Distribution of Sensory Loss	Clinical Diagnosis
Single nerve	Mononeuropathy
Multiple peripheral nerves in a single arm	Infraclavicular brachial plexopathy
Single nerve root	Radiculopathy
Multiple spinal roots in a single arm	Supraclavicular brachial plexopathy
Multiple spinal roots in a single leg	Lumbrosacral plexopathy
Symmetrical distal extremities	
Legs > arms	Polyneuropathy (e.g., diabetes)
Arms > legs	Polyneuropathy (e.g., vitamin B ₂ deficiency)
Symmetrical proximal extremities	Polyneuropathy (e.g., Tangier disease)
Multifocal peripheral nerve distribution	Mononeuritis multiplex
Multifocal partial nerve distribution	Subcortical white matter (e.g. multiple sclerosis)
Distinct sensory level	Spinal cord lesion
With sacral spanng	Extrinsic cord compression or central cord lesion
Saddle distribution	Conus medullans or cauda equina
Incomplete hemibody	Brain stem
Hemibody	Thalamic lesion
Face and arm sparing leg	Sensory cortex or superficial subcortical white matter

Underlying medical conditions that may predispose the patient to disease of the sensory axis must be explored, with careful attention to past medical illnesses, trauma, toxin exposure, and medications. Patients may present with sensory complaints as their only recognizable manifestation of toxin exposure. Toxic neuropathies secondary to medications or environmental exposure are seldom purely sensory neuropathies; however, [Table 19-2](#) lists some medications that may cause a predominantly sensory neuropathy. Although the sensory complaints associated with a toxic neuropathy may vary, pathologically there may be a predilection for involvement of a certain fiber type population.

TABLE 19-2 -- MEDICATIONS CAUSING PREDOMINANTLY SENSORY NEUROPATHIES ALONG WITH THE FIBER TYPE PREFERENTIALLY AFFECTED AS SEEN ON PATHOLOGIC SPECIMENS

Medication	Affected Pathologically
Almitrine	Large greater than small
Chloramphenicol	Small greater than large
Cisplatin	All fibers
Dideoxyeytidine (ddC)	All fibers
Disulfiram	All fibers
Metronidazole	All fibers
Misonidazole	All fibers
Phenytoin	Large greater than small
Pyndoxine	All fibers
Taxol	All fibers
Thalidomide	Small greater than large
Vincristine	Small greater than large

Almost all predominantly sensory toxic neuropathies due to medications are axonopathic rather than myelinopathic.

ANATOMY OF PROPRIOCEPTION, TOUCH, AND VIBRATORY SENSES [Table 19-3](#))

Receptors

Sensation begins most distally with the transduction of mechanical stimulation by mechanoreceptors in the dermis, epidermis, muscles, and joints. To stimulate the axon associated with a mechanoreceptor, the stimulus must first pass through intervening tissues. This process is referred to as *stimulus accession*. This is followed by *stimulus transduction*, in which the stimulus energy is transformed into electrical energy by depolarization of the axon terminal in proportion to the amount of mechanical energy applied. The amplitude of the mechanical stimulus determines the frequency at which the action potentials are initiated. This temporal summation of afferent impulses is preserved throughout the afferent course and is decoded centrally as subjective stimulus sensation magnitude. Increasing the intensity of a mechanical stimulus not only increases the firing frequency of the discharging mechanoreceptor but also recruits more sensory units. The intrinsic properties of the mechanoreceptors, however, determine how sustained the impulse activity is when stimulated. Rapid adaptation of a mechanoreceptor indicates that the unit is firing only as long as the stimulus is moving. Slow adaptation indicates that the unit also fires when the stimulus is held constant. Four subtypes of mechanoreceptors that have large fiber afferent nerves associated with them have been identified: (1) Meissner's end organ (RA) with rapid adaptation, a distinct receptor field border, and small receptive field size; (2) paciniform end organ (PC) with rapid adaptation, obscure field borders, and large field size; (3) Merkel's end organ (SA I) with slow adaptation, distinct field borders, and a small receptive field; and (4) Ruffini's end organ (SA II) with slow adaptation, obscure field borders, and large field size.

Any given mechanoreceptor may respond to various types of mechanical energy; however, most are particularly sensitive to one form of stimulation. This selectivity tends to be greatest at or near threshold levels of stimulation, that is, activation of the smallest number of sensory units necessary for stimulus perception.

It has been demonstrated, from intraneural microstimulation of a single myelinated fiber associated with a mechanoreceptor, that elementary sensations can be perceived and sensory quality, magnitude, and localization can be resolved at a cognitive level. Microstimulation of a single RA unit produces a sensation of intermittent tapping or fluttering. These receptors are related to texture discrimination

TABLE 19-3 -- CLINICO-ANATOMICAL CORRELATION OF LESIONS INVOLVING PROPRIOCEPTION AND VIBRATION SENSATIONS

Anatomic Site of Damage	Sensory Findings	Other Neurological and Medical Findings
Sensory receptors	Local diminution of all modalities	Edema or inflammation of skin
Primary neuron	Distal to proximal gradient loss of all modalities	Distal weakness and atrophy of lower extremity muscles, areflexia
Peripheral nerve		
Sensory root ganglion	Vibration and proprioceptive loss greater than pain and temperature in distal extremities; arms and legs equally affected; limb ataxia.	Areflexia; may have xerophthalmia, xerostomia, arthritis, rash, or pulmonary mass lesion
Dorsal columns and other spinal tracts	Proprioceptive and vibratory loss generally in bilateral lower extremities	Pupillary abnormalities, areflexia, ataxia in lower extremities
Secondary neurons	Selective loss of vibration and proprioception, in lower extremities for gracilis and in upper extremities for cuneatus	Cranial nerve deficit in lower brain stem
Nucleus cuneatus and gracilis		
Medial lemniscus	Loss of proprioception, vibration, and discriminative touch on the contralateral half of the body usually in an incomplete distribution	Cranial nerve palsy; the particular nerve involved is important in localizing at what level the medial lemniscus is lesioned as it courses through the length of the brain stem.
Tertiary neurons	Loss or decrease of all modalities on entire contralateral half of body, frequently accompanied by spontaneous pain	May be associated thalamic aphasia, memory deficit, or rubral tremor
Ventroposterolateral and ventroposteromedial nuclei		
Internal capsule	Loss of all modalities or combinations of selective loss of pain and temperature or vibration, proprioception, and discriminative modalities. Distribution is near complete or incomplete hemibody contralateral to the lesion; associated hemiparesis may be noted	
Sensory cortex	Mild and often transient loss of pain, temperature, and vibration; more severe and sustained loss of proprioception and discriminative touch. There is variability in distribution and severity from moment to moment. Distal extremities are affected more severely than proximal extremities, and extremities are affected more than the trunk. Unilateral face and arm or leg alone may be affected.	Neglect, aphasia, extinction on double simultaneous stimulation

in glabrous skin such as the fingertips. Microstimulation of a PC receptor produces a sensation of vibration or tickle. Microstimulation of an SA I receptor produces a sensation of pressure, and these receptors appear to be critical in resolving the spatial structures of objects or surfaces. Microstimulation of SA II receptors evokes no sensation when stimulated in isolation; however, they are excited by skin stretching and joint movement. The Ia afferents that represent the primary endings of muscle spindles also produce no sensation when stimulated in isolation.

First-Order Neuron

Beyond the mechanoreceptors, the sensory impulses are propagated centrally by a population of afferent nerve fibers. The cross-sectional diameter, degree of myelination, and conduction velocity of peripheral nerve fibers are useful categories that relate directly to the modality subserved by certain mechanoreceptors and nerve fiber populations. The accepted composition of the sensory nerve compound action potential includes Aalpha myelinated fibers (30-72 m/sec); Adelta lightly myelinated fibers (4-30 m/sec); and C unmyelinated fibers (0.4-2 m/sec). There is an association between activity in a fiber population and the sensation perceived: Aalpha fibers convey light touch, proprioception, vibratory, and discriminative sensations (large fiber modalities); Adelta fibers convey sensation of pinprick and coldness; and C fibers convey the sensation of dull aching and warmth. These latter two groups reflect the small fiber modalities discussed in [Chapter 20](#) on pain and temperature sensation.

In the case of the largest myelinated fibers, conduction block due to demyelination or conduction failure due to axonal damage can lead to impaired sensory impulse transmission centrally and thus a corresponding sensory deficit in these large fiber modalities. Uniform conduction slowing per se does not seem to have a clinical correlate. In patients with hereditary sensorimotor neuropathy type I, conduction velocities can approach 10 to 15 m/sec in the largest fiber population (normal for lower extremities is 40 m/sec and in upper extremities it is 50 m/sec) with few sensory symptoms. However, if there is an unequal slowing of conduction of select fibers within the Aalpha population (differential slowing), it is likely to interfere with clinical tests that depend on the delivery of synchronized bursts of impulses such as vibratory sensation.

These peripheral nerve fibers of the first-order neurons have their associated soma in the dorsal root ganglia (DRG). The separation of modalities that originated in the peripheral mechanoreceptors appears to be preserved in the DRG anatomically, with the most rapidly conducting peripheral fibers associated with a subpopulation of large clear cells within the DRG. On a neurophysiological level, membrane properties of DRG cells are correlated with the specific peripheral mechanoreceptor type and peripheral nerve fiber conduction velocity. The DRG neurons are T-shaped structures, with the afferent sensory axons coming from the

peripheral nerve and separate axonal projections that transmit the impulse centrally to the spinal cord through the dorsal roots.

Within the dorsal roots, the various sensory fibers are intermingled. However, as the fibers enter the spinal cord, the large myelinated fibers assume a more medial position. The more lateral aspect of the bundle is composed of thinly myelinated and unmyelinated fibers that ascend three to six segments and descend four to five segments before synapsing within the spinal gray matter of the dorsal horn. The spinal cord gray matter is described in terms of laminae, the separate areas being denoted cytoarchitectonically. These laminae often represent separate nuclei with distinctive function. Lamina IV plays a role in light touch, and lamina VI receives afferents from group I muscle afferents, for example. Most of the fibers that enter the dorsal columns of the spinal cord do so without synapsing in the dorsal horn. The dorsal columns generally represent direct projections from the DRG neurons to the nuclei gracilis and cuneatus within the brain stem. However, some of the primary afferents coursing in the dorsal columns send projections to the propriospinal neurons in the dorsal horn and some axons of second-order neurons from the dorsal horn course in the dorsal columns and terminate on dorsal column nuclei.

The classical view is that the impulses ascending in the fibers of the dorsal columns mediate sensations of touch, deep pressure, vibration, proprioception, and sensory discrimination. The fibers in the dorsal columns are steadily pushed in a medial direction as they course rostrally. The fibers entering at more rostral levels intrude themselves between the ascending fibers and the dorsal horn. The medial portion is referred to as the funiculus gracilis and is composed of fibers from caudal to and including the lowest six thoracic levels, and the lateral portion is referred to as the funiculus cuneatus and is composed of the upper six thoracic segments and cervical segments.^[20] The funiculus cuneatus occupies most of the ventral aspect of the dorsal columns, abutting the commissure from the second to the sixth cervical cord segments. At C3 it occupies all of the ventral aspect. There is a topographical representation within the dorsal columns by submodality such that discriminative touch is most superficial (dorsal), vibration is represented most deeply (ventral), and proprioception is intermediate.^[21]

Second-Order Neuron

The dorsal column fibers terminate in the nucleus gracilis and cuneatus at the level of the medulla. Again, the nucleus gracilis is medial to the cuneatus and each nucleus subserves the same body region, as represented in its respective funiculus. In these nuclei, the primary afferent fibers synapse and the second-order sensory afferents send projections more rostrally through the medial lemniscus after the fibers decussate as the internal arcuate fibers in the medulla. The somatotopic organization is preserved throughout the course of the medial lemniscus. The medial lemniscus remains medial in the medulla and pons, sweeping more laterally at the level of the midbrain.

Third-Order Neuron

The fibers of the medial lemniscus terminate in the ventroposterolateral (VPL) nucleus of the thalamus. This pathway is organized somatotopically such that the fibers

from the nucleus gracilis end most laterally within the VPL nucleus and those from the nucleus cuneatus end in the larger, medial part of the VPL nucleus. The VPL nucleus is the origin of the third-order sensory afferent neuron that sends projections to somatosensory cortex (Fig. 19-1 (Figure Not Available)).

Primary somatosensory cortex consists of the postcentral gyrus and its medial extension into the paracentral lobule (Brodmann areas 1, 2, and 3). There is somatotopic organization such that the amount of tissue within the primary sensory cortex that represents a particular region of the body is related to the importance of that region in somatic sensation and not to its absolute size. For example, the thumb has a much greater area of cortical representation than does the proximal arm. In the region of the postcentral gyrus, the calf and the foot are represented on the medial surface of the hemisphere and then laterally follow the foci for the thigh, abdomen, thorax, shoulder, arm, forearm, hand, fingers, and face. The foci for the bladder, rectum, and genitalia are located on the lowest aspect of the medial surface of the hemisphere (Fig. 19-2 (Figure Not Available)).

With regard to the subdivision of cortical regions by modality, Powell and Mountcastle have shown in monkey cortex that over 90 percent of the neurons in area 2 are related to receptors of the deep tissues of the body such as the joints, in area 3 most of the cells are activated by cutaneous stimuli, and area 1 has an intermediate position in terms of the modality specificity of its neurons.^[22]

Adjacent to primary sensory cortex are smaller cortical zones that receive input from primary somatosensory cortex referred to as secondary sensory areas. Although contralateral representation of the body predominates there is some bilateral representation within these areas.

Figure 19-1 (Figure Not Available) The formation and course of the posterior columns in the spinal cord and the medial lemniscus in the brain stem. The posterior columns are formed from uncrossed ascending and descending branches of spinal ganglion cells. Ascending fibers in the fasciculi gracilis and cuneatus synapse on cells of the nucleus gracilis and cuneatus. Fibers forming the medial lemniscus arise from cells of the nuclei gracilis and cuneatus, cross in the lower medulla, and ascend to the thalamus. Impulses mediated by this pathway include proprioceptive, vibratory and discriminative touch. Spinal ganglia and afferent fibers entering the spinal cord at different levels are coded as in (Modified from Carpenter MB: Human Neuroanatomy. Baltimore, MD, Williams & Wilkins, 1983.)

Figure 19-2 (Figure Not Available) Sensory homunculus. This diagram shows the relative size and distribution of the parts of the cerebral cortex from which sensations localized to different parts of the body can be elicited on electrical stimulation (From an. Penfield W, Rasmussen T: The Cerebral Cortex of Man. New York, Simon and Schuster, 1950.)

Spinocerebellar Pathways

A second type of sensory information enters the spinal cord through the dorsal columns. These fibers generally carry spinocerebellar impulses that terminate in various regions of the cerebellum and thus do not reach a level of conscious sensation.

The dorsal spino-olivary tract ascends within the dorsal columns, synapses in the cuneatus and gracilis nuclei, and then relays impulses to the contralateral accessory olivary nucleus. These fibers arise in the spinal cord and are activated by cutaneous and group Ib receptor afferents. The function of these fibers is largely spinocerebellar. There are fibers traveling in the anterior funiculi that have a similar termination and are referred to as the anterospino-olivary tract.

The dorsal spinocerebellar tract (DSCT) arises from neurons in the dorsal nucleus of Clarke from the T1 to L2 levels. The principal afferent fibers to Clarke's nucleus are collaterals of primary afferent fibers that are observed to descend directly from the dorsal columns. These cells have afferent peripheral inputs from muscle spindles, Golgi tendon organs, and touch and pressure receptors. The fibers enter the cerebellum through the inferior cerebellar peduncle in the medulla and terminate on the ipsilateral vermis. These impulses are utilized in the fine coordination of posture and movement of individual limb muscles.

The ventral spinocerebellar tract arises from cells in the dorsal horn and ascends largely contralaterally in the lateral funiculus of the cord ventral to the dorsal spinocerebellar tract. The fibers come from levels below the midthoracic cord. These fibers enter the cerebellum through the superior cerebellar peduncle.

The cuneocerebellar tract (CCT) is the forelimb equivalent of the DSCT. It consists of two separate components: one exteroceptive, which is activated by cutaneous afferents and higher threshold muscle afferents, and one proprioceptive, which is activated by group I muscle afferents. The CCT terminates ipsilaterally in lobule V of the anterior lobe of the cerebellum.^[23]

Discriminative Touch, Vibration, and Conscious Sense of Joint/Muscle Movement

There are three elements of proprioception with separate peripheral receptor representation: (1) the perception of limb movement is mediated by muscle spindle receptors, cutaneous mechanoreceptors, and joint receptors; (2) the perception of limb position is mediated by muscle spindle receptors and cutaneous mechanoreceptors; and (3) the perception of force of muscular contraction is mediated by corollary discharges and tendon organ receptors.^[24] Specific mechanoreceptors that have been implicated in proprioception include SA II cutaneous afferents that respond to planar stretch of the skin and muscle spindle endings that respond to muscle stretch. Neither of these receptors evokes a coherent sensation when stimulated in isolation. This suggests that spatial summation among various receptors is critical for the perception of position sense.^[25]

Proprioception is transmitted through heavily myelinated nerve fibers. The cell body of the first-order neuron is in the DRG and goes without synapsing into the

ipsilateral funiculus gracilis or cuneatus to synapse in the nucleus gracilis or cuneatus within the medulla. As these fibers travel in the dorsal columns they are topographically localized between the fibers transmitting vibration and those transmitting discriminative touch in the intermediate region of the dorsal columns. The second-order neurons are located within the gracilis and cuneatus nuclei. The third-order neurons are located in the VPL nucleus of the thalamus following the course of the dorsal column nuclei to the somatosensory cortex, as previously mentioned. The sensory cortex gets very precise information on the position and movements of the joints.

Pacinian corpuscles (PC) are the mechanoreceptors responsible for the sensory transduction of vibratory sensation. These receptors are excited by very rapid changes in tissue distortion such as that produced by sinusoidal vibration.^[12] When the skin is locally anesthetized by cocaine, there is a manyfold elevation in threshold for frequencies in the range of 5 to 40 Hz whereas that for higher frequencies is scarcely unchanged. This suggests that the perception of vibration depends on two separate primary afferents: one innervating the skin and the other innervating the deep tissues.^[11] Detection of vibration of the frequency range of 5 to 40 Hz probably depends more on RA transduction, whereas PC units account for detection at higher frequencies of vibration.^[25] As stimulus intensity is increased, PC fibers may initially discharge irregularly or at some submultiple of the stimulus frequency. With slight increments, however, the point of phase locking between stimulus and firing of afferent nerve fiber is quickly reached.^[9]

Vibratory stimuli are transmitted through large myelinated, group Abeta fibers through the dorsal columns to the

somatosensory cortex. Like proprioceptive fibers, the first-order neurons are in the DRG, second-order neurons in the cuneatus and gracilis nuclei, and third-order neurons in the VPL nucleus of the thalamus. With regard to the cortical representation of vibratory sensation, many years ago Holmes stated that the "appreciation of vibration is possible through the thalamus alone."^[26] Although the thalamus may play a significant role in the appreciation of vibratory sensation, Mountcastle has clearly demonstrated activity in cortical neurons in response to vibratory stimulation and has localized the function of frequency discrimination to a cortical level.^[27]

Discriminative or complex touch includes two-point discrimination, touch localization, direction of movement of an object drawn on the skin, stereognosis, and graphesthesia. The finest levels of surface structure are transduced by RA and PC afferent fibers.^[28] It is most probable that these complex sensations result from a simultaneous stimulation of several types of receptors. The nerve fibers transmitting discriminative modalities have their first-order neuron origin in the DRG. These fibers enter the DRG through myelinated fibers in the medial division of the dorsal root. They follow an identical course to that of proprioceptive fibers to the somatosensory cortex by means of the dorsal columns. Within the dorsal columns these fibers occupy the most posterior region.^[29]

Light Touch and Pressure

The mechanoreceptors associated with light touch include the RA and SA I. The sensory nerve fibers are large and myelinated. The central course of the fibers subserving tactile sensation is more diffuse than that of the other large fiber modalities with fibers coursing in both the anterior spinothalamic tract and the dorsal columns. It has long been recognized that a morbid process confined to the dorsal column will give no clear-cut loss of simple tactile sensibility. Conditions are similar for lesions affecting the anterolateral sensory tracts. It appears that if one of the two systems subserving touch sensibility is damaged, the reduction is so mild that it is of no practical clinical relevance.^[20]

Tactile sensory nerve fibers have their first-order neurons in the DRG and enter the spinal cord through the medial division of the dorsal root. These fibers are largely thought to traverse the medial strand of the dorsal roots and enter the dorsal columns ascending to the contralateral thalamus (see previous discussion of course of dorsal columns). Other fibers bifurcate into ascending and descending fibers that synapse within a few segments in the dorsal horn and laminae I, IV, V, and some of VI and VII. Some of these second-order neurons decussate in the anterior commissure and ascend in the contralateral anterior spinothalamic tract to the VPL nucleus of the thalamus. Within the thalamus the tactile sensory fibers are placed slightly caudad to those conveying pain. These third-order neurons then ascend to somatosensory cortex. The organization of this modality at the cortical level is not well understood.

Pressure is related to tactile sense but involves the perception of pressure sensations other than light touch from subcutaneous structures. It is closely related to proprioception and is mediated through the dorsal columns.

EXAMINATION OF THE POSITION, TOUCH, AND VIBRATORY SENSORY SYSTEMS

Directed Neurological Examination

The sensory examination is performed to delimit areas of abnormal sensation and the modalities involved within these limits and to compare these findings with established patterns of abnormal sensation. To ensure that the patient is attentive and cooperative, the examiner may need to interrupt the examination and complete it at a later time if the patient becomes fatigued or inattentive. The importance of the abnormal findings on the sensory examination are greatly enhanced by reproducibility, and it may be necessary to re-examine affected areas to verify initial findings.

In the patient who is without subjective sensory complaints, a quick survey of the body is all that is necessary, keeping in mind the distribution of the major sensory peripheral nerve and segmental root distributions ([Fig.19-3](#) [Fig.19-4](#) [Fig. 19-5](#)) and verifying that sensation perception is symmetrical. If there are specific sensory complaints or if abnormalities are found on the survey examination, a focused examination should be carried out to determine the exact distribution and the modalities impaired.

Some areas of the body are physiologically more sensitive to touch, and caution should be used in declaring an abutting area hypesthetic when only a minor difference in sensation occurs in these border zones. These areas include the antecubital fossa, supraclavicular fossa, and neck. An additional potential pitfall in misinterpreting a normal sensory examination is that as one passes from one skin area to an adjacent area supplied by a much higher spinal segment, it is normal for the patient to sense a sudden increase in the stimulus at the point of the segmental border. An example is seen on the chest where dermatomes C4 and T2 abut. ^[30] Some physical factors that may contribute to anesthesia on the sensory examination include areas of thicker skin, such as the elbow, or regions covered by calluses.

Some helpful landmarks and anatomical considerations to keep in mind when performing the sensory examination are listed below:

C1 has no supply to the skin.

The interaural line is the border between the areas supplied by the ophthalmic division of the trigeminal nerve and the C2 segment.

C5-C6 supply the radial side of the arm, forearm, and hand.

C8-T1 supply the ulnar side of the forearm and hand.

T3 supplies the axilla.

T4 supplies the nipple region.

T8 supplies the rib margin.

T10 supplies the umbilicus.

T12-L1 supply the groin.

L5 supplies the dorsum of the foot, lateral leg, and great toe.

32

Figure 19-3 A. Anterior view. The right side of the body depicts the cutaneous fields of the peripheral nerves. The unlabeled areas on the thorax are innervated by the cutaneous branches of the anterior primary rami. The left side of the body depicts the segmental (dermatomal) innervation of the skin. B. Posterior view. The right side of the body depicts the segmental (dermatomal) innervation of the skin. The left side of the body depicts the cutaneous fields of the peripheral nerves. The unlabeled area on the left back is innervated by the cutaneous branches of the posterior primary rami (Both figures modified from Haymaker W, Woodhall B: *Peripheral Nerve Injuries*. Philadelphia, W.B. Saunders Company, 1953.)

S1 supplies the small toe, sole of the foot, and the posterior thigh and leg.

S4-S5 supply the perineal region concentric to the coccyx and not the anus.

When a region of hypesthesia has been identified either subjectively by the patient or on the survey examination the most reliable method of defining the hypesthetic zone is to proceed from the hypesthetic area to areas of reportedly normal sensation. It is more typical for there to be a gradient of loss at the borders of the hypesthetic region rather than abrupt change at the segmental, peripheral nerve, or midline borders. This is due to some overlap of innervation in the border regions from adjacent peripheral nerves and segmental innervation.

In performing the sensory examination the observer can assess *threshold sensation*, which measures a single nerve fiber innervating a receptor or group of receptor cells, or *innervation density*, which measures multiple overlapping peripheral receptive fields. ^[31] In peripheral nerve disease, threshold changes tend to be more sensitive for identifying an abnormality. Examples are cutaneous pressure threshold for the slowly adapting mechanoreceptor population and cutaneous vibratory threshold for the rapidly adapting mechanoreceptor population. Once nerve fibers have degenerated there is a decrease in innervation density that is measured by two-point discrimination. ^[32]

Proprioception. Proprioception, or position sense, can be assessed in a number of ways:

1. With the patient's eyes closed, place his or her hand in a particular position, remove it, and ask the patient to resume the position. Alternatively, have the patient try to imitate the assumed position with the other hand. Poor performance on this exercise could also be related to a motor deficit or higher cortical dysfunction.
2. With the patient's eyes closed, hold the sides of one of his or her digits between your thumb and finger so that no uneven pressure above or below the digit reveals the direction of movement and then move the articulation up or down. The patient should identify the direction of passive movement, and the threshold for accurate detection is noted by the examiner. The normal threshold for passive movement of an articulation is 5 to 10 degrees in the interphalangeal joint of the index finger and 1 degree at the shoulder. ^[33] It is important to clearly identify the directions of movements of the joint with exaggerated excursion before testing so that the results are not falsified by miscommunication.
3. Have the patient hold his hand outstretched. Look for wavering of a hand or pseudoathetoid movements.
4. Ask the patient to place his or her forefinger accurately on the tip of the nose and his or her heel accurately on a knee.

33

5. Romberg testing. The Romberg sign is present when the patient is able to stand with the feet together while the eyes are open but sways or falls when the eyes are closed.

Figure 19-4 Side view. A. A side view of the cutaneous fields of the peripheral nerves. B. A side view of the dermatomes (Both figures modified from Haymaker W, Woodhall B: *Peripheral Nerve Injuries*. Philadelphia, W.B. Saunders, 1953.)

Pathologically, with minimal impairment of proprioception there is first loss of the sense of position of the digits then of the sense of motion. As the process becomes

more extensive, loss of recognition for an entire extremity or even at times for the entire body develops.

Vibration. The testing of vibration is an important part of the sensory examination because it is often the first sensation to disappear in nerve injury. The acknowledgment of vibration as a discrete modality is attributed to Weber in 1842.^[34] It was Rumpf who introduced the tuning fork to clinical medicine^[35] and the clinical studies of Symms and Williamson that secured vibratory sensation assessment as a part of the routine bedside examination.^[36],^[37]

Vibration is generally assessed with a 128- or 256-Hz tuning fork. The tuning fork is struck against a hard surface with sufficient force to cause the prongs to touch each other and emit a sound. It is applied with a pressure equal only to the weight of the apparatus over an area with a paucity of subcutaneous tissue, such as the anterior tibial area in the leg or the malleoli. The tuning fork is allowed to run down by itself, and the patient is asked to indicate when he or she can no longer feel it. The examiner should make sure the patient is not listening to the humming sound generated but is in fact attending to the vibratory sensation. The examiner should also note the duration of perceived vibration and quickly move the tuning fork to the identical spot on the contralateral limb without striking it again. It is normal to perceive 3 to 5 additional seconds of vibration after such a transference. Areas that can be tested include the great toe, anterosuperior iliac crest, sacrum, spinous process of the vertebrae, sternum, clavicle, styloid processes of the ulna or radius, and finger joints. It is best to apply the tuning fork to an affected site first and then to the same, contralateral, nonaffected site for comparison. An average duration can be quantitated over four to five trials.

The threshold for vibratory perception is lower in the arms than in the legs,^[38] with distal sites being more sensitive than proximal ones. In the order of most sensitive to least sensitive areas to vibratory threshold perception are palm; pad of the finger; dorsum of the finger; dorsum of the hand; dorsum of the great toe; sternum and malleolus; lip, tongue, forehead, mastoid, and patella; forearm; and sacrum.^[38] Thibault lists normal values of duration of vibratory perception as 19.21 seconds for the index fingerpads and 13.36 seconds for the ankle.^[39] Vibratory thresholds are increased in the legs but not the arms in patients older than 50. The degree of the impairment increases with age.^[40]

Touch. General tactile sensation is tested by the use of a light stimulus such as a wisp of cotton, feather, tissue, or fingertip. The stimulus should be so light that no pressure on subcutaneous tissues is produced. An allowance for decreased perception should be made for the thicker skin on the palms and soles. The tips of the tongue, lips, genitalia, and fingertips are the most sensitive areas. The upper arms, buttocks, and trunk are much less sensitive. The examination should be conducted with the patient's eyes

324

Figure 19-5 Perineum and limbs A, Cutaneous fields of the peripheral nerves of the perineum and limb B, Segmental (dermatomal) innervation of the skin of the perineum and limb (Modified from Haymaker W, Woodhall B: *Peripheral Nerve Injuries*. Philadelphia, W.B. Saunders, 1953.)

closed, and the patient is instructed to inform the examiner when the stimulus was perceived. For milder degrees of impairment of light touch a relative difference from side to side or abutting regions should be investigated.

A systematic approach to the assessment of the threshold of light touch is provided by the Semmes-Weinstein nylon monofilaments. The thickness of these monofilaments is standardized, creating a specific level of force at the point which the nylon monofilament bends after contact with the skin. There are 20 graduated nylon filaments calibrated in terms of the logarithm of 10 times the force in milligrams required to buckle the filament. Established normal values have been published.^[41],^[42]

Tactile thresholds are increased in the elderly.^[43] In normal persons, distal sites tend to have lower thresholds than proximal ones. In decreasing order of sensitivity are thumbs, palms, plantar surface of foot, and proximal arm.

Two-Point Discrimination. Two-point discrimination is a function of slowly adaptive peripheral mechanoreceptors and a measurement of innervation density. It is best carried out with a two-pronged instrument with blunt ends because sharp pointed objects will tend to stimulate pain fibers

325

rather than touch. Localization is most accurate on the palmar surfaces of the fingers, especially the thumb and index finger. On the fingers it should be possible to discriminate two points separated by less than 5 mm; however, on the dorsum of the foot a distance as great as 5 cm as the lowest level of discrimination may be normal.

Testing of Higher Cortical Function. Other discriminative modalities include graphesthesia, stereognosis, topesthesia, baresthesia, and double simultaneous stimulation. In the presence of normal tactile sensation, abnormalities in these discriminative modalities generally reflect a disorder of cortical sensation. In fact, however, graphesthesia and stereognosis may be impaired by lesions in the dorsal columns and rostrally.

Graphesthesia is tested by tracing a number or letter or figure on the surface of the skin. Test areas include the palm, anterior forearm, thigh, and lower leg. The clearest figures for interpretation tend to be 8, 4, and 5, whereas 6, 9, and 3 tend to be the most difficult.

Stereognosis depends on the sense of light touch and position. It is tested by placing an object in a patient's hand and having him or her identify it with eyes closed. The patient can manipulate the object freely in the hand but should not use the contralateral hand at the same time. If the patient is unable to identify the object, comparison with the contralateral hand should be made. Most studies of normal subjects indicate that familiar objects can be named within 5 seconds of contact.^[44] Baresthesia can be assessed in a similar fashion by placing two objections of different weight in sequence in the patient's hand and have him or her identify which is heavier.

Double simultaneous stimulation is tested with the patient's eyes closed, alternating patterns of touch of one limb and then two limbs simultaneously that are contralateral to each other. The patient must identify where he or she is touched. Extinction of a hemibody field is identified such that touch on the affected side is always recognized when done in isolation; however, when the nonaffected side and the affected side are stimulated simultaneously the affected side is not recognized. This is generally associated with lesions affecting the contralateral parietal lobe.

Stimulus localization or topesthesia can be examined either by asking the patient to touch with his or her finger where the examiner has touched or by asking the patient to state where he or she has been touched. The latter method eliminates joint position sense as a factor.

Examination in Suspected Psychogenic Sensory Loss. The sensory examination is subjective by nature, and it can be very difficult to delineate those patients who have factitious, feigned, or nonphysiological sensory findings. A number of clues and approaches can be utilized in the sensory examination if a nonorganic cause of the sensory complaints is suspected, including skin that is hyperesthetic for one sensation and anesthetic for another; anesthesia exactly to the midline; absolute loss of all cutaneous sensation; midline change for the sense of vibration over bony areas; and inapparent hyperesthesia when the patient is distracted.

A number of methods can be used during the sensory examination to assess for possible psychogenic sensory loss. These assessments are best applied in patients who are clearly alert and cooperative and in whom the standard sensory examination has raised a high degree of suspicion for nonphysiological sensory impairment:

1. Have the patient close his or her eyes and respond "yes" when he or she believes that a stimulus has been applied and "no" when he or she does not feel that a stimulus was applied. Occasionally, a patient with a nonorganic sensory complaint will be identified such that the timing of the answer "no" exactly coincides with each stimulus contact.
2. With the patient's eyes covered, find out by the aid of a light stimulus the alleged anesthetic area and mark the boundaries of it with a pen. If this procedure is repeated at short intervals the alleged area will be found to vary considerably.
3. The zig-zag test can be performed. With the patient's eyes covered, the border of an hypesthetic or anesthetic zone is marked. The observer starts again at the periphery of the limb and works upward with the stimulus in a zig-zag fashion. In the patient with a nonorganic sensory loss, the limit may have shifted downward and repeated tests will continue to bring it lower. The patient is led to feel a greater distance has been covered in a straight line reference. If an altered sensation depends on a genuine lesion of the sensory axis, the sense of localization is not called on and such a migration of the border of the hypesthetic zone

is not seen.^[45]

4. With the patient's eyes covered, the examiner draws figures of different shapes on the patient's skin. The figures are initially drawn such that part of the outline falls within the alleged anesthetic area and part without. The patient with nonorganic sensory loss may correctly identify the figure even when a critical portion of the figure necessary for identification is drawn within the alleged anesthetic area.
5. With the patient's eyes covered, cross his or her hands behind the back with the palms facing forward and then proceed to test his or her sensibility. In the patient with nonorganic sensory loss the observer may see bending of the alleged insensible finger as it is touched or hesitation in responding to the stimulus. ^[45]

Associated Neurological Findings

Cerebral. There are some potential distortions of body image that may accompany sensory loss helping to localize the sensory deficit to the cerebral cortex. Examples are *anosodiaphora*, which is a lack of concern over a profound loss of sensation or other neurological deficit; *anosognosia*, which reflects a lack of awareness of a profound sensory or neurological deficit; and *asomatognosia*, which represents loss of awareness of one half of the body. Additionally, the patient may manifest sensory neglect with a lack of orienting responses to unilateral stimuli. An aphasia and an increased susceptibility to distracting stimuli manifested as lack of attention or poor concentration are also signs localizing an accompanying sensory deficit to the cerebral cortex.

Thalamic sensory deficits may be associated with unilateral hyperpathia.

Cranial Nerves. As the medial lemniscal fibers course

through the brain stem they may be lesioned at any level. The level can be identified by an associated cranial nerve deficit (e.g., cranial nerve III in the midbrain or cranial nerve VII in the caudal pons). Patterns of multifocal sensory loss in the face, extremities, and trunk may represent multiple sclerosis. It is essential in such circumstances to look for typical findings of an internuclear ophthalmoplegia or an afferent pupillary defect on cranial nerve examination that might suggest remote or concurrent optic neuritis or a demyelinating plaque in the brain stem.

Bilateral facial weakness in a lower motor pattern may accompany mild distal extremity sensory loss in acute inflammatory demyelinating polyradiculoneuropathy.

Motor/Reflexes/Cerebellar/Gait. Motor power can be assessed and the distribution of any weakness found noted, such as the distal symmetrical weakness of peripheral neuropathy, which aids in localization of the deficit found on sensory examination. The examiner should look for atrophy of muscles and fasciculations that might suggest a peripheral nervous system process. Muscle tone should be assessed. Deep tendon reflexes are extremely important in the assessment of patients with sensory complaints because they are frequently abnormal in the patient with a lesion in the sensory axis. One should look for the analgic gait of a painful limb, such as in lumbosacral radiculopathy, or the slapping gait associated with a proprioceptive deficit. Ataxia or pseudoathetosis of the extremities may be associated with a proprioceptive loss in the affected limb.

Autonomic Nervous System. The autonomic nervous system can be evaluated in a noninvasive manner at the bedside with the following assessments: blood pressure and heart rate response to standing, isometric exercise, heart rate variation with respiration, Valsalva ratio, and plasma norepinephrine levels with standing.^[46]

Neurovascular. The size, character, and quality of heart sounds and gallop rhythms should be estimated. One should look for the stigmata of cardiogenic embolization: Osler nodes, Janeway lesions, and Roth spots are examples. The pulse is noted for 1 minute in a search for irregularities. The femoral artery, carotid artery, supraclavicular artery, and orbit are auscultated for evidence of bruits.

Associated Medical Findings. A good general medical examination of all systems is necessary to aid in generating a differential diagnosis for conditions affecting the sensory axis and can also aid in localization. Diseases commonly associated with peripheral nervous system dysfunction include cancer, diabetes mellitus, the acquired immunodeficiency syndrome, connective tissue disorders, alcohol abuse, uremia, myxedema, and paraproteinemias.

EVALUATION GUIDELINES (Table 19-4)

Neuroimaging. Plain radiographs may be helpful with peripheral localized nerve injury, such as identifying a humeral dislocation in the setting of an infraclavicular brachial plexopathy. Cervical spine or lumbar spine radiographs are useful in radicular complaints, and a chest radiograph is needed to evaluate lower trunk plexopathy of the brachial plexus to look for a cervical rib or an upper lobe structural lesion.

If the clinical pattern of sensory loss suggests a brain stem or hemispheric lesion, neuroimaging of the brain with magnetic resonance imaging (MRI) or computed tomography is indicated. MRI or myelography may be indicated based on sensory loss that localizes to the spinal column (e.g., myelopathy or radiculopathy). Also, if a lesion localizes to either the lumbar or brachial plexuses, an MRI of these regions should be obtained, especially if the patient has a history of cancer.

