For the neuroscientist (or other cognitive scientist), then, there are two questions: Do cerebral representations really exist, yes or no? And if so, what form/s do they take?

These questions aren't straightforward. For *just what could count* as a "cerebral model" or "representation" wasn't clear when Craik introduced the term—and it still isn't. Craik and Minsky both tried to clarify the concept (Chapter 4.vi.b), and—later—so did John R. Anderson and Sloman (7.v.a). But it's extremely slippery. For instance, the late 1980s AI scientists famed for *attacking* representations relied on them nonetheless—albeit of a (situation-bound) type different from those used in GOFAI (see 13.iii.b).

This section indicates how, in the fifty years after Craik, cognitive scientists tried to pin the term down. In addition, it looks at the evidence for (various kinds of) representation in the brain.

a. What's the problem?

Disputes about the nature of representation, or internal models, were—and still are—both empirical and philosophical. Craik himself realized this, and it became increasingly evident in the fifty years after his death.

On the one hand, Craik's (and Mayhew's) computational question of *how* this or that can be represented in the brain remained. Cognitive scientists offered various answers, including some very different from those described in Sections iii–vii above. The representational mechanisms they suggested included the following, each of which has been mentioned in one or more of the preceding chapters:

* GOFAI symbols, seen as stable, manipulable, and copyable entities;
* 'iconic' representations of various kinds;
* deictic (situationist) representations;
* activity patterns in PDP networks;
* "fluid" concepts;
* feature-detectors; and
* anticipatory schemas.

They also included examples introduced in this chapter (three of them in subsections b–c below):

* neurophysiological models reflecting real-world dynamics;
* systematic mappings of one functional/behavioural space onto another;
* emulator systems that 'march ahead' of the processes being modelled; and
* evanescent representations used 'online' and then discarded.

On the other hand, philosophers argued about what *counts* as a representation, in principle. Those sympathetic to cognitive science didn't always accept every item on the list above as a genuine representation.

And many who weren't sympathetic rejected all of them. They weren't denying that such neural-computational mechanisms might actually exist. Rather, they were claiming that *no* scientific theory could ever explain representation (or intentionality, or meaning) as such. Those disputes are outlined in subsection d.

b. From probabilities to geometries

A theory of neural representation fundamentally different from those described so far was initiated in the late 1960s by Pellionisz.

The notion of internal models was central: "[the theory] hinges on the assumption that the relation between the brain and the external world is determined by *the ability of the CNS to construct an internal model of the external world* using an interactive relationship between sensory and motor *expressions*" (Pellionisz and Llinas 1985: 246; italics added). But there were several hierarchical levels of "expressions", with specified ways of translating between them.

As a young man in Budapest, Pellionisz developed Farley's pioneering work on two-dimensional neural nets (see Chapter 12.ii.b). Still in his early twenties, he defined a network of over 64,000 neurones, consisting mostly of two neuronal fields of 31,510 units each (Pellionisz 1968, 1970). Besides this huge jump in scale (Farley had managed only 1,296 units), his system differed from Farley's in being modelled on specific aspects of the brain. It was, in fact, the first computer simulation of the cerebellum. (Marr's work had been formal analysis, not simulation.)

Even as a student (an engineer at Budapest's University of Technology), Pellionisz saw *geometry* as the key to the brain. But as we'll see, he didn't mean Euclid. In an early publication (his first in English), he declared: "[I] analyse the transfer function of the neuronal information preprocessing system of the cerebellar granular layer [in terms of a] geometrical model of the regular neuronal arrangement . . . illustrated by a pattern transformation method" (Pellionisz 1968). In other words, the key idea was that one pattern could be transformed into another, by way of a systematic geometrical method.

While still a teenager, he'd been inspired by reading the Hungarian translation of von Neumann's posthumous book (1958; see 12.i.c) in about 1960. But whereas von Neumann had tentatively suggested that thermodynamics is the language of the brain, for Pellionisz it was geometry:

> On literally the last page of his book, the man who knew the mathematical language of computers so well . . . confessed in public on his death bed that we have no idea of the mathematical language of the brain (but he was sure it is different from Boolean algebra, the mathematics of man-made computers).
>
> I always excelled in creating new stuff—thus I was flabbergasted in the era of "Cybernetics", ready to create "thinking machines"—that the "top expert" has no idea of its basic mathematics. And he dies, though he feels that he is coming close.
>
> My life was cut out, right there. We have to discover the mathematical language of brain structure and function (I never thought of the two as separate entities). Looking at the geometry of the brain, I was damn sure the mathematical language was geometrical. (personal communication)

Pellionisz's mathematical "teachers", he now says, were von Neumann, Einstein, and Roger Penrose (1931–). The last two described forms of geometry more general than Euclid's, which Pellionisz eventually used to describe the brain. (So Penrose has contributed constructively, if indirectly, to cognitive science after all: see Chapter 16.v.a, and Section x.d below.)

But he needed neurological teachers, too. Like Marr at much the same time, he relied on the recent surge in histological knowledge of the cerebellum. Indeed, he took this from the horse's mouth. His adviser for his Master's thesis on 'Neuronal Modeling' was Szentagothai, of the Semmelweiss Medical University—co-author of the definitive book on cerebellar anatomy (Eccles *et al.* 1967).

Pellionisz's first model of associative memory was described in some detail in 1970 (the 1968 publication was merely an abstract, based on a fuller talk he'd given in Hungary). It simulated the connections between four distinct cell-types: mossy fibres, granule cells, Purkinje cells, and basket cells. And it even included the relative distances, and the precise numbers of connections.

The different cell-types were represented as four two-dimensional matrices, with formulae expressing the excitatory and inhibitory connections between them. Having computed the activity resulting from mossy-fibre inputs, Pellionisz noted "the emergence of concentrated excitatory spots as a result of the local averaging effected by the granule cells" (1970: 78). And he pointed out that certain unexpected features of the simulation depended directly on the histological data incorporated in it. In other words, Farley's (neurally inspired) connectionism had endured a *rite de passage* to become computational neuroscience.

A further *rite de passage* ensued when Pellionisz, after working for a few years with Szentagothai in Budapest, began his collaboration (at NYU Medical School's Department of Physiology and Biophysics) with the experimentalist Rodolfo Llinas, an expert on the cerebellum. With Llinas's help, he developed his early geometrical approach and applied it to a wide range of neurological data. Following some exploratory simulations (Pellionisz and Szentagothai 1973; Pellionisz *et al.* 1977), his final theory of representation was defined in abstract terms by the late 1970s (Pellionisz 1979).

When they first applied it to the cerebellum, to explain the control of bodily skills, Pellionisz and Llinas took the brain's representational system as given (1979, 1980, 1982; Pellionisz 1983*a*,*b*). Later, they asked how it could be learnt (Pellionisz and Llinas 1985). They also applied the theory to vision, and to the balance-sensitive semicircular canals (Pellionisz and Llinas 1981, 1985; Pellionisz 1985). In short, they were talking about representation *in general*.

Their theory differed radically from other models of associative memory. Where those relied on Hebbian rules defined over isolated—and identical—neurone pairs, they described representation and learning in terms of systematic mappings between large *sets* of neurones. And "large" meant large: already by the mid-1970s, their computer network had jumped from 64,000 components to over 1.7 million. These included over 8,000 Purkinje units, and others modelling cerebellar and brainstem nuclei. Moreover, each Purkinje unit had its own distinctive role, determined by its precise position in the neural "space" concerned (see below).