In a suspected sensory loss of hemispheric origin, focal cerebral blood flow studies with SPECT scanning may be helpful in localizing a focal structural lesion or impairment of circulation.

Electrophysiology. The most important supplement to the history and physical examination in the patient with possible peripheral nervous system disease is an electrodiagnostic examination consisting of nerve conduction studies and electromyography. The sensory nerve conduction studies directly assess the large fiber peripheral sensory nervous system distal to the dorsal root ganglion. This examination is useful in localization of mononeuropathies, generalized peripheral neuropathies, and plexopathies. Although the needle electrode examination (NEE) assesses only motor axon involvement, it can be helpful in localizing sensory complaints in the spinal nerve root proximal to the region assessed by the standard sensory nerve conduction studies.

Somatosensory evoked potentials allow assessment of sensory impulse conduction along the entire sensory axis from peripheral nerve to sensory cortex. They have their greatest application in lesions proximal to the dorsal root ganglion. In the upper extremity the median nerve is the most frequent site of stimulation; in the lower extremity it is the tibial nerve. This test is useful in patients with multiple sclerosis, brain stem structural lesions, Friedreich's ataxia, spinal cord injury, plexopathy, or radiculopathy. The brain stem auditory evoked response may be useful in identifying a subclinical focus of demyelination in multiple sclerosis, a brain stem structural lesion, or Friedreich's ataxia.

Fluid and Tissue Analysis. In a patient with peripheral neuropathy a serological workup including a complete blood cell count, antinuclear antibody, erythrocyte sedimentation rate, rheumatoid factor, glucose level, vitamin B₁₂ level, thyroid function tests, test for human immunodeficiency virus, blood urea nitrogen determination, phosphate level, cholesterol level, triglyceride level, cryo-globulin level, serum protein electrophoresis, porphobilinogen/epsilon-aminolevulinic acid value, urine heavy metal level, and vitamin E level covers the majority of identifiable causes.

Specifically for a pure sensory neuropathy an abbreviated serological evaluation with complete blood cell count, chemistry panel, vitamin B₁₂ level determination, erythrocyte sedimentation rate, anti-SSA and anti-SSB tests for Sjogren's syndrome, and anti-Hu antibody test for paraneoplastic sensory neuropathy is sufficient, owing to the limited differential diagnosis.

Cerebrospinal Fluid. A lumbar puncture can be helpful when multiple sclerosis, myelitis, meningitis, acute inflammatory demyelinating polyneuropathy, and certain other peripheral neuropathies are suggested. Attention

TABLE 19-4 -- USEFUL STUDIES IN THE EVALUATION OF DISORDERS OF TOUCH AND VIBRATION SENSATIONS

Syndrome	Neuroimaging	Electrophysiology	Fluid and Tissue Analysis	Other Tests
Primary sensory neuropathy	Normal	Low-amplitude sensory response: prolonged distal latency or slow conduction velocity confined to the single sensory nerve involved	Normal	Plain radiograph may demonstrate fracture locally
Diffuse sensory polyneuropathy	Normal	Generalized low-amplitude sensory responses on nerve conduction studies	Elevated ESR, anti-Hu antibody anti-ssA anti-ssB HIV low vitamin B ₁₂	Lip biopsy positive for Sjogren's syndrome
Dorsal root ganglia: tabes dorsalis	Normal	Abnormal tibial sensory evoked potential	Positive RPR, ETA, mild lymphocytic pleocytosis in cerebrospinal fluid with elevated protein level	
Radiculopathy	Nerve root compression due to osteophyte, herniated disc, or other structural lesion	Normal sensory nerve conduction; may have low amplitude CMAP and denervation of NEE if there is motor root involvement abnormal sensory evoked potential	Normal	
Plexopathy	Mass compressing plexus such as tumor or hematoma	Low amplitude sensory and motor nerve conduction responses in involved nerves; Mykymic potentials on NEE in radiation plexopathy		Chest radiograph shows cervical rib or apical lung lesion
Spinal cord lesion: posterior column	Structural lesion involving posterior column: infarction, spondylitic changes, tumor, epidural hematoma	Abnormal tibial sensory evoked potential	Elevated cerebrospinal fluid protein, IgG index, positive oligoclonal bands	
Combination of spinal cord and peripheral nerve lesions: vitamin B ₁₂ deficiency	Normal	Abnormal sensory evoked potential Cord level on NEE Normal sensory conduction	Low vitamin B ₁₂ , megaloblastic anemia	
Psychogenic sensory loss	Normal	Normal	Normal	

ESR, erythrocyte sedimentation rate; HIV, human immunodeficiency virus; AIDS, acquired immunodeficiency syndrome; RPR, rapid plasma reagin test FTA, fluorescent treponemal antibody test; CMAP, compound muscle action potential; NEE, needle electrode examination

should be paid to the white blood cell count, protein value, IgG synthesis rate, IgG index, and oligoclonal banding.

Other Tests. Lip biopsy for high clinical suspicion of Sjogren's syndrome and nerve biopsy for progressive neuropathy of unclear etiology or suspected vasculitis may be done.

CLINICAL SYNDROMES ([Table 19-5](#))

The sensory examination aims to establish the sensory modality involved, the intensity of involvement, and the anatomical distribution of the sensory change. In combination, these patterns isolate the likely neurological location of disease and later suggest etiology.

In lesions of the peripheral nervous system the sensory loss tends to be intense, with fixed, clearly defined zones. With central nervous system sensory deficits the boundaries are vague and the deficit is more mild as compared with peripheral processes. There may be considerable variation in both the distribution of and intensity of this type of sensory deficit.

Mechanoreceptor Dysfunction

Non-neural factors including dermatitis, keratosis, cutaneous inflammation, and edema may compromise sensation either through limiting stimulus accession to the mechanoreceptor or through mechanoreceptor decay. The pattern of the sensory deficit will correspond to the distribution of the local cutaneous process.

Primary Sensory Neuropathy: Pure Sensory Distal Nerve Lesions

Primary sensory neuropathies reflect a focal mononeuropathy of a nerve that carries only sensory fibers. Examples (see [Fig. 19-3](#) and [Fig. 19-4](#)) include the following:

- Meralgia paresthetica with involvement of the lateral femoral cutaneous nerve
- Gonalgia paresthetica due to entrapment of the infrapatellar saphenous nerve
- Cheiralgia paresthetica due to entrapment of the superficial branch of the radial nerve
- Medial antebrachial cutaneous neuropathy
- Dorsal ulnar neuropathy
- Sural neuropathy

Diffuse Sensory Polyneuropathy

In generalized peripheral neuropathy the sensory loss is length dependent such that it begins symmetrically at the most distal aspect of the lower extremities and ascends proximally. Generally the distal upper extremities will begin to show involvement when the sensory deficit in the lower extremity has ascended to the level of the proximal calf. In the most severe stage of peripheral neuropathy only a midline strip over the posterior trunk and neck and the peripheral aspects of the face have sustained sensation.^[47]

TABLE 19-5 -- ETIOLOGY OF DISORDERS AFFECTING POSITION AND VIBRATION SENSES

Etiological Category	Specific Etiologies	Chapter
STRUCTURAL DISORDERS		
Developmental	Tethered spinal cord	28
Degenerative and compressive	Herniated disc	29
HEREDITARY AND DEGENERATIVE DISORDERS		
Storage diseases: lipidoses, glycogen disorders, and leukoencephalopathies	Tangier disease	30
Amino/organic acidopathies	Hereditary tyrosinemia	31
Chromosomal abnormalities and neurocutaneous disorders	Neurofibromatosis with foramen magnum tumor or neurofibroma	32
Movement disorders	Parkinsons disease	34
Ataxias	Friedreichs ataxia	35
Degenerative motor, sensory, and autonomic disorders	Hereditary spastic paraplegia	36
Inherited muscle, neuromuscular and neuronal disorders	Hereditary sensory autonomic neuropathy 1	37
ACQUIRED METABOLIC AND NUTRITIONAL DISORDERS		
Endogenous metabolic disorders	Hypothyroid neuropathy	38
Exogenous acquired metabolic disorders of the nervous system: toxins and illicit drugs	Pyridoxine toxic neuropathy	39
Nutritional deficiencies and syndromes associated with alcoholism	Vitamin B ₁₂ -subacute combined degeneration	40
INFECTIOUS DISORDERS		
Viral infections	Herpes zoster "shingles"	41
Nonviral infections	Acute disseminated encephalomyelitis	42
Human immunodeficiency virus infection and acquired immunodeficiency syndrome	Distal sensorimotor peripheral neuropathy	44
NEUROVASCULAR DISORDERS		
	Mononeuritis multiplex	
	Parietal stroke	45
	Abdominal aortic dissection	
NEOPLASTIC DISORDERS		
Primary neurological tumors	Neurofibroma	46
Metastatic neoplasms and paraneoplastic syndromes	Brachial plexopathy-usually lower trunk	47
	Sensory ganglionitis	
DEMYELINATING DISORDERS		
Demyelinating disorders of the central nervous system	Multiple sclerosis	48
Demyelinating disorders of the peripheral nervous system	Chronic inflammatory demyelinating polyradiculoneuropathy	49
AUTOIMMUNE AND INFLAMMATORY DISORDERS		
	Sensory neuronopathy associated with Sjogrens syndrome	50
TRAUMATIC DISORDERS		
	Infraclavicular brachial plexopathy from humeral dislocation	51

EPILEPSY	Parietal lobe irritative focus with focal sensory seizure	52
HEADACHE AND FACIAL PAIN	Migraine with sensory aura	53
DRUG-INDUCED AND IATROGENIC NEUROLOGICAL DISORDERS	Radiation plexitis Postanesthesia brachial plexopathy	55

Examples of causes of diffuse sensory neuropathy include a dysproteinemic state (IgM monoclonal gammopathies with antimyelin-associated glycoprotein), amyloidosis (generally small fiber), hereditary, diabetes mellitus, uremia, hypothyroidism, immunological (scleroderma, sarcoid), and toxins. A generalized peripheral neuropathy can show selective involvement of certain fiber types such as large myelinated fibers. In these circumstances there will be a dissociated sensory loss with a deficit of vibration and proprioception while sparing pain and temperature on sensory examination. Examples of these conditions include Friedreich's ataxia, Charcot-Marie-Tooth disease, uremia, and Guillain-Barre syndrome.

There are more unusual length-dependent generalized symmetrical proximal neuropathies such that the shortest peripheral nerves are selectively involved. This results in sparing of sensation at the distal aspects of the extremities. This pattern may be seen in the neuropathy associated with Tangier disease, in acute intermittent porphyria, and in a unique familial sensorimotor neuropathy. ^[48]

Plexopathy

Sensory loss due to a lesion of the brachial plexus will appear in the distribution of two or more peripheral nerves if the lesion is infraclavicular and in the distribution of multiple cervical dermatomes if the lesion is supraclavicular. All sensory modalities may be involved.

In radiation-induced plexopathy, 77 percent of patients have upper trunk involvement predominantly that generally occurs 3 months to 26 years after irradiation of the chest. It is quite characteristic to find myokymia on the needle electrode examination in these patients. ^[49] Metastatic plexopathy has a predilection for the lower trunk, possibly owing to its proximity to the axillary lymph nodes. Pain is a predominant and early symptom in metastatic plexopathy.

Other causes of brachial plexopathy include traction, obstetrical paralysis, surgical injury, neuralgic amyotrophy, true neurogenic thoracic outlet syndrome, and trauma.

In the lumbar region a pattern of weakness, loss of reflexes, and sensory disturbance is found that cannot be

localized to a single lumbosacral root or peripheral nerve. Pain is a prominent early manifestation when secondary to neoplasm. The differential diagnosis includes idiopathic plexitis, vasculitis, diabetic polyradiculopathy, infection (e.g., with herpes zoster or *Schistosoma japonicum*) hereditary liability to pressure palsies, hemorrhage, trauma, obstetrical complications, and tumor irradiation.

Dorsal Root: Radiculopathy

Radiculopathy is generally associated with back or neck pain radiating into an extremity. The pain is poorly localizing for nerve root level but typical in the fact that it is radiating. There will generally be a loss of all modalities of sensation in a dermatomal distribution, a corresponding weakness in a myotomal distribution (i.e., with ventral root involvement as well), and segmental hyporeflexia. The most common cause is a herniated disc or osteophyte compressing on a nerve root. A structural lesion such as a neurofibroma or a metastatic focus must also be taken into consideration as possible causes.

Dorsal Root Ganglion/Dorsal Horn Lesions: Tabes Dorsalis

Generalized sensory neuropathies should be distinguished from subacute sensory neuronopathies, which are characterized by pain, paresthesia, and numbness in the limbs. The latter demonstrate a marked loss of proprioception and vibration, ataxia, and areflexia in an entire limb with a loss of pain and temperature to a lesser degree. The sensory loss may be more pronounced in the upper extremities than the lower extremities; therefore, it is not strictly length dependent, distinguishing it from a polyneuropathy. The differential diagnosis is Sjogren's syndrome, paraneoplastic origin, hereditary disease, and idiopathic disease. The lesion is at the level of the dorsal root ganglion.

Dorsal root ganglion and dorsal horn lesions tend to have very similar anatomical patterns of sensory loss to radiculopathies; however, dorsal horn lesions are more likely to have dissociated loss as the dorsal root fibers separate into the medial (large myelinated) and lateral (thinly myelinated and unmyelinated) bundles as they enter the dorsal horn.

Tabes dorsalis is characterized by diminished proprioception and vibration in the legs, sensory ataxia of gait, areflexia, and aching/lancinating pains in the legs. Additionally, there may be autonomic disturbances, including bladder atony, pupillary abnormalities, and impotence. Generally there is preservation of touch, pain, and temperature sensation. Distal weakness and atrophy may be a late manifestation of tabes dorsalis attributed to extension of syphilitic process to the anterior horn cell. Pathologically, tabes dorsalis is concentrated in the dorsal roots, dorsal funiculi, and posterior columns of the lumbosacral and lower thoracic spinal cord. The dorsal root ganglion is rarely affected.

Spinal Cord: Myelopathy

Generally with transverse lesions of the spinal cord there is a demonstrable sensory level with bilateral loss of all modalities of sensation below a definite level. With involvement of the dorsal columns there is loss of proprioception, discriminative modalities, and vibration within a couple of levels caudad to the lesion site. With smaller lesions it is possible to selectively involve certain dorsal column modalities owing to the topographical distribution of the various modalities: fibers carrying discriminative touch are most posterior, vibratory fibers are most anterior, and proprioceptive fibers are intermediate within the dorsal funiculi. There will be no significant loss of light touch; however, pressure sensation may be impaired. Examples are a metastatic lesion to the spinal cord, cord infarction, and multiple sclerosis plaque.

In the patient with a pattern sparing sensation in the sacral dermatomes, an extrinsic cord compression or central cord lesion is suggested at the level of the upper border of the sensory deficit. Sensory loss confined to the sacral dermatomes, a so-called saddle lesion, localizes the lesion to the conus medullaris or cauda equina. There will be involvement of all modalities; however, if there is preservation of touch, the lesion is more likely to be in the conus medullaris.

Central cord lesions and anterior spinal artery syndrome are discussed in [Chapter 20](#). Brown-Sequard syndrome is discussed in [Chapter 15](#).

Combination of Spinal Cord and Peripheral Nerve: Subacute Combined Degeneration

Subacute combined degeneration is characterized by mild distal weakness in the lower limbs associated with increased patellar reflexes, absent ankle reflexes, bilateral Babinski responses, unsteady gait, and positive Romberg sign. Vibration and proprioception are impaired. Vitamin B₁₂ deficiency is implicated as the cause. This is a disease of posterior and lateral columns of the spinal cord with associated sensorimotor peripheral neuropathy.

Brain Stem Lesions

A unilateral lesion of the medial lemniscus, usually vascular in origin, is followed by an impairment or loss of vibration, proprioception, and reduced or abolished sense of discriminative touch on the contralateral half of the body if the lesion is situated above the crossing of the fibers in the medulla. Owing to the segmental arrangement of the fibers in the long ascending tracts there frequently will not be a complete unilateral sensory or motor impairment. Circumscribed areas of sensory loss are not rare, and the regions presenting sensory impairment are only distinctly outlined. ^[20] Because of the medial placement of the medial lemniscus, the midline

cranial nerves or medial longitudinal funiculus are affected, causing ocular paresis that helps to define the level of the brain stem involved.

118

Thalamic Lesions

A lesion in the thalamus causes a loss or a decrease of all modalities of sensation on the half of the body contralateral to the lesion. Very small lesions such as lacunes strategically placed in the thalamus may cause tract specific sensory deficits confined to a variable pattern of modalities. In thalamic disorders, sensations evoked by peripheral stimulation may outlast the stimulus for a longer period of time than is normally the case. ^[28]

Sensory Cortical Lesion

Acutely in pure cortical lesions all modalities are affected; however, the modalities of deep sensation (proprioception and discriminative touch) tend to be involved more than the superficial sensory modalities. Vibratory sensation is the exception. Head noted that vibratory sensation was consistently diminished with lesions of the sensory cortex albeit mildly as compared with peripheral lesions. ^[50] With time, pain, touch, and temperature tend to return. The sense of discriminative touch is usually permanently and severely impaired.

There is generally unilateral loss of these modalities. When the loss is over one entire half of the body with cortical lesions the limbs are almost invariably more involved than the face or trunk. This is partly because in the limbs loss of spatial perception is usually the most prominent feature, whereas the face and trunk are poorly endowed with sensibility of this quality.

As the lesion becomes more superficial it would have to be increasingly large to affect all the diverging fibers. Superficial lesions, therefore, tend to affect one localized area only. The sensory disturbances are usually more marked in the distal than in the proximal segments of the limbs, probably owing to wider representation in the cortex.

Responses are characteristically variable from moment to moment. There is not a definite or sharp border, as the sensory loss generally fades away gradually into the region of normal sensibility. The different parts of the body do not regain their sensibility at the same rate. The face regains it fastest, especially the oral region, larynx, and anogenital region. The distal parts of the extremities have restitution that is far from complete. Patients with cortical lesions may also experience sensory phenomena like the inability to recognize their own limbs, or alien hand syndrome.

Sensory Syndromes Associated with Psychogenic Sensory Loss

A psychogenic sensory loss should be suspected in patients with sensory loss that demonstrates hyperesthesia for one modality in a given area and anesthesia for another in the same area, absolute loss of all cutaneous sensation, hyperesthesia that resolves with mild distraction, and sensory levels that correspond to the patient's body image rather than organic sensory levels. The examiner should look for abrupt midline changes, vibration asymmetry over a fixed bone that spans the midline, vibration asymmetry at a fixed midline point as the tuning fork is pivoted from one side to the other, and marked variation with repeated examination. The validity of determining a psychogenic sensory loss with these factors has been debated. ^[51], ^[52]

[PreviousNext](#)

GENERAL MANAGEMENT GUIDELINES

Regardless of the cause of the sensory loss in the patient with an insensate extremity, it is important to increase the patient's awareness of potential injuries. For example, the patient should be instructed (1) not to use the insensate hand when cooking or smoking; (2) not to place the insensate extremity in hot water; and (3) to type on a manual typewriter or play a piano/guitar to avoid trauma to the hands.

In the patient with a functional impairment secondary to sensory loss, a rehabilitative process should be instituted. The objectives of sensory re-education are to improve the perception of sensory information arising from receptors in the hand and to improve motor skills. It is important for the patient to integrate the involved limb into normal movement patterns as early as possible.

The principle of sensory re-education focuses on allowing the patient to learn to make sense of unfamiliar somatic sensations through repeatedly matching them to vision and at the same time developing tactics of perception in the form of purposeful exploratory movements of the hand. One method illustrating the latter is to have patients attempt to differentiate objects from a background medium such as sand, rice, or beans. To re-educate moving touch perception, the patient can be asked to repeatedly discriminate between a square nut and a hexagonal one, each of which is rolled across the finger. Constant touch can be rehabilitated by having the patient discriminate between large and small nuts. As discrimination improves, smaller objects are used to increase the difficulty. ^[53]

HISTORY AND DEFINITIONS

The theory of the specificity of sensation, proposed at the end of the last century, maintains that each type of sensation is conveyed by a separate anatomical pathway. This theory has been repeatedly questioned. Sir Henry Head postulated the existence of two sets of sensory inputs to the central nervous system (CNS), the epicritic and the protopathic inputs. Epicritic sensation allowed discrimination of touch, temperature, and pain, whereas protopathic sensation was a poorly localized, unpleasant, and long-lasting sensation. This protopathic sensation was physiologically inhibited in the central nervous system by the epicritic system. Head based his conclusions on careful observations of the recovery of sensation after experimental division of his own cutaneous nerves. Later, Trotter and Davies dismissed the theory of epicritic and protopathic sensations after performing equally careful experiments on themselves, maintaining that Head's findings could all be attributed to activity in the regenerating nerve fibers. The debate continues about whether sensation, particularly pain, is the result of a pattern of activity in the afferent sensory pathways or of activity in separate specific channels.

Pain is the consequence of stimulation of pain-sensitive structures and is often an early sign of disease or tissue damage. When pain is the result of physiological activity in the normal pain receptors, and there is no primary dysfunction of the nervous system, it is called nociceptive pain. Nociceptive pain may indicate a disorder in any other system or organ, and its diagnosis and treatment involve different medical specialties. Pain resulting from the dysfunction of the central or peripheral nervous system is called neuropathic pain,^[1] and its treatment usually involves the neurological team. Neuropathic pain actually involves different kinds of pain and reflects different pathophysiological mechanisms (see later discussion).

CLINICAL HISTORY

Sensory dysfunction becomes manifest through two types of symptoms: "negative" and "positive" sensory phenomena. ^[1] A negative sensory phenomenon is an expression of a deficit of sensory function such as loss of warm or cold sensation or hypalgesia. However, patients rarely recognize these deficits, and because of the protective role of nociceptors, such deficits frequently lead to painless, repetitive traumatic lesions such as those occurring in patients with syringomyelia or in the feet of diabetics.

A positive sensory phenomenon is an expression of an abnormally increased function of the sensory system such as paresthesias or neuropathic pain. Neuropathic pain may

334

be either spontaneous or stimulus-induced. ^[2] Spontaneous neuropathic pain has certain attributes that must be explored separately: quality, intensity, and distribution. Spontaneous pain may have a burning quality, usually referred to the skin, and is the expression of discharge of the peripheral C-nociceptors. ^[3] Such pain may be sharp when it is caused by excitation of small myelinated A-delta nociceptive cutaneous afferents. ^[4] Electric-like shooting pains, radiating to a limb segment or the face, are usually the result of the generation of ectopic impulses in the nociceptive pathways. ^[5] Unmyelinated C-fiber muscle afferents responsive to noxious mechanical and chemical stimuli have been described in the awake human being. Activity in this type of afferent is perceived as a cramplike sensation. ^[6]

In evaluating pain it is useful to rate its intensity using verbal or visual analog scales to record changes over time or with response to treatment. A frequently used scale rates pain between 0 and 10, 0 being no pain and 10 being "the worst pain one can imagine." The distribution of pain helps to localize the site of the lesion; for example, radicular, nerve, plexus, and central pains have a more or less stereotyped distribution (see later discussion).

Stimulus-induced neuropathic pain is traditionally divided into allodynia, pain induced by a stimulus that is normally not painful, and hyperalgesia, which is an increase in the pain produced by a stimulus that normally causes pain. In clinical practice, hyperalgesia and allodynia always coexist, and in this text the term hyperalgesia is used to refer to both. Hyperalgesia is usually elicited by mechanical and thermal stimuli. Mechanical hyperalgesia has been divided into dynamic and static subtypes. ^[7] Dynamic mechanical hyperalgesia is the unpleasant sensation induced by light stroking of the skin; static mechanical hyperalgesia is pain induced by sustained light pressure of the symptomatic area. Selective blockade of myelinated fibers abolishes dynamic mechanical hyperalgesia without affecting static hyperalgesia. In thermal hyperalgesias, a thermal stimulus, either cold or heat, is perceived as abnormally painful. ^[8]

Spontaneous pain and hyperalgesia may be influenced by certain factors. For example, heat may increase burning pain owing to the sensitization of C-nociceptors, whereas cold may relieve it. On the other hand, cold increases spontaneous burning pain in patients with selective loss of small myelinated fibers. ^[9] Patients with neuropathic pain often volunteer information about autonomic symptoms such as sweating and trophic alterations. An increase in temperature may be an expression of vasomotor sympathetic denervation or neurogenic inflammation. ^[10] A decrease in temperature may be the result of a reflex increase in sympathetic vasomotor tone in response to pain or the development of sympathetic denervation supersensitivity.

Neuropathic pain is usually chronic or recurrent, as in diabetic polyneuropathy or in the recurrent attacks of lancinating root pain. An exception is the acute burning pain characteristic of herpes zoster.

ossicular chain, ending at the stapes. Sound energy is then converted into changes in neural firing, which is passed more centrally through a complex cross-connected network of neurons. This neural network can be considered as a series of four orders of neurons. First order neurons are derived from the auditory (spiral) ganglion, second order neurons are those in the neighborhood of the cochlear nuclei in the brain stem. Third order neurons are found at the level of the inferior colliculus, and fourth order neurons travel from the medial geniculate body in the thalamus to the auditory cortex. Considerably more detail about these pathways can be found in Webster and colleagues.

FIRST ORDER NEURON

The vestibular and cochlear divisions of the inner ear are depicted in Figure 12-1 (Figure Not Available) A. Longitudinally (Figure 12-1 (Figure Not Available) B), the labyrinth is composed of an outer compartment containing perilymph (similar to extracellular fluid), and an inner compartment containing endolymph (similar to intracellular fluid). The hair cells are embedded in the

floor of the inner compartment, the basilar membrane. Two types of hair cells are in the cochlea, inner and outer. When sound is transmitted to the cochlea, oscillations are set up in the basilar membrane, and this stimulates the *inner hair cells*. Place-code mapping occurs between frequency of sounds to areas of the cochlea called a *tonotopic distribution*, which results in registration of higher frequencies at the base of the cochlea and lower frequencies at the apex.

The more numerous *outer hair cells* are motile and may help to dynamically tune the system. Appreciation of the motile nature of outer hair cells has led to a new test of hearing called *otacoustical emissions* or *OAEs* (see later). *Reissner's membrane* roofs the compartment containing the hair cells. In certain conditions in which endolymph pressure is increased (e.g., Meniere's disease), Reissner's membrane may bow out or rupture. The *spiral ganglion of the cochlea* is wrapped around the cochlea and receives output from the hair cells to create the *auditory nerve*, which runs with the vestibular nerve and facial nerve in the internal auditory canal (IAC). In addition to the afferent fibers in the vestibulocochlear nerve, there are also *efferent fibers*, which supply the outer hair cells.

Figure 12-1 (Figure Not Available) The cochlea(A) and vestibular labyrinth(B). (From Kandel ER, Schwartz JH, Jessell TM [eds]: *Principles of Neural Science*, 3rd ed. East Norwalk, CT, Appleton & Lange, 1991.)

SECOND ORDER NEURON

The cochlear nerve enters the brain stem at the pontomedullary junction, where it bifurcates and terminates in the two major subdivisions of the cochlear nucleus--the dorsal and ventral cochlear nuclei (Fig. 12-2). The most important outflow is to the *trapezoid body*, which contains fibers destined for the bilateral superior olivary nuclei in the brain stem. The *superior olive* is concerned with sound localization, based in interaural differences in sound timing and intensity. The superior olive is also an essential part of the stapedius reflex, which is a protective reflex in the middle ear. The simplest stapedius reflex arc involves the spiral ganglion neurons, the cochlear nucleus, superior olive, and facial nerve nucleus. Output from the superior olive joins crossed and uncrossed axons from the cochlear nucleus to form the *lateral lemniscus*. This pathway ascends to the inferior colliculus. Because the lateral lemniscus contains second order neurons from the cochlea and third and fourth order neurons from the superior olive, it contributes to three waves of the auditory brain stem response (described later). The tonotopic arrangement of the cochlea is maintained in the cochlear nucleus, lateral lemniscus and reticular formation. Because of the extensive crossing that occurs early in the central auditory circuitry, central auditory lesions usually do not cause monaural hearing loss.

THIRD ORDER NEURON

The inferior colliculus is a major integrating center for the auditory system and serves as a center for feedback pathways to the lower auditory system. Output from the

Figure 12-2 Central auditory pathways(Reprinted with permission from Kandel ER, Schwartz JH, Jessell T: *Principles of Neural Science*, 3rd ed. East Norwalk, CT, Appleton & Lange, 1991, p 495.)

inferior colliculus ascends to the medial geniculate body of the thalamus.

FOURTH ORDER NEURON

The medial geniculate body is the major auditory nucleus of the thalamus. Parts of the medial geniculate are hypothesized to function in directing auditory attention. The medial geniculate body sends output to the primary auditory cortex, also known as the *transverse temporal gyri of Heschl* (Brodmann areas 41 and 42) and auditory association cortex (areas 22 and 52) (Fig. 12-3 (Figure Not Available)). The medial geniculate also sends output to the auditory motor cortex, which controls body responses to sound. The auditory cortex is divided into three areas, including a primary area (AI), a secondary area (AII), and a remote projection region (Ep). Investigators have varied in assigning area 42 to the primary or secondary auditory cortex. The ventral medial geniculate projects almost entirely to AI, whereas the surrounding auditory areas receive projections from the rest of the geniculate body. As with the lower auditory systems, tonotopic relationships are maintained.

Vestibular System

The peripheral vestibular system consists of a set of three-dimensional angular velocity transducers, the semicircular canals, and a set of three-dimensional linear acceleration transducers, the otoliths (utricle and saccule) (see Fig. 12-1 (Figure Not Available)). These transducers are suspended by an assembly of membranes and connective tissue, the *membranous labyrinth*, within channels in the temporal bone, the *bony labyrinth*. Three important spatial arrangements characterize the semicircular canals. First, each canal within each

Figure 12-3 (Figure Not Available) Cortical auditory areas. Portions of the frontal and parietal lobes have been cut away above the sylvian fissure to expose the insula and the superior temporal lobe. The number of Heschl's gyrus is variable. In this illustration, primary auditory cortex (41) is shown on the first transverse gyrus of Heschl, and area 42 is shown on the second transverse gyrus. PT, planum temp.(Modified from Webster DB, Popper AN, Fay RF: *The mammalian auditory pathway: neuroanatomy*. New York, Springer-Verlag, 1992, p 17.)

labyrinth is *perpendicular* to the other canals, which is analogous to the spatial relationship between two walls and the floor of a rectangular room. Second, the planes of the semicircular canals, between the labyrinths, conform very closely to each other. The six individual semicircular canals become three *co-planar* pairs: (1) right and left lateral; (2) left anterior and right posterior; and (3) left posterior and right anterior. Third, the planes of the canals are close to the planes of the extraocular muscles. This relationship allows relatively simple connections between sensory neurons related to individual canals and motor output neurons, which are related to individual ocular muscles.

The otoliths register linear acceleration, and they respond both to linear head motion and to static tilt with respect to the gravitational axis. The otolithic membranes contain calcium carbonate crystals called *otoliths* and, therefore, they have substantially more mass than the surrounding structures. The increased mass of the otolithic membrane causes the maculae to be sensitive to gravity. In contrast, the cupulae of the semicircular canals have the same density as the surrounding endolymphatic fluid and are insensitive to gravity. Like the canals, the otoliths are arranged in a manner to enable them to respond to motion in all three dimensions. In an upright person, the saccule is vertical (parasagittal), whereas the utricle is horizontally oriented (near the plane of the lateral semicircular canals). In this posture, the saccule can sense linear acceleration in its plane, which includes the acceleration oriented along the occipitocaudal axis and linear motion along the anteroposterior axis. The utricle senses acceleration in its plane, which includes lateral accelerations along the interaural axis, as well as anteroposterior motion.

VESTIBULAR GANGLION AND NERVE

Vestibular nerve fibers are the afferent projections from the bipolar neurons of Scarpa's ganglion. The vestibular nerve transmits afferent signals from the labyrinths through the *internal auditory canal* (IAC). In addition to the vestibular nerve, the IAC also contains the cochlear nerve (hearing), the facial nerve, the nervus

intermedius (a branch of the facial nerve), and the labyrinthine artery. The IAC travels through the petrous portion of the temporal bone to open into the posterior fossa at the level of the pons. The vestibular nerve enters the brain stem at the pontomedullary junction and contains two divisions, the superior and inferior vestibular nerves. The *superior vestibular nerve* innervates the utricle, as well as the superior and lateral canals. The *inferior vestibular nerve* innervates the posterior canal and the saccule.

VESTIBULAR NUCLEI

The primary vestibular afferents transmit information mainly to the vestibular nuclear complex and the cerebellum. The vestibular nuclear complex is the primary processor of vestibular input, and it implements direct, fast connections between incoming afferent information and motor output neurons. The cerebellum monitors vestibular performance and keeps it "calibrated." In both locations, vestibular sensory input is processed in association with somatosensory and visual sensory input.

The *vestibular nuclear complex* consists of four "major" nuclei (superior, medial, lateral, and descending) and at least seven "minor" nuclei. It is a large structure, located primarily within the pons but also extending caudally into the medulla. The superior and medial vestibular nuclei are relays for the vestibulo-ocular reflex (VOR). The medial vestibular nucleus is also involved in vestibulospinal reflexes (VSR), and it coordinates head and eye movements that occur together. The lateral vestibular nucleus is the principal nucleus for the vestibulospinal reflex. The descending nucleus is connected to all of the other nuclei and the cerebellum, but it has no primary outflow of its own. The vestibular nuclei are linked together via a system of *commissures*, which for the most part are mutually inhibitory. The commissures allow information to be shared between the two sides of the brain stem, and they implement the pairing of canals (discussed earlier).

In the vestibular nuclear complex, processing of the vestibular sensory input occurs concurrently with the processing of extravestibular sensory information (proprioceptive, visual, tactile, and auditory). Extensive connections between the vestibular nuclear complex, cerebellum, ocular motor nuclei, and brain stem reticular activating systems are required to formulate appropriate efferent signals to the VOR and VSR effector organs, the extraocular and skeletal muscles. The vestibular nucleus sends outflow to the oculomotor nuclei, spinal cord, cerebellum, and vestibular cortex.

Three major white matter pathways connect the vestibular nucleus to the anterior horn cells of the spinal cord. The *lateral vestibulospinal tract* originates from the ipsilateral lateral vestibular nucleus, which receives the majority of its input from the otoliths and the cerebellum. This pathway generates antigravity postural motor activity, primarily in the lower extremities, in response to the head position changes that occur with respect to gravity. The *medial vestibulospinal tract* originates from the contralateral medial, superior, and descending vestibular nuclei; it mediates ongoing postural changes in response to semicircular canal sensory input (angular head motion). The medial vestibulospinal tract descends only through the cervical spinal cord in the medial longitudinal fasciculus; it activates cervical axial musculature.

The *reticulospinal tract* receives sensory input from all of the vestibular nuclei, as well as all of the other sensory and motor systems involved with the maintaining balance. This projection has both crossed and uncrossed components, and it is very highly collateralized. As a result, its pathway through the entire extent of the spinal cord is poorly defined. The reticulospinal tract is probably involved in most balance reflex motor actions, including postural adjustments made to extravestibular sensory input (auditory, visual, and tactile stimuli).

The cerebellum is a major recipient of outflow from the vestibular nucleus complex, and it is also a major source of input to the vestibular nucleus itself. Most of the signal traffic is routed through the inferior cerebellar peduncle. The cerebellum is not required for vestibular reflexes, but when removed, vestibular reflexes become uncalibrated and ineffective. Originally, the *vestibulocerebellum* was defined as the portions of the cerebellum that received direct input from the primary vestibular afferents. It is now appreciated that most parts of the cerebellar vermis (midline) respond to vestibular stimulation. The cerebellar projections to the vestibular nuclear complex have an inhibitory influence on the vestibular nuclear complex. The *cerebellar flocculus* adjusts and maintains the gain of the VOR. Lesions of the flocculus reduce the ability of experimental animals to adapt to disorders that reduce or increase the gain of the VOR. The cerebellar *nodulus* adjusts the duration of VOR responses; it is also involved with processing of otolith input.

Vascular Anatomy

The arterial circulation of the inner ear (Fig. 12-4 (Figure Not Available)) is completely supplied by the *labyrinthine artery*. The labyrinthine artery has a variable origin. Most often it is a branch of the *anterior inferior cerebellar artery* (AICA), but occasionally, it is a direct branch of the basilar artery. As it enters the inner ear, it divides into the *anterior vestibular artery* and the *common cochlear artery*. The anterior vestibular artery supplies the vestibular nerve, most of the utricle, and the ampullae of the lateral and anterior semicircular canals. The common cochlear artery divides into a main branch, the *main cochlear artery*, and the *vestibulocochlear artery*. The main cochlear artery supplies the cochlea. The vestibulocochlear artery supplies part of the cochlea, ampulla of the posterior semicircular canal, and inferior part of the saccule. The labyrinth has no collateral anastomotic network and is highly susceptible to ischemia. Only 15 seconds of selective blood flow cessation is needed to abolish auditory nerve excitability.

The *vertebral-basilar arterial system* provides the vascular supply for both the peripheral and central auditory vestibular system. The posterior inferior cerebellar arteries (PICA) branch off the vertebral arteries. They supply the surface of the inferior portions of the cerebellar hemispheres, as well as the dorsolateral medulla, which includes the inferior aspects of the vestibular nuclear complex. The *basilar artery* is the principal artery of the pons. The basilar artery supplies central vestibular structures via *perforator branches*, which penetrate the medial pons, *short circumferential branches*, which supply the anterolateral aspect of the pons, and *long circumferential branches*, which supply the dorsolateral pons. The *anterior-inferior cerebellar artery* (AICA) supplies both the peripheral vestibular system, via the labyrinthine artery, as well as the ventrolateral cerebellum and the lateral tegmentum of the lower two thirds of the pons. Central auditory cortex is mainly supplied by the middle cerebral artery.

EXAMINATION OF THE VESTIBULOCOCHLEAR SYSTEM

Directed Neurological Examination

The "directed" or focused neurological examination for the assessment of cranial nerve VIII includes an evaluation of the external ear, hearing, and vestibular responses. The examination begins with an assessment of *gait and balance*.

Figure 12-4 (Figure Not Available) Arterial supply of the inner ear (From Schuknecht HF: *Pathology of the Ear*. Philadelphia, Lea & Febiger, 1993, p 64.)