The reason was that they were addressing the *coordination* of movements. They accepted Brindley's idea that the cerebral cortex generates broadly defined motor "intentions", which the cerebellum converts into more detailed instructions (the output of the Purkinje cells). But they weren't interested in single body movements, still less in individual muscles. Rather, they considered movements generated within integrated behavioural suites, nicely adapted to the sensory information available at each moment.

They wanted to explain, for example, George Stratton's (1896, 1897*a*,*b*) and Ivo Kohler's (1962) intriguing findings that people can gradually compensate for distorting spectacles of various kinds. (See also the 'homeostatic' model discussed in Chapter 15.viii.d.)

Even if the visual image is turned upside down (i.e. if the retinal image is turned right side up), the person's movements and perception, hugely dislocated at first, become quasi-normal within a week or so. Only *quasi*-normal: both Stratton and Kohler had noted bizarre visual aberrations. And only a week "or so": Stratton (1897*b*) actually wore the inverting mechanism for only eighty-one hours out of the 200, although for the rest of the time he was blindfolded. (His detailed accounts of his changing experiences—including their relation to various movements, to bizarre dislocations in his body image, and at first to near-overwhelming feelings of depression—are fascinating reports of the phenomenology involved.)

Cats can compensate for distorted input, too (Melvill-Jones and Davies 1976). But some species never do. Snap little goggles, shifting the light 7 degrees to the right, over a chick's eyes as it hatches from the eggshell, and it will starve to death if it's given only sparsely scattered grains of corn to peck at (Hess 1956).

Why is it that people, unlike chicks, can adapt to such sensory distortions? Stratton, at the end of the nineteenth century, had sketched the answer as follows:

> Vision as a whole and by itself is indeed neither inverted nor upright. . . . [Upright] vision must mean a vision which gives us objects upright with reference to some non-visual experiences which are taken, for the time being, as the standard of direction. Upright vision, in the final analysis, is *vision in harmony with touch and motor experience*; and the only problem of upright vision is one concerning *the necessary conditions for a reciprocal harmony in our visual and tactual or motor perceptions*. (1897*a*: 184–5; italics added)

The different sense perceptions, Stratton said, "are organized into one harmonious spatial system", where the harmony consists in having our experiences meet our expectations. All that's needed is "a reliable cross-reference" between the senses, not any absolute marker of locations in reality.

Pellionisz and Llinas, too, were concerned with a complex representational *system*, not just a clutch of isolated representations. And they, too, considered the match/mismatch between actual and expected perceptions in guiding bodily action.

To integrate perception and action, they developed an arcane corner of mathematics: a form of non-Euclidean geometry known as tensor analysis. They defined systematic coordinate transformations, or "tensors". These provided a way of passing automatically between highly complex sensory and motor representations, looping through the environment to check on the sensory predictions in play.

The transformations had to be automatic because, as Karl Lashley (1951*a*) had pointed out, nervous conduction is too slow to explain bodily skills as chains of sensory-motor reflexes (Chapter 5.iv.a). They had to be complex, because any 'one' action involves a large number of cooperative and antagonistic muscles, and any 'one' perception involves many sensory receptors—in the retina, inner ear, tendons, and muscles (including the muscle spindles mentioned in Chapter 2.viii.d). There are countless ways of using one's muscles to pick up a coffee cup, and the skilled coffee-drinker finds the most efficient: *these* specific muscle movements are executed, given *those* sensory data about one's current bodily attitude and the position of the cup.

That was already well known. But where Arbib had used schema theory to compute how this could be done (see Section vii.c), Pellionisz and Llinas used tensor geometry.

Tensor network theory wasn't for the faint-hearted. The pure mathematics involved had been developing since Einstein's use of it early in the century, and had "a legendary reputation for difficulty and complexity" (J. A. Anderson *et al.* 1990*a*: 352). (When I mentioned this assessment to my young astrophysicist son-in-law, he agreed: "It bloody is!") Accordingly, their papers bristled with references to "non-Riemannian overcomplete CNS hyperspaces" and "spectral representation of the covariant metric tensor and its proper inverse (or Moore–Penrose generalized inverse) as expressed by their eigendyads".—Light reading, this was not.

Fortunately (for me, at least), the mathematical details needn't concern us. What's important is that tensor theory maps one geometry onto another. The projective geometry used in blocks world (Chapter 10.iv.b) maps Euclidean 2D space onto 3D space, in a very simple (non-perspectival) way. But tensor theory can coordinate multidimensional hyperspaces.

For an intuitive example of a hyperspace, consider the set of people eligible to apply for an imaginary scholarship. Applicants must be male, and must also satisfy at least two of these criteria: between 18 and 32 years old, but the younger the better; born in Derbyshire or Yorkshire; father (preferably) or grandfather a clergyman or a soldier; educated at one of twelve named schools; intending to study science at university; orphaned before the age of 15, and the earlier the better.

(This hyperspace isn't quite so "imaginary" as you may think. In 1961 I spent some hours in a large reference library searching for scholarships to study in the USA: of the forty or so that I found, many listed criteria just as bizarre as these—and only six of the forty were open to women.)

The 'geometry' of this scholarship space has many dimensions, namely the criteria just listed. Some are binary, some continuous; some are mandatory, some optional; and some are disjunctions, with two or twelve disjuncts (e.g. the two counties and twelve schools). An applicant at the 'centre' of the space would satisfy every criterion. Someone on the 'periphery' (besides being male) would satisfy only two, and those only weakly. Try thinking about just how you would locate fifty different applicants within this multidimensional space, deciding on their 'positions', 'neighbours', and 'distances'—and your mind may well begin to boggle. Imagine mapping them onto fifty points in some even more complex space, such as the criteria defining an ideal husband (GSOH etc.), and you might as well give up.

In tensor network theory, such decisions—for highly complex, and diverse, neuronal spaces—were computed precisely, coherently, and testably. And algorithms (sets of neural connections) were defined for transforming one set of hyperspatial coordinates into another, so that the *appropriate* movements were made at each moment, given the sensory information available. The GOFAI robot SHAKEY (Chapter 10.iii.c) had computed only simple 2D-to-3D mappings, and chose from a highly restricted set of movements. But a tensor network robot could generate a much wider range of behaviour, informed by a more complex array of sensory inputs (Pellionisz 1983*a*).

On this view, a cerebral 'intention' is sculpted into a more precise representation of action by the cerebellum, starting from the current bodily attitude. This attitude is known (represented) by mapping the proprioceptive input from the many tendons and muscle spindles onto 'muscle space'. The series of many-muscled movements that ensues is computed by finding a path through muscle space so as to arrive at the end point (e.g. holding the coffee cup).

Each movement 'predicts'—is associatively mapped onto—a particular set of proprioceptive (and visual and/or tactile) inputs. If the *actual* sensory input is different, perhaps because the arm is blocked by some obstacle, a different muscular 'starting point' is found by automatic mapping, and a new muscular 'pathway' computed accordingly. When such failures of prediction occur systematically (as in wearing distorting spectacles), an adaptive process of *meta-organization* gradually refigures and recoordinates the sensori-motor spaces concerned. This process was mathematically defined, and was described by the authors as the first precise definition of the "largely intuitive" concept of self-organization (Pellionisz and Llinas 1985, sect. 4.1).