Gait can often be observed as the patient walks into the examination room. The most useful test to quantify balance is the *eyes-closed tandem Romberg's* test. Low-normal performance consists of the ability to stand for 6 seconds, heel to toe, with eyes closed. Young adults should be able to perform this test for 30 seconds, but performance declines with age. It is helpful to develop a judgment as to how much ataxia is appropriate for a given degree of vestibular injury. Patients with *bilateral vestibular loss* are moderately ataxic—they make heavy use of vision and (with a narrow base) are unsteady when their eyes are closed. No patient with *bilateral vestibular loss* can stand in eyes-closed tandem Romberg's test position for 6 seconds. Patients with an additional superimposed posterior column position sense deficit, as well as patients with cerebellar dysfunction, are unsteady even with their eyes open. Patients with *chronic unilateral vestibular loss* show very little ataxia, and they can usually perform the eyes-closed tandem Romberg's test. The need to quantify ataxia does not come up in patients with recent unilateral vestibular imbalance, because these patients have a prominent nystagmus. Although numerous vestibulospinal tests have been described over the years, such as the Unterberger and Fukuda stepping test, the test results are not clinically useful because of variable performance in the normal population. In patients with head injury or in those in whom there are other reasons to suspect a central nervous system (CNS) origin of imbalance, basal ganglia function (pulsion/retropulsion tests) should also be performed.

The examination proceeds with an inspection of the external ear and ear canal looking for malformations, infections, masses, or asymmetry. Next, the tympanic membranes should be inspected for wax, perforation, otitis, or mass lesions. It is usually prudent to remove wax before embarking on more sophisticated diagnostic procedures. The tympanic membranes contribute about 20 db to the hearing level. Disorders such as perforation, scarring, fluid accumulation, or wax impaction can cause a conductive hearing loss. A normal tympanic membrane is translucent. Fluid behind the tympanic membrane imparts a straw color.

For *bedside hearing assessment*, the Rinne's and Weber's tests can be used. In the Weber's test, a vibrating 512-Hz tuning fork is placed on the patient's forehead. If the sound predominates in one ear, the patient may have either a conductive hearing loss in that ear or a contralateral sensorineural hearing loss. In the Rinne's test, the base of a vibrating tuning fork is placed on the mastoid and then placed about an inch away from the ear. Sound is normally appreciated better through air than through bone. If sound is heard better through bone, it is likely that there is a conductive hearing loss. Other tuning fork tests include the Bing's and Schwabach's tests. In the Bing's test, the fork is struck and placed on the mastoid tip. The examiner alternately occludes the patient's ipsilateral external meatus. If the patient has normal hearing or a sensorineural loss, he or she notices a change in intensity with occlusion. If the patient has a conductive hearing loss, he or she notices no change. The Schwabach's test is contingent on the examiner having normal hearing; the patient's hearing is compared with the examiner's. For bone conduction testing, if the patient stops hearing the sound before the

examiner, this finding is consistent with a sensorineural loss. If the patient hears the sound longer than the examiner, it suggests a conductive hearing loss.

In current clinical practice, the wide availability of excellent audiometric testing allows a much briefer screening maneuver to be used with excellent results. The examiner's thumb and second finger are rubbed together at an arm's length from one of the patient's ears. Persons with normal hearing can perceive this sound at this distance. If the sound is not perceptible, this noise is brought closer and closer until it is heard, and the distance is recorded. This simple test identifies high-tone hearing loss, and an unexpected loss or asymmetrical findings may warrant formal audiogram studies or further investigations with the tuning fork maneuvers described earlier.

Spontaneous nystagmus is next assessed using Frenzel's goggles, which are illuminated, magnifying goggles worn by the patient. The goggles are placed on the patient, and over the next 10 to 15 seconds, the eyes are observed for the presence of spontaneous nystagmus. The typical nystagmus produced by inner ear dysfunction is a "jerk" nystagmus—the eyes slowly deviate off center and then there is a rapid jerk, which brings them back to the center position. Most other patterns of nystagmus (e.g., sinusoidal, gaze-evoked) is of central origin. If Frenzel's goggles are not available, clinicians can obtain similar information about nystagmus from the ophthalmoscopic examination, by monitoring the movement of the back of the eye. As the back of the eye moves in the opposite direction to the front of the eye, for horizontal and vertical movements, the examiner must remember to invert the direction of the nystagmus when noting the direction of the fast phase. Furthermore, an attempt should be made to determine the effect of fixation on nystagmus. Nystagmus derived from the inner ear is increased by removal of fixation, whereas nystagmus of central origin is variably affected by fixation. Some types of central nystagmus, such as congenital nystagmus, may increase with fixation. Most forms of central nystagmus, however, decrease with fixation. Frenzel's goggles are an excellent means of removing fixation. In the ophthalmoscope test, fixation can also be removed by covering the opposite eye.

If there is little or no spontaneous nystagmus and if Frenzel's goggles are available, the *head-shake test* may be performed in an attempt to provoke a nystagmus. In this maneuver, the patient's eyes are closed and the head is moved in the horizontal plane, back and forth, for 20 cycles. A 45-degree excursion of the head to either side, and a 2-cycle/second frequency should be used. Nystagmus lasting 5 seconds or more is indicative of an organic disorder of the ear or CNS and supports further detailed investigation.

All patients with vertigo should receive a *Dix-Hallpike positional test* (Fig. 12-5). The patient is first positioned on the examination table, so that when lying flat the head will extend over the end of the table. If Frenzel's goggles are available, they are used; however, the test may be adequately performed without them. The patient is moved backward rapidly to lie on the table in the head-hanging-down position. The eyes are observed for the development of nystagmus. If no dizziness or nystagmus is appreciated after 20 seconds, the patient is returned to the sitting

Figure 12-5 Dix-Hallpike Maneuver (From Baloh RW, Halmagyi GH [ed]: *Disorders of the Vestibular System*. New York, Oxford University Press, 1996, p 331.)

position. The head is then repositioned 45 degrees to the right, and the patient is again brought down to the head-right supine position. After another 20 seconds, the patient is returned to the sitting position, and the procedure is repeated to the left (head-left). A burst of nystagmus, provoked by either the head-right or head-left position, should be sought. The nystagmus of classic BPPV beats upward and also has a rotatory component, such that the top part of the eye beats toward the down ear. The nystagmus typically has a latency of 2 to 5 seconds, lasts 5 to 60 seconds, and is followed by a downbeating nystagmus when the patient is placed upright in sitting position. A lateral-canal variant of BPPV occurs in which the eyes beat horizontally, toward the down ear. Nystagmus that is sustained longer than 1 minute is unlikely to be BPPV.

Although other positional tests can be used, they are of considerably less utility than the Dix-Hallpike test because of the relatively low incidence of causes of positional nystagmus other than BPPV. Central positional nystagmus such as a persistent downbeat or lateral beating nystagmus may be registered best by simple positional maneuvers wherein the head is supine rather than hyperextended, as in the Dix-Hallpike maneuver. Rarely, patients may develop nystagmus related to the position of their head on neck rather than with respect to gravity, and in these instances maneuvers should be done wherein the trunk is rotated with respect to a stable head.

Maneuvers used at the *assessment of VOR gain* are aimed at documenting bilateral vestibular loss. They need

not be done unless the patient has failed the eyes-closed tandem Romberg's test (see earlier). *The dynamic illegible E test* is the easiest and most sensitive of these

tests. Using an eye chart located at least 10 feet away from the patient, visual acuity is recorded with the head still. Then, the examiner moves the patient's head horizontally at roughly 1 Hz, ± 30 degrees, and visual acuity is again recorded. Normal individuals lose zero to two lines of acuity with head movement. Patients with partial to complete loss of vestibular function have a reduction of three to seven lines of acuity. The *ophthalmoscope test* is done when the dynamic illegible E test result is positive. The examiner focuses on the optic disc and then gently moves the head as described earlier. If the disc moves with the head, it confirms that the VOR gain is abnormal. This test is less sensitive than the illegible E test but is objective in nature. The *rapid doll's head test* can also be used when the illegible E test result is positive. The examiner stands in front of the patient, and the patient focuses on the examiner's nose. The examiner slowly rotates the patient's head to one side, roughly 30 degrees. Then, while asking the patient to continue to fixate, the head is rapidly rotated to the opposite mirror image position. In a normal subject, the eyes remain fixated on the examiner's nose throughout the entire procedure, moving equal and opposite to the head. In a patient with a poor vestibular-ocular reflex, such as in bilateral vestibular loss, a refixational eye movement is necessary after the head has stopped moving. This test can also sometimes detect unilateral vestibular lesions, because there may be a refixation saccade only when the head is rotated toward the bad side.

The *hyperventilation test* is most useful in patients with normal examinations up to this point. In this test the patient breathes deeply and forcefully for 30 breaths at a rate of roughly one breath per second. Immediately after hyperventilation, the eyes are inspected for nystagmus with the Frenzel's goggles, and the patient is asked if the procedure reproduced symptoms. A subjectively positive test result without nystagmus suggests the diagnosis of hyperventilation syndrome and is thought to be a sign of an anxiety disorder. Nystagmus induced by hyperventilation can occur in patients with tumors or irritation of the eighth nerve or in the setting of multiple sclerosis.

Associated Neurological Findings

Cerebral. Assessment of *cognitive function* does not often contribute to diagnosis of syndromes involving cranial nerve VIII. Unless there are specific issues suggested by history, this portion of the neurological examination can usually be omitted. The examination for aphasia should be undertaken if it appears that there is a discrepancy between the ability to detect sound versus the patient's ability to interpret sound. For example, an individual with cortical deafness may startle to a hand-clap but otherwise appears deaf.

Cranial Nerves. Other *cranial nerves* are rarely involved in processes that affect cranial nerve VIII. Corneal reflexes should be assessed when there are sensory complaints involving the face. Rarely, tumors of cranial nerve VIII grow larger than 3 cm and may compress cranial nerve V. Because cranial nerve VII travels with VIII in the IAC, the examiner should evaluate facial movement. Facial weakness is unusual even with large acoustical neuromas, however. In the brain stem, the nuclei of cranial nerves IX, X, and XI are close to that of VIII, and an assessment of the voice, palatal function, and gag may reveal unilateral weakness in certain patients. A careful oculomotor examination is crucial for detecting many subtypes of central vertigo.

Motor/Reflexes/Cerebellar/Gait. The motor examination should include assessment of power in the upper and lower extremities. The cerebellar examination should particularly focus on the assessment of upper extremity coordination. Reflexes should be checked, because asymmetry or a positive Babinski's sign may be a valuable clue to a brain stem disorder.

Sensory. When the history suggests a sensory disturbance, examination should be made of pinprick in the face and extremities. Position sense should be checked in all ataxic patients.

Autonomic Nervous System. The pupils should be also checked for Horner's syndrome (miosis, ptosis, and rarely anhidrosis), because the sympathetic system in the brain stem is at times affected with CN VIII dysfunction, particularly with vascular lesions (Wallenberg's syndrome). Blood pressure and pulse are taken with the patient standing, and if the blood pressure is low (110/70 or lower), it should be repeated with the patient lying flat. These procedures are intended to exclude orthostatic hypotension, which needs to be considered in patients with symptoms suggestive of postural vertigo or ataxia.

Neurovascular Examination. The carotid and subclavian arteries are examined by auscultation in all patients with symptoms that suggest cranial nerve VIII dysfunction.

Associated Medical Findings

The heart and the carotid and subclavian arteries should be auscultated. In patients with pulsatile tinnitus, the head should be auscultated for bruits. In patients with potential syncope who are younger than 70 years of age and have no carotid bruit, 10 seconds of carotid sinus massage may be undertaken. This is done with the patient in the sitting position, first on one side, then on the other, in an attempt to reproduce symptoms.

EVALUATION GUIDELINES (Tables 12-5 and 12-6)

Numerous laboratory procedures are commonly used for evaluation of patients with vertigo and dizziness. For efficiency and cost, procedures should be selected according to specific symptom complexes present in the patient.

Neuroimaging. Skull films, cervical spine films, computed tomography (CT) scans of the head, and CT scans of the sinuses are not routinely recommended in the evaluation of vertigo or hearing disturbances. Magnetic resonance imaging (MRI) of the head can be used to evaluate

the structural integrity of the brain stem, cerebellum, periventricular white matter, eighth nerve complexes, and sinuses. The T1 MRI with gadolinium contrast is the most useful study. MRI is not routinely needed to evaluate vertigo or hearing disturbance without accompanying neurological findings. Although the MRI may show enhancement of the vestibular nerve in vestibular neuritis, the expense of this study should be considered when attempting to document the existence of this self-limited condition. MRI with contrast is preferred to brain stem auditory evoked responses (BAER) testing, when acoustic neuroma is suspected, because it detects tumors at an earlier stage. CT of the temporal bone provides higher resolution than MRI and is preferred in the evaluation of lesions involving bone, particularly when otosclerosis or cholesteatoma is suspected.

Electrophysiology. *Electroencephalography* has a low yield in most disorders related to cranial nerve VIII but is indicated when there is unexplained vertigo after head trauma or for the "quick spin" symptom complex. The BAER test, also known as *auditory brain stem response test*, assesses the auditory nerve and brain stem pathways. This test is usually ordered to rule out an acoustic neuroma, and this study has roughly a 90 percent sensitivity. Because BAER results may be inaccurate in patients who have no high-frequency hearing, audiometry is recommended before BAER testing. The presence of abnormal BAER results is an indication for a MRI evaluation of the posterior fossa (T1-weighted image with contrast). For cost efficiency, BAERs need not be obtained if an MRI is planned, and the MRI is generally the preferred test in most instances. Electrocochleography (ECOG) is a variant of the BAER in which needle electrodes are placed in the ear drum to obtain better definition of the cochlear potential. ECOG is sometimes helpful to confirm a diagnosis of Meniere's disease.

Numerous more unusual electrophysiological tests can be used to infer the integrity of central auditory pathways. The middle latency response, or MLR, is generated by thalamocortical pathways. The "mismatch" response is a test of higher order auditory discrimination. The role of these tests in clinical practice is uncertain.

Fluid and Tissue Analysis. *Blood tests* are triggered by specific symptom complexes, and there is no routine set of values obtained in every patient. In particular, chemistry panels, complete blood counts, glucose tolerance tests, and allergy tests need not be routinely ordered. Similarly, urine testing is rarely productive in disorders of cranial nerve VIII.

Cerebrospinal Fluid. Lumbar puncture has limited usefulness in disorders of cranial nerve VIII. Occasionally, it may be indicated in pursuit of the diagnosis of neurosyphilis, Lyme disease, and meningeal carcinomatosis.

Neuropsychological Tests. Neuropsychological testing of speech and language may be helpful in patients in whom the diagnosis of a central hearing disturbance is being entertained. Otherwise, these procedures have limited usefulness in the evaluation of disorders of cranial nerve VIII. The Minnesota Multiphasic Personality Inventory has some usefulness when the diagnosis of malingering is being considered. Neuropsychological testing may also be useful in determining how much anxiety is associated with the patient's symptom complex.

Other Tests. The audiogram is the single most useful test in the patient with a hearing disorder and/or vertigo. In hearing disorders, the audiogram is crucial in defining the degree and type of loss. In patients with vertigo, abnormalities in the audiogram usually narrow the differential diagnosis down to otological vertigo. Accompanying the audiogram is a battery of related measures. The *tympanogram* measures middle ear pressure, and tympanometry is helpful in identifying a perforated ear drum or middle ear infection. *Acoustical reflexes* measure the stapedius and tensor tympani reflex-generated ear drum movement in

response to intense sound, and they can be helpful in corroborating particular types of hearing loss. Reflexes that are present at abnormally low levels suggest recruitment with a cochlear site of lesion. Reflexes that decay rapidly suggest a retrocochlear lesion.

The *word recognition score (WRS)* (also called *speech discrimination*) measures the ability to repeat words presented at a comfortable loudness. Word recognition can be impaired by both auditory distortion and central abnormalities such as a nonfluent aphasia. Speech reception threshold (SRT) measures the auditory threshold of hearing for words. It should be consistent with pure-tone hearing. When they are not consistent, a nonperipheral hearing disturbance is more likely.

The short-increment sensitivity index (SISI), alternate binaural loudness balance (ABLB), and Bekesy's tests are no longer used in most clinical practices. Audiometry is particularly useful in the diagnosis of Meniere's disease. A fluctuating low-tone sensorineural hearing loss is typical of this condition ([Fig. 12-6](#)).

Otoacoustic emissions have become an added option to the hearing evaluation. A click is usually used to generate the response. The outer hair cells generate a sound in response to the stimulus, and this sound is captured by a microphone in the ear canal. The test has proven useful for infant hearing screening.

Four types of vestibular tests are selected according to the clinical situation. *Electronystagmography (ENG)* is the most useful, and it consists of a battery of procedures that can identify vestibular asymmetry (such as that caused by vestibular neuritis) and that document spontaneous or positional nystagmus (such as that caused by BPPV). Because of anatomical variability and technical difficulty, the ENG result can be misleading, most commonly suggesting an abnormality when none exists. An abnormal result that does not fit the clinical picture should be confirmed with *rotatory chair* testing. Rotatory chair testing measures vestibular function of both inner ears together and is also highly sensitive and specific for bilateral loss of vestibular function. Although rotatory chair testing does not establish the side of a unilateral vestibular lesion, there is a characteristic pattern on unilateral loss. For this reason it can also be helpful in corroborating an abnormal ENG. *Fistula testing* involves the recording of nystagmus induced by pressure in the external ear canal. Its sensitivity to a perilymph fistula is only 50 percent, but it is the only objective procedure that is available to substantiate a clinical suspicion of fistula. *Posturography* is an instrumented variant of the Romberg's test. The sole diagnostic indication for posturography at this writing is to document malingering.

Syncope is a common differential diagnosis in the evaluation of disorders of cranial nerve VIII; it is sometimes useful to check patients for arrhythmia or abnormal control

Figure 12-6 Audiogram depicting the low-tone sensorineural loss typical of Meniere's disease. The gray shaded area indicates the normal range. The $le(X$ marks) is normal at all frequencies. The right $ec(circles)$ has decreased hearing on both air and bone for lower frequencies.

of blood pressure. *Ambulatory event monitoring* or Holter monitoring is used to detect arrhythmia or sinus arrest. *Tilt-table testing* is sometimes advocated for the diagnosis of syncope. At present, however, this is a lack of data establishing a link between tilt-table test abnormalities and successful treatment outcomes, and thus the role of the tilt-table test in the evaluation of dizzy patients is presently unclear.

CLINICAL SYNDROMES ([Table 12-7](#))

Syndromes Primarily Involving Hearing

Hearing loss is highly prevalent, especially in the older population, and three types are commonly encountered: conductive, sensorineural, and central hearing loss. In conductive hearing loss, sound is not transmitted into the inner ear. Diagnosis is ordinarily made via observation of an "air-bone gap" on audiometry, meaning that hearing is superior when sound is transmitted in such a way that it bypasses the middle ear ossicular chain. Causes include a buildup of ear wax, foreign body in the ear canal, otosclerosis, external or middle ear infections, allergy with serous otitis, and perforation of the tympanic membrane. Characteristically, hearing aids work well for this population.

Sensorineural hearing loss is the most common type of hearing loss, occurring in 23 percent of the population older than 65 years of age. The term *sensorineural* is used to indicate that there is either a cochlear or an eighth nerve lesion. The diagnosis of a sensorineural pattern hearing loss is made through audiometry, which shows a significant hearing loss without the air-bone gap characteristic of conductive hearing disturbances. Common causes include old age (when the hearing pattern is often somewhat confusingly called *presbycusis*), Meniere's disease, toxin exposures (such as to high-dose aspirin), and noise. Treatments are mainly aimed at preventing further damage. If the loss is minor, avoidance of noise and avoidance of ototoxic medications are appropriate "treatments." If the loss is significant, a hearing aid should be tried. Occasionally, persons with acquired deafness can be treated with a surgically implanted prosthesis that directly stimulates the spiral ganglion.

Central hearing loss is extremely rare compared with the

TABLE 12-7 -- SELECTED ETIOLOGIES ASSOCIATED WITH DISORDERS OF CRANIAL NERVE VIII

Etiological Category	Specific Etiologies	Chapter
STRUCTURAL DISORDERS		
Developmental structural disorders	Arnold-Chiari malformation Mondini malformation	28

AICA, anterior inferior cerebellar artery; PICA, posterior inferior cerebellar artery.

sensorineural or conductive types. The diagnosis is usually not made by the pure tone audiogram, which often yields a normal result. Rather, patients usually have an aphasia, which may be associated with disproportionately poor scores on the speech reception threshold tests or word recognition scores portions of the audiogram.

Pure word deafness is a rare subtype of central deafness. This disorder is defined as disturbed auditory comprehension without difficulties with visual comprehension. Patients characteristically have fluent verbal output, severe disturbance of spoken language comprehension and repetition, and no problems with reading or writing. Nonverbal sounds are correctly identified. The lesion is classically postulated to be a disruption in connections between the dominant Heschl's transverse gyrus and the medial geniculate as well as callosal fibers from the opposite superior temporal region. Initially, it appears commonly as a Wernicke's aphasia. With recovery, difficulties in auditory comprehension persist. Although usually caused by a stroke, pure word deafness can arise from other causes of focal cortical lesions such as tumors.

Auditory agnosia, another rare subset of central deafness, is typified by relatively normal pure tone hearing on audiometry, but inability to interpret (recognize) nonverbal sounds such as the ringing of a telephone. Inability to interpret nonverbal sounds but preserved ability to interpret speech may be a result of a right hemisphere lesion alone. Amusia is a particular type of auditory agnosia in which only the perception of music is impaired. Again, right-sided temporal lesions are thought to be the cause.

Cortical deafness is essentially the combination of word deafness and auditory agnosia. It is characterized by an inability to interpret either verbal or nonverbal sounds with preserved awareness of the occurrence of sound (for instance, by a startle reaction to a clap). In most instances, the cause is bilateral embolic strokes in the area of Heschl's gyri. Patients present with sudden deafness evolving later so that they can hear sounds but are unable to recognize their meaning. Relatively few cases of this disorder have been studied, and it is possible that bilateral lesions of the central auditory pathways, other than the speech cortex, can also result in these deficits.

Auditory hallucinations consist of an illusion of a complex sound such as music or speech. These hallucinations most commonly occur as a result of an injury to the

superior temporal auditory association areas. Penfield discovered that stimulating this area induced an auditory sensation that seemed real to patients. Auditory hallucinations can also occur as a result of temporal lobe seizure.

Syndromes Primarily Involving Vestibular Function

Conditions that involve vestibular function can be separated into peripheral (otological vertigo) and central subgroups. Patients with these syndromes present clinically with a combination of vertigo and ataxia. Practically, there are far more cases of otological vertigo than central vertigo, and for this reason, in clinical practice, a detailed understanding of otological vertigo is essential.

BENIGN PAROXYSMAL POSITIONAL VERTIGO

Benign paroxysmal positional vertigo is the cause of half of all cases of otological vertigo; it accounts for about 20 percent of all patients with vertigo. Benign paroxysmal positional vertigo is diagnosed by the history of positional vertigo with a typical nystagmus pattern (a burst of upbeating/torsional nystagmus) on Dix-Hallpike positional testing. Symptoms are precipitated by movement or a position change of the head or body. Getting out of bed or rolling over in bed are the most common "problem" motions. A burst of nystagmus can often be provoked by placing the head in positions wherein the posterior canal is made vertical in space, and ENG testing may be helpful in documenting this condition. Benign paroxysmal positional vertigo is usually a straightforward clinical diagnosis. Ordinarily there is no need to obtain neuroradiological tests, audiometric testing, or posturography.

It is currently thought that BPPV is caused by the presence of free debris, possibly otoconia, within the semicircular canals, which is dislodged from the otolith organs by trauma, infection, or degeneration ([Fig. 12-7](#)). The otoconial debris can move about by changes in head position, causing vertigo and nystagmus when the debris tumble through the semicircular canals. The duration of symptoms is brief, because dizziness occurs only while the debris shifts position. Physical treatments based on the manipulation of head are the most effective remedies for BPPV. These maneuvers reposition the otolithic debris to an insensitive location within the inner ear.

VESTIBULAR NEURITIS AND OTHER UNILATERAL VESTIBULOPATHIES

Vestibular neuritis is a self-limited otological condition. Patients present with vertigo, nausea, ataxia, and nystagmus. Most cases of vestibular neuritis are monophasic. Hearing is not impaired, and when there are similar symptoms with abnormal hearing, the syndrome is termed *labyrinthitis*. A strong nystagmus is seen acutely, and Frenzel's

Figure 12-7 Debris hypothesis of benign paroxysmal positional vertigo. Otoconia displaced from the utricle gravitate to the most dependent parts of the inner ear.

goggles are particularly useful in seeing these eye movements. Vestibular neuritis is thought to be caused by viral infections involving the vestibular portion of the eighth nerve.

Similar symptoms may be seen with other etiologies. Meniere's disease is usually recognized by the episodic pattern (see later). Herpes simplex virus infection of the vestibular nerve is recognized by a combination of ear pain and the presence of vesicles on the external canal. Acoustic neuroma (discussed later) is recognized by a slower course and the occurrence of hearing loss. Vascular disorders such as a labyrinthine artery infarction are generally impossible to exclude, and their diagnosis is suggested by an identical symptom complex combined with vascular risk factors.

No laboratory testing is needed in straightforward cases. When a central disorder is suspected in the setting of multiple cerebrovascular risk factors or neurological diseases, however, further laboratory testing may be helpful to confirm the anatomical diagnosis. Electronystagmography testing often reveals a significantly decreased caloric response on one side as well as spontaneous nystagmus. Rotational testing is not necessary, but when obtained, it typically shows reduced gain and increased phase lead. Posturography is also not necessary, but results are typically abnormal, indicating that balance is impaired.

In vestibular neuritis, severe distress associated with constant vertigo, nausea, and malaise usually lasts 2 or 3 days, and less intense symptoms ordinarily persist for 1 or 2 weeks. The treatment strategy involves the use of vestibular suppressants and antiemetics ([Tables 12-8](#) and [12-9](#)). Roughly 10 percent of patients may take as long as 2 months for the condition to improve substantially. These patients usually have a significant fixed vestibular paresis combined with central dysfunction that slows their compensation. For example, patients with alcoholic cerebellar degeneration or persons of advanced age may recover much more slowly. Such patients often benefit from visual- vestibular exercises.

Vestibular exercise instructions may be given to patients in the form of a handout. These exercises are done three times daily, moving from the easier procedures to more difficult ones, as recovery ensues. Specialized physical therapy programs are also available in which individualized therapy can be offered and supervision provided, when appropriate. It should also be noted that numerous avocational activities serve well to promote vestibular compensation, and depending on the abilities and interests of patients, clinicians may prescribe golf, bowling, racquetball, bicycling, or even t'ai chi.

CEREBELLOPONTINE ANGLE SYNDROME

Acoustic neuromas and other tumors such as meningiomas, which can appear at the cerebellopontine angle, usually display asymmetrical sensorineural hearing loss. Usually, patients in the fifth or greater decade present with mild vertigo or ataxia, accompanied by a significant asymmetrical hearing loss. Generally, there are no other physical examination abnormalities, and facial and sixth nerve functions are ordinarily normal.

If the hearing loss is minor, an audiogram may be performed within 6 months. If hearing loss progressively worsens, an MRI scan should be pursued. If a tumor is identified and is small, or the patient is reluctant to have surgery, the tumor may be followed with periodical evaluations. MRI should be repeated every year, more frequently if there is a substantial change in hearing. In many instances, lesions remain stable over many years and surgery can be avoided. Gamma knife treatment is an emerging modality and may also be used when surgery is refused or when the patient is a poor surgical risk.

MeNIERE'S DISEASE

Classic Meniere's disease presents as a quadrad of paroxysmal symptoms, including tinnitus, monaural fullness, fluctuating hearing, and episodic vertigo. This clinical picture is sometimes called the "hydrops" symptom complex, inferring that the mechanism is related to dilation and

TABLE 12-8 -- VESTIBULAR SUPPRESSANTS

Drug	Dose	Adverse Reactions	Pharmacologic Class and Precautions
Meclizine (Antivert, Bonine)	12.5-50 mg every 4-6 hours	Sedating, precautions in prostatic enlargement, glaucoma	Antihistamine Anticholinergic
Lorazepam (Ativan)	0.5 mg twice daily	Mildly sedating Drug dependency	Benzodiazepine
Clonazepam (Klonopin)	0.5 mg twice daily	Mildly sedating Drug dependency	Benzodiazepine
Scopolamine (Transderm-Scop)	0.5 mg patch every 3 days	Topical allergy with chronic use. Precautions in glaucoma, tachyarrhythmias, prostatic enlargement	Anticholinergic

Dimenhydrinate (Dramamine)	50 mg every 4-6 hours	Same as meclizine	Antihistamine Anticholinergic
Diazepam (Valium)	2-10 mg (1 dose) given acutely orally, intramuscularly, or intravenously	Sedating Respiratory depressant Drug dependency Precaution in glaucoma	Benzodiazepine

Doses listed are used in adults Drugs arranged in order of preference.

TABLE 12-9 -- ANTIEMETICS

Drug	Usual Dose (Adults)	Adverse Reactions	Pharmacological Class
Droperidol (Inapsine)	2.5 or 5 mg sublingual or intramuscularly every 12 hours	Sedating Hypotension Extrapyramidal	Dopamine antagonist
Meclizine (Antivert, Bonine)	12.5-50 mg every 4-6 hours orally	Sedating Precautions in glaucoma, prostate enlargement	Antihistamine and anticholinergic
Metoclopramide (Reglan)	10 mg orally three times daily or 10 mg intramuscularly	Restlessness or drowsiness Extrapyramidal	Dopamine antagonist
Ondansetron (Zofran)	4-8 mg po single dose	Hypotension	5-HT ₃ antagonist
Prochlorperazine (Compazine)	5 mg or 10 mg intramuscularly or orally every 6-12 hours or 25 mg rectal every 12 hours	Sedating Extrapyramidal	Phenothiazine
Promethazine (Phenergan)	12.5-25 mg orally every 6-8 hours or 12.5-25 mg rectal every 12 hours	Sedating	Phenothiazine
Trimethobenzamide (Tigan)	12.5 mg intramuscularly every 6-8 hours 250 mg orally three times daily or 200 mg intramuscularly three times daily	Extrapyramidal Sedating Extrapyramidal	Similar to phenothiazine
Thiethylperazine (Torecan)	10 mg orally, up to three times daily or 2 ml intramuscularly, up to three times daily	Sedating	Phenothiazine

Doses listed are used in adults.

rupture of the endolymphatic compartment of the inner ear. The tinnitus is characteristically of two types. Between attacks the tinnitus is characteristically a ringing noise (about 75 percent of the population has ringing tinnitus from time to time). During an attack, the tinnitus becomes a multifrequency noise such as a roar, hiss, or buzz. Patients also generally complain of monaural fullness, a sensation as if the ear were full of water, beginning a day or two before an attack. Hearing is normal at the onset of the condition, but with each attack a low-frequency sensorineural reduction in hearing appears (see [Figure 12-5](#)), and then it usually resolves a day or two later. After many attacks, hearing begins to decline and involves the high frequencies. Ultimately, many individuals with Meniere's disease develop permanent sensorineural pattern deafness.

The clinical picture of Meniere's disease varies widely, with some patients developing deafness with their first attack and others retaining normal hearing after several decades of repeated attacks. Variants of Meniere's disease include a form that follows head injury (labyrinthine concussion or delayed endolymphatic hydrops), and a bilateral form attributed to autoantibodies or genetic predisposition.

The diagnosis of classic Meniere's disease can be made purely by history, but most commonly it is made by combining a history of episodic vertigo and hearing symptoms with audiometric documentation of a fluctuating low-tone sensorineural hearing loss. Electrocochleography may be useful in cases when the history is not classic. It is conventional practice to obtain several blood tests including fluorescent treponemal antibody, antinuclear antibody, complete blood count, and fasting blood glucose after diagnosing Meniere's disease to identify specific treatable causes.

In the treatment of Meniere's disease, vestibular suppressants and antiemetics are used in a way similar to that described for vestibular neuritis (see [Tables 12-8 and 12-9](#)). Because bouts generally last only 2 hours, acute treatment is usually episodic. Often patients can anticipate an attack and can start taking an antiemetic and/or vestibular suppressant before their full-blown symptoms occur. It is presently generally accepted that reduction of salt intake with a no-added-salt diet and daily use of a salt-wasting diuretic is helpful in reducing the number and intensity of spells over the long term.

Effective surgical treatment of Meniere's disease is based on procedures that destroy vestibular function. Three procedures are commonly used today, including labyrinthectomy, selective vestibular nerve section, and transtympanic gentamicin treatment. Gentamicin treatment is presently growing rapidly in popularity.

CENTRAL VERTIGO

In neurological practice, central vertigo typically makes up only about 25 percent of diagnoses of patients presenting with vertigo, because otological vertigo and vertigo of unknown cause are much more frequent ([Table 12-10](#)). Stroke and transient ischemic attacks account for one third of cases of central vertigo. Vertigo attributed to vertebrobasilar migraine accounts for another 15 percent of cases. A large number of individual miscellaneous neurological disorders such as seizures, multiple sclerosis, and the Arnold-Chiari malformation make up the remainder.

GENERAL MANAGEMENT GOALS

General pharmacological management of conditions affecting hearing is nearly nonexistent, in spite of many attempts over the years using vasoactive agents, steroids, and agents for allergy.^[10] When a specific etiology is known,

TABLE 12-10 -- ON CAUSES OF CENTRAL VERTIGO

such as Meniere's disease, treatment directed at the cause may be used, but there is no effective pharmacological management of tinnitus or hearing loss.

Hearing aids are indicated when hearing loss is significant and "aidable," meaning that improvement in word recognition scores may be obtained with amplification. Hearing aids are expensive. They are often not covered by standard insurance policies, and there are considerable performance differences between basic and "deluxe" models. For these reasons, hearing aids should ideally be fit by an experienced audiologist who offers at least a 1-month tryout period.

For tinnitus, an assortment of medications may be empirically tried, including antidepressants, minor tranquilizers, and anticonvulsants. Hearing aids or "maskers" (devices that generate white noise) are helpful in a few patients.

With respect to symptomatic management of peripheral vestibular disorders (see [Tables 12-4](#) and [12-5](#)), vestibular suppressants and antiemetics are generally used. In patients with static and significant structural vestibular lesions, vestibular rehabilitation approaches including vestibular exercises are substituted. In patients with central vestibular disorders, treatment approaches are generally eclectic. Agents used in peripheral disorders are usually tried, followed by empirical trials of other medication groups, including benzodiazepines and anticonvulsants. Vestibular rehabilitation again may be quite useful in this group.

Certain medications should be used with caution in patients with disorders of the eighth cranial nerve. A surprisingly large number of frankly ototoxic medications are in common clinical use (see [Table 12-2](#)). It is usually prudent to eliminate as many of these medications as possible in such patients. In addition, it is common practice to use potentially addictive medications, such as benzodiazepines, in the management of patients with vertigo or imbalance when other medications fail. Although these agents are indispensable in these settings, the doses should be kept low and patient use should be monitored.

Hearing protection is often indicated in patients with damage to the eighth cranial nerve, and patients need to be explicitly warned to avoid loud noises and use hearing protection devices in excessively noisy environments.

HISTORY AND DEFINITIONS

The early concepts of the autonomic nervous system date back to the Roman period, during which Galen described the sympathetic chain ganglion and the rami communicantes. Although he hypothesized that this chain originated in the brain and provided sensory function, he thought that the numerous interconnections allowed the spirits to travel between the various organs, maintaining a physiological "sympathy." Much later, in the sixteenth century, Bartholomeo Eustachio investigated the ganglionated nerves but did not contribute further to our understanding of this system. While still believing that this chain descended from the brain, Thomas Willis (1664) placed its origin in the posterior fossa and associated it with involuntary or automatic motion--specifically, with the motion of the heart and respiration. Francois Pourfour du Petit noted that pupil size and the amount of secretions from the eye were altered when the cervical sympathetic nerves were cut, and cast doubt on the sensory function of the sympathetic chain. In 1732, Winslow introduced the term sympathetic nerve, describing great, middle, and small components. In the nineteenth century, a flurry of research on the autonomic nervous system resulted in Walter Gaskell concluding that this system was actually composed of two subsystems. At the turn of the century, the terms preganglionic, postganglionic, and autonomic were first used by John Newport Langley, who theorized that this system contained both peripheral and central components. During this century, further refinements in our understanding of the autonomic nervous system were contributed by Thomas Elliott, Walter Dixon, and Otto Loewi, among others.

In discussing the autonomic nervous system and disorders related to it, a number of common terms require definition. Orthostatic hypotension (Greek, *orthos*: straight; *statikos*: causing to stand) refers to decreases of 20 mmHg in systolic blood pressure and 10 mmHg in diastolic pressure after standing. Syncope (Greek, *synkope*: cessation, pause), which can occur in the presence of autonomic dysfunction, is characterized by a loss of consciousness and postural tone due to a reversible reduction in blood flow to the reticular activating system in the brain stem. When both the sympathetic and parasympathetic neurotransmissions fail, the condition is typically termed a pandysautonomia. When only acetylcholine neurotransmission fails, the term cholinergic dysautonomia is used, whereas the term adrenergic dysautonomia is used to describe isolated failure of noradrenergic neurotransmission.

[PreviousNext](#)

CLINICAL HISTORY

The presenting symptoms of patients with autonomic failure are extremely varied because the autonomic nervous system (ANS) controls the visceral processes involving the cardiovascular system, gastrointestinal system, urinary bladder, and sexual function as well as thermoregulation. Defective autonomic innervation of blood vessels can cause orthostatic hypotension, and with the subsequent reduction

in blood flow to the brain, a variety of symptoms can develop. Typically, patients complain of visual disturbances (e.g., blurring, tunneling, or darkening of vision), sensations such as dizziness, lightheadedness, giddiness, and feeling faint, as well as a dull neck and shoulder ache (so-called coathanger pain). When orthostatic hypotension is pronounced and cerebral blood flow decreases below a critical level (approximately 25 ml/min/100 g), syncope occurs.

Orthostatic symptoms may be worse in the morning because nocturnal hypertension results in renal sodium and water loss and intravascular volume depletion.^[1] Patients may also note that the symptoms of orthostatic hypotension are worse after eating, after standing still for a period of time, or following exercise or exposure to a warm environment such as a hot shower. All these circumstances divert blood from the central circulation (to the splanchnic area postprandially, to the skin following a hot shower, and to the lower part of the body while standing still) and thus reduce venous return to the heart.