An important general point, here, is that this theory posited *hierarchies* of dual geometries in the nervous system, with different tensors linking each pair of contiguous levels. This idea was used (for example) to explain mammalian gaze control—which isn't a simple matter, since both eye movements and neck movements are involved. (Hoverflies lack both, so don't need a complex mechanism of gaze control: Chapter 15.vii.b.) Pitts and McCulloch (1947) had discussed some relevant visual computations. But Rafael Lorente de No (1933*b*) had already suggested that vision isn't enough, that gaze control also involves feedback from the inner ear (see Chapter 4.v.c). Pellionisz (1985) took this added complexity on board—later adding the neck muscles (Pellionisz and Peterson 1988). He even sketched, though couldn't simulate, the frog's *entire* nervous system in (multilevel) tensorial terms (1983*b*), depicting the animal as what he might have called—but didn't—*Rana geometrica*.

The theory was applied to self-organization in the embryo, too. People had long observed spontaneous oscillations, or coordinated twitches, in the legs of chick embryos. Now, Pellionisz and Llinas (1985) suggested that these apparently useless movements enable the chick to develop its (initially vague) proprioceptive space in coordination with its (fixed) muscular space. That is, tensor coordinations enable established neural representations to be used, on successive levels, to organize less well-developed ones. (A related idea, of "representational trajectories", was being developed informally in connectionist psychology: Chapter 12.viii.d.)

Tensor theory was tested by biological experiments in Llinas's lab, by computer simulation, and (later) by robotics. By the late 1980s, it was beginning to receive independent experimental support (e.g. Gielen and van Zuylen 1986). James Anderson included the meta-organization paper in his influential *Neurocomputing 2*, and invited Pellionisz to co-edit the volume (J. A. Anderson *et al.* 1990*a*). And Pellionisz received the first international award for neurocomputing (Germany's Alexander von Humboldt Prize) in 1990.

One might think this would have 'licensed' Pellionisz as a professional researcher, but it didn't. (Llinas didn't need a licence, being already established when their collaboration began.) Like Grossberg and 'cerebellar Marr' (see Sections v–vi), Pellionisz suffered from neuroscientists' suspicion of fancy mathematics. Even mathematically competent researchers such as Arbib and Shun-Ichi Amari were sceptical, although Amari later adopted somewhat similar ideas (Arbib and Amari 1985; Amari and Wu 1999; cf. Pellionisz and Llinas 1985, endnote).

Pellionisz wasn't offered a tenured academic job, and left NYU in 1989—soon to be employed by NASA, to design software controls for F-15 jet fighters (Pellionisz *et al.* 1992). Later, he worked in the IT industry, and founded a company using tensor network theory to do personalized pattern matching—applying his four-level PureMatch software in finance and medicine, for example (personal communication). Whether he'd have had more to offer to neuroscience, who can tell?

c. Emulation and subjectivity

Tensor network theory—once it was applied to the body's geometry, in the late 1970s—was an early example of what's now called an emulator system (Grush 2004). It's partly because of neural emulators that our walking can be continually adjusted (unlike the path of a ballistic missile, or the hoverfly's flight towards its mate: see Chapter 15.vii.b).

An emulator is an internal model of a feedback system, which works in a similar way but faster. Using feed-forward processes, it continually anticipates the system's responses *and the resultant sensory information*. Given a mismatch between expected and actual input, the emulator can adjust the output controls immediately, instead of just a little late. Without the emulator, and especially if the stimulus is continually changing, the output would be jerky rather than smooth.

Emulators have been used in control engineering from about 1960. Craik couldn't cite them, because they hadn't yet been built. However, they're a paradigm case of the type of representation he had in mind. Since their appearance on the engineering scene, they've been found in the nervous system.

Tensor network theory, as remarked above, defines a hierarchy of emulator systems. Another example was described by Mayhew and colleagues, in a study of the cerebellar control of visual saccades—in which the eyes move to focus on, and track, a particular object (Dean *et al.* 1994). Yet another concerned the control of hand movements made in the dark (Wolpert *et al.* 1995). In view of the controversy over the very existence of cerebral representations, it's worth remarking that those authors saw their results as "direct support for the existence of an internal model" (Wolpert *et al.* 1995: 1880).

The same authors soon argued that emulators and other representations are involved in sensori-motor integration *in general*, where the organism combines multiple sources of information to estimate its own state and that of the environment (Ghahramani *et al.* 1997). And after further research in this area by themselves and many others, they concluded:

> The computational study of motor control is fundamentally concerned with the relationship between sensory signals and motor commands. . . .
>
> *Computational approaches have started to provide unifying principles for motor control.* Several common themes have already emerged. First, internal models are fundamental for understanding

a range of processes such as state estimation, prediction, context estimation, control and learning. Second, optimality [i.e. optimal control theory] underlies many theories of movement planning, control and estimation and can account for a wide range of experimental findings. Third, the motor system has to cope with uncertainty about the world and noise in its sensory inputs and motor commands, and the Bayesian approach provides a powerful framework for optimal estimation in the face of such uncertainty. We believe [thanks to a wide range of experimental evidence] that these and other unifying principles will be found to underlie the control of *motor systems as diverse as the eye, arm, speech, posture, balance and locomotion*. (Wolpert and Ghahramani 2000: 1212, 1217; italics added)

Such neurological theories support Stratton's *psychological* insight that it was the difference between the actual and expected sensory inputs which enabled him to adapt to an inverted visual world. A hundred years after Stratton's experiments, Jennifer Freyd (with Geoffrey Miller) offered further psychological evidence for neural processes emulating the world.

She posited dynamic mental models having "representational momentum", to explain her finding that people who perceive a moving object tend to misremember it as having moved further than it actually did (Freyd 1987; G. F. Miller and Freyd 1993). Such models have evolved, she said, to help us track real-world motion by anticipating it rather than merely following it.

Like Roger Shepard and Stephen Kosslyn before her (see Chapter 7.v.a), she reported a linear relation between representation and reality. The size of the mistake in the memory of final position depended directly on (1) the speed of movement and (2) the time elapsed between perception and memory probe. That's just what one would expect, if there were some physically realistic internal model that "keeps moving in the mind"—or, as Craik would have put it, keeps running in the brain—after the actual movement has ceased.

Freyd's evidence may be persuasive to neuroscientists working in the Craikian tradition, and to psychologists—such as Shepard himself—who argue that "second-order isomorphism" has evolved in our perceptual systems (see 7.v.a). But it wouldn't convince committed formalists such as Jerry Fodor and Zenon Pylyshyn. They'd interpret it in GOFAI-friendly terms, as they did Shepard's and Kosslyn's data on mental imagery (Pylyshyn 1973). On that view, her results show that the perception and/or memory of movement is "cognitively penetrable", owing to top-down symbolic inference (see Chapter 7.v.a). Her representational hypothesis would be vindicated only if a Craikian emulator of the type she implied were actually identified by neuroscience.

Lashley (1951*a*) had argued that there must be some central anticipatory mechanism controlling skilled movement, but could say very little about just how it might work. Today, neural emulation is the key to our understanding of bodily skills. Ito, who in the 1960s co-authored (with Eccles and Szentagothai) *The Cerebellum as a Neuronal Machine*, now says:

With respect to cerebral control functions, cerebellar chips appear to [form] *an internal model of a controller or a control object*. If, while a chip and the system to be modeled are supplied with common input signals, differences in their output signals are returned to the chip as error signals, the chip will gradually assume *dynamic characteristics equivalent to those of the system to be modeled*.

> Cerebellar chips [in one area] are connected to the cerebral motor cortex in such a way that these chips constitute *a model that mimics the dynamics of the skeleto-muscular system* (Ito 1984). The motor cortex thus becomes capable of performing a learned movement with precision *by referring to the model* in the cerebellum and not to the skeleto-muscular system. [The] failure to perform a precise reaching movement without visual feedback could be due to the loss of such internal models. (Ito 1999: 111; italics added)

Indeed, the emulator control of skilled (automatic) movement is seemingly only one function of the cerebellum. Brain-imaging techniques have recently suggested that it might also be crucial in skilled thinking (Schmahmann 1997). So Ito adds this:

> During thought repetition, a cerebellar chip may form a model of the parietolateral cortex or the prefrontal cortex. A repeatedly learned thought may thus be performed quickly yet accurately even without reference to the consequences of the thought or without conscious attention. (p. 111)

Craik, had he lived, might have seen this suggestion as confirming his claim that thinking involves analogue symbols, too.

Neural emulators—like their control-engineered cousins—are online representations, used to improve the efficiency of behaviour while it's happening. In human beings they can also be run 'offline', so that people can practise physical activities by imagining them. This explains why (as a Norwegian diving instructor told me many years ago, to my amazement at the time) top-level divers living beyond easy reach of an Olympic swimming pool can improve their performance by diving 'in their heads'.

The emulators themselves are enduring memories. The connections that implement them are retained, once they've been learnt. But their adaptive function is to represent momentary 'present-tense' events: where the muscles are *now*, and what the input data are *now*. In other words, they are subject-dependent representations, not objective ones.

Some representations posited by cognitive science are even less objective than this. For they are evanescent structures, coding intermediate results in some multi-stage computational process. Neuroscientific evidence is difficult to come by, for obvious reasons—although high-resolution fMRI might help, especially if combined with electrophysiology (Logothetis 2002). But both computational arguments and psychological evidence are relevant:

* For instance, Aaron Sloman argued in the late 1970s that high-level visual interpretation requires temporary data structures, and implemented them in his POPEYE project (see Chapter 10.iv.b).

* Marr's theory of vision distinguished the viewer-dependent $2\frac{1}{2}$D sketch from representations at the level of object models (Chapter 7.v.c).

* And Perrett's group explained the monkey's face recognition in terms of a limited set of "viewer-centred descriptions" (see Section iv.d, above).

* As for psychological evidence, Ann Treisman (1988) explained her experimental data on perception and problem solving by positing temporary "object files", generated 'on the fly' (i.e. during processing) in working memory.

The crucial point here is that there are relatively 'subjective' and relatively 'objective' representations. In the last decades of the twentieth century, neuroscientists—and some philosophers—increasingly accepted this. They tried to specify the differences, and to explain how objectivity could develop from subjectivity, whether in evolution or in ontogeny (see Chapter 12.x.e–f and Cussins 1990).

In short, by the new millennium cognitive scientists had posited representations galore. Neuroscience now used the term liberally, offering a wide range of hypothetical examples (Parker *et al.* 2002).

d. The philosophers worry

That's not to say, however, that the *philosophers* regarded all of these 'representations' as the genuine article. Their quarrels weren't with the biological evidence, but with its intentional interpretation—and (predictably) with each other.

Craik's philosophy of mind had defined "symbols" and "models" in analogue terms. GOFAI philosophers, by contrast, tried to restrict such concepts to formalist examples (hence their top-down interpretation of imagery, mentioned above). For them, connectionism was concerned with "implementation details", not representation. PDP philosophers favoured a third position (see Chapters 12.x.a–c and 16.iv.e). They argued that activation patterns distributed over many computational units, none of which can be assigned a constant meaning or regarded as a symbol for a nameable concept, are genuine representations too. And some allowed talk of *subjective* representations, as precursors to full-blooded objective concepts (see 12.x.f).

Some philosophers preferred a very wide definition: *any* internal mechanism that was reliably correlated with an external event and causally implicated in ecologically appropriate behaviour (Dretske 1984, 1995). This would include single-cell feature-detectors (which aren't "models" in the Craikian sense, although the circuitry activating them may be), and also the relatively subjective, evanescent, examples noted above. Both of those would be excluded, however, by the familiar definition—familiar to philosophers—of a representation as a (non-semantically identifiable) internal state that causes behaviour to be adaptively coordinated with some environmental feature *even when that feature is absent.*

Moreover, the reference to "an identifiable internal state" excludes cases (highlighted by the dynamical approach) where there's a complex interaction of body, brain, and environment. Of the philosophers who recognized this interactive causation, some allowed that certain aspects of the causal nexus play a special role in adaptive behaviour and should be counted as representations accordingly (Clark and Grush 1999; Clark and Wheeler 1999). Others—including 'Frog's Eye' Maturana (wearing his autopoietic philosopher's hat)—denied the existence of *any* representations in the brain. Far from there being representations galore, there are none at all. (The reasoning behind this unfashionable, even counter-intuitive, view is sketched in Chapters 15.vii and 16.vii and x.c.)

Those philosophers of mind who had no special interest in cognitive science focused on the centuries-old concept of representation, or intentionality, *as such*. They ignored the specifics of neuroscience and AI, although some did ground intentionality in evolutionary biology (see Chapter 16.x.d).

Finally, neo-Kantians didn't simply ignore science but explicitly dismissed it. Or rather, they wished to keep it strictly in its place—which was to answer *empirical* questions. According to them, there can be no naturalistic explanation of intentionality—

not even in neuroscience, never mind AI. They weren't merely saying that there's a distinction between empirical and philosophical questions. Rather, they were saying that science is irrelevant, so much so that it can't even give us helpful clues on philosophical matters. It would follow, for instance, that *even if* scientists discovered innate 'syntactic' mechanisms, Chomsky's *philosophical* claims wouldn't be supported, still less proved.

Clearly, that wasn't the view of the many philosophers of cognitive science I've cited throughout this book, who *did* think that cognitive science could help us to a more adequate philosophy of mind. But even they had to admit that they had no knock-down arguments against neo-Kantianism (see 2.vi and 16.vi–viii).

On one thing, however, all the philosophers agreed. Namely, that empirical cognitive scientists used the words "representation" and "model" in largely intuitive senses—obscuring important distinctions and begging controversial questions.

Craik and Minsky each tried to define these concepts in *philosophical* terms, as we've seen (Chapter 4.vi.b). So did Newell and Simon (16.ix.b). But most of their scientific colleagues didn't. They simply picked them up from the Zeitgeist and ran with them. If they offered 'definitions' at all, these concerned the mechanism rather than the concept.

From the late 1970s on, gallons of philosophical ink were spilled on trying to define representation more strictly. Indeed, it's still spilling, unabated. I've no intention of tracking each drop. Several rivulets are traced in other chapters, however. And two major streams of disagreement—concerning *reportability* and *intentionality*—will be followed in Chapter 16.