Patients with gastrointestinal autonomic dysfunction have a variety of symptoms resulting from abnormal motility of the stomach and gut. The examiner should inquire about the presence of constipation, diarrhea, nausea, postprandial vomiting, bloating, belching, loss of appetite, and early satiety. Urinary bladder symptoms associated with autonomic dysfunction include hesitancy, poor stream production, increased intervals between micturition, and a sense of inadequate bladder emptying. Patients may also report symptoms associated with urinary retention and overflow incontinence. Male patients may additionally complain of impotence, which often is the earliest symptom of generalized autonomic failure. Sympathetically mediated ejaculatory failure may be an early complaint that precedes erectile failure.

Other characteristic symptoms of autonomic failure are caused by deficient thermoregulatory sweating. Initially, patients may notice reduced sweating only by the presence of dry socks and a lack of skin moisture. When abnormalities are severe, the patient may develop heat intolerance, flushing, or even heat-stroke symptoms.

Pure autonomic failure with no other neurological deficits is rare. More often, autonomic failure occurs in combination with other neurological disorders such as Parkinson's disease and multiple system atrophy (see [Chapter 34](#)). In these patients, it is important for the examiner to inquire about abnormalities in gait, changes in facial expression, the presence of dysarthria, difficulty in swallowing, and balance problems. Autonomic failure also occurs in patients with some peripheral neuropathies, such as those associated with diabetes and amyloidosis. Symptoms related to these disorders, for example, limb weakness and sensory deficits, should also be sought. Because autonomic failure may be caused by lesions at different levels of the nervous system, a history of secondary trauma, cerebrovascular disease, tumors, infections, or demyelinating diseases should be established. Additionally, because the most frequent type of autonomic dysfunction encountered in medical practice is pharmacological, a thorough review of medication use, especially antihypertensives and psychotropic drugs, should be undertaken.

Some conditions may be confused with autonomic failure, including neurally mediated syncope, which is referred to as vasovagal, vasodepressor, or reflex syncope. This condition is caused by a paroxysmal reversal of the normal pattern of autonomic activation that maintains blood pressure in the standing position; these patients do not have autonomic failure. A detailed history is important to differentiate this disorder. In contrast to patients with chronic autonomic failure in whom syncope appears as a gradual fading of vision and loss of awareness, patients with neurally mediated syncope often have signs and symptoms of autonomic overactivity such as diaphoresis and nausea prior to the event. This distinction and the episodic nature of neurally mediated syncope should be part of a thorough clinical history.

ANATOMY OF THE AUTONOMIC NERVOUS SYSTEM

The term autonomic (autonomous, self-governing) nervous system was introduced to describe "the system of nerves which controls the unstriated tissue, the cardiac muscle and the glandular tissue of mammals." Originally, the term applied only to neurons with axons outside the central nervous system (CNS). More recently, the discovery that discrete neuronal groups in the brain stem, diencephalon, and cerebral cortex are involved in the control of autonomic function has broadened the definition of the ANS to include not only peripheral afferent and efferent pathways but also a complex network of neurons within the CNS.

The cell bodies of afferent autonomic (visceral) neurons are in the dorsal root ganglia of the spinal or cranial nerves and travel in both sympathetic and parasympathetic nerves toward the CNS (Fig. 21-1 (Figure Not Available)). The autonomic CNS neurons are located at many levels from the cerebral cortex to the spinal cord. Efferent autonomic pathways are organized in two major outflows: the sympathetic and parasympathetic. Finally, the enteric nervous system, which is considered a separate and independent division of the autonomic nervous system, is located in the walls of the gut.

Central Autonomic Network

The ANS, like the somatic nervous system, is organized in segmental levels. Neurons in the cerebral cortex, basal forebrain, hypothalamus, midbrain, pons, and medulla participate in autonomic control. Autonomic neurons are reciprocally interconnected by neurochemically complex pathways and constitute a functional unit referred to as the central autonomic network (CAN). The CAN integrates visceral, humoral, and environmental information to produce coordinated autonomic, neuroendocrine, and behavioral responses to external or internal stimuli. Within the CAN, there is segmental and regional specialization for the control of autonomic functions. A coordinated response is generated through interconnections among the amygdala and the neocortex, basal forebrain, ventral striatum, hypothalamus, and autonomic and somatic motor nuclei of the brain stem.

Figure 21-1 (Figure Not Available) Organization of visceral and somatic afferents in the spinal cord (Reproduced from Westmoreland BF, et al: Medical Neurosciences: An Approach to Anatomy, Pathology, and Physiology by Systems and Levels, 3rd ed. Boston, Little, Brown and Company, 1994. By permission of Mayo Foundation.)

CEREBRAL CORTEX AND AMYGDALA

The insular and medial prefrontal cortices (paralimbic areas) and nuclei of the amygdala are the higher centers involved in the processing of visceral information and the initiation of integrated autonomic responses. The insular cortex is the primary viscerosensory cortex and receives viscerotopically organized sensory information from visceral and arterial chemoreceptors and baroreceptors. The ventromedial prefrontal and anterior cingulate cortices initiate autonomic responses associated with affective behavior. The amygdala receives exteroceptive and interoceptive information and provides it with emotional significance.

HYPOTHALAMUS

The hypothalamus integrates the autonomic and endocrine responses that are critical for homeostasis. It is functionally divided into three longitudinal zones: a *periventricular zone* involved in circadian rhythms and endocrine responses, a *medial zone* involved in the control of sexual function, osmoregulation, and thermoregulation, and a *lateral zone* involved in behavioral arousal (Fig. 21-2 (Figure Not Available)). All three zones project to the autonomic nuclei of the brain stem and spinal cord.

The paraventricular hypothalamic nucleus is the site of integrated autonomic and neuroendocrine responses to stress. It contains different subpopulations of "effector" neurons including magnocellular neurons that secrete vasopressin, parvocellular neurons that produce corticotrophic-releasing hormone and other regulatory hormones that control pituitary function, and neurons that innervate all brain stem and spinal autonomic nuclei. The medial preoptic nucleus contains thermosensitive neurons that initiate autonomic, endocrine, and motor responses. Warm-sensitive neurons, excited by an increase in core temperature, initiate responses such as skin vasodilatation, sweating, and slow-wave sleep, which lead to heat loss. Cold-sensitive neurons initiate vasoconstriction and shivering. In humans, these thermoregulatory sudomotor and vasomotor pathways descend in the equatorial plane of the lateral column of the spinal cord.

The ventromedial nucleus is involved in energy metabolism and reproduction. In animals, ventromedial hypothalamic lesions result in obesity, which is associated with a decrease in sympathetic and an increase in parasympathetic nervous system activity. Finally, the lateral hypothalamic area participates in arousal, motivated motor behavior, and autonomic control and has widespread projections. The hypothalamic autonomic pathways descend predominantly ipsilaterally in the dorsomedial and ventrolateral tegmentum of the brain stem.

PERIAQUEDUCTAL GRAY MATTER

The periaqueductal gray matter (PAG) of the midbrain is the site of integrated autonomic, behavioral, and antinociceptive stress responses. It is organized into separate columns that control specific patterns of response to stress. The lateral PAG mediates sympathoexcitation, opioid-independent analgesia, and motor responses consistent with the fight-or-flight reaction. The ventrolateral PAG produces sympathoinhibition, opioid-dependent analgesia, and motor inhibition. The PAG constitutes a critical relay

Figure 21-2 (Figure Not Available) Subdivisions of the hypothalamus (Reproduced from Westmoreland BF, et al: Medical Neurosciences: An Approach to Anatomy, Pathology, and Physiology by Systems and Levels, 3rd ed. Boston, Little, Brown and Company, 1994. By permission of Mayo Foundation.)

station for the micturition reflex (see later discussion on Bladder).

BRAIN STEM

Neurons in the medulla are critical for the control of cardiovascular, respiratory, and gastrointestinal functions. The medullary nucleus of the solitary tract (NTS) is the first relay station for the arterial baroreceptors and chemoreceptors, as well as cardiopulmonary and gastrointestinal afferents. The NTS integrates multiple autonomic reflexes and projects to other central autonomic regions. Neurons in the reticular formation of the ventrolateral medulla are arranged in distinct groups that maintain cardiomotor, vasomotor, and respiratory functions. Neurons in the rostral ventrolateral medulla project directly to sympathetic preganglionic neurons and maintain basal arterial blood pressure, while neurons in the ventral medulla are critical for respiratory rhythmogenesis. The nucleus ambiguus provides parasympathetic innervation to the heart.

These ventromedullary vasomotor, cardiomotor, and respiratory neurons form a network that is coordinated via interneurons of the medullary reticular formation. Together with the NTS, this network is involved not only in the generation of respiratory and cardiovascular rhythms but also in complex motor patterns such as vomiting, swallowing, sneezing, and coughing. The descending reticulospinal pathways for the automatic control of breathing and blood pressure, as well as those for sweating and micturition, run in the ventral half of the white matter of the lateral columns of the spinal cord.

Efferent Autonomic Pathways

The autonomic output to effector organs consists of a two-neuron pathway with one synapse in the peripheral autonomic ganglia. The central neuron is called preganglionic, and the ganglionic neuron is called (illogically) postganglionic. Sympathetic preganglionic neurons are located in the intermediolateral cell column of the gray matter of the spinal cord at all thoracic and high lumbar levels (T1-L3) (thoracolumbar outflow) (Fig. 21-3 A). Parasympathetic preganglionic neurons are located both in the brain stem and at the sacral (S2-S4) level of the spinal cord (craniosacral outflow) (Fig. 21-3 B). Sympathetic and parasympathetic preganglionic axons emerge from the brain stem or spinal cord as small myelinated fibers, but postganglionic sympathetic and parasympathetic axons to the peripheral effector organs are unmyelinated.

SYMPATHETIC OUTFLOW

Preganglionic sympathetic neurons are organized into different functional units that control blood flow to the skin and muscles, secretion of sweat glands, skin hair follicles, systemic blood flow, as well as the function of viscera. Preganglionic sympathetic neurons receive direct descending excitatory input from the paraventricular and lateral nuclei of the hypothalamus as well as the ventromedial and ventrolateral medulla. These pathways coordinate selective rather than massive patterns of sympathetic discharge by innervating different specific subsets of preganglionic sympathetic neurons. Selectivity is further refined by the release of different neurotransmitters.

Preganglionic sympathetic axons exit through the ventral roots and pass through the white rami of the corresponding spinal nerve toward paravertebral or prevertebral ganglia (see following paragraphs). These axons have a segmental organization, but their distribution does not follow the dermatomal pattern of somatic nerves. Segments T1-T3 innervate the head and neck, T3-T6 the upper extremities and thoracic viscera, T7-T11 the abdominal viscera, and T12-L2 the lower extremities and pelvic and perineal organs.

Sympathetic ganglia are organized into two anatomical and functionally distinct groups: paravertebral and prevertebral ganglia. At the paravertebral ganglia (located at the sides of the spinal cord), preganglionic fibers may synapse on a postganglionic neuron at the same level or branch and run rostrally or caudally to synapse on a large number of postganglionic neurons at different levels. Preganglionic fibers also pass through the paravertebral ganglia without synapsing to form the splanchnic nerves that innervate the prevertebral ganglia (located anterior to the spinal cord) or the adrenal medulla.

The paravertebral ganglia provide long unmyelinated axons to all sympathetically innervated tissues and organs except those in the abdomen, pelvis, and perineum. The superior cervical ganglion (T1-T2) provides pupilodilator

Figure 21-3 Sympathetic(A), and parasympathetic(B) divisions of the autonomic nervous system: efferent system (Modified from Noback C, Demarest R: *The Human Nervous System. Basic Principles of Neurobiology*. New York, McGraw Hill, 1981, p 228.)

and sudomotor fibers to the face. The stellate ganglion (T2-T6) innervates the upper limb through branches of the brachial plexus, and the lumbar sympathetic ganglia (T9-L1) innervate the lower limb through branches of the lumbosacral plexus. The postganglionic sympathetic fibers join the peripheral somatic nerve via the gray rami communicantes, and thus their distribution is similar to that of the corresponding somatic nerve. Sympathetic fibers in somatic nerves provide vasomotor, sudomotor, and pilomotor innervation to the extremities and trunk. The lower cervical and upper thoracic ganglia innervate the heart via the cardiac plexus and the tracheobronchial tree via the pulmonary plexus.

The prevertebral ganglia innervate the abdominal, pelvic, and perineal organs. Preganglionic fibers from T5-T12 levels are carried by the thoracic splanchnic nerves, which pierce the diaphragm and enter the abdomen to synapse on the celiac and superior mesenteric ganglia. These form the celiac plexus, which innervates all abdominal viscera except the descending colon. Sympathetic activation produces splanchnic vasoconstriction, inhibition of secretion and motility of the gut, as well as secretion of epinephrine, renin, and glucagon. Preganglionic axons from L1-L3 levels, carried by the lumbar splanchnic nerves, synapse on the inferior mesenteric ganglion. The postganglionic axons innervate the descending colon, rectum, bladder, and genitalia via the hypogastric plexus. Sympathetic nerves inhibit muscle contractility of the bladder and bowel, thus allowing storage of urine and feces. These postganglionic neurons also produce the contraction of the vas deferens that is necessary for ejaculation.^[13]

PARASYMPATHETIC OUTFLOW

The cranial parasympathetic neurons are located in the general visceral efferent column of the midbrain, pons, and medulla. Their preganglionic axons travel in the third, seventh, ninth, and tenth cranial nerves (see [Chapters 9](#), [11](#), and [13](#)). Parasympathetic outputs carried via the third nerve produce pupillary constriction and accommodation of the lens. Output carried via the seventh and ninth cranial nerves stimulates lacrimal and salivary secretion. The vagus nerve (tenth nerve) provides the most widespread brain stem parasympathetic output. Vagal preganglionic neurons are located in the dorsal motor nucleus, which controls respiratory and abdominal viscera, and in the region of the nucleus ambiguus, which innervates the heart. The vagus provides inputs to parasympathetic ganglia located in or near the target organs, and its main effects are cardioinhibitory, visceromotor, and secretomotor.

The sacral preganglionic parasympathetic neurons are located in the intermediolateral cell column at the S2-S4

levels of the spinal cord. Their axons pass through the ventral roots to the pelvic splanchnic nerves (nervi erigentes), which join the inferior hypogastric (pelvic) plexus. The sacral parasympathetic system is critical for defecation, micturition, and erection.^[13]

EFFERENT AUTONOMIC NEUROTRANSMITTERS

Acetylcholine is the neurotransmitter of the sympathetic and parasympathetic preganglionic neurons. Acetylcholine produces fast excitation of ganglion neurons via nicotinic receptors. The main postganglionic sympathetic neurotransmitter is norepinephrine, which acts through alpha- and beta-adrenergic receptors. The sympathetic innervation of the sweat glands is mediated by acetylcholine, acting via muscarinic receptors. The main postganglionic parasympathetic neurotransmitter is acetylcholine, which acts through different subtypes of muscarinic receptors. Postganglionic sympathetic terminals to the heart and smooth muscles also release adenosine triphosphate and neuropeptide Y, whereas postganglionic parasympathetic terminals may release vasoactive intestinal polypeptide or nitric oxide.

Alpha-adrenergic receptors mediate sympathetically induced pupillary dilatation (mydriasis), vasoconstriction, and contraction of the vas deferens and bladder and rectal internal sphincters. Beta receptors mediate cardiac stimulation, vasodilation, bronchodilation, relaxation of the bladder, and endocrine-metabolic effects. Muscarinic receptors mediate pupil constriction (miosis), salivary and lacrimal secretion, cardiac inhibition, bronchoconstriction, stimulation of motility and secretion in the gastrointestinal tract, evacuation of the bladder and rectum, and erection.

Afferent Autonomic Pathways

Visceral afferents transmit conscious sensations (e.g., gut distention, cardiac ischemia) and unconscious visceral sensations (e.g., blood pressure, chemical composition of the blood). Their most important function is to initiate autonomic reflexes at the local, ganglion, spinal, and supraspinal levels.^[14] Visceral receptors are innervated by small myelinated and unmyelinated fibers that have cell bodies in the dorsal root ganglia of the spinal or cranial nerves. Spinal visceral afferents are carried by thoracolumbar sympathetic and sacral parasympathetic nerve trunks. In the spinal cord, they branch extensively and synapse on viscerosomatic neurons in the dorsal horn and intermediate gray matter. These neurons receive convergent visceral and somatic inputs and are the substrate for referred pain (i.e., visceral pain referred to overlying or nearby somatic structures). Visceral sensation is carried primarily by the spinothalamic and spinoreticular pathways, which transmit visceral pain and sexual sensations. The dorsal columns may relay sensations related to micturition, defecation, and gastric distention. Viscerosensory inputs, after a relay in the thalamic nuclei, project to the insula and other cortical autonomic areas.^[14]

Brain stem visceral afferents are carried by the vagus and glossopharyngeal nerves, and have their cell bodies in the nodose and petrosal ganglia, respectively. Vagal afferents carry information from aortic, cardiac, pulmonary, and gastrointestinal receptors. Glossopharyngeal afferents carry signals from baroreceptors and chemoreceptors in the carotid sinus. These vagal and glossopharyngeal afferents synapse on neurons of the NTS. Taste and general visceral afferent information from the NTS is relayed, either directly or via the parabrachial nucleus, to the ventroposteromedial nucleus of the thalamus, which in turn projects to the insular cortex. Brain stem visceral afferents are important in complex automatic motor acts such as swallowing, vomiting, and coughing.^[9], ^[15]

Autonomic Innervation of Specific Organs

CARDIOVASCULAR SYSTEM

The heart receives parasympathetic and sympathetic innervation. The cell bodies of the parasympathetic preganglionic neurons innervating the heart are located in the medulla (nucleus ambiguus and dorsal motor nucleus of the vagus). The axons of these neurons, which are part of the vagus nerve, join the cardiac neural plexus after entering the thorax to synapse with neurons in the intracardiac ganglia. ^[16] From these ganglia, short postganglionic parasympathetic neurons emerge to innervate the myocardial tissue. Vagal innervation is particularly abundant in the nodes and the atrioventricular (A-V) conduction system.

The heart draws its sympathetic innervation from neurons in the intermediolateral columns of the spinal cord at the T1-T4 levels. Axons of these neurons synapse in superior, middle, and inferior (stellate) cervical ganglia, which are the origin of postganglionic sympathetic neurons that reach the heart in a mixed neural plexus along with preganglionic parasympathetic neurons. Sympathetic axons innervate the sinoatrial (SA) and atrioventricular (AV) nodes, the conduction system, and myocardial muscle fibers, most prominently in the ventricles. The arteries and veins of the systemic circulation are innervated primarily by the sympathetic system.

Postganglionic parasympathetic neurons release acetylcholine, which activates muscarinic receptors in the heart, causing a decrease in heart rate as well as reductions in the conduction, excitability, and contractility of myocardial cells. Postganglionic sympathetic axons release norepinephrine, which, primarily via beta-adrenergic receptors, increases heart rate and the conduction, excitability, and contractility of the myocardium. Cardiac vagal neurons are activated through the baroreflex (see later discussion) when arterial pressure increases and are inhibited during inspiration. ^[17] Because acetylcholine acts quickly and is rapidly inactivated by cholinesterase, the vagus controls heart rate on a beat-to-beat basis.

Sympathetic outflow to the arteries, arterioles, and veins of the peripheral circulation produces vasoconstriction by activating alpha-adrenergic receptors. The presence of vasodilator cholinergic sympathetic fibers to skeletal muscle in humans is debatable. Sympathetic vasoconstrictor outflow to the blood vessels of skeletal muscle is strongly modulated by the baroreflex (see later discussion) and is important for buffering acute changes in arterial pressure.

38

Splanchnic vasoconstriction produced by sympathetic activation is critical for the maintenance of arterial pressure in the upright posture. Loss of splanchnic vasomotor outflow is the main mechanism causing orthostatic hypotension in autonomic failure.

Autonomic outflow to the heart and blood vessels is controlled on a moment-to-moment basis by a variety of reflexes, which are initiated by arterial baroreceptors and chemoreceptors and by several types of cardiac receptors. Of these reflexes, the one that has been best studied is the arterial baroreflex, which is a classic negative feedback mechanism that buffers fluctuations in arterial blood pressure. Afferent fibers in the vagus and glossopharyngeal nerves with cell bodies in the nodose and petrosal ganglia are sensitive to pressure or mechanical distention (i.e., baroreceptors). These neurons have arborizations that are distributed in the adventitial layer of the carotid sinus and the aortic arch, and their first synapse occurs in the NTS. Impulses from the NTS modify the activity of cardiac vagal motor neurons in the nucleus ambiguus and neurons in the ventrolateral medulla that control sympathetic outflow. ^[15] When arterial pressure increases, afferent baroreceptor discharge in the NTS increases. This results in a rapid increase in cardiovagal efferent activity, which slows the heart, and in inhibition of sympathetic vasoconstrictor outflow, which causes vasodilatation. Conversely, when blood pressure falls, for example when standing up, baroreceptors are "unloaded," and their afferent discharge to the NTS decreases. This results in reflex sympathetic excitation and parasympathetic inhibition, which cause vasoconstriction and tachycardia.

Cardiovascular reflexes also control the release of vasopressin from the supraoptic and paraventricular hypothalamic nuclei. These neurons are tonically inhibited by baroreceptor input, and therefore a fall in arterial pressure elicits an increase in vasopressin release. ^[18]

SKIN

Sympathetic innervation of the skin plays an important role in thermoregulation and the expression of emotional states. The sympathetic outflow to the skin includes cholinergic neurons innervating sweat glands (sudomotor neurons) and adrenergic neurons innervating blood vessels and hair follicles (vasoconstrictor and pilomotor neurons). Cutaneous vasomotor activity and sweating in the face is controlled by the T2-T3 segments of the spinal cord via the superior cervical ganglion. Postganglionic axons accompany branches of the internal carotid (for innervation of the forehead) and external carotid arteries (innervating the rest of the face) and follow branches of the trigeminal nerve. Sympathetic outflow produces vasoconstriction in the ears and lips but predominantly vasodilatation in the rest of the face. Fibers from the stellate ganglion (which receives innervation from T2-T6 preganglionic neurons) innervate the arm via branches of the brachial plexus. The lumbar sympathetic ganglia (which receives innervation from T9-L1 preganglionic neurons) innervate the lower limb via branches of the lumbosacral plexus. The trunk is innervated by the intercostal nerves.

Exposure to cold produces skin vasoconstriction (pallor) and piloerection (goose flesh) via alpha-adrenergic mechanisms; conversely, a warm environment elicits vasodilatation (redness, flushing) and sweating via muscarinic receptors. During certain emotional states (fear, anxiety) and hemodynamic stimuli (severe fall in arterial pressure), both vasoconstrictor and sudomotor outputs are activated simultaneously, producing a cold, clammy skin ("cold sweat").

GASTROINTESTINAL TRACT

The dorsal nucleus of the vagus innervates the entire gastrointestinal tract with the exception of the proximal esophagus and the distal colon and rectum. The vagus produces increases in propulsive motility, relaxation of sphincters, and secretions of the exocrine and endocrine glands of the stomach, intestine, pancreas, and liver. Sympathetic outflow to the gastrointestinal tract, which arises from preganglionic neurons at the T1-L1 segments of the spinal cord and relays, via the splanchnic nerves, in the celiac and mesenteric ganglia, is involved in reflexes that decrease gut motility. Extrinsic vagal and sympathetic influences are relayed and integrated at the level of the enteric nervous system, located in the wall of the gut.

BLADDER

The function of the bladder, rectum, and sexual organs is controlled by three outflows: sacral parasympathetic, lumbar sympathetic, and somatic. Control of the bladder serves as a paradigm for innervation of the other pelvic organs. The sacral parasympathetic (S2-S4) output to the bladder is carried via the pelvic nerves and is mediated by muscarinic cholinergic receptors. These parasympathetic nerves promote bladder emptying (micturition) through activation of the detrusor muscle and relaxation of the bladder neck. The lumbar sympathetic (T11-L2) output is carried via the hypogastric nerves. The sympathetic nerves produce relaxation of the detrusor muscle by way of beta receptors and contraction of the bladder neck by way of alpha receptors, thus favoring storage of urine. The sacral somatomotor output, which arises from motor neurons of the nucleus of Onuf (S2-S4) and is carried by the pudendal nerve, stimulates contraction of the external sphincter via nicotinic cholinergic receptors. Activation of these somatomotor nerves promotes storage of urine. ^[13]

In normal individuals, micturition involves a spino-ponto-spinal reflex that is initiated by bladder tension receptors and integrated in pontine micturition centers. This reflex coordinates the simultaneous activation of sacral parasympathetic autonomic neurons and inhibition of somatic sphincter motor neurons, thus allowing synergistic bladder contraction and sphincter relaxation during micturition. ^[13]

Interruption of the sacral parasympathetic outflow in patients with lesions of the conus or cauda equina results in a hypotonic areflexic bladder. In patients with spinal cord lesions the suprasegmental pathway is interrupted, and micturition occurs through segmental spinosacral reflexes, which are triggered by perineal or nociceptive stimulation. In this condition, bladder and sphincter contractions are not well coordinated, resulting in detrusor-sphincter dyssynergia. Cortical inputs are responsible for

39

voluntary control of initiation and interruption of micturition. Lesions involving the medial aspects of the frontal lobes, including the anterior cingulate and paracentral gyri, result in involuntary but coordinated micturition, referred to as uninhibited bladder.

OTHER ORGANS

Autonomic innervation of the pupil (see [Chapter 9](#)) and the lacrimal and salivary glands (see [Chapter 11](#) and [Chapter 13](#)) is reviewed in the chapters discussing the specific cranial nerves controlling these structures.

[Previous](#)[Next](#)

EXAMINATION OF THE AUTONOMIC NERVOUS SYSTEM

Directed Neurological Examination

The directed bedside neurological examination includes clinical observation and pharmacological testing with adrenergic and cholinergic agonists. Pharmacological tests can detect a decrease or increase in response of the effector organs due to denervation supersensitivity. Denervation supersensitivity is a manifestation of postganglionic, as opposed to preganglionic, neuronal autonomic failure. ^[19]

SKIN

The examiner may recognize sudomotor failure by noting a dryness of the skin and a lack of resistance to gentle stroking with the fingerpads or to a tuning fork run over the skin. Sudomotor failure may take the form of an isolated generalized anhidrosis or a diffuse autonomic failure with other associated findings. A search should be made for localized increases in or absence of sweating and for asymmetrical patterns of skin temperature or color. In patients with disturbances of autonomic innervation of the face, the physician may note gustatory sweating, flushing, and facial anhidrosis. Acral vasomotor changes that may be observed include acrocyanosis, pallor, mottling, livedo reticularis, or erythema. ^[20] Skin temperature changes can be assessed by palpation. Other findings to be noted include atrophic skin changes, alopecia, hypertrichosis, nail thickening, skin decoloration or deformation, and Charcot's joints. Allodynia and hyperalgesia are components of a complex regional pain syndrome that in some cases may involve sympathetic mechanisms.

A bedside intradermal injection of pilocarpine can be used to assess the sweat glands; a supersensitive response to diluted pilocarpine indicates the presence of postganglionic sympathetic sudomotor denervation. Intradermal injection of histamine produces a "triple response" (erythema, flare, and wheal) through an axon reflex mediated by nociceptive C-afferent fibers. Loss of the histamine flare indicates severe loss or absence of nociceptive C axons, as in patients with familial dysautonomia or peripheral neuropathies affecting the sympathetic nerves.

CARDIOVASCULAR REFLEXES

To assess cardiovascular autonomic function, blood pressure and heart rate should be measured while the patient is supine and after he or she has been standing for at least 3 minutes. In normal conditions, there is a 5- to 20-mm Hg drop in systolic blood pressure on changing from the supine to the standing position with no change or only a slight rise in diastolic pressure; heart rate increases 5 to 25 beats per minute ^[21] (see later section, Evaluation Guidelines). Orthostatic hypotension is defined as a reproducible fall of more than 20 mm Hg in systolic pressure or of more than 10 mm Hg in diastolic pressure within 3 minutes of adopting the erect position. ^[22] In patients with severe orthostatic intolerance, it is useful to monitor the length of time the patient can stand in place before he or she experiences symptoms. Severe orthostatic hypotension results in a "standing time" of less than 30 seconds. If orthostatic hypotension is not apparent, it is useful to ask the patient to squat several times and then repeat the blood pressure measurement. The presence of orthostatic hypotension without reflex tachycardia is evidence of sympathetic and cardiovagal failure. If a reflex tachycardia is present, hypovolemia should be excluded. However, the presence of tachycardia does not exclude an autonomic cause of orthostatic hypotension. An increase in heart rate of more than 30 beats per minute above the basal rate or more than 120 beats per minute on adopting the erect position, if associated with symptoms, is characteristic of the postural tachycardia syndrome. This syndrome is a heterogeneous disorder that has multiple possible causes. ^[23]

BLADDER

Clinical evaluation of bladder function includes assessment of the ability to control initiation or interruption of micturition voluntarily and the integrity of the bladder and perianal sensation. Reflexes that are integrated at the level of the conus medullaris and are mediated by sensory and motor roots in the cauda equina should also be checked. The bulbocavernosus and anal reflexes are somatic reflexes that are integrated at the S2-S4 levels, and the scrotal and internal anal reflexes are autonomic reflexes that are integrated at the S2-S4 and T12-L2 levels, respectively. Palpation and percussion of the bladder can identify the presence of abnormal bladder distention. Measurement of post-void residual urine after catheterization is used to assess residual urinary volume.

PUPIL

Examination of the pupil is fully reviewed in the chapter on evaluation of cranial nerve III ([Chapter 9](#)).

LACRIMAL GLANDS

Reduced or absent tearing occurs with lesions that affect the parasympathetic innervation of these glands (see [Chapter 11](#)). Schirmer's test is a means of quantifying lacrimal gland secretion; it consists of application of a standard sterile filter paper strip over the lower eyelid border. The

standard minimum for tear production is a length of wetness of this strip of 15 mm after 5 minutes.

Ancillary Neurological Examination

Cerebral. Assessment of mental status, particularly the function of the frontal lobe, is important because it allows detection of abnormalities involving memory or the higher cognitive processes, which may be associated with incontinence due to uninhibited neurogenic bladder.

Cranial Nerves. Examination of the optic and oculomotor nerves allows for the localization of lesions that produce asymmetrical pupils or absent pupillary responses to light. Because the pupilloconstrictor fibers are located peripherally in the oculomotor nerve, compressive (extrinsic) lesions such as aneurysms or an uncal herniation elicit unilateral mydriasis before extraocular motor paralysis. Intrinsic (vascular) lesions, such as the neuropathy resulting from diabetes, affect the central fascicles of the nerve and produce a "pupil-sparing" oculomotor palsy. There are some exceptions to this classic distinction. Examination of the function of the trochlear and abducens nerves and of facial sensation in the ophthalmic and maxillary distribution of the trigeminal nerve helps to localize lesions at the level of the cavernous sinus and orbit. A facial nerve palsy may be associated with absence of lacrimation. Nystagmus, vertigo, and paralysis of the glossopharyngeal, vagus, and spinal accessory cranial nerves may occur in patients with lateral medullary infarctions that produce ipsilateral Horner's syndrome. These features, which suggest lower brain stem dysfunction, may also accompany syringobulbia, which is associated with orthostatic hypotension, and Arnold-Chiari malformations, which produce syncope. ^[24] In patients with symmetrical polyneuropathies such as Guillain-Barre(c) syndrome, facial diplegia and other cranial nerve pareses can occur, especially in patients with the Miller-Fisher variant, which is often associated with autonomic instability.

Motor/Reflexes/Cerebellar/Gait. Autonomic dysfunction is a frequent accompaniment of central and peripheral motor syndromes. Muscle weakness in the distribution of a peripheral nerve or root may accompany hyperhidrosis or vasomotor changes resulting from nerve injury. Distal symmetrical motor weakness with loss of the deep tendon reflexes indicates a large-fiber peripheral polyneuropathy that can be seen in patients with peripheral demyelinating diseases such as Guillain-Barre(c) syndrome and in those with certain toxic or drug reactions to agents such as vincristine. Proximal muscle weakness and areflexia occur in patients with prejunctional neuromuscular transmission defects that occur with cholinergic autonomic failure, such as botulism ^[25] and the Lambert-Eaton myasthenic syndrome.

Spastic paraparesis is frequently found in patients with neurogenic bladder and detrusor-sphincter dyssynergia (e.g., as in multiple sclerosis). Areflexia in the lower extremities, which is associated with loss of the anal and bulbocavernosus reflexes, indicates a lesion of the cauda equina that produces hypotonic bladder, bowel hypomotility, and sphincter incontinence. Extrapyramidal, pyramidal, cerebellar, and autonomic deficits in varying combinations are characteristic of multiple system atrophy (i.e., the Shy-Drager syndrome), a neurodegenerative disorder of unknown etiology. Autonomic failure may also accompany Parkinson's disease with its associated resting tremor, bradykinesia, rigidity, and postural reflex impairment.

Sensory. Distal, symmetrical loss of sensation to pinprick and temperature is typical of the small-fiber peripheral neuropathies associated with diffuse autonomic failure (e.g., diabetes, amyloidosis). Insensitivity to pain occurs in patients with some hereditary sensory and autonomic neuropathies, including familial dysautonomia (Riley-Day syndrome). Loss of the vibration and joint position sense occurs in paraneoplastic sensory ganglioneuronopathies and Sjogren's syndrome--both of which are commonly associated with autonomic failure. Hypesthesia and allodynia in a limb, associated with vasomotor and sudomotor changes, occur in patients with

damage to a peripheral nerve (causalgia) or the poorly understood reflex sympathetic dystrophy.

Associated Medical Findings

Skin examination may reveal angiokeratomas in the trunk and lower limbs in patients with Fabry's disease, and the tongue may be enlarged in those with amyloidosis. Absence of fungiform papillae may also be demonstrated in children with familial dysautonomia (Riley-Day syndrome)

EVALUATION GUIDELINES (Table 21-1)

Neuroimaging. Magnetic resonance imaging (MRI) is useful for the evaluation of patients with focal or organ-specific autonomic syndromes. It can detect lesions that involve the frontal lobes (e.g., hydrocephalus) or the cervical, thoracic, or lumbar spine, producing different types of neurogenic bladder. It is also indicated for the detection of hypothalamic lesions, lateral medullary infarctions, syringomyelia, or lesions in the cavernous sinus that produce Horner's syndrome. MRI of the neck is required when a diagnosis of paragangliomas arising from the carotid body or the vagus nerve is considered in patients with severe baroreflex failure. MRI of the abdomen can localize pheochromocytomas arising from chromaffin cells in the adrenal medulla or elsewhere in the abdomen, and imaging of the neck, chest, and pelvis should be used when pheochromocytomas are considered.

Neuroimaging has a low yield in the evaluation of patients with generalized autonomic failure, although it may show atrophy of the basal ganglia, pons, or cerebellum in patients with multiple system atrophy. In these patients, areas of hypointensity in T2-weighted MRI images of the posterolateral putamen have been reported.

Electrophysiology. Electromyography (EMG) and nerve conduction velocities (NCVs) are useful in evaluating patients with peripheral neuropathy. However, the studies may be normal in conditions that selectively affect small nerve fibers. Small fiber function may be assessed using quantitative sensory testing to determine the sensory threshold for heat and cold sensation; these sensory modalities are mediated by the C and A-delta nerve fibers. This technique measures the intensity of a stimulus necessary

TABLE 21-1 -- USEFUL STUDIES IN THE EVALUATION OF DISORDERS OF THE AUTONOMIC NERVOUS SYSTEM

Syndrome	Neuroimaging	Electrophysiology	Fluid and tissue Analysis	Neuropsychological Tests	Other Tests
PANDYSAUTONOMIA					
Preganglionic disorders (multiple system atrophy)	MR1 brain: decreased putaminal signal intensity on T2-weighted images	EMG of anal sphincter: large motor units	Supine NE normal; no increase with standing	N/A	Cardiovagal and adrenergic innervation tests abnormal; TST abnormal
Autonomic ganglionic and postganglionic disorders	N/A	NCV/EMG: Abnormal in peripheral neuropathies with motor/sensory involvement	Supine plasma NE low; no increase with standing ANNA: paraneoplastic syndromes	N/A	Cardiovagal and adrenergic innervation tests abnormal; TST abnormal Rectal biopsy: amyloiosis
PURE CHOLINERGIC DYSAUTONOMIA	N/A	EMG abnormal in botulism and LEMS	Normal plasma NE Antibodies to voltage-gated calcium channels: LEMS	N/A	GI motility studies
PURE ADRENERGIC DYSAUTONOMIA	N/A	N/A	Very low plasma NE	N/A	Test of adrenergic innervation abnormal; TST normal.
FOCAL DISORDERS					
Telencephalic	MRI brain	EEG monitoring for limbic seizures	N/A	Temporal lobe dysfunction	N/A
Diencephalic	MRI brain	N/A	Endocrinological tests for hypothalamic dysfunction Elevated creatinine kinase	Memory Cognition	N/A
Brain stem	MRI brain	N/A	CSF abnormalities in MS	N/A	N/A
Spinal cord	MRI spinal cord	N/A	CSF abnormalities in MS	N/A	Bladder EMG or cystometrogram

MRI Magnetic resonance imaging; EMG, electromyography; NCV, nerve conduction velocity; LEMS, Lambert-Eaton myasthenic syndrome; ANNA, antineuronal nuclear antibody (anti-Hu); NE, norepinephrine; TST, thermoregulatory sweat test; CSF, cerebrospinal fluid; MS, multiple sclerosis

to evoke a specific sensation. Electromyography and NCVs are used to evaluate peripheral nerve injuries that may result in focal autonomic abnormalities. Nerve conduction velocity studies may also be used to identify the cause of the predominantly cholinergic autonomic abnormalities that accompany the prejunctional disorders of neuromuscular transmission (e.g., botulism, the Lambert-Eaton myasthenic syndrome and the autonomic abnormalities that accompany paraneoplastic sensory ganglioneuronopathy). Finally, EMG of the external anal sphincter may show denervation in patients with lesions of the conus or cauda equina and in patients with multiple system atrophy.

Electrodermal activity is generated by the sweat glands and overlying epidermis and mediated by supraspinal sites that include the orbitofrontal cortex, the posterior hypothalamus, the dorsal thalamus, and the ventrolateral reticular formation. This response, which occurs spontaneously and can be evoked by stimuli such as respiration, startling, mental stress, and electrical stimuli, is referred to as the sympathetic skin response or peripheral autonomic surface potential. The sympathetic skin response is used in some EMG laboratories to assess sudomotor function. It consists of a slow change in the electrical potential of the skin of the palms and feet that depends on sweat production and is evoked reflexly by unexpected noise, deep inspiration, and electrical stimuli. Absence of the sympathetic skin response occurs in patients with autonomic failure, but it has limited specificity and no localizing value.