(*How to find the rivulets*: David Kirsh's critique of non-representational robotics is outlined in Chapter 13.iii.c. Andy Clark's defence of PDP, and Adrian Cussins's of increasing objectivity, appear in Chapter 12.x. Fodor's 'classical' representationalism is outlined in Chapter 16.iv.c–d; Timothy van Gelder's dynamical critique in Chapter 16.vii.c; and Maturana's autopoietic theory in Chapters 15.vii.b and 16.x.c. Finally, Michael Morris's argument that *no* brain mechanism is a representation is given in Chapter 16.viii.a.)

Here, let's just note that neo-Kantian philosophers insisted on reportability as a criterion of representation. For them, language is essential for mind, intelligence, and thought (16.vi–viii). They would never write books called *Animal Thinking* or *Animal Minds* (Griffin 1984, 1992), and regarded "cognitive ethology" (Ristau 1991) as a contradiction in terms. However, experimental psychology, ethology, AI, and neuroscience developed within the opposing philosophical tradition (see Chapter 2). They drew no sharp line between 'mindful' *Homo sapiens* and 'mindless' dumb animals.

The slipperiness of the concept of representation affects how people think about cognitive science itself. Since the concept was often used in defining the field, disagreements about *what representation is* were reflected in judgements about its scope, and its success.

If one accepts Fodor's sense of representation, for instance, connectionism is either a *refutation* of cognitive science (as Dreyfus claimed) or a mere implementational *adjunct* to it (as Fodor himself believed). Accepting a more catholic definition of representation, connectionism is an interesting *example* of cognitive science (and further putative examples have been given in this section). Similarly, dynamical theories and situated robotics (for instance) must be excluded if, by definition, cognitive science posits representations in explaining behaviour.

This is why, as I said right at the start, the boredom barometer would shoot through the roof if one compared every definition of cognitive science. And it's why I deliberately avoided the elusive term "representation" in my own definition of the field (Chapter 1.ii.a).

It's not even clear that trying to legislate on "the best" definition of representation is sensible. The same applies to life (see 16.x), and to theoretical terms in general (Quine 1951, 1960; Putnam 1962*a*). Comparing putative definitions carefully is one thing, and can be highly illuminating. But announcing *just one* to be the only defensible option is quite another. That's especially so in scientific contexts. As Craik put it, when discussing perception:

> [Scientists and philosophers alike] fail to see that their remedy of exact definition may be *impossible and unattainable* by the very nature of the physical world and of human perception, and that their definition should be corrected in the way of *greater extensiveness and denotative power, rather than greater analytical, intensive, or connotative exactitude.* (p. 4; italics added)

The catch-all sense of 'representation' (which I deliberately haven't tried to *define*) is therefore useful. It acknowledges the intriguing variety of intentional and quasi-intentional mechanisms that generate adaptive behaviour. Philosophers can help clarify the differences, for they're already familiar with a wide range of relevant distinctions and implications. But that variety becomes apparent through empirical research, not philosophical diktat.

14.ix. Computation Challenged

In the final decades of the century, seven research themes in neuroscience challenged certain aspects of the computational approach. Those challenges were largely met—sometimes, by modelling in radically novel ways.

All seven were older ideas revivified by new data. The first four—self-organization, dynamical systems, epigenesis, and neural selection—were closely interrelated, as we'll see. The fifth concerned grandmother cells; the sixth, neurochemicals; and the last, time.

a. Structure without description

At the mid-century Hixon symposium, McCulloch had argued that the information stored in our genes could determine the connections between at most 10,000 neurones, "[even] if that was all it had to do" (W. S. McCulloch 1951: 85). "As we have 10^{10} neurons", he continued, "we can inherit only the general scheme of the structure of our brains. The rest must be left to chance." And by "chance", he said, he really meant learning from experience.

Only a few years afterwards, he and his 'Frog's Eye' colleagues discovered a detailed 'mapping' between the frog's retina and tectum (see Section iii.a). Soon, others found organized columns of orientation detectors in the visual cortex of cats—and in newborn kittens too (Section iv.d). This was a puzzle, for the kittens couldn't have "learnt from experience" in the womb. Their detailed brain structure, it was therefore assumed, *must* have been cleverly programmed by the genes—perhaps by means of genetically specified chemical 'labels' to guide the developing neurones. (McCulloch's worry about the amount of information required for such a program was seemingly forgotten.) After all, brains can't get organized by magic.

In the final quarter-century, however, a number of people showed that (as Ashby had suggested in the 1940s: Chapter 4.vii.c) there may be *general* mechanisms in the developing brain which structure it spontaneously, without either 'external' learning or specific genetic instructions. Specifically, the claim was that the various feature-detector cells, *and* their systematic arrangement in neighbouring clumps and columns in the cortex, were self-generated. Highly influential versions of this claim were due to the biologists Willshaw and von der Malsburg, the engineer Kohonen, and the computer scientist Ralph Linsker.

Willshaw and von der Malsburg (1976) asked how patterned structures might arise within an unorganized mass of cells in the *embryo's* brain. Von der Malsburg had already shown that specific visual inputs could lead to columns of feature-detectors (Section vi.b, above). But the womb doesn't provide specific visual inputs. So now, he and Willshaw generalized the point.

They showed that for any two interconnected sensory cell layers, simple Hebbian rules will make the second develop a 'map' of the first. The one constraint was the presence of short-range excitation and long-range inhibition (as in the 'Mexican hat' detectors described in Chapter 7.v.d). Both of these, of course, had long been observed in the brain.

They proved—and demonstrated by computer modelling—that those mappings will arise in an orderly way, owing to properties of the system as a whole:

> [We] have shown that the mappings are set up in a system-to-system rather than a cell-to-cell fashion. The pattern of connections develops in a step-by-step and orderly fashion, the orientation of the mappings being laid down in the earliest stages of development. (Willshaw and von der Malsburg 1976: 431)

They described two independent factors, operating at different scales. One was an optimizing process ensuring a topographical mapping, since "neighbouring presynaptic cells come to connect to neighbouring postsynaptic cells" (p. 433). The other used boundary and initial conditions to affect the position, size, and orientation of the final mapping. They varied the boundary conditions in their computer models, showing how this affected the network's self-structuring.

As if in response to McCulloch's worry, they pointed out that theories of self-organization "have the advantage of requiring only an extremely small amount of information to be specified genetically". Indeed, they noted that the amount of information that would be required for pre-wiring is even greater than inspection of adult brains suggests.

A frog's retina and tectum, for instance, grow at different rates and in different ways, so "the only way the systems could remain matched throughout development [is] for the synaptic relations between retina and tectum to be constantly changing" (p. 432). A rigid pre-wiring plan wouldn't provide the flexibility required. To 'settle' this plasticity into one form or another, the *intra-cerebral* environment was crucial. Their models showed how "the same genetical program for the topographic part can in different situations lead to quite different retinal points being connected to a given tectal location, without the need for [chemical] relabelling".

In saying this, Willshaw and von der Malsburg weren't denying that the brain may use chemical labelling to guide *this* neurone to connect with *that* one. Their point, rather, was that Hebbian self-organization is functioning too (perhaps to 'tune' the results of initial chemical guidance), and that it's potentially powerful enough to work alone. Moreover, a 'chemical' method could in principle specify *any* mapping, however bizarre. Their theory generated only 'natural' (topographical) mappings. (Compare Allen Newell and Herbert Simon's decision to constrain their production systems, converting a universal programming language into a 'weaker' but more biologically realistic framework: see Chapter 7.iv.b.)

A few years later, Kohonen (1982)—who'd been modelling associative memories since the 1960s (see Chapter 12.v.e)—generalized these ideas still further. His analysis applied in principle not only to mappings of spatial features but also to "completely abstract or conceptual items"—*provided that* "their signal representations or feature values are expressible in a metric or topological space that allows their ordering".

The good news was that Barlow's hunch (Section ii.b), that logical reasoning may be grounded in the mechanisms that make efficient perception possible, was reinvigorated. (It had survived also in Grossberg's and Arbib's work, of course.) The bad news was that establishing a suitable "topological space" for concepts (*plough*, *betrayal*, *cousin*, *justice* . . .) is easier said than done. Margaret Masterman's computerized thesaurus (Chapter 9.x.a) and Robert Abelson's matrix of "themes" (Chapter 7.i.c) might be seen as early attempts, and theories of semantic primitives too (Chapter 9.viii.c). But much greater subtlety and richness would be required to define the "topology" of a plausible self-organizing concept-mapper.

Kohonen (1988) soon used his analysis to build a device for speech recognition. It took speech (single words, or strings of words separated by pauses) as input, analysed it into similar but varying phonemes, and output the words on a typewriter. (In Finnish, unlike English, sound and spelling match closely.) The phoneme classes weren't built in; and they weren't identical with the linguist's phonemes (Kohonen called them "quasi-phonemes", accordingly). Nevertheless, the system learnt to recognize the 'same' phoneme in differing phonetic contexts, and spoken by individuals with different voices and accents. It developed a large vocabulary, and was the best speech-recognizer at the time.

This 'science-fictional' automatic secretary was described in the widely read pages of *Computer Magazine*. The same issue also featured an elegant pebble thrown into the theoretical waters by Linsker. And this made even more of a splash.

Based at IBM's T. J. Watson Research Center, Linsker (1949–) had defined—and implemented—highly abstract models of multi-layer feed-forward networks (1986, 1988, 1990). These showed that simple Hebbian rules, given *random* activity, could lead to structured orientation detectors. Again, the newborn kitten's visual skills were less surprising than they'd seemed.

So far, so familiar. What was original here was Linsker's formulation, using Shannon's information theory, of the "infomax" principle. He applied this both to individual cells and to the network as a whole:

> The organizing principle I propose is that the network connections develop in such a way as to maximize the amount of information that is preserved when signals are transformed at

each processing stage, subject to certain constraints . . . The constraints or costs may reflect, for example, biochemical and anatomical limitations on the formation of connections, or on the character of the allowed transformations. (Linsker 1988: 529, 536)

In other words, the nervous system has found *the best possible* way of analysing complex sensory input, given that flesh and blood is doing this at all. The broad idea wasn't new (Marr had relied on it in his theory of edge detection: see Chapter 7.v.b–d). But Linsker had apparently found a powerful way to generalize it.

Admittedly, he said, much work would be required to apply the infomax principle to real biology. For example, it wasn't clear whether it could be generalized to cover 'circular' networks involving feedback—as in top-down action by schemas, or recurrent networks. Moreover, only empirical neuroscience could show which "constraints" had been favoured by evolution, or perhaps "by other principles not yet identified". (His reference to "other principles" *besides* evolution was a sign of the times: A-Life had recently revived interest in such principles—see Chapter 15.iii–iv and viii–ix.)

Two additional bonuses were remarked at the close of his paper. "Infomax" made it much more likely that an isolated mutation, in the evolution of a complex neural system, would be adaptive. The apparent 'necessity' for several *simultaneous* mutations evaporates if each neural level can spontaneously adapt to a small alteration in another. The same may apply to other bodily organs too. For the paper's final squib was the suggestion that infomax might apply to dynamical systems of many different types.

In other words: neural development, goal seeking, immune response, and biological evolution might all share similar self-organizing properties. This exciting idea had recently hit the news-stands (see Chapter 15.ix.a), and Linsker's mathematics was taken as strong support.

The "splash" caused by Linsker's ideas is evident in Cowan's rueful comment a few years later:

In the late 1970s, Christoph von der Malsburg and I worked together on the formation of orientation detectors. I had the idea that maybe this idea of a natural tendency to form stripes and blobs [he'd already cited Turing: see Chapter 15.iv.b] was the key to understanding it, and all you needed was a two-layer network stimulated by noise, and it would automatically make the correct feature detectors.

Christoph didn't believe me; he said, "That's magic."

I said, "No, it's just spontaneous symmetry breaking."

It turns out I was right. We never did it, and I have been kicking myself ever since because Ralph Linsker did it. That's exactly what Linsker discovered: that stripes and blobs will spontaneously form in a map. That's the origin of center–surround orientation detectors in the visual cortex. (J. A. Anderson and Rosenfeld 1998: 120–1)

Neuroscientists, besides further analysing Linsker's general results (D. J. C. Mackay and Miller 1990), built more 'realistic' models. For example, a different Hebbian rule was used; and ocular dominance columns were generated partly by neural competition between cells connected to the two eyes (Linsker had considered only one eye): K. D. Miller *et al.* (1989). This work also showed *why* certain sorts of abnormal visual experience result in distinct neural pathologies.

Harry Barrow—a pioneer of AI vision (see Chapter 10.iv.b)—also built on von der Malsburg's 1973 paper, and later on Linsker's work. He and Alistair Bray modelled the origin of the simple and complex cells of visual cortex, to find out which types of pattern were 'preferred' by the brain. They used natural images, whereas von der Malsburg had used artificial line patterns.

Their networks developed systematically structured groups of orientation-sensitive edge- and bar-detectors, or of detectors for colour or position-invariant orientation (Barrow 1987; Barrow and Bray 1992*a*,*b*, 1993, 1996; Bray and Barrow 1996). (They suspected that a 'composite' version of their model would develop *all* these feature-detectors, but didn't have enough computational power to test this.) They asked why the networks developed as they did, and showed how the results would differ if various parameters were altered.

In short, they explored the mathematical core of several *superficially distinct* self-organizing systems. Barrow and Bray, Linsker, and Willshaw and von der Malsburg were all asking important questions about the inevitability of crucial types of brain mechanism. These mechanisms didn't have to be sketched by some all-powerful Designer in the sky. They didn't even have to be nicely prefigured in the genes. They arose naturally, as a result of self-organizing principles dependent on relatively low-level properties of neural tissue. (If D'Arcy Thompson had still been alive, he'd have been fascinated: see Chapter 15.iii.a.)

b. Dynamics in the brain

The studies described above weren't the only examples of late twentieth-century neuroscience taking self-organization seriously. A number of people (including Arbib, as we've seen) were now drawing not only on Hebb but also on dynamical systems theory. (In general, a dynamical system cycles between a finite number of holistic 'attractors'—Ashby's "equilibrium" states—in a more or less regular fashion.) They weren't alone: people in other areas of science were also exploring these ideas (Chapter 15.viii.c, ix, and xi; and 16.vii.c).

Some philosophers were doing so, too. They described the mind/brain in terms of spontaneous self-organization, instead of the input–output systems favoured by classical cognitivism. Besides those to be mentioned in Chapter 16.vii and x, these writers included Susan Oyama (1985). Her unorthodox approach to the developmental sciences (including evolutionary biology) resembled Romantic views that had 'died the death' in scientific circles with the publication of *The Origin of Species* more than a century before (Chapter 2.vi). Nevertheless, it now influenced a number of hard-headed developmental scientists and A-Life researchers.