Microneurographic recordings of activity in sympathetic fibers innervating muscle and skin allow direct assessment of sympathetic vasoconstrictor and skin sudomotor outflows, respectively. However, because this technique is laborious and invasive and requires considerable expertise as well as a very cooperative patient, it remains only a research tool.^[39]

Electroencephalography may show epileptiform activity in the temporolimbic areas, which may be associated with syncope or other paroxysmal autonomic phenomena. Sleep polysomnograms in patients with multiple system atrophy may allow the physician to make a diagnosis of sleep apnea.

Fluid and Tissue Analysis. Blood tests useful in the evaluation of patients with autonomic failure include blood glucose and glycosylated hemoglobin (diabetes), protein immunoelectrophoresis and genetic tests for the transthyretin variant (amyloidosis), vitamin B₁₂ (pernicious anemia), erythrocyte sedimentation rate, antinuclear antibody (connective tissue diseases), antineuronal nuclear (anti-Hu) antibody (paraneoplasia), human immunodeficiency virus (HIV) serology, and, in selected cases, porphyrins (acute intermittent porphyria) or alpha-galactosidase (Fabry's disease).^[39]

Measurements of plasma cortisol in the morning and evening and, as previously mentioned, plasma catecholamines in the supine and standing positions may be helpful in the evaluation of patients with orthostatic hypotension.

Cerebrospinal Fluid. Cerebrospinal fluid examination may show albuminocytological dissociation with an elevated protein concentration and no pleocytosis in patients with Guillain-Barre syndrome and other acute pandysautonomias. Abdominal fat aspirate, rectal biopsy, or sural nerve biopsy should be considered in

patients in whom amyloid neuropathy or Fabry's disease is suspected, and salivary or lacrimal gland biopsy should be done in patients in whom Sjogren's syndrome is suspected.

Special Autonomic Function Testing

Many laboratory tests are used to diagnose autonomic disorders, quantify autonomic function, and evaluate the efficacy of treatment. Disorders for which autonomic testing provides useful information include those involving generalized autonomic failure such as the Shy-Drager syndrome, Parkinson's disease, and pure autonomic failure, suspected distal small-fiber and other peripheral neuropathies, orthostatic intolerance of uncertain etiology, syncope, localized autonomic disorders, unexplained autonomic symptoms or signs, and complex regional pain syndromes. The blood pressure and heart rate response to active standing, the passive head-up tilt test, and the Valsalva maneuver are the most commonly performed noninvasive tests used to assess reflex circulatory control.

EVALUATION OF CARDIAC VAGAL INNERVATION

Heart Rate Response to Deep Breathing. Normally, heart rate varies from beat to beat, primarily due to changes in vagal activity. The most noticeable variation is that which is synchronous with the respiratory cycle (respiratory sinus arrhythmia). Heart rate increases during inspiration and decreases during expiration. The heart rate response to deep breathing is maximal at around six deep breaths per minute. Laboratory measures of heart rate variability include the peak-to-trough amplitude during a single breath, the standard deviation of the electrocardiogram RR intervals during 1 minute, and other statistical measures such as the mean square successive difference, the expiratory-inspiratory ratio (E/I ratio), and the mean circular resultant. [26], [27] The subject's age and the rate and depth of respiration influence heart rate variation in response to deep breathing. When these variables are taken into account, the maximum heart rate variation in response to deep breathing is the best noninvasive test for the assessment of cardiac vagal innervation. [26], [27]

Heart Rate Response to Valsalva Maneuver. The Valsalva maneuver is typically performed by blowing through a mouthpiece connected to a mercury manometer for 15 or 20 seconds. The mercury column of the manometer is maintained at 40 mm. The normal cardiovascular response to a Valsalva maneuver has four phases (Fig. 21-4). Phase 1 consists of a transient rise in arterial pressure and an associated decrease in heart rate. In phase 2, during the expiratory phase of the maneuver, there is a gradual fall in blood pressure followed by a recovery. An increase in heart rate accompanies this phase. Phase 3 consists of a sudden brief fall in blood pressure with an accompanying increase in heart rate that occurs with the cessation of straining. In phase 4 there is an increase in blood pressure above the resting value (the "overshoot") that is accompanied by a bradycardia. Phases 1 and 3 most likely reflect mechanical factors, while phases 2 and 4 are a consequence of sympathetic, vagal, and baroreflex

Figure 21-4 Valsalva maneuver induced changes in RR intervals and blood pressure by Finapres recording:(A) a normal subject and (B) a patient with autonomic failure (Reproduced with permission by Korczyn A, Handbook of Autonomic Nervous System Dysfunction. New York, Marcel Dekker, Inc, 1996.)

interactions. The Valsalva ratio (i.e., the ratio between the tachycardia occurring during the maneuver and the postmaneuver bradycardia) provides an index of cardiac vagal function. [28]

Heart Rate Response to Postural Change (The "30:15 Ratio"). The heart rate changes that occur during the first 30 seconds of standing result mostly from modification of cardiovagal activity and are blocked by atropine (Fig. 21-5). Heart rate increases sharply on standing, peaking at about 12 seconds (about the fifteenth beat). It then becomes progressively slower until about 20 seconds after standing (so that the thirtieth RR interval is usually the longest), and then it gradually rises again. This transient relative bradycardia is due to reflex activation of efferent cardiac vagal fibers. These changes are reflected by the 30:15 ratio, which is calculated by dividing the longest RR interval around the thirtieth beat by the shortest RR interval around the fifteenth beat ($RR_{\max 30} / RR_{\min 15}$ ratio). In subjects with abnormal cardiovagal function the bradycardia is reduced or absent. [29], [30], [31]

Other tests of cardiovagal function include the *carotid sinus massage*, the *cold face test* (which assesses the trigeminovagal reflex), the *atropine test*, [21] and *power spectral analysis*, which detects high-frequency oscillations of heart rate. [32]

EVALUATION OF CARDIOVASCULAR SYMPATHETIC INNERVATION

Cardiovascular Response to Postural Change. Measurement of changes in blood pressure and heart rate induced by passive tilt or active standing is the most useful test of sympathetic function. During upright tilt to 60 degrees or more, normal subjects undergo a transient reduction in systolic, diastolic, and mean blood pressure, followed by a recovery within 1 minute. The heart rate also increases by 10 to 20 beats per minute. Patients with adrenergic failure have a marked reduction in systolic, diastolic, and pulse pressure with no recovery, and they have an inadequate compensatory tachycardia. [21]

Blood Pressure Response to Valsalva Maneuver. Beat-to-beat recordings of the blood pressure during a Valsalva maneuver may be used to measure cardiac adrenergic function. Sympathetic failure is characterized by a profound decrease of blood pressure in phase 2 and an absence of the blood pressure "overshoot" in phase 4 of the Valsalva maneuver. [28]

Other Tests. Other tests used to assess sympathetic cardiovascular outflow include the hemodynamic response to physical or emotional perturbations such as immersion of a hand in cold water for 1 minute (*cold pressor test*), isometric exercise (e.g., the *sustained handgrip* maneuver), or emotional stress (e.g., *mental arithmetic*). In normal subjects these maneuvers produce increases in diastolic pressure of more than 15 mm Hg and in heart rate of more than 10 beats per minute. [21] The *venoarteriolar reflex* is an axon reflex mediated by sympathetic C fibers. This reflex is provoked by distention of the veins of a dependent limb that produces local arteriolar constriction; the reflex can be detected by a decrease in skin blood flow. [21]

In research laboratories, other techniques used to evaluate autonomic circulatory control include the application of lower body negative pressure, which pools blood in the lower part of the body and elicits autonomic responses similar to those induced by standing up. The neck chamber device can also be used. This device modifies transmural pressure and allows assessment of the carotid sinus baroreflexes. Finally, changes in heart rate in response to pressor or depressor drugs can be evaluated. [21]

Plasma Catecholamines. Circulating norepinephrine (NE) originates primarily in the sympathetic nerves innervating the blood vessels of muscles. Plasma NE constitutes approximately 10 percent of NE released into the synaptic cleft that escapes neuronal reuptake and "spills over" into the bloodstream. Patients with postganglionic autonomic disorders, such as pure autonomic failure or diabetic neuropathy, frequently have reduced plasma NE

Figure 21-5 Posturally induced changes in continuous RR intervals and blood pressure by Finapres recording:(A) a subject with primary autonomic failure and (B) a subject with neurally mediated syncope. The initial arrow denotes when the head is tilted up, and the latter arrow denotes when the head is tilted down after syncope has been induced (Reproduced with permission from Robertson D, Low P, Polinsky R, et al: Primer on the Autonomic Nervous System. San Diego, Academic Press, 1995.)

levels at rest in the supine position. In normal subjects, plasma NE levels double with the assumption of the upright posture. In contrast, this response is absent in patients with both pre- and postganglionic sympathetic failure. [33] Determination of plasma and urinary levels of NE metabolites, such as dihydroxyphenylglycol (DHPG) and normetanephrine, may also be useful for separating preganglionic from postganglionic causes of autonomic failure (Table 21-2). [34] In patients who lack dopamine beta hydroxylase, the enzyme that converts dopamine to NE, NE in plasma is virtually undetectable, whereas dopamine is high and increases further with maneuvers that increase sympathetic neural discharge. [35]

Norepinephrine levels can be measured following an infusion of edrophonium, a cholinomimetic agent. This agent induces the release of NE by stimulating the sympathetic ganglia. Norepinephrine levels can also be measured following the infusion of tyramine, an indirect sympathomimetic agent, which releases NE from sympathetic terminals. The pressor response to an infusion of NE and other alpha-adrenergic agonists may be used to assess denervation supersensitivity and

baroreflex function.

These pharmacological tests have been used to differentiate preganglionic from postganglionic causes of sympathetic failure. Postganglionic autonomic failure is characterized by decreased NE release and lack of a pressor response to edrophonium and tyramine. There is also a decreased threshold for the pressor effects of NE and other adrenergic agonists consistent with denervation hypersensitivity. [19]

EVALUATION OF SYMPATHETIC CHOLINERGIC (SUDOMOTOR) INNERVATION

Testing of the eccrine sweat glands can localize the site of sympathetic nervous system dysfunction in patients with

TABLE 21-2 -- DIFFERENTIATION OF PREGANGLIONIC VERSUS POSTGANGLIONIC DISORDERS

	Preganglionic	Postganglionic
Pandysautonomia	Multiple system atrophy	Pure autonomic failure Small fiber neuropathy
Plasma norepinephrine	Normal	Reduced
Norepinephrine response to standing	Abolished	Abolished
Norepinephrine response to edrophonium	Normal	Impaired
Blood pressure response to tyramine	Increased	No increase
Blood pressure response to norepinephrine	Increased, with normal threshold	Decreased threshold (denervation supersensitivity)
Vasopressin response to standing	Impaired	Normal or exaggerated
Thermoregulatory sweat responses	Impaired	Impaired
Cholinergic sudomotor axon reflex	Normal	Impaired
Horner's syndrome		
Pupil response to phenylephrine	Dilated	No response
Pupil response to diluted alpha agonist	No response	Dilated (supersensitivity)
Adie's pupil		Constricts with diluted muscarinic agonist (denervation supersensitivity)

autonomic failure. Thermoregulatory sweat testing is used to evaluate both the central and peripheral sympathetic efferents, including the hypothalamus, the cervical and thoracic spinal cord, the peripheral autonomic nerves, and the sweat glands. This test, however, does not differentiate between preganglionic and postganglionic causes of anhidrosis. Postganglionic sudomotor function can be determined by measuring the sweat output after iontophoresis or intradermal injection of cholinergic agonists such as pilocarpine, nicotine, or methacholine. These agents either stimulate the sweat glands directly or affect a neighboring population of sweat glands via an axonal reflex. The site of a lesion can be established if the thermoregulatory sweat test is combined with a test measuring postganglionic sudomotor function. For example, an abnormal result of a thermoregulatory sweat test combined with normal postganglionic function indicates a preganglionic cause of anhidrosis. On the other hand, an abnormal thermoregulatory sweat test result in a patient with abnormal postganglionic function indicates a postganglionic cause of anhidrosis. Skin potential recordings that measure skin conductance, skin resistance, or the sympathetic skin potential provide an alternative measure of sudomotor function. The following tests of sudomotor function may be performed:

Thermoregulatory Sweat Test. Thermoregulatory sweating is tested by raising the body temperature with an external heating source. This test evaluates the distribution of sweating by measuring the change in color of an indicator powder such as iodine with starch, quinizarin, or alizarin-red in response to a rise in core body temperature. [20]

Quantitative Sudomotor Axon Reflex Test. The quantitative sudomotor axon reflex test (QSART) provides a quantitative measure of postganglionic sudomotor function. The sudomotor response measured by the QSART is mediated by an "axon reflex" carried by unmyelinated postganglionic sympathetic cholinergic sudomotor fibers. This axon reflex can be elicited by iontophoresis of a cholinergic agonist. [37]

Sweat Imprint. A sweat imprint is formed by the secretion of active sweat glands into a plastic or silicone mold in response to iontophoresis of a cholinergic agonist. This test can be used to determine sweat gland density, sweat droplet size, and sweat volume per unit of area.

CLINICAL SYNDROMES INVOLVING THE AUTONOMIC NERVOUS SYSTEM (Table 21-3)

Clinical syndromes involving ANS dysfunction may be divided into those involving diffuse autonomic failure and pure cholinergic or adrenergic disorders (Table 21-4).

Diffuse Autonomic Failure (Pandysautonomia)

CENTRAL (PREGANGLIONIC) DISORDERS

Multiple System Atrophy. Multiple system atrophy (MSA, Shy-Drager syndrome) is a degenerative disorder of the CNS that affects the extrapyramidal, cerebellar, and autonomic neurons (see Chapter 34). Autonomic dysfunction in patients with MSA is due to the loss of preganglionic neurons in the brain stem and spinal cord. Patients with MSA typically present with diffuse autonomic failure and parkinsonian, cerebellar, or pyramidal deficits in different combinations.^[40] Autonomic features include orthostatic intolerance, erectile dysfunction in males, bowel hypomotility, urinary incontinence due to denervation of the external urinary sphincter, and respiratory disturbances (sleep apnea and laryngeal stridor). There is usually a poor response to levodopa. Pathologically, cell loss and gliosis in striatonigral, olivopontocerebellar, and autonomic neurons are evident, and intracytoplasmic oligodendroglial and neuronal inclusions are frequently present.

Parkinson's Disease. Autonomic dysfunction in patients with Parkinson's disease (see Chapter 34) is rarely as severe as that seen in patients with MSA. Autonomic failure frequently occurs late in the course of the illness and is often associated with levodopa and dopamine agonist therapy. In patients with Parkinson's disease, Lewy bodies are found not only in central but also in peripheral neurons, suggesting that autonomic dysfunction in this disorder may be caused by both preganglionic and postganglionic neuronal dysfunction.

TABLE 21-3 -- SELECTED ETIOLOGIES ASSOCIATED WITH DISORDERS OF THE AUTONOMIC NERVOUS SYSTEM

Etiological Category	Selected Etiologies	Chapter
STRUCTURAL DISORDERS		
Developmental structural disorders	Arnold-Chian malformation Synngomyelia Normal pressure hydrocephalus	28
HEREDITARY AND DEGENERATIVE DISORDERS		
Movement disorders	Multiple system atrophy	34
Degenerative motor, sensory, and autonomic disorders	Riley-Day syndrome Pure autonomic failure	36
Inherited muscle, neuromuseular, and neuronal disorders	Amyloidosis	37
ACQUIRED METABOLIC AND NUTRITIONAL DISORDERS		
Endogenous metabolic disorders	Diabetes	38
Nutritional deficiencies and syndromes associated with alcoholism	Wernicke's encephalopathy/thiamine deficiency	40
INFECTIOUS DISORDERS		
Viral infections	Poliomyelitis	41
Transmissible spongiform encephalopathy	Fatal familial insomnia	43
HIV and AIDS	HIV-associated neuropathy HIV-related Guillain-Barre syndrome	44
NEUROVASCULAR DISORDERS	Vertebrobasilar ischemia	45
NEOPLASTIC DISORDERS		
Pnmary neurological tumors	Brain stem glioma	46
DEMYELINATING DISORDERS		
Demyelinating disorders of central nervous system	Multiple sclerosis with bladder dysfunction	48
Demyelinating disorders of the peripheral nervous system	Guillain-Barre syndrome	49
AUTOIMMUNE AND INFLAMMATORY DISORDERS	Lambert-Eaton myasthenic syndrome	50
TRAUMATIC DISORDERS	Spinal cord: blunt or penetrating trauma	51
EPILEPSY	Temporal/limbic seizures	52
HEADACHE AND FACIAL PAIN	Cluster headaches	53
DRUG-INDUCED AND IATROGENIC	Drugs: chemotherapeutic agents (vincristine)	55
NEUROLOGICAL DISORDERS		
AIDS, Acquired immunodeficiency syndrome; HIV, human immunodeficiency virus.		

AUTONOMIC GANGLIONIC AND POSTGANGLIONIC DISORDERS

Pure Autonomic Failure. Pure autonomic failure (PAF) is an idiopathic, sporadic, degenerative disorder of the autonomic nervous system of adult onset.^[41] Unlike MSA and Parkinson's disease, PAF has no motor manifestations. The disorder is slowly progressive and has a better prognosis than MSA (Table 21-2).

Autonomic Peripheral Neuropathies and Neuropathies. Acute autonomic neuropathies with prominent sympathetic and parasympathetic involvement (i.e., acute pandysautonomia) occur in isolation or accompany the Guillain-Barre syndrome and acute paraneoplastic neuropathies. The CSF protein level may be elevated, and the autonomic features may respond to intravenous immunoglobulin. Paraneoplastic dysautonomia may occur in association with carcinoma of the lung, pancreatic carcinoma, Hodgkin's disease, testicular cancer, and other neoplasms. Paraneoplastic gastrointestinal dysfunction with constipation and intestinal pseudo-obstruction has been reported in patients with small-cell carcinoma of the lung and elevated titers of antineuronal nuclear (anti-Hu) antibodies. Acute autonomic dysfunction may also be a feature of porphyria and of the neuropathies due to drugs (e.g., vincristine, taxol, cis-platinum) and toxins (e.g., thallium, acrylamide).^[42]

Dysautonomia is a prominent feature of some chronic neuropathies affecting small-diameter unmyelinated fibers. Diabetes mellitus is the most common cause of autonomic neuropathy in the developed world. Typical features of diabetic autonomic neuropathy are orthostatic intolerance, impotence, voiding difficulties, gastroparesis, constipation alternating with diarrhea, and gustatory sweating. Patients with primary or familial amyloid neuropathy typically present with distal sensory symptoms, although the autonomic manifestations may be the presenting feature (see Chapter 37). Sensory neuronopathy with autonomic failure may be a paraneoplastic phenomenon that may be associated with Sjogren's syndrome (see Chapter 50) or may be idiopathic.^[42]

Hereditary sensory and autonomic neuropathies (HSAN) are characterized by prominent sensory loss and dysautonomia. Autonomic manifestations are mild in

patients with HSAN type I and II but prominent in those with HSAN type III (Riley-Day syndrome, familial dysautonomia) (see [Chapter 36](#)). Familial dysautonomia is an autosomal recessive disorder that is seen primarily in Ashkenazi Jewish

TABLE 21-4 -- AUTONOMIC NERVOUS SYSTEM SYNDROMES

Diffuse Autonomic Failure (Pandysautonomia)

Preganglionic autonomic failure central neurodegenerative diseases
 Multiple system atrophy (Shy-Drager syndrome)
 Parkinson's disease with autonomic failure
 Ganglionic and postganglionic disorders-peripheral neurodegenerative disorders
 Pure autonomic failure
 Peripheral neuropathies and neuronopathies with autonomic failure
 Acute and subacute (preganglionic and postganglionic)
 Acute pandysautonomia
 Guillain-Barre syndrome
 Others (porphyria, toxins, drugs)
 Chronic small-fiber (postganglionic) neuropathies)
 Diabetes
 Amyloidosis
 Hereditary (familial dysautonomia, Fabry's disease)
 Subacute or chronic sensory and autonomic ganglionopathies
 Paraneoplastic
 Sjogren's syndrome
 Other peripheral neuropathies
 Infections (human immunodeficiency virus)
 Connective tissue disease (systemic lupus erythematosus)
 Metabolic-nutritional (alcohol, uremia, vitamin B₁₂ deficiency)

Pure Cholinergic or Adrenergic Disorders

Cholinergic dysautonomias
 Associated with neuromuscular transmission defect
 Botulism (acute)
 Lambert-Eaton myasthenic syndrome (chronic)
 Not associated with neuromuscular transmission defect
 Acute cholinergic dysautonomia
 Chronic idiopathic anhidrosis
 Adie's syndrome
 Chagas' disease
 Adrenergic dysautonomias
 Pure adrenergic neuropathy
 Dopamine-beta-hydroxylase deficiency

children. Its clinical features include insensitivity to pain and temperature, absence of tears, hypoactive corneal and tendon reflexes, and absence of fungiform papillae of the tongue. Patients with familial dysautonomia have poor suck and feeding responses, esophageal reflux with vomiting and aspiration, uncoordinated swallowing, episodic hyperhidrosis, vasomotor instability, postural hypotension, hypertensive crises, supersensitivity to cholinergic and adrenergic agents, and absent histamine flare.^[39]

Fabry's disease is an X-linked recessive disorder caused by a deficiency of alpha-galactosidase A (see [Chapter 30](#)). Its manifestations include painful distal peripheral neuropathy, a truncal reddish-purple macular papular rash, and angiectases of the skin, conjunctiva, nail bed, and oral mucosa, progressive renal disease, corneal opacities, and cerebrovascular accidents. The autonomic manifestations include hypohidrosis or anhidrosis, reduced saliva and tear formation, impaired histamine flare, and gastrointestinal dysmotility.^[39]

Pure Cholinergic or Adrenergic Disorders

Cholinergic Dysautonomias. Acute or chronic cholinergic dysautonomias may occur in isolation or in patients with impaired neuromuscular transmission. In the Lambert-Eaton myasthenic syndrome (see [Chapter 50](#)) and in botulism (see [Chapter 39](#)), acetylcholine release from motor as well as autonomic neurons fails. Thus, neuromuscular and autonomic cholinergic neurotransmission is impaired, and muscle weakness, reflex loss, and autonomic failure result.^[25]

Chronic disorders that affect cholinergic function without neuromuscular impairment include Adie's syndrome, chronic idiopathic anhidrosis, Ross's syndrome (a combination of Adie's pupils and segmental anhidrosis), and Chagas' disease, a disease caused by *Trypanosoma cruzi* that affects the neurons of the parasympathetic ganglion and produces megaesophagus, megacolon, and cardiomyopathy (see [Chapter 42](#)).

Pure Adrenergic Neuropathy. Dopamine-beta hydroxylase deficiency is a hereditary disease characterized by an inability to convert dopamine (DA) to NE. This disorder is characterized by severe orthostatic hypotension accompanied by ptosis, ejaculatory failure, nocturia, nasal congestion, and hyperextensible joints. Typically, the serum NE/DA ratio is 0.1 (normal 10).^[35]

Autonomic Dysfunction Secondary to Focal Central Nervous System Disease

The autonomic nervous system syndrome may also be classified anatomically into telencephalic, diencephalic, brain stem, and spinal cord disorders ([Table 21-5](#)).

Telencephalon Syndromes. Temporolimbic seizures may induce changes in heart rate, heart rhythm, and blood pressure. Cardiovascular manifestations of seizures include sinus tachycardia or bradyarrhythmias (including sinus arrest) with syncope. Seizure-induced ventricular tachycardia and fibrillation have been implicated in sudden death. Other autonomic manifestations of seizures include flushing, pallor, shivering, sweating, symmetrical or unilateral piloerection, visceral sensations, vomiting (ictus emeticus), and respiratory changes.^{[4], [34]} Ischemic damage to the insula

TABLE 21-5 -- LEVEL-SPECIFIC CENTRAL AUTONOMIC NERVOUS SYSTEM DISORDERS

Telencephalon	Stroke Temporolimbic seizures
Diencephalon	Wernicke's syndrome Episodic hyperhidrosis with hypothermia Paroxysmal autonomic hyperactivity Fatal familial insomnia Iatrogenic Neuroleptic malignant syndrome Serotonin syndrome
Brain stem	Tumors Vertebrobasilar disease Synngobulhia Arnold-Chian type I malformation Inflammation (multiple sclerosis, poliomyelitis)
Spinal cord	Trauma Syringomyelia Multiple sclerosis Tetanus Stiff-person syndrome

has been associated with cardiac arrhythmias and contralateral hyperhidrosis. When the cingulate and paracentral cortices are involved, urinary incontinence may occur because of uninhibited bladder contractions.

Diencephalon Syndromes. Disorders affecting the hypothalamus may produce disturbances of thermoregulation, osmotic balance, endocrine function, and state of alertness.^[4] Chronic expanding lesions such as tumors or granulomas cause hypothermia, whereas acute lesions may cause hypothermia or hyperthermia. Wernicke's encephalopathy should be suspected in alcoholic and other malnourished patients presenting with unexplained hypothermia, particularly in the presence of disturbances of consciousness and oculomotor function.^[4] Episodic hyperhidrosis with hypothermia may occur with no apparent cause,^[44] as a manifestation of agenesis of the corpus callosum,^[45] or during paroxysms of autonomic hyperactivity.

Although such paroxysmal autonomic hyperactivity in patients with brain tumors and other diseases of the diencephalon has been referred to as diencephalic seizures, this term is a misnomer. The EEG shows no ictal activity, and the episodes are refractory to antiepileptic drugs. Paroxysmal autonomic hyperactivity was first described in patients with tumors situated in the region of the third ventricle that caused hydrocephalus and abrupt increases in intracranial pressure. The majority of cases, however, are due to severe closed head injuries marked by episodic increases in intracranial pressure and acute hydrocephalus following sub-arachnoid hemorrhage.^[4]

Sympathetic hyperactivity also occurs in a transmissible spongiform encephalopathy characterized by severe atrophy of the anteroventral and dorsomedial nuclei of the thalamus. This autosomal dominant disorder presents with disruption of endocrine circadian rhythms, motor dysfunction, and progressive intractable insomnia--thus its name, familial fatal insomnia (see [Chapter 43](#)).^[46]

Brain Stem Syndromes. Cerebrovascular disease is the most common cause of dysautonomia associated with brain stem dysfunction. Transient ischemic attacks in the basilar artery territory may present with paroxysmal hypertension before any focal neurological deficit becomes apparent. Lateral medullary infarction (Wallenberg's syndrome) produces Horner's syndrome and, occasionally, more severe autonomic abnormalities such as profound bradycardia, supine hypotension, or central hypoventilation.^[4]

Other brain stem disorders associated with autonomic dysfunction include tumors, syringobulbia, Arnold-Chiari malformation type 1, multiple sclerosis, and poliomyelitis. Brain stem tumors may present with intractable vomiting, orthostatic hypotension, or paroxysmal hypertension. Syringobulbia may produce Horner's syndrome, orthostatic hypotension, cardiovagal dysfunction, lability of arterial pressure, and central hypoventilation.^[24] Syncope, sleep apnea, and cardiorespiratory arrest have been reported in association with the Arnold-Chiari malformation type 1. Less common manifestation of brain stem dysfunction include hypertension due to involvement of the medullary reticular formation in poliomyelitis (see [Chapter 41](#)); autonomic hyperactivity, most likely due to disinhibition of preganglionic sympathetic and parasympathetic neurons in tetanus (see [Chapter 39](#)); and fulminant neurogenic pulmonary edema due to demyelination of the area surrounding the NTS in patients with multiple sclerosis (see [Chapter 48](#)).^[4]

Spinal Cord Syndrome. Traumatic spinal cord injury, particularly injury above the T5 level, is associated with severe and disabling cardiovascular, gastrointestinal, bladder, and sexual dysfunction. These patients have both supine and orthostatic hypotension and are at risk of developing bradycardia and cardiac arrest during tracheal suction or other maneuvers that activate the vagovagal reflexes. Vasopressin and the renin-angiotensin-aldosterone system have an enhanced role in maintenance of orthostatic arterial pressure in patients with spinal cord lesions. Lack of vasomotor and sudomotor thermoregulatory responses below the level of the lesion may lead to severe hypothermia or hyperthermia in response to changes in environmental temperature. Acute spinal injury or spinal shock produces a paralytic atonic bladder. The pattern of dysfunction seen in the chronic stages of disease, however, depends on the level of the lesion. Lesions above the sacral parasympathetic nucleus produce spastic bladder, commonly with detrusor-sphincter dyssynergia, whereas lesions of the conus medullaris produce a flaccid, areflexic bladder.

In patients with chronic tetraplegia with lesions at or above the T5 level, stimulation of the skin, muscle, or viscera innervated by segments below the lesion may result in a massive reflex activation of sympathetic and sacral parasympathetic outflows, referred to as autonomic dysreflexia.^[47] Stimuli that trigger autonomic dysreflexia arise primarily from the bladder, bowel, or skin. Vasodilation above the level of the lesion produces flushing of the face, chest, and upper arms and congestion of the nasopharyngeal mucosa. There may be excessive sweating above the anesthetic dermatome, piloerection, pallor in the abdomen and lower extremities, and pupillary dilatation. Severe hypertension is a prominent feature of autonomic dysreflexia and can result in hypertensive encephalopathy or intracranial, subarachnoid, or retinal hemorrhage. The combined parasympathetic and sympathetic stimulation may cause potentially dangerous supraventricular and ventricular arrhythmias.

Multiple sclerosis (MS) may affect autonomic pathways at the level of the spinal cord, brain stem, or diencephalon. Bladder, bowel, and sexual dysfunction are prominent autonomic manifestations of MS. The pathophysiological basis of the bladder dysfunction seen in patients with MS is detrusor hyperreflexia and detrusor-sphincter dyssynergy. Subclinical abnormalities in cardiovascular sympathetic and parasympathetic function and abnormal thermoregulatory sweating detected by testing in the autonomic laboratory are common in patients with MS.

Syringomyelia produces partial interruption of sympathetic output pathways in the intermediolateral cell columns. Its autonomic manifestations include Horner's syndrome, sudomotor and vasomotor dysfunction, and trophic changes in the limbs, especially the hands.

Tetanus and the stiff-person syndrome may be associated with sympathetic hyperactivity due to lack of synaptic inhibition of preganglionic autonomic neurons. This results in hyperpyrexia, sweating, tachycardia, hypertension, tachypnea, and pupillary dilatation, usually associated with the muscle spasms.

TABLE 21-6 -- TOPOGRAPHIC OR ORGAN RESTRICTED AUTONOMIC DISORDERS

Disorders of the Pupil
Affecting parasympathetic outflow
Third nerve lesion
Argyll Robertson pupil
Adie's pupil
Affecting sympathetic outflow
Horner's syndrome
Pourfour du Petit syndrome
Facial Hyperhidrosis and Flushing
Gustatory sweating
Harlequin syndrome
Cluster headache
Vasomotor and Sudomotor Disorders of the Limb
Vasomotor disorders
Raynaud's phenomenon
Acrocyanosis
Livedo reticulans
Erythromelalgia
Essential hyperhidrosis
Complex neuropathic pain syndromes
Painful distal peripheral neuropathy
Nerve trauma (causalgia)
Undetermined and multifactorial: Complex regional pain syndrome
Reflex sympathetic dystrophy
Neurogenic Bladder
Spastic bladder with or without detrusor-sphincter dyssynergia
Flaccid bladder
Gastrointestinal Dysmotility
Pseudo-obstruction
Sexual Dysfunction
Erectile dysfunction
Ejaculation dysfunction

Topographic or Organ-Specific Disorders ([Table 21-6](#))

PUPILS

Argyll Robertson Pupils. Argyll Robertson pupils are irregular and smaller than normal in darkness and demonstrate lack of the pupillary light reflex with preserved pupillary constriction during accommodation and convergence for near objects. These features, as in patients with large pupils with light-near dissociation, usually indicate a lesion in the rostral midbrain at the level of the posterior commissure.

Adie's Pupil. These tonic pupils are large and irregular in shape, poorly reactive to light, and indicate a lesion of the ciliary ganglion or short ciliary nerves. On slit-lamp evaluation, regional palsies of the iris sphincter are visible. These pupils have a hypersensitive constrictor response to administration of diluted muscarinic agonists, such as a 2.5 percent solution of methylcholine chloride or a 0.1 percent solution of pilocarpine. Adie's pupils are tonic pupils associated with reduced or absent tendon reflexes.

Horner's Syndrome. A unilateral small pupil is commonly due to underactivity of the ipsilateral sympathetic pathways. Miosis is commonly associated with ptosis (lid droop) due to sympathetic denervation of the tarsal muscle and facial anhidrosis (loss of sweating). This combination is known as Horner's syndrome. Oculosympathetic paralysis occurs ipsilaterally owing to (1) central lesions involving the hypothalamospinal pathways at the dorsolateral brain stem tegmentum (e.g., a lateral medullary infarct); (2) preganglionic lesions (e.g., compression of the sympathetic chain by a tumor in the apex of the lung); or (3) postganglionic lesions at the level of the internal carotid plexus (e.g., lesions of the cavernous sinus). Postganglionic Horner's syndrome does not result in facial anhidrosis because pupilodilator and sudomotor axons follow separate paths along branches of the internal and external carotid arteries, respectively.

Local instillation of drugs that affect sympathetic neurotransmission in the pupil helps to localize the lesion causing oculosympathetic paralysis. Cocaine hydrochloride (5 to 10 percent), which prevents NE reuptake, will not dilate a pupil that is miotic because of a lesion anywhere in the sympathetic pathway. The responsible lesion can be further localized by hydroxyamphetamine hydrobromide (Paredrine 1 percent), which is an indirect sympathomimetic agent that releases norepinephrine from the synaptic terminals, thus eliciting pupillary dilatation in patients with preganglionic but not postganglionic Horner's syndrome. Phenylephrine hydrochloride (Neo-Synephrine) is a direct alpha agonist that in a low concentration (1 percent) dilates the pupil only in patients with a postganglionic Horner's syndrome associated with denervation hypersensitivity of the pupil.

FACIAL HYPERHIDROSIS AND FLUSHING

Facial flushing may result from the release of tonic sympathetic vasoconstriction, active sympathetic vasodilatation, increased parasympathetic activity via the greater petrosal nerve, and the release of vasoactive peptides. Gustatory sweating and flushing occur in the following conditions: idiopathic hemifacial hyperhidrosis associated with hypertrophy of the sweat glands; following bilateral cervicothoracic sympathectomy with reinnervation of the superior sympathetic ganglion by preganglionic sympathetic fibers destined for the sweat glands; after local damage to the autonomic fibers traveling with the peripheral branches of the trigeminal nerve (e.g., in parotid or submaxillary gland surgery or V3 zoster) with reinnervation of sweat glands and blood vessels by parasympathetic vasodilator fibers destined for the salivary glands; and accompanying peripheral neuropathies, most frequently diabetes mellitus. ^[48]

Sympathetic failure may produce loss of sweating and flushing as manifestations of Horner's syndrome. In contrast, the Porfour du Petit syndrome consists of a dilated pupil with flushing and hyperhidrosis due to sympathetic hyperactivity. This syndrome is seen in patients with sympathetic nervous system lesions, frequently following injuries of the neck that damage the sympathetic plexus around the carotid artery. The harlequin syndrome consists of a sudden onset of flushing and

sweating on one side of the face. This disorder may be due to lesions in the contralateral central or peripheral sympathetic nervous system pathways. Attacks of cluster headache may be accompanied by ipsilateral signs of parasympathetic hyperactivity (lacrimation and nasal discharge), sympathetic overactivity (forehead sweating), and ocular sympathetic paralysis (miosis and ptosis). The mechanisms producing these phenomena have no widely accepted explanation. Changes in both the

sympathetic and the trigeminovascular pathways may be responsible for the autonomic features that accompany migraine and cluster headaches. ^[48]

VASOMOTOR AND SUDOMOTOR DISORDERS OF THE LIMBS

Hyperhidrosis may be generalized or localized. Localized hyperhidrosis is rare and may occur with injury to the spinal cord (e.g., in syringomyelia), peripheral nerves (e.g., with partial median or sciatic nerve injury), or eccrine sweat glands. Perilesional hyperhidrosis may surround an anhidrotic region produced by a lesion of the sympathetic ganglia or rami. The axillary eccrine sweat glands are activated by thermal stimuli, whereas the palmar and plantar glands are activated by emotional stimuli. Primary or essential hyperhidrosis affects the axillary, palmar, and plantar regions and may be familial. Generalized hyperhidrosis may be secondary to infections, malignancies, or neuroendocrine disorders (e.g., pheochromocytoma, thyrotoxicosis, acromegaly, carcinoid, anxiety, hypotension, hypoglycemia, and cholinergic agents). ^[48]

Vasomotor disorders in the limbs include Raynaud's phenomenon, acrocyanosis, livedo reticularis, vasomotor paralysis, and erythromelalgia. Raynaud's phenomenon is the episodic, bilateral, symmetrical change in skin color (pallor, followed by cyanosis and terminating in rubor after rewarming) that is provoked by cold or emotional stimuli. This response is due to episodic closure of the digital arteries. There is, however, no consistent evidence of exaggerated sympathetic outflow to the skin. Raynaud's phenomenon may be associated with connective tissue disease (e.g., scleroderma, rheumatoid arthritis, psoriasis), occupational trauma (such as the use of pneumatic hammers, chain saws producing vibration), the thoracic outlet syndrome, the carpal tunnel syndrome, or certain drugs (e.g., beta blockers, ergot alkaloids, methysergide, vinblastine, bleomycin, amphetamines, bromocriptine, and cyclosporine). ^[48]

Acrocyanosis is a symmetrical distal blue discoloration, usually occurring below the wrists and ankles, that is due to arteriolar constriction and is aggravated by cold. In contrast, livedo reticularis is a vasomotor disorder that affects the extremities and the trunk and is due to vasospasm with obstruction of the perpendicular arterioles or stasis of blood in the superficial veins. It may be a benign disorder or may be associated with vasculitis, antiphospholipid antibodies (Sneddon's syndrome), connective tissue disease, hyperviscosity syndrome, thrombocythemia, and drugs (e.g., amantadine, quinine, and quinidine). ^[48]

Vasomotor paralysis may be seen in patients with lesions of the sympathetic pathways at the level of the spinal cord, preganglionic nerves, ganglia, or postganglionic nerves. Examples include surgical sympathectomy (e.g., for treatment of selective cases of hyperhidrosis, Raynaud's phenomenon, and reflex sympathetic dystrophy), trauma (e.g., carpal tunnel syndrome, ulnar nerve lesions), and tumor infiltration (e.g., Pancoast's tumor, malignant retroperitoneal disease).

Erythromelalgia is a painful acral erythematous condition that occurs with cutaneous warming and is associated with an intense burning sensation. It may occur in patients with small-fiber neuropathies. The mechanism may be activation of neurogenic flare by a polymodal C nociceptor axon and release of vasodilator and algogenic neuropeptides such as substance P. ^[20]

REGIONAL PAIN SYNDROMES

Reflex sympathetic dystrophy is a pain syndrome defined as a continuous burning pain, hyperpathia (exaggerated response to painful stimuli), and allodynia (perception of an innocuous stimulus as painful) in a portion of an extremity. This disorder is associated with signs of sympathetic hypoactivity or hyperactivity and usually follows minor trauma that does not involve major nerves. Causalgia is a similar syndrome that occurs after partial injury of a nerve or one of its major branches. Vasomotor and sudomotor instability, manifestations of sympathetic hyperactivity or hypoactivity, are commonly seen. Reflex sympathetic dystrophy is not a single pathological entity, but different central, peripheral, and psychogenic mechanisms may coexist in a particular case. Sympathetic blockade may be of benefit. ^[20]

NEUROGENIC BLADDER

Disturbances at different levels of the bladder control system result in the development of neurogenic bladder. Neurogenic bladders can be subdivided into two types: the reflex or upper motor neuron type, and the nonreflex or lower motor neuron type. The terms reflex and nonreflex denote the presence or absence, respectively, of bulbocavernosus and anal reflexes. The reflex type of neurogenic bladder includes the uninhibited bladder associated with lesions of the medial frontal region that results in urinary incontinence but not urinary retention because the detrusor-sphincter synergy is preserved. The automatic bladder results from lesions of the spinal cord that interrupt the pathway from the pontine micturition centers. An automatic bladder is associated with urgency, frequency, incontinence, and urinary retention that is due to detrusor-sphincter dyssynergia. The lower motor neuron type of neurogenic bladder, such as that occurring with lesions of the cauda equina or peripheral nerves, is characterized by incomplete bladder emptying, urinary retention, and overflow incontinence. ^[13]

GENERAL MANAGEMENT GOALS

Orthostatic Hypotension

Management of orthostatic hypotension requires patient education to avoid factors that precipitate a fall in blood pressure. Patients should be made aware of the hypotensive effects of certain drugs, large meals, environmental temperature increases, and physical activities. Other instructions include institution of a high-fiber diet to lessen straining resulting from constipation and the use of physical maneuvers that help to increase postural tolerance. These maneuvers include crossing the legs, lowering the head in a stooped position, bending forward, and placing a foot on

a chair or squatting. Some patients may be helped by sleeping with the head of the bed elevated 15 to 30 cm (the reverse Trendelenburg position) to avoid supine hypertension and decrease nocturnal natriuresis and volume depletion. This maneuver alone may reduce postural hypotension in the morning. To reduce postprandial hypotension, patients should eat smaller, low-carbohydrate meals more frequently and drink strong coffee. Finally, custom-fitted elasticized garments (a Jobst or Barton-Carey leotard) may reduce venous pooling in the legs.

Pharmacological interventions are directed toward increasing intravascular volume and peripheral vascular resistance without markedly increasing supine hypertension. Volume expansion can be achieved by ensuring adequate hydration (2 to 2.5 liters of fluid per day) and increasing sodium intake (150 to 250 mEq, or 10 to 20 gr).

Fludrocortisone is the drug most frequently used for the treatment of orthostatic hypotension in patients with autonomic failure. Even at low doses, it expands blood volume by its mineralocorticoid action. The initial dose is 0.1 mg po qd; this is increased slowly in 0.1-mg increments at 1- to 2-week intervals. Few patients require more than 0.4 mg. Side effects include volume expansion, congestive heart failure, supine hypertension, and hypokalemia.

The next line of therapy entails the use of vasoconstricting sympathomimetic agents. Several types are available. Indirect sympathomimetic drugs, such as ephedrine and methylphenidate (Ritalin), release norepinephrine both centrally and peripherally and therefore may produce tachycardia, anxiety, and tremor. Direct alpha agonists, such as phenylpropanolamine or phenylephrine, may be helpful but have erratic gastrointestinal absorption, a short duration of action, an increased risk of supersensitive hypertensive responses, and tachyphylaxis. Midodrine, a pro-drug metabolized in the liver to desglymidrodrine, is a potent alpha-1 adrenergic agonist that acts on both the arteries and the veins. This new agent is well absorbed following oral administration and does not cross the blood-brain barrier.^[49] All sympathomimetic agents may produce supine hypertension and should not be used at night.

Dihydroxyphenylserine is a synthetic amino acid that is decarboxylated by L-amino acid decarboxylase to norepinephrine, thus bypassing the dopamine-beta-hydroxylase step of catecholamine synthesis. It is therefore the agent of choice for the treatment of hypotension in patients with inherited dopamine-beta-hydroxylase deficiency. Its efficacy in more common forms of autonomic failure is currently under investigation.

Recombinant erythropoietin alpha (25 to 75 U/kg sc two or three times weekly) corrects the mild anemia frequently seen in patients with severe autonomic failure and may increase blood pressure and orthostatic tolerance.^[50] Other agents that may be of benefit in the treatment of orthostatic hypotension include ergotamine tartrate, dihydroergotamine, monoamine oxidase inhibitors, yohimbine, and nonsteroidal anti-inflammatory agents. It is unclear whether any of these agents is effective.

Severe supine hypertension, particularly at night, is a troublesome feature of this disorder that may be prevented by sleeping in the reverse Trendelenburg position, avoiding vasoconstrictor drugs in late afternoon, and eating a small carbohydrate-rich snack or drinking alcohol before bedtime. If needed, a short-acting vasodilator agent (e.g., nifedipine 10 mg po) may also be used at night.

Neurogenic Bladder

Detrusor Hyperreflexia Without Outlet Obstruction. In patients with detrusor hyperreflexia without outlet obstruction, the treatment most frequently given is an anticholinergic drug such as oxybutynin, propantheline, or dicyclomine. Timed voiding and moderate fluid restriction are helpful in reducing frequency, urgency, and urge incontinence. DDAVP may also be useful in patients with significant incontinence and nocturia. In patients with severe spasticity, both intrathecal baclofen infusion and dorsal rhizotomy may be effective. Augmentation cystoplasty has a place in the treatment of patients with MS and refractory detrusor hyperreflexia.

Detrusor Hyperreflexia with Outlet Obstruction. Treatment of patients with detrusor hyperreflexia and detrusor-sphincter dyssynergia is more difficult, and these patients are at higher risk of sustaining upper urinary tract damage. Alpha-1 antagonists such as phenoxybenzamine or prazosin may decrease bladder-outlet sphincter tone. Dantrolene, baclofen, or benzodiazepines may reduce the tone of the striated external sphincter. The most useful method is the combined use of anticholinergics and intermittent self-catheterization. Surgical external sphincter-otomy or diversion procedures are treatments of last resort.

Detrusor Areflexia or Poor Bladder Contractility. Bethanechol hydrochloride is a muscarinic agonist that has a relatively selective action on the urinary bladder and may be effective in treating patients with chronic detrusor atony or hypotonia. Other options include the use of adrenergic antagonists, prostaglandins, and narcotic antagonists, but their efficacy is unproved. The simplest and most effective form of management in patients with hypotonic bladder and detrusor areflexia is intermittent self-catheterization. Patients who are unable to perform intermittent self-catheterization because of motor difficulties may require an indwelling catheter or suprapubic diversion. Women may benefit from using the Crede(c) maneuver. In patients with conus or cauda equina lesions, alpha-adrenergic agonists (e.g., ephedrine or phenylpropanolamine) may be used to increase bladder outlet resistance.

Sexual Dysfunction

Treatment of organic impotence includes treatment of secondary psychological problems and reducing or eliminating aggravating factors such as poor sleep, chronic pain, malnutrition, alcohol use, and some medications. Yohimbine can be used orally to increase penile arterial vasodilatation and enhance relaxation of the cavernous trabeculae. Direct injection of papaverine (direct smooth muscle relaxant), phentolamine, or prostaglandin E1 into the corpora cavernosa may be effective but poses the risks of priapism and scarring of the tunica albuginea. A vacuum device may also be used to enhance corporal filling.

Gastrointestinal Dysmotility

The principles of management of any gastrointestinal motility disorder include restoration of hydration and nutrition by the oral, enteral, or parenteral route, suppression of bacterial overgrowth, use of prokinetic agents or stimulating laxatives, and resection of localized disease.

Bowel Hypomotility. The first line of treatment of bowel hypomotility is to increase dietary fiber as well as water intake and exercise. Psyllium or methylcellulose with a concomitant increase in fluid intake may be used to further increase stool bulk. Some caution is required in diabetic patients, in whom high fiber may pose a risk of distention, cramping, and potential bezoar formation in the presence of gastroparesis. If these measures are ineffective, stool softeners (e.g., docusate sodium) or lubricants (e.g., mineral oil) together with an osmotic agent (e.g., milk of magnesia or lactulose) may be used. Glycerine suppositories or sodium phosphate enemas promote fluid retention in the rectum and thus stimulate evacuation. Contact cathartics such as diphenylmethane derivatives (e.g., phenolphthalein, bisacodyl) or anthraquinones (e.g., senna and cascara) should be used sparingly because these agents may damage the myenteric plexus, producing a "cathartic bowel."

This regimen can be used in conjunction with the prokinetic agents, which include the following: metoclopramide, which has antiemetic effects due to blockade of central dopaminergic D2 receptors and indirect prokinetic effects through cholinergic mechanisms; cisapride, which increases the release of acetylcholine from neurons of the myenteric plexus; erythromycin, which mimics the prokinetic actions of motilin, a gastrointestinal polypeptide; and misoprostol, a synthetic prostaglandin E1 analog. Patients who do not respond to medical therapy may require colonic surgery.

Bowel Hypermotility. Diarrhea may result from bacterial overgrowth in patients with intestinal hypomotility. A trial with tetracycline or metronidazole is generally

conducted in patients with unexplained chronic diarrhea, particularly if steatorrhea is present. Prokinetic agents may paradoxically improve diarrhea in this situation. If these measures fail, synthetic opioid agonists such as loperamide or diphenoxylate can be used. Opioid agonists decrease peristalsis and increase rectal sphincter tone. Clonidine, an alpha-2 agonist, has been used to treat diarrhea associated with diabetic dysautonomia.

Idiopathic fecal incontinence may be associated with delayed conduction in the pudendal nerves and denervation changes in the sphincter muscles. High-fiber bulking agents may be beneficial because semi-formed stools are easier to control than liquid feces. Fecal disimpaction is indicated in some patients. Daily tap water enemas aid in clearing the residue from the rectum between evacuations and may improve continence. Biofeedback may be successful in some cases. Patients who undergo surgical sphincter repair may gain some continence for solid stool, although the presence of pudendal neuropathy is associated with a poor outcome. Other surgical treatments include colostomy, artificial anal sphincters, and creation of a neosphincter with muscle grafts.

HISTORY AND DEFINITIONS

The modern study of neurovascular function owes much of its success to important, early contributors to the field. Some of the earliest drawings of the cerebral circulation were done in the 1500s by Andreas Vesalius. ¹ Gabriel Fallopius provided a detailed description of the cerebral vasculature, including a description of what was later called the circle of Willis. ¹ Thomas Willis was the first to describe the function of the circle that bears his name. ¹ Vascular anatomy was transformed into physiology through the work of William Harvey in the early 1600s. ¹ The most important early advances in the study of "apoplexy" were a result of meticulous studies of the cerebral blood vessels of patients with apoplexy by Johann Jakob Wepfer. ¹ The actual demonstration that the paralysis was on the side opposite the brain lesion in "apoplexy" was through the work of Domenico Mistichelli, and Francois Bayle was among the first to relate atherosclerosis in cerebral arteries to "apoplexy." ¹

A transient ischemic attack (TIA) is an episode of focal, nonconvulsive neurological dysfunction caused by a reversible interference of the blood supply to an area of the retina or brain that lasts less than 24 hours, and often lasts less than 30 minutes. The episodes are sudden and often are unprovoked. They reach a maximum intensity almost immediately. The duration of a TIA was determined on an arbitrary basis. Subsequent studies have revealed that the typical carotid distribution TIA lasts less than 10 to 20 minutes. ¹, ¹

A reversible ischemic neurologic deficit (RIND) is a focal neurological deficit that lasts longer than 24 hours but resolves with complete recovery within 3 weeks. ¹ This term has not been used much because this division does not represent a unique group prognostically or therapeutically. ¹

373

A completed (established) stroke is the preferred term to describe an acute episode of focal brain ischemia that lasts longer than 24 hours. Most completed strokes reach a maximal neurological deficit within an hour of onset. Older terms that have been used in the past include apoplexy (literally meaning "struck with violence" or "being thunderstruck") and cerebrovascular accident. Both of these older terms imply a random, unpredictable, or uncertain nature to these events, which often is not the case.

Stroke in evolution or progressive stroke describes a temporal profile in which the neurological deficit occurs in a stepwise or progressive pattern. In the carotid artery distribution, there is usually little likelihood of progression after 24 hours. In the vertebrobasilar distribution, progression may continue for up to 72 hours. ¹ There are numerous causes to consider ([Table 22-1](#)) when there is "progression" of an ischemic event.

Stroke may be divided into ischemic infarctions, which may be bland or hemorrhagic, and hemorrhages, including intracerebral hemorrhages and subarachnoid hemorrhages. Ischemic infarctions can be due to intrinsic vascular occlusion (thrombus) or an occlusion from intravascular material that originates elsewhere, such as heart or other vessels (embolism).

Common focal sites of cerebrovascular atherosclerosis include the proximal common carotid artery, the origin of the internal carotid artery, the carotid siphon, and the proximal middle cerebral and vertebral arteries. The aortic arch has been recognized as a source for atheroembolism.

Small arteries are also susceptible to atherosclerotic changes. Examples of these small arteries would be the lenticulostriate arteries, thalamoperforating arteries, the basilar paramedian penetrating arteries, and the medullary arteries. These arteries supply deep cerebral white matter. The most frequent sites of lacunar infarcts are the putamen, basis pontis, thalamus, posterior limb of the internal capsule, and caudate nucleus. They may also occur in the anterior limb of the internal capsule, subcortical cerebral white matter, and cerebellar white matter.

Overall, embolism accounts for between 15 and 30 percent of strokes. ¹ ¹ Emboli that cause brain ischemia may arise from the heart, the aorta, the venous system in combination with a transcardiac defect, or from other intracerebral or extracerebral arteries (artery-to-artery embolism).

TABLE 22-1 -- CAUSES OF NEUROLOGICAL WORSENING AFTER AN ISCHEMIC EVENT

Thrombus propagation
Occlusion of a stenotic artery due to thrombus
Recurrent embolism
Hemorrhagic transformation
Failure of collateral blood supply
Hypoperfusion due to systemic hypotension
Hypovolemia or decreased cardiac output
Hypoxia
Cerebral edema
Herniation
Seizures
Medication effects
Medical conditions such as pneumonia, pulmonary embolus, myocardial ischemia, congestive heart failure, electrolyte disturbances, or urosepsis

Diffuse perfusion deficits may lead to brain ischemia and may occur with severe hypotensive crises due to sepsis, anaphylaxis, acute blood loss, pharmacologic alterations, cardiac surgery, and other acute medical crises. These situations may lead to infarctions, typically in the border zone regions (watershed areas) between the anterior, middle, and posterior cerebral arteries.

Hemorrhages may be subarachnoid, intraparenchymal, or a combination of both. Intraparenchymal hemorrhages are the result of bleeding from an arterial source directly into the brain. Subarachnoid hemorrhages are the result of bleeding into the subarachnoid spaces.

Another distinction needs to be made between hematomas within the brain parenchyma, which are referred to as intracerebral, and those outside the brain parenchyma, which are referred to as extracerebral. Examples of extracerebral hematomas are subdural and epidural hematomas.

CLINICAL HISTORY

One of the first questions to address in the history is whether the problem involves neurovascular dysfunction. The clinical hallmark of many forms of neurovascular dysfunction is an acute focal change in neurological status. Therefore, an event that has an indistinct onset or course may not involve the neurovascular system. There are two exceptions to consider. One is the indistinct time of onset of symptoms in an individual who awakens with the neurological dysfunction. The other is a stuttering or waxing or waning course that can be seen in some patients with cerebral arterial thrombosis. In most instances of neurovascular dysfunction, the neurological deficit is maximum from its onset, with the involved body parts being simultaneously affected. The diagnosis of neurovascular dysfunction is weakened if there is a series of events in which neurological deficits accumulate, or if there is a march of symptoms from one area to another. Focal seizures can usually be differentiated by obtaining a history of associated involuntary motor activity and a march of symptoms. A gradual onset of symptoms with accumulation of deficits over time would suggest the possibility of a space-occupying lesion. It would be distinctly unusual for neurovascular dysfunction to present with positive neurological phenomena such as visual hallucinations or scintillating visual symptoms. Fleeting positive visual phenomenon would be more consistent with migraine. Isolated vertigo may be more consistent with a labyrinthine disorder. Hypoglycemia should be considered in the diabetic with transient paresis or aphasia, particularly if there is associated altered consciousness or confusion.

Specific details need to be sought in the history to adequately evaluate the possible underlying type and mechanism of neurovascular dysfunction. It is important to review any cerebrovascular risk factors with the patient, including a history of cardiac disorders, hypertension, hematological abnormalities, hyperlipidemia, diabetes, tobacco use, alcohol or drug use, migraine, oral contraceptive use, and a personal history or family history of TIA or stroke. Information should be obtained about use of medications such as oral anticoagulants or antiplatelet agents

374

and the use of illicit drugs. Patients may have other medical illnesses associated with stroke, including connective tissue diseases, malignancies, and hypercoagulable states. Rarely, a preceding or concurrent infection may predispose to stroke. A history of recent trauma should be sought in patients with symptoms of carotid or vertebral dissection. A history of posterior circulation symptoms with arm exercise may suggest subclavian steal.

It is often difficult to differentiate an ischemic infarction from a hemorrhage. Some historical features that suggest a hemorrhage would be an altered level of consciousness or a seizure at the onset, prominent nausea and vomiting, or a severe headache. However, onset headaches can also be present in 17 percent of patients with ischemic infarction.¹⁴ A carotid dissection may present with pain involving the neck, ipsilateral head, or the periorbital region.

While it is difficult to distinguish cardiogenic stroke from other causes based on the neurological profile, historical features that may suggest a cardioembolic cause are an abrupt onset with a maximum deficit at the onset, a history of infarctions in more than one vascular territory, or systemic emboli to the limbs or other organs.

Patients noting monocular visual loss or having complaints of a speech disorder suggestive of aphasia most likely have carotid distribution ischemia. Complaints of binocular visual loss, vertigo, balance difficulties, gait instability, bilateral or alternating weakness or altered sensation, swallowing difficulties, or diplopia suggest ischemia in the vertebrobasilar distribution. Etiologies other than vertebrobasilar ischemia should be considered with isolated vertigo, diplopia, or dysarthria. Localization of the neurovascular dysfunction to the cortical or subcortical region may be possible based on historical features. Patients with complaints of any degree of altered consciousness may have cortical or combined subcortical and cortical ischemia. Loss of vision in one field or forced eye deviation usually implies a cortical or combined cortical and subcortical localization. A history of weakness or sensory loss affecting the face, arm, and leg equally usually implies a subcortical or brain stem localization. Complaints of severe dysarthria are often indicative of a subcortical or combined cortical and subcortical infarction.

ANATOMY

Extracranial Arterial System

HEART, AORTA, COMMON CAROTID, SUBCLAVIAN, INNOMINATE ARTERIES

The ascending aorta arises from the left ventricle. The aortic arch gives rise to several important branches. The first branch of the aorta is normally the innominate artery, which is also referred to as the brachiocephalic trunk. Shortly after its origin, the innominate artery divides into the right subclavian and right common carotid arteries. The right vertebral artery arises from the right subclavian artery, courses posteromedially, and then enters the foramen transversarium of C6. The right common carotid artery bifurcates into the internal and external carotid arteries in the midcervical region, usually at C3 or C4, about 3 cm below the angle of the mandible. However, the bifurcation may be as rostral as C1 or as caudal as T2.

The next branch of the aorta is the left common carotid artery, which bifurcates into the internal and external carotid arteries at the same level as the right common carotid artery ([Fig. 22-1](#)). The last branch of the aortic arch is the left subclavian artery. The left vertebral artery is the first branch of the left subclavian artery. This branch usually arises from the superior portion of the artery and then courses cephalad to enter the foramen transversarium of C6. It is reported that the left vertebral artery is as large or larger in caliber than the right vertebral artery in approximately 75 percent of cases. ^[11]

EXTERNAL CAROTID ARTERY AND BRANCHES

The external carotid artery arises from the common carotid artery in the midcervical region. The proximal portion of this artery lies anteromedial to the internal carotid artery, but as it ascends, it courses posteromedially to supply structures of the face. The external carotid artery has nine major branches ([Fig. 22-2](#)). Several of these branches, particularly the maxillary artery and its branches, the ascending pharyngeal artery, and the facial artery, can be important sources of collateral blood flow in the event of internal carotid artery occlusion. The order in which these branches arise and the selected important structures they supply are as follows:

1. Superior thyroid artery, which supplies the larynx and portions of the thyroid.
2. Ascending pharyngeal artery, which supplies portions of the meninges, middle ear, lower cranial nerves, and the upper cervical nerves.
3. Lingual artery, which supplies the tongue and pharynx.
4. Facial artery, which supplies the face, palate, and pharynx.
5. Occipital artery, which supplies musculocutaneous structures of the scalp and neck.
6. Posterior auricular artery, which supplies the scalp, tympanic cavity, pinna, and the parotid gland.
7. Maxillary artery, which is the larger terminal branch that has three major portions, each with its own branches. The most important branches to remember are the middle meningeal artery, which can be lacerated in head trauma and produce an epidural hematoma, and the anterior deep temporal artery, which can be a source of collateral blood flow through the ophthalmic artery when the internal carotid artery is occluded.
8. Transverse facial artery, which with the facial artery supplies the buccal area.
9. Superficial temporal artery, which is the smaller terminal branch that supplies the anterior two thirds of the scalp and portions of the face.

VERTEBRAL EXTRACRANIAL PORTION AND ANTERIOR SPINAL ARTERY

The vertebral artery is divided into four segments. ^[12] The first or V1 segment is the portion from its origin at the

Figure 22-1 Branches of the aortic arch. (© 1996 Indiana University Medical Illustration Dept.)

Figure 22-2 Major branches of the external carotid artery. (© 1996 Indiana University Medical Illustration Dept.)

subclavian artery to its entry into the costotransverse foramen of C6 or C5. The second or V2 segment travels between C6 and C2, entirely within the transverse foramina. The third or V3 segment takes a tortuous course between C2 to the suboccipital triangle between the atlas and the occiput, where it is covered by the atlanto-occipital membrane. The fourth segment or V4 is the intracranial portion, after it has pierced the dura mater to enter the foramen magnum to join the opposite vertebral artery at the medullopontine level.

The anterior spinal artery is formed by the anastomosis of the two branches of the vertebral arteries. This artery extends from the olivary nucleus to the conus medullaris and supplies the ventral surface of the medulla and the anterior two thirds of the spinal cord.

Intracranial Arterial System: Circle of Willis

INTERNAL CAROTID ARTERY AND BRANCHES (OPHTHALMIC AND ANTERIOR CHOROIDAL)

The internal carotid artery (ICA) can be conceptually divided into three main segments: cervical, petrosal, and intracranial. The cervical portion extends from the carotid bifurcation to the base of the skull. This segment has no branches. The petrosal segment begins after the artery enters the base of the skull and travels through the carotid canal in the petrous portion of the temporal bone. The artery then crosses the foramen lacerum and enters the cavernous sinus. The intracranial portion begins distal to the petrosal segment and proximal to the anterior clinoid process. At this point, the presellar and juxtaseilar portions of the ICA are distinguished. The juxtaseilar portion lies within the cavernous sinus and is closely associated with cranial nerves III, IV, VI, and the ophthalmic and maxillary divisions of cranial nerve V. Meningohypophyseal branches arise from the presellar and juxtaseilar portions to supply the meninges and the posterior lobe of the hypophysis. The ICA pierces the dura mater medial to the anterior clinoid process to become supraclinoid.

The first major branch of the ICA, the ophthalmic artery, arises at the level of the anterior clinoid process ([Fig. 22-3](#)). After initially running intracranially, this artery traverses the optic canal and then goes to the orbit. The most important of the ocular branches is the central retinal artery. Numerous anastomotic channels between the internal and external carotid arteries ultimately involve the ophthalmic artery.

After giving rise to the ophthalmic artery, the ICA gives rise to the posterior communicating artery (PCoA) and then the anterior choroidal artery (AChA). The AChA has a proximal or cisternal segment that courses posteromedially below the optic tract and medial to the uncus of the temporal lobe. The artery then turns laterally and passes through the crural cistern and around the cerebral peduncle to enter the choroidal fissure of the temporal lobe. ^[13] The distal or plexal segment of the AChA starts at the choroidal fissure and goes posteriorly in a cleft of the temporal horn. The AChA may terminate near the lateral

(Courtesy of Karen S. Caldemeyer, M.D.)

geniculate body or extend around the pulvinar of the thalamus. ^[13] There is a rich anastomotic relationship between the AChA and the lateral posterior choroidal, posterior communicating, and posterior cerebral arteries. Therefore, the regions supplied by the AChA and its branches can be extensive, but also variable. Possible regions supplied by this artery include the choroid plexus of the temporal horn, the amygdaloid nucleus, the piriform cortex and uncus of the temporal lobe, the

hippocampus and dentate gyri, the lateral geniculate body, the optic tract and the origin of the optic radiations, the genu and inferior and medial parts of the posterior limb of the internal capsule, the medial globus pallidus, tail of the caudate nucleus, and the upper brain stem.

After giving off the AChA, the ICA bifurcates to form the anterior cerebral and middle cerebral arteries ([Figs. 22-3](#) and [22-4](#)).

CIRCLE OF WILLIS

The circle of Willis is an arterial anastomosis at the base of the brain that connects the internal carotid and vertebrobasilar arterial systems. The circle surrounds the ventral surface of the diencephalon adjacent to the optic nerves and tracts. The anterior portion of the circle of Willis consists of the two internal carotid arteries, the anterior cerebral arteries, and the anterior communicating artery. The posterior portion of the circle consists of the proximal portions of the posterior cerebral arteries and the two posterior communicating arteries.

ANTERIOR CEREBRAL AND ANTERIOR COMMUNICATING ARTERY

The anterior cerebral artery (ACA) arises below the anterior perforated substance and runs anteromedially to

277

Figure 22-4 AP internal carotid artery arteriogram, arterial phase. 1, Internal carotid artery. 2, Anterior cerebral artery. 3, Middle cerebral artery. 4, Medial lenticulostriate a(Courtesy of Karen S. Caldemeyer, M.D.)

the interhemispheric fissure, where it joins the opposite ACA by way of the anterior communicating artery (ACoA). The ACA supplies the medial surface of the cerebrum and the upper border of the frontal and parietal lobes. ^[14]

The ACA is often divided into A1 and A2 segments. The A1 segment is the horizontal, proximal portion that extends from the origin of the ACA to its union with the contralateral ACA by way of the ACoA. The A2 segment is the portion of the ACA that is distal to the ACoA. It runs superiorly into the interhemispheric fissure, coursing around the genu of the corpus callosum. It has an important relationship anatomically to two other midline structures, lying above the optic chiasm and the pituitary gland.

The ACA gives rise to medial lenticulostriate, pericallosal, and hemispheric branches (see [Fig. 22-4](#)). The medial lenticulostriate branches include basal branches, which supply the dorsal aspect of the optic chiasm and hypothalamus, and the medial striate artery (recurrent artery of Heubner), which supplies the anteroinferior limb of the internal capsule and the anterior aspects of the putamen and caudate nuclei. The callosal branches arise from the pericallosal artery, which is that portion of the ACA distal to the ACoA. Some reserve the term pericallosal artery for the segment beyond the origin of the callosomarginal artery. The ACA and the pericallosal arteries also supply the septum pellucidum and the fornix. The hemispheric branches supply the medial surface of the hemisphere and include the orbitofrontal, frontopolar, internal frontal (anterior, middle, and posterior), paracentral, and internal parietal (superior and inferior) branches.

MIDDLE CEREBRAL ARTERY AND ITS BRANCHES

The middle cerebral artery (MCA), the largest branch of the ICA, arises below the medial part of the anterior perforated substance. It supplies most of the lateral surface of the cerebral hemisphere including the lateral frontal, parietal and temporal lobes, insula, claustrum, and extreme capsule. ^[15]

The MCA is divided into proximal, sylvian, and distal segments. The posterior-superior aspect of the proximal segment gives rise to the lenticulostriate arteries that supply the corona radiata, external capsule, claustrum, putamen, part of the globus pallidus, body of the caudate nucleus, and superior portion of the anterior and posterior limbs of the internal capsule. Other branches that may arise from the horizontal segment are the orbitofrontal and the anterior temporal arteries, but there are many variations. The sylvian segment includes all of the branches on the insula of Reil and in the sylvian fissure. After the takeoff of the anterior temporal artery, the main trunk of the MCA usually bifurcates into two branches: a superior and inferior division. Less common patterns include a trifurcation into superior, middle, and inferior divisions and a ramification pattern into four or more trunks. One branch gives rise to the anterior or proximal group of arteries, and the other branch gives rise to the posterior or distal group. The anterior group includes the orbitofrontal, precentral, central, and anterior parietal arteries. The posterior group includes the posterior parietal, posterior temporal, and the angular or terminal arteries.

POSTERIOR COMMUNICATING ARTERY

The posterior communicating artery (PCoA) arises from the posteromedial aspect of the intracranial internal carotid artery and runs caudally and medially, above the oculomotor nerve to join the posterior cerebral artery. The two PCoAs from each side provide a connection between the carotid and vertebrobasilar systems. The posterior communicating arteries supply the anterior and medial portions of the thalamus, and the walls of the third ventricle.

POSTERIOR CEREBRAL ARTERY AND BRANCHES

The posterior cerebral arteries (PCAs) usually arise as the terminal bifurcation of the basilar artery ventral to the midbrain ([Fig. 22-5](#)). Approximately 15 to 22 percent of people have a fetal (embryonic) origin of the PCA from the ICA. ^[16], ^[17] The PCA supplies the occipital lobes, inferomedial portions of the temporal lobes, midbrain, thalamus, and deep structures including the choroid plexus and ependyma of the third and lateral ventricles. The first branches are the small thalamoperforating arteries that penetrate and supply the midbrain, thalamus, and lateral geniculate body. The next branches are the medial and lateral posterior choroidal arteries that supply the posterior portion of the thalamus and the choroid plexus. An anterior division of the PCA gives rise to the inferior temporal arteries (hippocampal, anterior, middle, posterior, and common temporal arteries) that supply the inferior portions of the temporal lobes. A posterior division includes the two terminal branches of the PCA; the parieto-occipital artery, which supplies part of the cuneus and precuneus, the superior occipital gyrus, and occasionally, the precentral and superior

278

Figure 22-5 AP vertebral angiogram. 1, Vertebral artery. 2, Posterior inferior cerebellar artery. 3, Anterior inferior cerebellar artery. 4, Basilar artery. 5, Superior cerebellar artery. 6, Posterior cerebellar artery. (Courtesy of Karen S. Caldemeyer, M.D.)

parietal lobule; and the calcarine artery, which supplies the visual cortex, inferior cuneus, and part of the lingual gyrus. The splenial arteries may arise directly from the PCA or from the parieto-occipital artery.

Vertebral System

VERTEBRAL ARTERIES

The vertebral arteries (VAs) normally arise as the first branches of the subclavian artery (see [Fig. 22-1](#)). They course superiorly and medially to enter the transverse foramen of C6. The VAs course vertically through the transverse foramen of C3-C6 and then turn superolaterally to pass through the C2 foramen. After the arteries pass through the foramen of the atlas, they curve around the atlanto-occipital joint and lie in a horizontal groove along the posterior arch of C1. The VAs then curve cephalad to enter the skull through the foramen magnum.

BASILAR ARTERY

The basilar artery is formed by the union of the two vertebral arteries, which takes place at the lower border of the ventral pons (see [Fig. 22-5](#)). It continues superiorly to terminate in the interpeduncular cistern by dividing into the posterior cerebral arteries. The branches of the basilar artery can be divided into paramedian arteries, short circumferential arteries, and long circumferential arteries. The paramedian vessels are four to six in number, and they penetrate into the pontine parenchyma to

supply the medial basal pons. The short circumferential arteries enter the brachium pontis to supply the ventrolateral basis pontis. The long circumferential arteries include the superior cerebellar artery (SCA), anterior inferior cerebellar artery (AICA), and the internal auditory artery.

LONG CIRCUMFERENTIAL ARTERIES (PICA, AICA, SCA)

The arterial supply to the cerebellum includes the posterior inferior cerebellar artery (PICA), the anterior inferior cerebellar artery (AICA), and the superior cerebellar artery (SCA). PICA is the largest branch of the vertebral artery ([Figs. 22-5](#) and [22-6](#)). PICA encircles the medulla to supply the lateral medulla. The distal portion of PICA then bifurcates into a medial trunk that supplies the vermis and the adjacent cerebellar hemisphere and a lateral trunk that supplies the cortical surface of the tonsil and cerebellar hemisphere.

AICA most often arises directly from the basilar artery (see [Figs. 22-5](#) and [22-6](#)). Rarely, it may arise from the vertebral artery. In its normal course, it runs across the pons, enters the cerebellopontine angle cistern, and then forms a tight loop before running over the cerebellum. AICA supplies the lateral tegmentum of the lower two thirds of the pons and the ventrolateral cerebellum. The internal auditory artery arises from AICA to supply the auditory and facial nerves.

The SCA arises from the basilar artery near its terminal bifurcation (see [Figs. 22-5](#) and [22-6](#)). It courses posterolaterally in the perimesencephalic cistern to circle the brain stem in the region between the pons and the mesencephalon. The SCA supplies the superolateral cerebellar hemispheres, the superior cerebellar peduncle, the dentate nucleus, and part of the middle cerebellar peduncle.

Vascular Supply to the Spinal Cord

EXTRASPINAL SYSTEM (EXTRAMEDULLARY ARTERIES)

The anterior spinal artery arises from the anastomosis of two branches from the intracranial vertebral arteries. It travels in the anterior sulcus of the spinal cord and extends from the level of the olivary nucleus to the conus medullaris. It supplies the ventral surface of the medulla and the anterior two thirds of the spinal cord. The artery is continuous in the upper cervical region. However, in the segments inferior to the upper cervical region, it consists of anastomosing branches from the anterior radicular arteries.

The two posterior spinal arteries most commonly arise from the vertebral arteries. However, in some instances, they arise from PICA. There are contributions from numerous

Figure 22-6 Lateral vertebral. 1, V-3 segment of the vertebral artery. 2, V-4 segment of the vertebral artery. 3, Posterior meningeal artery. 4, Posterior inferior cerebellar artery. 5, Basilar artery. 6, Anterior inferior cerebellar artery. 7, Superior cerebellar artery. 8, Posterior cerebral artery (Courtesy of Karen S. Caldemeyer, M.D.)

posterior radicular arteries that form an anastomotic network on the posterior surface of the spinal cord. ^[18] These arteries supply the posterior one third of the spinal cord. The anterior and posterior spinal arteries join in an anastomotic loop at the conus medullaris. ^[19]

The different regions of the spinal cord receive an unevenly distributed blood supply. The upper cervicothoracic region between C1 and T2 is richly vascularized by the anterior spinal artery in the most superior segments, and radicular arteries in the lower cervical and upper thoracic segments. The artery of the cervical enlargement is the most important of these radicular arteries. There are a number of radiculomedullary arteries that feed the posterior spinal arteries. The intermediate or midthoracic portion of the cord between T3 and T8 is poorly vascularized by intercostal arteries. There is a single radiculomedullary artery between T6 and T8. There are a limited number of segmental feeders to the posterior spinal arteries. In the lower or thoracolumbosacral region, there is again a rich vascular supply through the radiculomedullary branches of the intercostal and lumbar arteries. One important artery is the great anterior radicular artery of Adamkiewicz (artery of the lumbar enlargement). There are numerous posterior radicular arteries at this level. An understanding of these variations is important in spinal cord vascular syndromes, particularly with hypoperfusion of the spinal cord due to hypotension.

INTRASPINAL SYSTEM (INTRAMEDULLARY ARTERIES)

Branches of the anterior and posterior spinal arteries form a vascular plexus or peripheral vasocorona that encircles the cord. There are also sulcal arteries arising from the anterior spinal system that travel in the anterior median fissure of the cord and then branch and penetrate the cord. There are fewer sulcal arteries in the midthoracic region, which may contribute to the susceptibility of this region to ischemia. The branches of this plexus supply a major portion of the white matter and the dorsal horns of the gray matter. The arterial supply of the gray matter is richer than that of the white matter. The gray matter, except the dorsal horns, is supplied by the largest branches of the anterior spinal artery called the sulcocommissural arteries. The dorsal horns and the funiculi are supplied by paired posterior spinal arteries, posterior medullary feeders, and perforating pial branches.

Arterial Structure

Arteries are classified into three categories based on their size and histological features. The large or elastic arteries, such as the aorta and its major branches, have three layers: the tunica intima, the tunica media, and the tunica adventitia. In large arteries, the intima is a smooth layer of thin endothelial cells on a basement membrane, the media is the muscular layer that is rich in elastic tissue, and the adventitia is a layer of connective tissue with elastic fibers, nerve fibers, and the vasa vasorum. With aging, the elastic fibers of the media in large vessels become less resilient. This causes less expansion with blood pressure elevations and predisposes to tortuosity. The medium or muscular arteries also consist of three layers. The distinguishing features of muscular arteries are the internal elastic lamina that forms the outer limit of the intima and the external elastic membrane that forms the outer layer of the media and is more defined than in large arteries. The adventitial layer in muscular arteries contains more nerves than this layer in large vessels due to their role in autonomic control. Arteriosclerosis and atheromatosis are most characteristic of the large and medium-sized vessels. Medial calcific sclerosis can affect medium-sized arteries. Finally, small arteries are characterized by a progressive loss of the three layers such that arterioles have no identifiable layers. The extracranial cerebral arteries have the usual structure of elastic or muscular arteries. However, intracranial

arteries differ because they have no external elastic lamina and there is no vasa vasorum. ^[20]

Blood-Brain Barrier

The microcirculation of the brain is unique because of the blood-brain barrier (BBB). This barrier to free metabolic exchange keeps a homeostatic environment around neurons. There are actually two parts to the BBB, including the BBB itself and the blood-CSF barrier. ^[21] The BBB consists of capillary endothelial cells that are joined at tight junctions devoid of fenestrae. There is very little pinocytosis occurring, and passage of substances depends on their affinity for lipids and the presence of carrier proteins. The blood-CSF barrier consists of the periventricular region, including the choroid plexus, median eminence, and the area postrema. In these locations, there is active pinocytosis that allows small molecules into the subependymal interstitial space. Cerebral edema occurs when there is an increase in water content in the brain. Cerebral infarctions, hemorrhages, and contusions cause vasogenic edema as a result of leakage of water and plasma directly into the central nervous system due to damaged capillary endothelial cells that have lost their BBB function.