Oyama criticized GOFAI cognitivism—and most neuroscience—for treating the mind/brain as a given, static, structure. Instead, she argued, it's an ever-changing system, developed by a lengthy process of self-organization. Unless we take this seriously, we can't understand *adult* cognition. It followed that developmental neuroscience/psychology isn't an optional extra, to be studied by those who like that sort of thing and safely ignored by everyone else. On the contrary, it's central to neuroscience/psychology *in general*.

She wasn't making an empirical claim, although she did cite empirical evidence in support. Rather, she was making a philosophical point. To ask, like McCulloch for example, whether the structuring information is in the genes or in the stimulus, or even in some epigenetic interaction between the two (see subsection c), is to imply that the system—genome, embryo, brain, cortex, feature-detector . . . —accepts its structure from something else. This, she argued, is unsatisfying *in principle*, because it leaves the ultimate origin of structure unexplained. We must show how the system can structure itself, owing to its inherent nature. If not, then the mystery remains.

The psychologist Esther Thelen (1941–2004) agreed (1989: 556–7). Putting empirical flesh onto Oyama's philosophical bones, she studied integrated motor actions, including those described by Sherrington (Chapter 2.viii.d). She focused on the nature and development of rhythmic patterns such as walking, kicking, rocking, and communicative waving, and the sudden shift between (for example) crawling/toddling, suckling/ingesting, and sleep/waking (1981, 1985, 1989; Thelen *et al*. 1987; A. Fogel and Thelen 1987; Thelen and Smith 1994).

Where Marr had ascribed bodily skills to specific neurone circuits, and Pellionisz and Llinas to tensor transformations, Thelen ascribed them to stable attractors in dynamical systems (see Chapter 7.vi.g).

Everyone allows, Thelen said, that behaviour arises from a 'system'. But they usually do this only in the Discussion section, after admitting failures in their main-effect theories (1989: 557). She had scant respect for these empty admissions, which "can dilute systems concepts to the point of vacuousness" (1989: 557). What we need, she said, is a mathematically precise account showing how complex systems can produce emergent order without a prior description of it, and how one type of order is 'chosen' over another.

For Thelen, what are normally regarded as mentally guided, pre-prepared, actions are best thought of as forms of self-organizing bodily skill. She ascribed such skills to stable attractors in dynamical systems (see Chapter 15.viii.c–d). Even a small change may tip the system into the basin of a different attractor, so we should expect sudden behavioural shifts. But not *any* change will do: we must discover the 'switches' involved.

On this view, sensori-motor development involves the construction and stabilization of new attractors, and the 'setting' of control parameters that shift the system from one to another. The system complexity is hierarchical, since new attractors are generated by "a cascade of successive bifurcations or phase-shifts" (1989: 570). (Hence the impossibility of going *directly* from a trot to a gallop.)

For example, consider Piaget's "A-not-B error", in which infants search for a toy in its original place even though they've seen it being moved (Chapter 5.ii.c). Piaget himself had explained this in cognitive terms, speaking of the developing "object concept". But Thelen didn't. Instead, she analysed perseverative reaching by differential equations representing the interacting constraints involved (Thelen *et al*. 2001).

These constraints included alternative movement-suites such as reaching and looking (*seeing*, for Thelen, is a form of motor activity); the distance between object and child; the perceptual salience of the hiding place; the time passed before the child is allowed to reach for it; the attractiveness (for the child) of the object; and the past history of the child's actions in respect of it. Each of these had previously been shown to affect whether the child succeeded (which is a puzzle, if some object concept 'inside the head' is supposed to be responsible). But Thelen united them in a coherent way.

Her approach to action was very different from GOFAI planning. This had already been criticized as over-intellectualized by people within the AI stable. Now, Thelen provided psychological meat, and measurement. (How far dynamical theorizing can be applied to paradigm cases of 'rational' planning remained controversial: see 12.vii.c.)

Although her theory was couched at the psychological level, Thelen related her findings to neural mechanisms whenever she could. Among the neuroscientists she cited with approval was Berkeley's Walter Freeman. He'd been the first to apply chaos theory (a variant of dynamical systems theory) to the brain.

'Chaos' in the mathematical sense is very different from 'chaos' in the everyday sense: it sometimes looks random, but it isn't. Chaotic phenomena (which include the weather and the heartbeat) are deterministic, but in practice unpredictable. The reason is that they're hugely influenced by tiny variations in initial conditions. Nevertheless, their overall behaviour shows a number of holistic patterns, or dynamical attractors.

Freeman had been drawn to dynamical theorizing by Turing's 'Morphogenesis' paper and by Ilya Prigogine's work on dissipative structures in physics (J. A. Anderson and Rosenfeld 1998: 31–2). From the 1960s on, he'd experimented—unfashionably—with EEG recordings. Most of his peers paid little attention: as he put it later, there was "a virtual obsession with unit recording" (J. A. Anderson and Rosenfeld 1998: 27).

By the late 1980s, however, some were ready to listen. (Both biological-Turing and Prigogine had by then become names to conjure with: Chapter 15.iv and viii.d.) A widely read paper on the neurobiology of smell, written with Christine Skarda, appeared as a target article for interdisciplinary peer review in *Behavioral and Brain Sciences* (Skarda and Freeman 1987). It claimed that a particular scent is represented (after Hebbian learning) not by single-cell feature-detectors but by a spatial pattern of EEG-recorded activity distributed over the brain's olfactory bulb, and involving "every neuron of the bulb".

And smell was just the beginning: "We hypothesize that chaotic behavior serves as the essential ground state for the neural perceptual apparatus [in general]," and "[We see] implications of our neural model for behavioral theories [too]" (Skarda and Freeman 1987: 161). This claim received an even wider audience four years later, when it appeared in *Scientific American* (Freeman 1991).

As a young man, Freeman had avoided computer models:

> [This] was, of course, when the perceptron was in vogue and a dozen other network type of devices . . . which I looked upon as, well, interesting gadgets, but they had nothing to do with how nervous systems work. (J. A. Anderson and Rosenfeld 1998: 27–8)

Later, he did do computer modelling alongside his extensive animal experiments (Freeman 1979, 1987). But further simulation (and experiments) would be needed: "[Our claims can't be advanced] until engineers have built hardware models based on our equations and determined whether they behave the way parts of brains do" (Skarda and Freeman 1987: 170).

Many neuroscientists weren't persuaded—some, because they were still in the grip of the "obsession" with unit recording. In 1993 Freeman said:

> We've found the same dynamical patterns as in the olfactory system in the visual and auditory and somatosensory cortices. But they [other neuroscientists, such as Koch and Francis Crick] are still interpreting the process in terms of coupled single cells. They characterize it as "the binding problem"—how to get together a bunch of feature detectors. They're not thinking of the processes in terms of a dynamical systems approach. (J. A. Anderson and Rosenfeld 1998: 38)

Others were sceptical for different reasons. Chaos theory, Donald Perkel (1987) suggested, was a "fad", one in a long line of technological–mathematical metaphors for the brain (he cited under-sea cables, telegraphs and telephones, holograms, tensors, maps, non-linear networks, and computer programs) that were superficial or even misleading. Chaos theory had recently become popular. Indeed, a widely read account by a science journalist had fed the "news-stands" excitement mentioned above with respect to Linsker (Gleick 1987).