Venous Supply

The venous system of the head and neck is extensive. Emphasis is made here only to those vessels that are relevant to cerebrovascular syndromes ([Fig. 22-7](#)).

The blood from the brain is drained by the cerebral veins, which empty into dural sinuses that are primarily drained by the internal jugular veins. The extracranial

draining veins of the neck consist of the external jugular vein, the internal jugular vein, and the vertebral vein.

The venous drainage of the brain and meninges can be divided into the diploic veins, the meningeal veins, the dural sinuses, and the cerebral veins. The diploic veins run between the tables of bone of the skull to drain the diploe. These vessels communicate extensively with the extracranial venous system, the meningeal veins, and the dural sinuses. The meningeal veins are epidural vessels that supply drainage for the falx cerebri, the tentorium, and the cranial dura mater. The major dural sinuses include the superior and inferior sagittal sinuses, the cavernous and intracavernous sinuses, the superior and inferior petrosal sinuses, the occipital sinus, and the straight, transverse, and sigmoid sinuses.^[22]

The dural sinuses that are most often affected by thrombosis are the superior sagittal sinus (SSS), the lateral sinuses (LS), and the cavernous sinuses (CS). The SSS originates

Figure 22-7 Major veins of the cerebral venous system. (© 1996 Indiana University Medical Illustration Dept.)

near the crista galli where it communicates with the facial and nasal veins.^[22] It courses posteriorly in the midline along the falx cerebri, and then courses backward toward the occipital protuberance, where it joins the lateral and straight sinuses to form the torcular Herophili. The SSS drains a major portion of the cortex. Due to its connection with the diploic veins that drain the scalp through the emissary veins, the SSS can be affected by infections or contusions of the face and scalp.

The LS course from the torcular Herophili to the jugular bulbs. They have a transverse portion that lies in the attached border of the tentorium and a sigmoid portion that runs on the mastoid process. Due to the latter anatomical configuration, this sinus can be affected by mastoiditis and otitis media. The drainage territory of the LS includes the cerebellum, brain stem, and the posterior portion of the cerebral hemisphere.

The CS are paired venous structures that lie next to the sphenoid bone. There are several important structures that lie within the CS, including cranial nerves (CNs) III, IV, V₁, and V₂ in the lateral wall, and CN VI and the carotid artery with its sympathetic plexus in the central portion of the sinus. The CS drain blood from the orbits and the anterior portion of the base of the brain. They drain via the superior and inferior petrosal sinuses into the internal jugular veins.

The three important groups of veins that drain blood from the brain are the superficial cerebral veins, the deep cerebral veins, and the veins of the posterior fossa. The superficial cerebral veins lie along the cortical sulci. These vessels drain the cerebral cortex and portions of the white matter. The frontal, parietal, and occipital cortical veins drain into the SSS, while the middle cerebral veins drain into the LS. The middle cerebral veins run along the sylvian fissure to drain the opercular region. These veins are unique because they have no muscular layers or valves, which enables them to dilate and reverse the direction of blood flow if a sinus into which they drain is occluded. The deep cerebral veins, including the internal cerebral and basal veins, drain blood from the deep white matter of the cerebral hemispheres and the basal ganglia. These veins join to form the great vein of Galen, which subsequently drains into the straight sinus. The veins of the posterior fossa are divided into three major systems. The superior group drains into the galenic system. The anterior group drains the anterior cerebellum, pons, and medulla. The posterior group drains into the torcular Herophili and adjacent dural sinuses. They supply the cerebellar tonsils and the posteroinferior cerebellar hemispheres.

[PreviousNext](#)

EXAMINATION OF THE NEUROVASCULAR SYSTEM

Directed Neurological Examination

The carotid artery should be palpated gently for the presence and the intensity of the impulse. The artery should be auscultated for a bruit. However, a bruit is not always indicative of carotid artery stenosis. In addition, the absence of a bruit does not rule out carotid stenosis. A vertebral artery bruit can be auscultated over the posterior upper cervical region. The temporal region, the orbits, and the mastoid region are good locations to auscultate cranial bruits, as in the case of arteriovenous malformations or aneurysms. Attention should be paid to the scalp, looking for prominence, or tenderness of the superficial temporal artery that may be seen with temporal arteritis. Bounding pulsation of the superficial temporal or the supraorbital arteries may be seen with internal carotid occlusive disease owing to increased collateral flow through the external carotid artery. Necrosis of the scalp can be seen with temporal arteritis.

Attention should be paid to the ocular globe, looking for scleral injection, dilated ocular and orbital vessels, pulsating exophthalmos, chemosis, or ophthalmoplegia that can be seen with carotid-cavernous fistulas. A dilated funduscopic examination can demonstrate the ocular manifestations of carotid vascular disease, including hypoperfusion or venous stasis retinopathy, anterior ischemic optic neuropathy, retinal infarctions, and rubeosis iridis. There may be evidence of microemboli such as bright orange-yellow, refractile, or Hollenhorst plaques; white platelet-fibrin intra-arterial plugs; or gray-white nonrefractile calcific emboli.

A careful auscultation of the heart should focus on the detection of structural lesions or rhythm disturbances. The aorta and peripheral pulses should be palpated and auscultated to provide clues to underlying peripheral atherosclerosis.

Associated Neurological Findings

Cerebral. Patients with ischemic stroke or intracerebral hemorrhage may have a number of varied cortical deficits ([Table 22-2](#)). Patients should be evaluated for disturbances in attention, emotion, memory, and speech. Examination of higher cortical functions may be difficult acutely, but serial examinations are often helpful to detect the type and extent of cognitive disturbances.

A basic mental status examination should be performed, evaluating orientation, object recall, calculations, reading, writing, and comprehension. Patients should be examined for disturbances in spatial relationships including anosognosia, spatial disorientation, hemispatial neglect, constructional apraxia, and other apraxias that are seen with nondominant hemisphere lesions. Finger agnosia and right-left disorientation are seen with dominant hemispheric lesions. The typical deficits seen with the various stroke syndromes are detailed in [Table 22-2](#) .

Detailed classification of aphasia subtypes is helpful in localizing the area of stroke. There are typical findings with regard to fluency, comprehension, repetition, and naming with lesions in different locations (see [Chapter 6](#)).

Cranial Nerves. Visual acuity should be checked with correction to evaluate for a decrement that can be seen with retinal vascular lesions. A dilated funduscopic examination may show evidence of retinal emboli. Visual fields examination may show a homonymous hemianopia that can be seen with middle cerebral artery, or posterior cerebral artery territory stroke or with posterior cerebral artery occlusion secondary to basilar artery disease. Bilateral homonymous

TABLE 22-2 -- CLINICO-ANATOMICAL CORRELATION OF DISORDERS OF NEUROVASCULAR FUNCTION

	Neurovascular	Cerebral	Cranial Nerves	Motor/Reflexes/ Cerebellar/Gait	Sensory	Autonomic Nervous System
GLOBAL ISCHEMIA						
Diffuse hypoperfusion						
Cerebral	Usually normal	Confusion, somnolence	Lower altitudinal defect; saccade/pursuit defects	Bibrachial weakness	Bibrachial sensory loss	Orthostatic hypotension
Spinal cord	Usually normal	Normal	Normal	Paralysis below lesion	Sensory loss below lesion	bladder/bowel incontinence
Extracranial steal syndrome	Decreased radial pulse in affected arm	Normal	Transient CN dysfunction	Transient uni- or bilateral quadriparesis	Transient sensory loss, body not face	Decreased blood pressure in affected arm
TIA						
Carotid	Carotid bruit, decreased carotid pulse, atherosclerosis	Transient aphasia and dysarthria	Ipsilateral amaurosis fugax, contralateral HH	Transient contralateral weakness or clumsiness	Transient bilateral sensory loss	Cardiac arrhythmia, hypertension
Vertebrobasilar	Vertebral or basilar bruit	Normal	Transient CN findings-diplopia, dysarthria	Transient bilateral weakness or clumsiness	Transient bilateral sensory loss	Cardiac arrhythmia, hypertension
FOCAL STATIC ISCHEMIA						
Carotid System						
Carotid	Carotid pulse diminished or absent	Depressed consciousness, global aphasia	Retinal emboli, contralateral HH, conjugate eye deviation	Weakness contralateral face, arm, leg	Contralateral hemisensory loss face, arm, leg	Cardiac arrhythmia, hypertension
Middle cerebral	Possible bruit mid/upper cervical area	Aphasia (left), apraxia (right)	Contralateral HH	Weakness contralateral face, arm greater than leg	Contralateral hemisensory loss face, arm greater than leg	Cardiac arrhythmia, hypertension
Anterior cerebral	Possible bruit mid/upper cervical area	Emotional lability, aphasia (left), apraxia (right)	Conjugate eye deviation	Weakness contralateral leg more weak than face, arm	Contralateral hemisensory loss, leg more involved than face and arm	Cardiac arrhythmia, hypertension
Anterior choroidal	Possible cervical bruit, atherosclerosis	Affect changes, hemineglect	Contralateral HH	Weakness contralateral face, arm, leg	Contralateral hemisensory loss face, arm, leg	Cardiac arrhythmia, hypertension
Small vessel, lacunar infarction	Possible carotid or vertebral bruit	Dementia, inattention	Normal	Paralysis, if present, usually involves face, arm, leg	Sensory loss, if present, involves face, arm, leg	Cardiac arrhythmia, hypertension
Vertebrobasilar System						
Posterior inferior cerebellar	Possible vertebral bruit	Normal	Ipsilateral weak palate, Horner's syndrome, decreased p/t ipsilateral face	Ipsilateral limb ataxia	Decreased p/t contralateral body	Cardiac arrhythmia, hypertension

Anterior inferior cerebellar	Normal	Normal	Ipsilateral deafness, ipsilateral facial weakness, decreased sensation, ipsilateral face	Ipsilateral limb ataxia	Decreased p/t contralateral body	Cardiac arrhythmia, hypertension
Superior cerebellar	Normal	Normal	Nystagmus, ipsilateral deafness, diplopia (CN IV)	Ipsilateral limb ataxia	Decreased all sensory modalities contralateral body	Cardiac arrhythmia, hypertension
Posterior cerebral	Possible vertebral bruit	Visual agnosia, visual neglect, dyslexia	Contralateral HH, cortical blindness, Balint's syndrome	Usually normal, possible chorea or ballism	Normal unless thalamic pain	Cardiac arrhythmia, hypertension
Medial midbrain basilar	Usually normal	Normal	Internuclear ophthalmoplegia, CN III paresis	Contralateral body weakness, ataxia	Normal	Cardiac arrhythmia, hypertension
Medial pontine basilar	Usually normal	Normal	Intennuclear ophthalmoplegia, CN VI paresis or conjugate eye deviation to side of lesion	Contralateral body weakness, bilateral lesions cause quadriparesis and "locked-in" syndrome	Normal, may have decreased position and vibration contralateral body	Cardiac arrhythmia, hypertension
Medial medullary	Usually normal	Normal	CN XII: dysarthria, may have upbeat nystagmus	Contralateral body weakness, ataxia	Decreased position and vibration contralateral body	Cardiac arrhythmia, hypertension
Transient global amnesia	Normal	Loss of memory for recent events, cannot learn new information	Normal	Normal	Normal	Normal
HEMORRHAGE						
Subarachnoid	Possible cranial bruits	Variable depressed level of consciousness	CN III paresis if internal carotid posterior communicating artery aneurysm, fundus: subhyaloid hemorrhages	Normal, unless intraparenchymal extension or secondary vasospasm	Normal, unless intraparenchymal extension or secondary vasospasm	Hypertension, cardiac arrhythmia
Intracranial hematoma	Possible cranial bruits	Depressed level of consciousness	Depends on location: Brain stem-CN findings prominent; cortical / subcortical -homonymous hemianopia; thalamic-conjugate downward deviation	Hemi- or quadriplegia	Cannot assess well if comatose. If thalamus or parietal lobe affected, hemisensory loss contralateral	Hypertension
Extracranial hematoma	Normal	Normal or depressed level of consciousness	Normal, possible CN VI palsy from increased pressure	Varying degree of hemiparesis	Varying degree of hemisensory loss	Cushing triad if increased intracranial pressure
VASCULAR ANOMALIES						
Intracranial steal	Cranial bruits	May have cognitive deficits	Transient visual deficits	Transient hemiparesis	Transient hemisensory deficits	Normal
Vessel dissection	Diminished carotid, superficial temporal or supraorbital pulses	Normal unless infarction occurs	CN XII lesions, other CN (II, III, V, XI) may be involved, Horner's syndrome	Variable hemiparesis	Variable hemisensory loss	
Vascular fistula	Orbital bruit, ocular pulsation	Normal	Variable visual loss and restriction of eye movements and chemosis	Normal	Normal	Normal
SPINAL CORD ISCHEMIA						
Anterior spinal artery	Aortic pulsation or aortic dissection	Normal	Normal	Flaccid paraplegia or quadriplegia below lesion	Loss of pain and temperature below lesion	Hypotension
Posterior spinal artery	Normal	Normal	Normal	Loss of reflexes below lesion	Loss of position and vibration below lesion	Hypotension_

HH, Homonymous hemianopia; p/t, pain/temperature sensation

hemianopia results in cortical blindness and is most often due to simultaneous or successive posterior cerebral artery occlusions.

Vertical eye movements are impaired with midbrain infarctions. Examination of CN III may disclose an oculomotor paresis that can be seen with the midbrain syndromes, an aneurysm at the junction of the internal carotid and posterior communicating arteries, an aneurysm of the internal carotid artery in the cavernous sinus, or with uncal herniation. Horizontal eye movements are impaired with pontine infarctions. CN IV may be affected with midbrain infarction or hemorrhage. CN VI may be affected by pontine infarction or hemorrhage, carotid aneurysms or carotid-cavernous fistulas within the cavernous sinus, or compressive lesions within the prepontine cistern such as with fusiform basilar artery aneurysms. Pupillary responses may be helpful in localization of the vascular lesion. Pinpoint pupils that are reactive are seen with pontine tegmental lesions. Fascicular or peripheral III nerve lesions seen with compression due to aneurysms and herniation produce an ipsilateral dilated and unresponsive pupil. Lesions in the midbrain tegmentum produce midposition, irregular, and corectopic pupils (noncentered). Lesions in the midbrain tectum produce midposition and unreactive pupils, often with spontaneous hippus.

Horner's syndrome (ptosis, miosis, and anhidrosis) may be seen with disruption of the descending oculosympathetic system in lateral medullary infarctions (Wallenberg's syndrome), or infarctions in the territories of the superior cerebellar or anterior inferior cerebellar arteries, or with mesencephalic hemorrhages. Cervical carotid dissection or occlusion can be associated with a postganglionic Horner syndrome.

An internuclear ophthalmoplegia (INO), characterized by adduction weakness on the side of the medial longitudinal fasciculus lesion and monocular nystagmus of the abducting eye, can be seen with brain stem infarctions. The INO may be unilateral or bilateral.

CN IV may be affected with midbrain infarction or hemorrhage. CN V may be affected with vascular disease of the pons or medulla or in the cavernous sinus. Dysfunction of CN VII can be manifested as a central facial palsy due to supranuclear corticobulbar lesions that cause a contralateral paresis of the lower portion of the face, with relative sparing of upper facial function. This type of involvement is commonly seen with cortical or subcortical cerebral hemorrhage or ischemia. A peripheral type facial nerve palsy with paralysis of the upper and lower facial muscles can be seen with pontine lesions.

Acute hearing loss can occur with AICA infarctions. Vascular lesions of the auditory cortex do not lead to complete deafness, even if the lesions are bilateral. Pure

word deafness can occur with unilateral or bilateral temporal lesions affecting Heschl's gyri. Due to the binaural representation of the ascending auditory tracts above the level of the cochlear nuclei, lesions of the brain stem involving the auditory pathways do not cause deafness.

Dysfunction of CN IX and X with vascular lesions is manifested by dysphagia and an altered gag response. Bilateral supranuclear corticobulbar lesions, as can occur with bilateral infarctions, can result in severe dysphagia as well as other pseudobulbar signs. Lateral medullary infarctions affect CN IX and X function due to involvement of the nucleus ambiguus and cause hoarseness, hiccups, dysphagia, and paralysis of the pharynx, palate, and vocal cords.

Lesions of CN XII can be assessed by observing the tongue at rest and with protrusion. With supranuclear lesions due to infarction or hemorrhage, the tongue will deviate toward the side of the hemiplegia. This nerve can also be affected in its intramedullary course due to infarction or hemorrhage. The medial medullary syndrome can cause paresis of the tongue with the tongue protruding away from the hemiplegia.

Motor/Reflexes/Cerebellar/Gait. The motor deficits with cerebrovascular disease can vary from a mild limb drift to hemiplegia. The different clinical syndromes have different patterns of motor deficits, and the extent of weakness varies (see [Table 22-2](#)). The presence of bilateral or crossed weakness may suggest vertebrobasilar circulation ischemia, particularly in the presence of other signs of vertebrobasilar ischemia. Weakness of the face and arm more than the leg usually indicates MCA ischemia. Involvement of the face, arm, and leg equally can be seen with capsular or pontine ischemia. Prominent weakness of the leg may be seen with ACA ischemia. In spinal cord vascular lesions, there is paralysis below the level of the lesion if the anterior spinal artery is involved.

It is also important to evaluate tone, since hypotonia may be seen with cerebellar lesions and varying degrees of hypertonicity can be seen with cerebral infarcts or hemorrhages or with brain stem compression. Paratonia (Gegenhalten) is present often with frontal infarction or hemorrhage.

Asymmetry of the muscle stretch reflexes or a unilateral extensor toe sign or Hoffman response may be the only indication of corticospinal tract dysfunction. There may be "primitive" reflexes, such as a grasp or snout reflex with extensive frontal lesions.

Ataxia or dystaxia of the limbs, trunk, or gait is seen with cerebellar lesions. The gait may be wide based with impaired tandem gait. Asynergia, dysdiadochokinesia and dysmetria may be present. The presence of truncal ataxia and titubation suggests a lesion in the midline cerebellum.

Sensory. Tactile sensory loss may be seen with many of the stroke syndromes (see [Table 22-2](#)). Patients can be tested for graphesthesia and stereognosis. Lesions of the postcentral gyrus in the parietal lobe can cause contralateral sensory loss with astereognosis, impaired position sense, and impaired tactile sensation greater than to pain, temperature, and vibration. There may be extinction to double simultaneous tactile stimulation. Hemisensory deficits can occur with thalamic infarctions in the territory of the thalamogeniculate arteries that supply the somatosensory nuclei. There are crossed sensory findings with lateral medullary infarctions.

In spinal cord vascular lesions, there is loss of pain and temperature sensation below the level of the infarction if the anterior spinal artery is involved. Loss of position, vibration, and light touch sensation below the level of the lesion is seen with infarction of the posterior spinal artery.

Autonomic Nervous System. Other autonomic testing is usually normal with disturbance of neurovascular function. With the anterior spinal artery syndrome, there is loss

of bowel, bladder, and sexual function due to dysfunction of autonomic pathways.

Orthostatic blood pressure and pulse will provide information on ambient autonomic function and reflex response to gravitational changes. In cases in which vascular abnormalities in the neck are suspected (e.g., subclavian steal syndrome), left versus right blood pressure and pulse comparisons are useful.

EVALUATION GUIDELINES

The goals of the diagnostic evaluation are to establish the diagnosis of ischemic or hemorrhagic cerebrovascular disease as a cause of the patient's symptoms and to determine the underlying cause of the event. Early diagnosis and management in the first few hours after stroke are critical. Since proper management begins with an accurate diagnosis, it is paramount to differentiate between cerebral infarction and hemorrhage. The tests that may assist with diagnosis are detailed in [Table 22-3](#). There are a number of potential etiologies of cerebral infarction and hemorrhage that need to be considered ([Tables 22-3](#) and [22-4](#) and see [Chapter 45](#)).

Neuroimaging. In all patients with suspected ischemic stroke, an unenhanced computed tomogram (CT) of the brain is the first test to differentiate between infarction and hemorrhage. In addition, other disorders that mimic acute cerebrovascular disease must be excluded, including tumors, abscesses, and subdural hematomas. Intravenous contrast-enhanced CT is needed only when these diagnoses are a consideration. Thin CT cuts through the posterior fossa should be done if posterior fossa pathology is suspected. Magnetic resonance imaging (MRI) is superior to CT in cerebral ischemia, particularly in the evaluation of ischemic areas in the posterior fossa.

In patients with suspected intracerebral hemorrhage, CT is the most effective initial test to accurately identify the location, site, direction of extension, and type of an acute intracerebral hemorrhage. The presence and degree of hydrocephalus, ventricular shift or compression, and edema can be assessed. While MRI is not used acutely, it becomes an important diagnostic tool later for identifying whether vascular malformations or tumors are present.

Carotid Doppler ultrasonography is used as a noninvasive means of evaluating for stenosis or occlusion of the common and proximal portions of the internal and external carotid arteries. Transcranial Doppler ultrasound is a technique that allows identification of alteration in direction or velocity of flow in the basal intracranial arteries. This test can be helpful in subarachnoid hemorrhage to evaluate for vasospasm.

Angiography is indicated in patients who are possible candidates for carotid endarterectomy with moderate to severe carotid artery stenosis on noninvasive testing or in patients with suspected vasculitis, arterial dissection, or with suspicion of other intracranial vasculopathies. Cerebral angiography plays an important role in the evaluation of selected patients with intracerebral hemorrhage. Angiography is of importance when there is reason to suspect an aneurysm, arteriovenous malformation (AVM), vasculitis, or moyamoya disease. Angiography is performed in patients who have an atypical location for hypertensive hemorrhage or in the young patient without hypertension.

In patients with spinal cord ischemia, a spinal MRI may show an area of infarction or hemorrhage or a vascular malformation.

Fluid and Tissue Analysis. A basic workup that should be performed in all patients with ischemic stroke includes a complete blood count with differential and platelet count, erythrocyte sedimentation rate, prothrombin time with International Normalized Ratio (INR), partial thromboplastin time, plasma glucose level, blood urea nitrogen, serum creatinine, lipid analysis, luetic serology, and urinalysis (see [Table 22-3](#)).

A basic evaluation that should be performed in all patients with intracerebral hemorrhage includes a complete blood count with differential and platelet count, prothrombin time with partial thromboplastin time, erythrocyte sedimentation rate, plasma glucose, serum alkaline phosphatase, serum glutamic oxalate transaminase, serum calcium, blood urea nitrogen, serum creatinine, and urinalysis. Additional paraclinical evaluation is listed in [Table 22-3](#).

Cerebrospinal Fluid. There is almost no indication for a lumbar puncture in patients suspected of having ischemic stroke or intracerebral hemorrhage. Rarely, patients suspected of having infection as a cause of stroke may need CSF analysis. In patients with intracerebral hemorrhage or a large hemispheric stroke, a lumbar puncture can be dangerous because of sudden intracranial compartmental shifts with resultant herniation. Patients with suspected subarachnoid hemorrhage with a CT scan that does not reveal hemorrhage should undergo a lumbar puncture. There is no need to perform a lumbar puncture if the CT scan shows subarachnoid blood.

Neuropsychological Tests. Depression occurs in 30 to 50 percent of stroke patients within 2 years of the initial event. ^[23] Poststroke depression produces physical, emotional, and cognitive symptomatology and may have a major impact on the recovery of these patients. Approximately 40 to 50 percent will display depressive symptomatology in the first month after stroke. About half of the patients meet criteria for major depression. The other half have minor depressive symptoms. A particularly interesting finding, not corroborated by all investigators, has been that depression is most common with strokes involving the frontal lobe and head of the caudate nucleus, particularly with lesions close to the frontal pole. Depression is more common with lesions affecting the left dorsolateral frontal lobe in comparison with the right frontal pole. One possible explanation for this neuroanatomical correlation is that such lesions may interrupt noradrenergic and serotonergic pathways. Poststroke depression responds to tricyclic antidepressants and selective serotonin reuptake inhibitors. Persuading patients to comply with treatment requires a detailed explanation of the potential unwanted effects of the medications. The selection of the antidepressant is based on the side effect profile of the medication and the clinical characteristics of the patient.

Other neuropsychiatric problems that can occur after stroke include mania, anxiety, bipolar affective disorders, and psychosis. Another problem that can develop is a pseudobulbar affect or emotional incontinence that may be

TABLE 22-3 -- USEFUL STUDIES IN THE EVALUATION OF DISORDERS OF NEUROVASCULAR FUNCTION

Syndrome	Neuroimaging	Electrophysiology	Fluid and Tissue Analysis	Neuropsychological Tests	Other Tests
ISCHEMIA					
Diffuse hypoperfusion					
Cerebral	Uni- or bilateral infarcts in watershed" areas	EEG: diffuse slowing	NA	Depressed LOC	None
Spinal cord	Infarct in thoracic "watershed" areas	SSEP delay	NA	Normal	None
Extracranial steal syndrome	Normal unless infarct occurs	EEG usually normal	NA	NA	None
TIA					
Focal ischemia					
Large vessel		Polymorphic delta waves over region	Lab tests	Variable depending on site	Chest x-ray, ECG, NV tests
Small vessel lacunae	Infarct in involved region Small infarcts subcortex and brain stem	Normal	Lab tests	Variable depending on site	Chest x-ray, ECG, NV tests
HEMORRHAGE					
Subarachnoid	Blood subarachnoid space, MR angiogram may visualize aneurysm	Varying degrees of diffuse slowing	CSF: RBC's/xanthochromia	Depressed LOC dependent on extent of bleeding, hydrocephalus, and vasospasm	Cerebral angiography to show aneurysm
Intracranial hematoma		EEG: polymorphic slow waves over region	Decreased CSF cystatin C (cerebral amyloid angiopathy)	Variable depressed LOC depending on site	Biopsy of hematoma site may reveal tumor cells or cerebral amyloid angiopathy
	Intraparenchymal blood				

Extracranial hematomas	Extradural or subdural defects	EEG: attenuated background over hematoma	NA	Variable degrees of depressed consciousness	Cerebral angiogram, if done shows avascular mass
VASCULAR ANOMALIES					
Intracranial steals	MR/CT: vascular mass	EEG: slow waves in contralateral hemisphere	Normal	Variable cognitive effects depending on site of AVM	AVM on cerebral angiogram
Vessel dissection	Cerebral or brain stem infarct	EEG: polymorphic slow waves over ipsilateral hemisphere	Normal	Aphasia in carotid dissection	Dissection seen on angiogram
Fistula	MR/CT shows dilated vascular structure, esp. cavernous sinus	Normal	NA	Normal	Cerebral or MR angiogram, dilated vascular channels
Spinal cord ischemia	MR: infarction of cord	SSEP: normal (anterior spinal artery) or prolonged (posterior spinal artery)	NA	NA	Spine x-rays, aortic ultrasound, TEE angiography useful in aortic dissection

MR magnetic resonance scan; CT, computed tomography scan; EEG, electroencephalography; LOC, level of consciousness; SSEP, somatosensory evoked potentials; AVM, arteriovenous malformation; NA, not applicable; TEE, transesophageal echocardiography.

Lab tests = standard battery of neurovascular evaluation: includes CBC with differential, platelet count, ESR, PT, PTT, plasma glucose, BUN, creatinine, lipid analysis, luteal serology, urinalysis. More detailed testing for hematological abnormalities are added as indicated.

NV tests = noninvasive vascular diagnostic procedures are carotid and vertebral duplex, 2 D echo, or TEE. These are useful in evaluating a cerebrovascular lesion. Cerebral angiography is invasive and therefore used only in selected instances.

TABLE 22-4 -- SELECTED ETIOLOGIES ASSOCIATED WITH NEUROVASCULAR DISORDERS

Etiological Category	Specific Etiologies	Chapter
STRUCTURAL DISORDERS		
Developmental	Saccular aneurysms Arteriovenous malformations	28
HEREDITARY AND DEGENERATIVE DISORDERS		
Storage diseases: Lipidoses, glycogen disorders and leukodystrophies	Fabry's disease	30
Amino/organic acidopathies, mitochondrial enzyme defects, and other metabolic errors	MELAS Menkes' disease	31
Chromosomal abnormalities and neurocutaneous disorders	Rendu-Osler-Weber Ehlers-Danlos type IV	32
Movement disorders	Sydenham's chorea	34
Inherited muscle, neuromuscular and neuronal disorders	Inherited disease producing accelerated atherosclerosis Inherited nonatherosclerotic vasculopathies	37
ACQUIRED METABOLIC AND NUTRITIONAL DISORDERS		
Endogenous metabolic disorders	Acquired prothrombotic states	38
Exogenous acquired metabolic disorders of the nervous system: toxins and illicit drugs	Heroin, cocaine, phenylelidine, phenylpropanolamine, amphetamines, methanol intoxication	39
Nutritional deficiencies and syndromes associated with alcoholism	Binge alcohol intoxications	40
INFECTIOUS DISORDERS		
Viral infections	Herpes zoster arteritis	41
Nonviral infections	Meningovascular syphilis, meningitis (bacterial, tuberculosis), fungal infections, sarcoidosis	42
HIV and AIDS	Bleeding diatheses, opportunistic infection	44
NEUROVASCULAR DISORDERS		
	Arterial hypertension	45
	Atherosclerotic vasculopathy	
	Embolic	
	Cardiac diseases: valvular heart disease, arrhythmias, intracardiac defects, cyanotic congenital heart disease, atrial myxoma, infective endocarditis	
	Hemoglobinopathies	
	Vascular anomalies (e.g. aneurysms, AVMs)	
	Nonatherosclerotic vasculopathies	
	Cerebral venous thrombosis	
NEOPLASTIC DISORDERS		
Primary neurological tumors	Intracranial hemorrhage into tumor	46
Metastatic neoplasms and paraneoplastic syndromes	Paraproteinemias, intracranial hemorrhage into tumor	47

AUTOIMMUNE AND INFLAMMATORY DISORDERS	Temporal arteritis	50
	Takayasu's arteritis	
	Wegener's granulomatosis	
	Polyarteritis nodosa	
	Behcet's disease	
	Buerger's disease	
TRAUMATIC DISORDERS	Arterial dissection	51
	Extracerebral hemorrhage	
HEADACHE AND FACIAL PAIN	Migraine	53
DRUG-INDUCED AND IATROGENIC NEUROLOGICAL DISORDERS	Oral contraceptives	55
	MAO inhibitors	
	Radiation vasculopathy	
	Anticoagulants	
	Stroke associated with surgery	

due to bilateral infarctions. These patients often respond to nortriptyline. [\[2\]](#)

Other Tests. Other tests that should be performed in all patients with ischemic stroke include chest roentgenography and electrocardiography. Noninvasive tests that should be considered include Doppler imaging, B-mode scanning, duplex scanning, and transcranial Doppler imaging. Cardiac investigations to determine whether emboli have a cardiac source are advised in selected circumstances. Two-dimensional echocardiography in older patients with ischemic stroke should be limited to those with clinical clues of heart disease. Two-dimensional echocardiography should be considered in all patients younger than 45 years with otherwise unexplained ischemic stroke. Transesophageal echocardiography should be used in selected individuals, particularly for the evaluation of mitral and aortic

288

prosthetic valves or vegetations, or whenever there is a need for better visualization of the left atrial appendage or interatrial septum, or when a right-to-left shunt or debris from atherosclerosis of the aortic arch is suspected.

CLINICAL SYNDROMES

There are a number of syndromes that result from ischemia or hemorrhage involving the central nervous system. [Table 22-2](#) details typical clinical features, while [Table 22-3](#) details tests that assist in the diagnosis of the syndromes. Causes of stroke are discussed in [Chapter 45](#).

Diffuse Hypoperfusion Syndromes (Cerebral and Spinal Cord)

As discussed in the section on arterial anatomy, the midthoracic spinal cord is a border zone or watershed area that is susceptible to ischemia due to the unequal blood supply in this region. In situations of systemic hypoperfusion, there can be a spinal cord infarction. Conditions such as an aortic dissection can also cause a global decrease in spinal cord perfusion that results in gray matter infarction with relative sparing of the white matter tracts.

There can be border zone or watershed infarctions in the brain between the major arterial circulations. These conditions may occur with severe hypotension or in association with cardiac surgery. There are several described syndromes.^[24]

If there is ischemia in the border zone territory of the anterior, middle, and posterior cerebral arteries, there may be bilateral parieto-occipital infarcts. There can be a variety of visual defects, including lower altitudinal visual field defects, optic ataxia, cortical blindness, disorders of ocular pursuit, and abnormalities in judging size, distance, and movement. If there is ischemia between the territories of the anterior and middle cerebral arteries bilaterally, a syndrome of bibrachial sensorimotor impairment can occur. Initially, there is weakness of the entire upper limbs, but later the weakness may be confined to the forearms and hands. Saccadic eye movements may be impaired due to involvement of the frontal eye fields. In ischemia to the border zone regions between the middle and posterior cerebral arteries, there can be bilateral parietotemporal infarctions. Patients have cortical blindness initially that may improve. However, there are a number of defects in higher cortical function, including dyslexia, dysgraphia, dyscalculia, and memory defects, that persist.

Extracranial Steal Syndromes from Disease of the Aortic Branches

Occlusive disease in the subclavian arteries or the innominate artery can give rise to extracranial steal syndromes. The most defined syndrome is the subclavian steal syndrome. In this condition, occlusive disease in the proximal subclavian artery can lead to a siphoning of blood away from the brain by a reversal of flow down the vertebral artery on the affected side to the ischemic limb. The pulse and blood pressure are diminished in the affected limb. The symptoms may include headache, vertebrobasilar ischemia, and limb claudication, often precipitated by exercise. A bruit may be heard over the subclavian artery. The limb may become cyanotic if it is held above the level of the heart. It should be noted that a majority of persons with subclavian steal detected by noninvasive techniques have no neurological symptoms.^[25]

Transient Ischemic Attacks (TIAs)

A TIA is a transient episode of focal neurological or retinal dysfunction secondary to impaired blood supply in a vascular territory. Clinical signs typical of TIAs in the carotid and vertebrobasilar territories are outlined in [Table 22-2](#). It should be noted that transient vertigo, diplopia, dysarthria, or dysphagia in isolation is insufficient to establish a diagnosis of vertebrobasilar TIAs. In addition, isolated drop attacks in which the patient falls to the ground, maintains consciousness, and then arises without a deficit are seldom due to vertebrobasilar ischemia. The annual risk of stroke after a TIA is 3 to 4 percent per year. However, the risk of a subsequent stroke is at least three times greater for individuals who have had a TIA than in those individuals who have not had a TIA.^[26]

Amaurosis fugax may be described as a sudden onset of a "fog," "haze," "scum," "curtain," "shade," "blur," "cloud" or "mist." A curtain or shade pattern with the loss of vision moving superiorly to inferiorly is described only by 15 to 20 percent of patients.^{[27], [28]} Less commonly, there can be a concentric visual loss presumed to be due to marginal perfusion causing diminished blood flow to the retina. The visual loss is sudden in onset, often brief in duration, and painless in nature. The length of visual loss is usually 1 to 5 minutes and rarely lasts more than 30 minutes. Positive phenomena such as scintillation, fortification spectra, or flashing lights are rarely indicative of amaurosis fugax. After an episode of amaurosis fugax, the vision is usually fully restored, although some patients may have permanent visual loss due to a retinal infarction (see [Table 22-2](#)).^[28]

In amaurosis fugax, it is key to evaluate for internal carotid artery stenosis with a carotid duplex ultrasound and to exclude temporal arteritis or a cardiac abnormality as a cause.

Carotid System Stroke Syndromes

INTERNAL CAROTID ARTERY OCCLUSION

Occlusion of the ICA can produce symptoms and signs of infarction in either the ACA or MCA territories (or both) as described below. The sole feature that distinguishes the MCA syndrome from a carotid artery syndrome is the presence of amaurosis fugax.^{[29], [30]} Infarctions are often large, involving multiple lobes. Cerebral edema may be a life-threatening concern. The carotid pulse may be absent ipsilaterally. Horner's syndrome may be present due to oculosympathetic involvement along the carotid artery.

MIDDLE CEREBRAL ARTERY SYNDROME

An MCA infarction is one of the most common manifestations of cerebrovascular disease ([Fig. 22-8](#)). The clinical picture with an MCA infarction is varied and depends upon whether the site of the occlusion is in the stem, the superior division, the inferior division, or the lenticulostriate branches and whether there is good collateral blood flow.

When the stem of the MCA is occluded, there is usually a resultant large infarction with contralateral hemiplegia, conjugate eye deviation toward the side of the infarct, hemianesthesia, and homonymous hemianopia. There is associated global aphasia if the dominant hemisphere is involved and hemineglect with nondominant hemispheric lesions. The difference between an upper division MCA infarction and a MCA stem lesion is that the hemiparesis usually affects the face and arm more than the leg with upper division infarction. A Broca aphasia is more common in upper division infarcts due to preferential involvement of the anterior branches of the upper division in occlusions. With lower division MCA syndromes, a Wernicke type aphasia is seen with dominant hemisphere infarction and behavioral disturbances are seen with nondominant infarction. A homonymous hemianopia may be present. A lenticulostriate branch occlusion may cause a lacunar infarction with involvement of the internal capsule producing a syndrome of pure motor hemiparesis. These described syndromes are variable and are dependent on the presence of collaterals and whether edema is present.^{[31], [32], [33]}

Figure 22-8 CT of a large acute right middle cerebral artery territory infarct (Courtesy of Karen S. Caldemeyer, M.D.)

Alexia with agraphia may occur with left angular gyrus involvement. Gerstmann's syndrome, which consists of finger agnosia, acalculia, right-left disorientation, and agraphia, may be seen with dominant hemisphere parietal lesions. The perisylvian aphasias seen with dominant hemispheric infarctions may be of the Broca, Wernicke, conduction, or global type, depending on the site and extent of involvement. Anosognosia most commonly is associated with right hemispheric strokes. Nondominant infarction may cause inattention, neglect, denial, apraxia, impaired prosody, and rarely acute confusion and agitated delirium.^[34] A contralateral homonymous hemianopia or contralateral inferior quadrantanopia can occur with infarctions in either hemisphere.

ANTERIOR CEREBRAL ARTERY SYNDROME

ACA territory infarctions are uncommon. They can be seen in patients with vasospasm after subarachnoid hemorrhage due to ACA or ACoA aneurysms. Excluding these causes, the percentage of acute cerebral infarcts that are in the ACA territory is less than 3 percent.^{[35], [36], [37]} The characteristics of ACA infarction vary

according to the site of involvement and the extent of collateral blood flow.^[39] Contralateral weakness involving primarily the lower extremity and, to a lesser extent, the arm is characteristic of infarction in the territory of the hemispheric branches of the ACA (see [Table 22-2](#)). Other characteristics include abulia, akinetic mutism (with bilateral mesiofrontal damage), impaired memory or emotional disturbances, transcortical motor aphasia (with dominant hemispheric lesions), deviation of the head and eyes toward the lesion, paratonia (gegenhalten), discriminative and proprioceptive sensory loss (primarily in the lower extremity), and sphincter incontinence (see [Table 22-2](#)).

An anterior disconnection syndrome with left arm apraxia due to involvement of the anterior corpus callosum can be seen. Pericallosal branch involvement can cause apraxia, agraphia, and tactile anomia of the left hand. Infarction of the basal branches of the ACA can cause memory disorders, anxiety, and agitation.

Infarction in the territory of the medial lenticulostriate artery (artery of Huebner) causes more pronounced weakness of the face and arm without sensory loss due to this artery's supply of portions of the anterior limb of the internal capsule.

ANTERIOR CHOROIDAL ARTERY SYNDROME

The AChA syndrome is often characterized by hemiparesis as a result of involvement of the posterior limb of the internal capsule, hemisensory loss due to involvement of the posterolateral nucleus of the thalamus or thalamocortical fibers, and hemianopia secondary to involvement of the lateral geniculate body or the geniculocalcarine tract^[39],^[40] (see [Table 22-2](#)). The visual field defect that is seen with AChA infarcts is characterized by a homonymous defect in the superior and inferior visual fields that spares the horizontal meridian.^[41] In a small number of patients, there may be left spacial hemineglect with right hemispheric

infarctions and a mild language disorder with left hemispheric infarctions.^[40],^[42] With bilateral infarctions in the AChA territory, there can be pseudobulbar mutism and a variety of other features including facial diplegia, hemiparesis, hemisensory loss, lethargy, neglect, and affect changes.^[43]

Lacunar Stroke Syndromes

While there are over twenty described lacunar syndromes, the four that have been best described will be addressed here. These syndromes have been described with ischemic lacunar infarctions as well as with discrete hemorrhages.^[44]

Pure motor hemiparesis is characterized by a unilateral motor deficit involving the face, the arm, and, to a lesser extent, the leg. There may be a mild dysarthria. There is no associated aphasia, apraxia, or agnosia. In addition, there is no sensory, visual, or higher cortical dysfunction. This syndrome may be secondary to a lacunar infarction in the posterior limb of the internal capsule, corona radiata, basis pontis, cerebral peduncle, or the medullary pyramid.^[45] However, an ischemic cortical lesion may also cause a pure motor hemiparesis.^[44]

Pure sensory stroke (pure hemisensory or paresthetic stroke) is characterized by unilateral numbness, paresthesias, and a hemisensory deficit involving the face, arm, trunk, and leg. Subjective complaints may be out of proportion to objective findings. Lacunae in the ventroposterolateral nucleus of the thalamus may cause this syndrome. However, pure sensory stroke can also be due to ischemic infarctions in the corona radiata or in the parietal cortex.^[44]

Ataxic hemiparesis (homolateral ataxia and crural paresis) is characterized by weakness that is more prominent in the lower extremity in association with ipsilateral arm and leg incoordination. Involvement of the face is uncommon. Dysarthria is usually not present. There may be an extensor plantar response. Lacunae in the posterior limb of the internal capsule, basis pontis, red nucleus, or in the thalamocapsular region can cause this syndrome.^[44],^[46]

The dysarthria-clumsy hand syndrome is characterized by supranuclear facial weakness, tongue deviation, dysphagia, dysarthria, impaired fine motor control of the hand, and an extensor plantar response. There is no sensory deficit. Lacunae in the basis pontis, at the junction of the upper one third and lower two thirds of the pons, or in the genu of the internal capsule may cause this syndrome.^[44]

Vertebrobasilar Stroke Syndromes

The circumferential vessels perfuse the lateral brain stem, and the perforant vessels directly from the large basilar or vertebral arteries perfuse the midline structures. While obstruction of the circumferential arteries gives rise to standard syndromes, there is great variability in the perforant vessels, and therefore several syndromes are described. As a rule, midline syndromes affect the pyramidal system, consciousness, and midline cranial nerves (extraocular muscles), whereas lateral syndromes affect the cerebellum, sensation, and the lateral cranial nerves. There are additional overlap syndromes when vessels perfuse areas in between.

POSTERIOR INFERIOR CEREBELLAR ARTERY SYNDROME

The areas of the cerebellum supplied by the PICA are variable. There are several different patterns of PICA territory cerebellar infarctions. Typical clinical findings are detailed in [Table 22-2](#). If the medial branch territory is affected, involving the vermis and vestibulocerebellum, the clinical findings include prominent vertigo, ataxia, and nystagmus. If the lateral cerebellar hemisphere is involved, patients can have vertigo, gait ataxia and limb dysmetria and ataxia, nausea, vomiting, conjugate or dysconjugate gaze palsies, miosis, and dysarthria. If the infarction is large, there may be altered consciousness or confusion. Hydrocephalus or herniation may develop. There is also a syndrome of combined dorsolateral medullary and cerebellar infarction that may be due to a vertebral artery occlusion or a medial PICA occlusion.^[47] While a PICA occlusion can be the cause of a Wallenberg (lateral medullary) syndrome, this syndrome is more often due to a vertebral artery occlusion ([Fig. 22-9](#)).^[48]

ANTERIOR INFERIOR CEREBELLAR ARTERY SYNDROME

The AICA syndrome causes a ventral cerebellar infarction that has a characteristic clinical picture^[49],^[50] (see [Table 22-2](#)). The signs and symptoms that are seen include vertigo, nausea, vomiting, and nystagmus due to involvement of the vestibular nuclei. There may be ipsilateral facial hypalgesia and thermoanesthesia and corneal hypesthesia due to involvement of the trigeminal spinal nucleus and tract. There is ipsilateral deafness and facial paralysis due to involvement of the lateral pontomedullary tegmentum. Ipsilateral Horner's syndrome is present due to compromise of the descending oculosympathetic fibers. There is contralateral trunk and extremity hypalgesia and thermoanesthesia due to involvement of the lateral spinothalamic tract. Finally, there is ipsilateral ataxia and asynergia due to involvement of the cerebellar peduncle and cerebellum.

SUPERIOR CEREBELLAR ARTERY SYNDROME

Infarction in the territory of the SCA produces a dorsal cerebellar syndrome that may also involve the lateral superior pons^[51] (see [Table 22-2](#)). Vertigo may be present, although it is less common with SCA infarcts than with the other cerebellar syndromes. Nystagmus is present due to involvement of the medial longitudinal fasciculus and the cerebellar pathways. Ipsilateral Horner's syndrome is seen due to involvement of the descending sympathetic tract. Ipsilateral ataxia and asynergia and gait ataxia are noted due to involvement of the superior cerebellar peduncle, brachium pontis, the superior cerebellar hemisphere, and the dentate nucleus. There is an intention tremor due to involvement of the dentate nucleus and superior cerebellar

Figure 22-9 Forty-seven-year-old man involved in motor vehicle accident presenting with lateral medullary syndrome due to a vertebral artery dissection. A, T2-weighted image shows hyperintensity in the right posterior lateral medulla (arrow). B, Axial T1-weighted image shows lack of flow void in the right vertebral artery (straight arrow). Notice the normal flow void in the left vertebral artery (curved arrow). C, Time of flight magnetic resonance arteriogram shows no flow in the right vertebral artery (Courtesy of Karen S. Caldemeyer, M.D.)

peduncle. Choreiform dyskinesias may be present ipsilaterally. Contralaterally, there is hearing loss due to lateral lemniscus disruption and trunk and extremity hypalgesia and thermoanesthesia due to spinothalamic tract involvement. A contralateral fourth nerve palsy may be present due to involvement of the midbrain tectum. The diagnostic findings are detailed in [Table 22-3](#).

MIDLINE BASILAR ARTERY SYNDROMES: MIDBRAIN

It should be emphasized that there is great variability in the arterial blood supply to the brain stem. The syndromes that are described may be oversimplified, and several variations are possible.

Weber's Syndrome. Weber's syndrome (ventral cranial nerve III fascicular syndrome) is due to infarction in the distribution of the penetrating branches of the PCA affecting the cerebral peduncle, especially medially with damage to the fascicle of CN III and the pyramidal fibers. The resultant clinical findings are contralateral hemiplegia of the face, arm, and leg due to corticospinal and corticobulbar tract involvement and ipsilateral oculomotor paresis, including a dilated pupil. A slight variation of this syndrome is the midbrain syndrome of Foville, in which the supranuclear fibers for horizontal gaze are interrupted in the medial peduncle, causing a conjugate gaze palsy to the opposite side.

Benedikt's Syndrome. Benedikt's syndrome is caused by a lesion affecting the mesencephalic tegmentum in its ventral portion, with involvement of the red nucleus, brachium conjunctivum, and the fascicle of cranial nerve III. This syndrome is due to infarction in the distribution of the penetrating branches of the PCA to the midbrain. The clinical manifestations are ipsilateral oculomotor paresis, usually with pupillary dilation and contralateral involuntary movements, including intention tremor, hemiathetosis, and hemichorea.

Claude's Syndrome. Claude's syndrome is caused by lesions that are more dorsally placed in the midbrain tegmentum than with Benedikt syndrome. There is injury to the dorsal red nucleus that results in more prominent cerebellar signs without the involuntary movements. There is oculomotor paresis.

Nothnagel's Syndrome. Nothnagel's syndrome is characterized by an ipsilateral oculomotor palsy with contralateral cerebellar ataxia. Infarctions in the distribution of the penetrating branches of the PCA to the midbrain are the cause of this syndrome.

Parinaud's Syndrome. Parinaud's (dorsal rostral midbrain) syndrome can result from infarctions in the midbrain territory of the PCA penetrating branches. This syndrome is characterized by supranuclear paralysis of eye elevation, defective convergence, convergence-retraction nystagmus, light-near dissociation, lid retraction (Collier's sign), and skew deviation.

Top of the Basilar Syndrome. Top of the basilar syndrome is due to infarction of the midbrain, thalamus, and portions of the temporal and occipital lobes. ^[52], ^[53] It is due to occlusive vascular disease, often embolic in nature, of the rostral basilar artery. The signs that may be present include the following:

1. Behavioral abnormalities, including somnolence, peduncular hallucinosis (see [Chapter 8](#)), memory disturbances, and agitated delirium.
2. Ocular findings include unilateral or bilateral paralysis of upward or downward gaze, disordered convergence, pseudoabducens palsy, convergence-retraction nystagmus, abnormalities of abduction, Collier's sign (elevation and retraction of the upper eyelids), skew deviation, and oscillatory eye movements. Visual defects that may be present include hemianopia, cortical blindness, and Balint's syndrome (see [Chapter 8](#)).
3. Pupillary abnormalities that may be seen include small and reactive pupils, large or midposition and fixed pupils, corectopia, and occasionally oval pupils.
4. Motor and sensory deficits.

MIDLINE VERTEBROBASILAR SYNDROMES: PONS

While there are many named pontine syndromes, the most beneficial categorization is based on neuroanatomical divisions.

Locked-in Syndrome. Locked-in syndrome (de-efferented state) is the result of bilateral ventral pontine lesions that produce quadriplegia, aphonia, and impairment of the horizontal eye movements in some patients. Wakefulness is maintained due to sparing of the reticular formation. Patients can move their eyes vertically and can blink because the supranuclear ocular motor pathways lie more dorsally (see [Chapter 1](#)). In some patients, there is a "herald" hemiparesis that makes the lesion appear to be cortical in nature. However, within a few hours, there is progression to bilateral hemiplegia and CN findings associated with the locked-in syndrome. ^[54]

Medial Inferior Pontine Syndrome. This syndrome is due to occlusion of a paramedian branch of the basilar artery. There is ipsilateral paralysis of conjugate gaze to the side of the lesion, abducens palsy, nystagmus, and ataxia. Contralateral to the lesion, there is hemibody impairment of tactile and proprioceptive sensation and paralysis of the face, arm, and leg.

Medial Midpontine Syndrome. Medial midpontine syndrome is due to ischemia of the medial midpontine region from occlusion of the paramedian branch of the midbasilar artery. It can lead to ipsilateral limb ataxia. Contralateral to the lesion, there is eye deviation and paralysis of the face, arm, and leg. While there are predominant motor symptoms, there can be variable impaired touch and proprioception.

LATERAL AND COMBINED VERTEBROBASILAR SYNDROMES

Lateral Midpontine Syndrome. Occlusion of the paramedian branch of the midbasilar artery can lead to ipsilateral impaired sensory and motor function of the trigeminal nerve with limb ataxia.

Total Unilateral Inferior Pontine Syndrome. An occlusion of AICA can lead in some circumstances to a combination of the symptoms and signs seen with the lateral and medial pontine syndromes.

Lateral Pontomedullary Syndrome. This syndrome can be seen with occlusion of the vertebral artery. The manifestations seen are a combination of the medial and lateral inferior pontine syndromes.

Lateral Medullary Syndrome (Wallenberg's Syndrome). The lateral medullary syndrome is most often due to occlusion of the vertebral artery. Less commonly, it is due to occlusion of the PICA. This syndrome produces an ipsilateral Horner syndrome; loss of pain and temperature sensation of the face; weakness of the palate, pharynx, and vocal cords; and cerebellar ataxia. Contralateral to the lesion, there is hemibody loss of pain and temperature sensation.

Total Unilateral Medullary Syndrome. Occlusion of the vertebral artery can lead to a combination of medial and lateral medullary syndromes.

MIDLINE VERTEBROBASILAR SYNDROME: MEDULLA

Medial Medullary Syndrome. This syndrome is less common than the lateral medullary syndrome. It may be due to occlusion of the vertebral artery, a branch of the vertebral artery, or the lower basilar artery. The findings with this syndrome include an ipsilateral lower motor neuron paralysis of the tongue and contralateral paralysis of the arm and leg. In addition, there is contralateral hemibody loss of tactile, vibratory, and position sense.

POSTERIOR CEREBRAL ARTERY SYNDROME

The signs and symptoms seen with posterior cerebral artery (PCA) territory infarctions are variable, depending on the site of the occlusion and the availability of collateral blood flow. Unilateral infarctions in the distribution of the hemispherical branches of the PCA may produce a contralateral homonymous hemianopia. This is due to infarction of the striate cortex, the optic radiations, or the lateral geniculate body. There is partial or complete macular sparing if the infarction does not reach the occipital pole. The visual field defect may be limited to a quadrantanopia. A superior quadrantanopia is caused by infarction of the striate cortex inferior to the calcarine fissure or the inferior optic radiations in the temporo-occipital lobes. An inferior quadrantanopia is the result of an infarction of the striate cortex superior to

the calcarine fissure or the superior optic radiations in the parieto-occipital lobes (see [Chapter 8](#)).

There may be more complex visual changes, including formed or unformed visual hallucinations ("release hallucinations"), visual and color agnosias, and prosopagnosia (agnosia for familiar faces).^[56] Finally, there can be some alteration of sensation with PCA hemispherical infarctions, including paresthesias and altered position, pain, and temperature sensations.

Infarction in the distribution of the callosal branches of the PCA involving the left occipital region and the splenium of the corpus callosum produces alexia without agraphia.^[56] In this syndrome, patients can write, speak, and spell normally. However, they are unable to read words and sentences. Naming of letters and numbers may be intact. However, there can be inability to name colors, objects, and photographs.^[57] Right hemispheric PCA territory infarctions may cause contralateral visual field neglect. Amnesia may be present with PCA infarctions that involve the left medial temporal lobe or when there are bilateral mesiotemporal infarctions. In addition, an agitated delirium may occur with bilateral penetrating mesiotemporal infarctions. Large infarctions of the left posterior temporal artery territory may produce an anomia or transcortical sensory aphasia (see [Chapter 6](#)).^[58]

Infarctions in the distribution of the penetrating branches of the PCA to the thalamus can cause aphasia if the left pulvinar is involved, akinetic mutism, global amnesia, and/or Dejerine-Roussy syndrome. In the latter syndrome, the patient has contralateral sensory loss to all modalities, severe dysesthesias on the involved side (thalamic pain), vasomotor disturbances, transient contralateral hemiparesis, and choreoathetoid or ballistic movements. There are also a number of syndromes that can result from infarctions in the distribution of the penetrating branches of the PCA to the midbrain that were previously discussed with the midbrain syndromes. Bilateral infarctions in the distribution of the hemispheric branches of the PCAs may cause bilateral homonymous hemianopia. With bilateral occipital or occipitoparietal infarctions, one can have cortical blindness, often with denial or unawareness of blindness (Anton's syndrome). Another syndrome--Balint's syndrome--may be seen with bilateral occipital or parieto-occipital infarctions. The characteristics of this syndrome include optic ataxia, psychic paralysis of fixation with inability to look to the peripheral field, and disturbance of visual attention.

TRANSIENT GLOBAL AMNESIA SYNDROME

Transient global amnesia (TGA) is an episode of total amnesia that lasts little more than 24 hours. Patients classically ask many questions repeatedly. During the episode, there are no visual, motor, sensory, or brain stem abnormalities. After the episode, the individual has no recall for the events during the period of TGA, but there are no other cognitive residuals. The mechanism of TGA is not known. Theories advanced suggest either medial temporal lobe seizure activity or a vascular phenomenon, such as posterior cerebral artery territory ischemia involving the medial temporal lobes bilaterally. There seems to be an association with strenuous exertion, sexual intercourse, and emotional stress.^[59]

Spinal Cord Stroke Syndromes

ANTERIOR SPINAL ARTERY SYNDROME

The anterior spinal artery syndrome is characterized by an abrupt onset of flaccid paraplegia or tetraplegia below the level of the lesion due to bilateral corticospinal tract damage. There is thermoanesthesia and analgesia below the level of the lesion due to compromise of the spinothalamic tracts bilaterally. Position, vibration, and light touch are spared due to preservation of the dorsal columns, which

are supplied by the posterior spinal arteries. Bowel and bladder function is impaired. There may be associated radicular or "girdle" pain.

These infarctions most commonly occur in the "watershed" areas or boundary zones where the distal branches of the major arterial systems of the cord anastomose, between the T1 and T4 segments and at the L1 segment. Common etiologies of arterial spinal cord infarction are detailed in [Table 22-3](#).

POSTERIOR SPINAL ARTERY SYNDROME

The posterior spinal artery syndrome is uncommon, probably due to the presence of numerous posterior radicular arteries and the reversal of flow that is possible at the conus medullaris if there is compromise of the artery of Adamkiewicz. The characteristics of this syndrome are loss of proprioception and vibration sense below the level of the lesion and loss of segmental reflexes. The common etiologies are listed in [Table 22-3](#).

Subarachnoid Hemorrhage Syndrome

Aneurysmal subarachnoid hemorrhage (SAH) syndrome accounts for 6 to 8 percent of all strokes, affecting approximately 28,000 individuals each year in the United States. The most common cause of spontaneous SAH is a ruptured intracranial saccular aneurysm ([Fig. 22-10](#)). In addition, SAH may be due to many other causes that are outlined in [Tables 22-3](#) and [22-4](#).

The clinical presentation of SAH is usually an abrupt onset of a severe headache, photophobia, nausea, vomiting, meningismus, and, often, unconsciousness and other neurological deficits (see [Table 22-2](#)). In some instances, a premonitory headache, representing a sentinel bleed, may occur days to weeks before the presenting hemorrhage. Misdiagnosis of SAH occurs in up to 25 percent of cases.^[60] A ruptured aneurysm should be suspected in patients complaining of "sudden onset of the worst headache of my life," later onset of migraine headache with no family history of migraine, a change in the headache pattern in a known migraineur, severe localized and persistent headache, and severe "vascular" headaches that are refractory to conventional therapy.

Neurological signs are detailed in [Table 22-2](#). Meningismus with nuchal rigidity and Kernig's sign is present in two thirds of patients. A dilated ophthalmologic examination may show papilledema or hemorrhages (see [Table 22-2](#)). Ptosis or diplopia due to oculomotor nerve palsy can be seen with internal carotid-posterior communicating artery aneurysms, distal basilar aneurysm, or uncal herniation. Other neurological findings depend on the location of the aneurysm.

Clinical deterioration after SAH may be due to multiple causes, including seizures, electrolyte disturbances such as hyponatremia, cerebral vasospasm, rebleeding, hydrocephalus, and development of medical complications such as pneumonia, hypotension, electrolyte abnormalities, and cardiac arrhythmias. Diagnosis and treatment of these disorders are detailed in Part 3.

Syndromes of Extracranial Hematomas

SUBDURAL HEMATOMA

Subdural hematomas can be acute, subacute, or chronic. Acute subdural hematomas occur within 24 to 48 hours

Figure 22-10 A. Nonenhanced axial CT shows subarachnoid hemorrhage in the left sylvian fissure and adjacent intraparenchymal hemorrhage in the temporal lobe. **B.** AP left common carotid arteriogram shows a lobulated left middle cerebral artery trifurcation aneurysm. (Courtesy of Karen S. Caldemeyer, M.D.)

after an injury. They can be secondary to arterial or venous bleeding into the subdural space. The usual cause is a blow to the head by falling or being struck. The neurological symptoms depend on the area of the brain involved. There can be rapidly evolving focal signs that produce aphasia, memory disturbances, hemiparesis and hemisensory deficits, and altered consciousness. Signs of increased intracranial pressure may be present. Diagnosis is made by CT scan. Chronic subdural hematomas present at weeks to months after the injury. Patients presenting with this type of hematoma include the elderly with cerebral atrophy, patients with epilepsy, patients with alcohol dependence, and persons with coagulation defects. These hematomas may become quite large without producing symptoms. The

neurological findings may vary from no or minimal deficit, to focal neurological symptoms that may be transient or progressive. In some, there may be florid symptoms of increased intracranial pressure with headaches, nausea, vomiting, and papilledema. There may be accompanying seizures. Diagnosis of a chronic subdural hematoma may require a CT scan without and with contrast due to the possibility of isodensity of the hematoma with the surrounding brain at some point in its evolution (see [Chapter 23](#)).

EPIDURAL HEMATOMA

The most important type of epidural hematoma to be acquainted with is the acute epidural hematoma usually due to arterial bleeding from damage to the middle meningeal artery. Patients with this condition may have a history of trauma with a lucid interval followed by rapid development of focal neurological signs and deterioration in consciousness. The deterioration is due to high-pressure arterial bleeding with increased intracranial pressure. Like subdural hematomas, epidural hematomas can present subacutely or chronically, with the same time frame and similar symptoms. A CT scan classically shows a lens-shaped density that does not follow sulcal margins. Skull roentgenograms may show an associated skull fracture. Prompt diagnosis is important because a craniotomy with evacuation of the clot is often needed.

Intracranial Steal Syndromes

In some patients with arteriovenous malformations (AVMs) that are large and are fed by both deep and superficial vessels, there has been some anecdotal clinical support for intracerebral steal. The theory is that the presence of low-resistance shunt vessels compromises blood and nutrient flow to adjacent areas of the brain supplied by the same blood vessels, causing transient or permanent damage to neurons.^[61] The clinical reports, although limited in number, report that these patients with AVMs have a variety of focal neurological deficits, cognitive deficits, visual deficits, and seizures that recover after the AVM is excised. In most patients, the neurological deficits are confined to the area of the brain supplied by the AVM. However, there have been reports of EEG abnormalities in the hemisphere contralateral to the AVM and lower cerebral blood flow in the contralateral hemisphere that may support relative areas of ischemia.^[62] More documentation of this syndrome in large numbers of patients is needed.

Vascular Dissection Syndromes

Dissections of arteries develop when there is blood extravasated within the medial or subintimal layers of the arterial wall with resultant compromise of the arterial lumen and development of a pseudoaneurysm. Vascular dissections can be associated with blunt trauma, penetrating trauma, or even trivial trauma. There are a number of associated conditions, including fibromuscular dysplasia, Marfan's syndrome, Ehlers-Danlos type IV syndrome, atherosclerosis, pronounced vessel tortuosity, moyamoya, cystic medial degeneration, pharyngeal infections, alpha₁-antitrypsin deficiency, and luetic arteritis. However, dissections may occur spontaneously. Cervicocephalic arterial dissections may present with ischemic stroke due to arterial occlusion or secondary embolization. The vessel that is most commonly involved is the extracranial carotid artery between C2 and the base of the skull. The vertebrobasilar system, intracranial carotid, and middle cerebral arteries are less frequently involved.^[63] The patients may present with symptoms of transient retinal ischemia, hemispheric or posterior fossa ischemia, cerebral infarction, or subarachnoid hemorrhage. Pain along the forehead, eye, face, or neck may be present with carotid dissections. Vertebral dissections can cause pain in the occiput and neck. Other associated symptoms may include a Horner syndrome, audible bruits, and pulsatile tinnitus. Other cranial nerves that may be involved include II, III, V, VII, VIII, IX, X, XI, and XII.^[64] Diagnosis requires a high level of clinical suspicion that is confirmed with typical arteriographic signs (see [Chapter 45](#) and [Chapter 50](#)).

Carotid-Cavernous Fistula

A carotid-cavernous fistula is an abnormal communication between the carotid artery and the veins of the cavernous sinus, creating a high-pressure, high-flow system. There is often a history of trauma. Patients may present with an audible bruit and progressive pulsatile proptosis with chemosis, restricted eye movement, and progressive visual loss in late stages (see [Table 22-2](#)). The diagnosis is made by cerebral angiography, but a CT scan with contrast, MRI, or magnetic resonance angiography (MRA) may show the lesion (see [Table 22-3](#) and [Chapter 23](#)).

Cerebral Venous Thrombosis

Intracranial venous occlusive disease is significantly less common than arterial disease. The symptoms can be nonspecific. The symptoms that are present depend upon the venous structure that is affected, the extent and rapidity of thrombosis, and the extent of venous collaterals. Common symptoms include headache, nausea, vomiting, altered consciousness, and seizures. Examination may show papilledema,

meningismus, and subtle focal neurological deficits (see [Table 22-2](#)). Possible findings on CT and MRI are presented in [Table 22-3](#) . Diagnosis may be made with magnetic resonance venography (MRV) or conventional or digital intravenous angiography.

Syndromes of Intracerebral Hemorrhage

There are general features of the clinical syndrome of intracerebral hemorrhage that may help to characterize it. Historical features include a presentation that is maximum at the onset in one third of patients and gradual with smooth progression over 30 minutes in two thirds of patients. Interestingly, most hemorrhages occur during activity rather than during sleep.^[65], ^[66]

A headache is present in approximately one half of patients. Nausea and vomiting are present in over 50 percent of patients. The level of consciousness may be variable. Seizures rarely occur at the onset. There is usually no history of any prodromal attacks. There is often a history of arterial hypertension. On examination, meningeal irritation can be seen if the bleeding extends to the subarachnoid space. Retinal hemorrhages may be present on fundoscopic examination (see [Table 22-2](#)). There are a number of potential etiologies of intracerebral hemorrhage (see [Table 22-3](#)).

The various forms of intracerebral hemorrhage have distinctive clinical presentations that are dependent on the location, size, direction of spread, and the rate of development of the bleeding^[65] (see [Table 22-2](#)). The results of testing are detailed in [Table 22-3](#) .

PUTAMINAL HEMORRHAGE

A putaminal hemorrhage is the most common form of intracranial hemorrhage because the putamen is the most common site involved with hypertensive intracranial hemorrhage. Hemorrhages in this location may be confined to the putamen, or they may enlarge to involve the internal capsule, corona radiata, centrum semiovale, temporal lobe, or intraventricular system. The classic presentation with putaminal hemorrhages that are large involves rapidly progressing contralateral hemiparesis or hemiplegia with less severe contralateral hemisensory loss.^[67] Rarely, with a small hematoma, there can be a pure motor hemiparesis.^[68] There is a conjugate horizontal gaze palsy, with the eyes conjugately deviated toward the side of the hematoma. Homonymous hemianopia is present. A dominant hemisphere putaminal hemorrhage produces associated global aphasia, while a nondominant lesion results in hemi-inattention with apractagnosia, left visual neglect, and constructional apraxia.^[69] Occasionally, patients with a nondominant putaminal hemorrhage have allesthesia, in which a noxious stimulus on the side of the hemisensory disturbance is perceived on the opposite normal side in the corresponding area.^[70] Pupillary size is normal unless there is associated uncal herniation.

LOBAR HEMORRHAGE

This type of hemorrhage refers to bleeding occurring within the subcortical white matter. Underlying structural lesions are more common than arterial hypertension as a cause. The clinical presentation can resemble that of a thromboembolic cerebral infarction. There are characteristic findings with hemorrhages in different locations.^[71] With frontal lobe hemorrhages, characteristic findings are abulia, contralateral hemiparesis, and a conjugate gaze palsy toward the side of the hemorrhage. Parietal lobe hemorrhages may cause contralateral hemisensory loss, neglect of the contralateral visual field, mild hemiparesis, and occasionally a hemianopia or anosognosia. A temporal lobe hemorrhage may present with variable degrees of visual field deficit, or occasionally agitated delirium. With dominant temporal lobe hemorrhages, there can be a Wernicke aphasia. If there is an extension into the dominant parietal lobe, there can be conduction or global aphasia. A

hemorrhage in the occipital lobe may cause a contralateral homonymous hemianopia and ipsilateral orbital pain. ^[71], ^[72]

THALAMIC HEMORRHAGE

The usual cause of thalamic hemorrhages is hypertension. However, an underlying structural lesion such as a vascular malformation or tumor is another consideration. Thalamic hemorrhages may be confined to the thalamus or may extend laterally to involve the internal capsule, inferomedially to compress the subthalamus and midbrain, or medially to involve the third ventricle. Classic signs of a thalamic hemorrhage include a hemisensory deficit with a lesser degree of hemiparesis. Ocular findings may include convergence-retraction nystagmus, impairment of vertical gaze, pupillary light-near dissociation, downward-inward deviation of the eyes (depression-convergence syndrome), unilateral or bilateral pseudo-sixth nerve paresis, skew deviation and conjugate gaze palsy to the side of the lesion ("wrong-way eyes"), and a conjugate horizontal gaze palsy. If the hemorrhage is located in the posterior thalamus, there can be distinctive features. ^[73]

PONTINE HEMORRHAGE

The signs and symptoms of pontine hematomas depend on size, location, and presence or absence of ventricular involvement or hydrocephalus. Primary pontine hematomas usually are symmetrically placed at the junction of the basis pontis and tegmentum. Large pontine hematomas cause coma, decerebrate rigidity, quadriparesis, centrally positioned eyes with absent oculocephalic and oculovestibular reflexes, and pinpoint reactive pupils. Ocular bobbing, characterized by rapid conjugate downward movements of the eyes followed by a slow upward drive to primary position, may be present. Hyperthermia and respiratory abnormalities may be present. Partial damage to the lateral basis pontis may cause pure motor hemiparesis. Lateral pontine tegmentum hemorrhage may cause ipsilateral conjugate gaze paresis, ipsilateral internuclear ophthalmoplegia, the "one-and-a-half" syndrome, and ocular bobbing (see [Chapter 9](#)). Lateral tegmental hemorrhages may cause ipsilateral hemiataxia with contralateral hemiparesis and hemisensory deficits.

287

CEREBELLAR HEMORRHAGE

The signs present with cerebellar hematomas depend on their location and size and whether there is associated brain stem compression or hydrocephalus. The most common location for a cerebellar hemorrhage is in the region of the dentate nucleus. The vermis is less frequently involved. The most frequently observed findings are truncal or limb ataxia, ipsilateral gaze palsy, and small reactive pupils. Other ocular findings may include skew deviation, gaze-paretic nystagmus, or ocular bobbing. Other cranial nerve findings may include ipsilateral peripheral facial weakness and ipsilateral absence of the corneal reflex. Dysarthria is often present.

CAUDATE HEMORRHAGE

Caudate hemorrhages can cause headache, nausea, vomiting, meningismus, confusion, and decreased short-term memory. ^[74] Findings that are variably present include a transient contralateral conjugate gaze paresis, contralateral hemiparesis, transient hemisensory deficits, and, rarely, ipsilateral Horner's syndrome.

GENERAL MANAGEMENT GOALS

Rapid diagnosis of stroke and initiation of treatment are important to maximize recovery and to prevent recurrence of stroke (see [Chapter 45](#)). Patients with an acute stroke should be admitted to the hospital for emergency evaluation and treatment, preferably in a stroke unit or intensive care unit where close medical and nursing observation is available. A multidisciplinary approach with referral to specialists with expertise in stroke is beneficial. Care should focus not only on the treatment of the stroke, but also on the prevention of complications.

Patients should be thoroughly investigated in an attempt to determine the likely etiology of the stroke. Appropriate therapy should be instituted to reduce the likelihood of a recurrent stroke. Choices for therapy that are available include antiplatelet therapies such as aspirin or ticlopidine, anticoagulation with heparin acutely followed by warfarin (usually reserved for a cardiac etiology of stroke), thrombolytic agents such as tissue plasminogen activator (in appropriate situations), and carotid endarterectomy (in appropriate situations). In the patient with an intracranial hemorrhage, hemostatic defects should be sought and corrected, if present. Offending drugs such as warfarin, heparin, and thrombolytic therapy should be stopped and, in appropriate situations when there is an antidote, reversed immediately. Neurosurgical consultation and intervention may be indicated in patients with large cerebellar infarctions; large, nondominant hemispheric ischemic infarctions with deterioration and herniation; and in selected patients with accessible, large lobar hemorrhages, when there is a progressive course. Patients with cerebellar hemorrhages should have a neurosurgical consultation. Further guidelines for specific therapy are detailed in Part III (see [Chapter 45](#)).

Frequent neurological checks are vital to early recognition of neurologic changes associated with herniation, recurrent or progressive stroke, recurrent hemorrhage or vasospasm in the patient with subarachnoid hemorrhage, and seizures. Cerebral edema with resultant herniation is the leading cause of death in the first week after an ischemic or hemorrhagic stroke.^[75] Cerebral edema caused by ischemia overlaps both cytotoxic and vasogenic forms. Vasogenic edema is the type of edema seen most frequently after a subarachnoid hemorrhage.

In patients with stroke, the blood pressure should be monitored frequently or even continuously for the first 48 to 72 hours. It is not unusual for the blood pressure to be transiently elevated after a stroke. Within a few days, the blood pressure may return to prestroke levels. Whether transient elevations should be treated is controversial.^[76], ^[77] It is important not to overtreat the blood pressure and cause hypotension. The most important objective is to maintain adequate cerebral blood flow in the presence of impaired autoregulation.

Cardiac monitoring is recommended for the first 24 to 48 hours after stroke due to the high frequency of cardiac dysfunction associated with stroke. In approximately 3 percent of cases, concomitant cerebral and myocardial ischemia can occur. A variety of cardiac arrhythmias can occur after ischemic or hemorrhagic stroke and subarachnoid hemorrhage (SAH), including tall P waves, longer or shorter PR and QT intervals, ST segment elevation or depression, peaked or inverted T waves, U waves, sinus bradycardia, wandering atrial pacemaker, paroxysmal atrial pacemaker, nodal bradycardia, AV block, premature atrial or ventricular contractions, atrial fibrillation and flutter, and AV dissociation. These abnormalities have generally been attributed to increased circulating levels of catecholamines. If ischemic ECG changes occur, serial creatine kinase and lactate dehydrogenase isoenzymes are indicated. Ventricular wall motion abnormalities have been demonstrated by echocardiography in patients with aneurysmal SAH. Patients with SAH often have microscopic changes consistent with subendocardial necrosis at post mortem.

Prevention of pulmonary complications is necessary in the bedridden patient or in the patient with impaired oropharyngeal function. Management of the airway and maintenance of adequate oxygenation and ventilation should be accomplished immediately. Ventilatory assistance is indicated if there are signs of respiratory depression, a Glasgow Coma scale of less than 8, or raised intracranial pressure and herniation. Pneumonia is the most common cause of non-neurological death in the first 2 to 4 weeks after a stroke.^[78] The mortality rate from pneumonia is as high as 15 to 25 percent. It is important to place a temporary enteral feeding tube if there is evidence of oropharyngeal dysfunction to avoid aspiration. Good pulmonary toilet is needed, including chest physical therapy, frequent turning, and volumetrics.

Lower extremity deep venous thrombosis (DVT) in the hemiparetic limb is a common occurrence if DVT prophylaxis is not initiated. If there are no contraindications, low-dose subcutaneous heparin is used at a dosage of 5000 units twice daily. If heparin is contraindicated, as in the patient with intracranial hemorrhage, intermittent pneumatic compression stockings are recommended.

The patient's nutritional status and fluid requirements

should be assessed. Patients with a large ischemic stroke may need fluid restriction during the first few days. In patients with intracranial hemorrhage, one should try to maintain euvoolemia. In patients with SAH, strict fluid restrictions should be avoided due to the possible risk of increasing cerebral ischemia in patients developing vasospasm. The patient's swallowing function should be assessed before intake of fluid or food is initiated. Patients who have significant oropharyngeal dysfunction will require parenteral or tube feeding.

Indwelling catheters should be placed only if absolutely necessary and should be removed at the earliest possible time to avoid urosepsis. The chronic use of an indwelling catheter should be limited to patients with incontinence or urinary retention that is refractory to other treatments.

The development of pressure sores occurs in approximately 15 percent of patients after a stroke.^[79] Steps to avoid this complication include frequent inspection of the skin, routine skin cleansing, frequent turning, use of special mattresses and protective dressings, maintaining adequate nutritional status, and trying to improve the patient's mobility as soon as possible after stroke.

One of the most common causes of injury to the patient with a stroke is falling. Assessments of the risk for falling should be made at regular intervals during the acute hospitalization. Measures should be instituted to minimize the risk of falls. Rehabilitation plays an important role in recovery in patients who are good candidates for intensive therapies.