Despite his use of the word "fad", Perkel couldn't accuse Freeman of jumping on the bandwagon. For Freeman had been using chaos theory for years. But he did accuse him of being seduced by the mathematics:

> [The] beauty, versatility, and power of the mathematical approach may have led its aficionado to find areas of application in the spirit of the proverbial small boy with a hammer, who discovers an entire world in need of pounding. (Perkel 1987)

He recalled Sherrington's (1940) description of the brain as an "enchanted loom", wherein "millions of flashing shuttles weave a dissolving pattern though never an abiding one; a shifting harmony of subpatterns". This newly fashionable approach, said Perkel, *might* be the right way to describe the loom's activity. But only "more fine-grained experimental evidence and correspondingly realistic simulation studies" could show this to be so.

The target authors had already made the last point themselves (1987: 170–1). Now, in their *BBS* Reply, they countered that their theory was "no more or less metaphorical than any other use of descriptive equations properly selected" (p. 187). If it seemed promising, they said, it would continue to be used; if not, some other theoretical tool would be found. That's how science works.

For our purposes, what's interesting is that Skarda and Freeman had considered self-organization at all. But they soon had company: eventually, Freeman co-edited two special numbers of the *Journal of Consciousness Studies*, in which several authors defended comparable views (Núñez and Freeman 1999). Thanks to both dynamical systems theory and connectionism, the last quarter-century saw this topic being taken seriously in neuroscience, much as it was in theoretical biology and A-Life. Even Ashby was now respectable.

'Brain-as-program' had suffered a stunning blow (though not a knockout: see 12.ix.b). But computational neuroscience *in general* hadn't. In fact, this change couldn't have happened without it.

c. Epigenesis

The computational work described in subsections a–b rode a coach and horses through the familiar notion of 'innateness'. For it destroyed the cosy assumption that behaviour already present at birth *must* be genetically specified. (Sometimes, such behaviour is partly due to 'external-world' learning in the womb. It was known by the 1980s that newborn babies can recognize their mother's voice—and also the intonation patterns of her language: DeCasper and Fifer 1980; Mehler *et al.* 1988; Kisilevsky *et al.* 1989.)

Most people had previously thought that behaviour must be due either to genetic specification or to post-natal learning. The long-standing debate on 'innate ideas', for example, reflected this assumption (see Chapters 2.vi.a and 9.ii.c and vii.c–d). But there'd been an important exception: namely, Jean Piaget (Chapter 5.ii.c and 7.vi.g).

Piaget had argued since the 1920s that behaviour is neither purely innate nor purely environmental, but a subtle "epigenetic" interaction of the two. (He borrowed this term from the biologist Conrad Waddington: see 15.iii.b.) He'd offered psychological evidence, based on observations of babies and children. But convincing neurobiological evidence wasn't then available. Cognitive neuroscience didn't get off the ground until Piaget's old age (see Section x.b, below), and the *developmental* version blossomed only after his death.

By end-of-century, however, developmental cognitive neuroscience was an established discipline, with its own textbooks (e.g. M. H. Johnson 1993*a*, 1996). By that time, many examples of epigenesis, in brain as well as behaviour, had been discovered.

As we saw in Chapter 7.vi.g, six co-authors—including neuroscientist Mark Johnson, connectionists Jeffrey Elman and Kim Plunkett (12.viii.b–e), and Piaget's ex-colleague Annette Karmiloff-Smith—wrote a book called *Rethinking Innateness*, accordingly (Elman *et al.* 1996). This book challenged the widely held belief that cognition rests on inherited, unchangeable, 'modules'.

That view had been championed by two towering figures in the early years of cognitive science, Jerry Fodor and Chomsky (see 7.vi, 9.vii.c–d, and 16.iv.d). Meanwhile, evolutionary psychologists such as Steven Pinker and Leda Cosmides had applied Chomsky's and Fodor's ideas to many different types of behaviour, which they supposed to be innate in a strong sense (Chapters 7.vi.d–e and 8.ii.d–e). The modular, "Swiss army knife", picture of the mind/brain was rife.

Nevertheless, the evidence against 'simple' modularity was now strong—not modules, but modularization, was the key (Karmiloff-Smith 1992). Granted, something like Fodorian modules exist in the adult brain. But they weren't there at the beginning, and their specific content depends crucially on what happens during development.

Let's consider the example of face recognition, a skill possessed not only by humans but also by birds and mammals. Building on research on imprinting in chicks by Gabriel Horn (one of my anatomy supervisors for human dissection at Cambridge!), Johnson constructed a biologically plausible model of the forebrain region involved (O'Reilly and Johnson 1994). This generated a range of 'behaviours' like those observed in imprinting experiments, and provided various predictions for further experimental study.

He and Horn also did experiments on chicks (Johnson and Horn 1986, 1988). These showed that imprinting is grounded in two independent neural mechanisms, one subcortical and one cortical, with *no* neural connections growing between them. The first, present at birth, makes the chick turn towards stimuli—natural or artificial—patterned like certain elements of a hen's head and neck. (This mechanism is *not* strictly species-specific: it also works if the stimulus is a duck's face, or even a polecat's.) The second develops later, enabling the chick to distinguish its mother from other hens.

Soon afterwards, with the psychologist John Morton (Director of the MRC's Cognitive Development Unit in London), Johnson turned to study face recognition in young babies (M. H. Johnson and Morton 1991; Morton and Johnson 1991; Johnson 1993*b*). And "young" means young: some of the baby subjects were only half an hour old (and other researchers had even got down to 10 minutes). The method used was to record the baby's head and eye movements in tracking—or ignoring—various stimuli: faces, jumbled 'faces', and non-faces. Here also, his experiments suggested two independent neural mechanisms, with different behavioural effects and time courses.

The first is subcortical, as it is in the chick. It develops in the womb, and its function is to make the newborn baby orient to, and fixate on, facelike stimuli: two dark blobs above another blob, in the general spatial relations of eyes and mouth. 'Scrambled' or malpositioned stimuli are ignored (as they are by the chick). Moreover, any face will do: mother, puppy, teddy bear . . . Given three blobs in the relevant positions, the newborn will orient towards them.

The other mechanism is cortical. It develops two or three months after birth, 'bootstrapping' on the first. But this is a behavioural bootstrapping, not a matter of neural connectivities. The blob system does its job simply by predisposing the neonate to look towards faces. What happens after that doesn't affect it.

The newborn baby shows no preference for pictures of faces over crude facelike blob designs, and doesn't seem to notice any difference. Gradually, however, a preference for faces—and for individual faces—emerges (*sic*). Since the baby's visual attention is drawn to faces, which in ecologically normal conditions will belong to other humans (especially the mother), he/she will receive many stimuli that can be provided only by these particular experiences. As Johnson and Morton put it, the baby is born into a "species-typical environment" which leads to the construction of more complex mechanisms from the seed of the "primal components"—e.g. the blob–attention circuit.

The environmental face stimuli configure the developing cortical circuitry before it gains control over behaviour in the third month of life—after which *that* circuit disposes the infant to look at faces. (The subcortical circuit appears to 'fade' around the fifth week of life, when preferential face tracking declines sharply—M. H. Johnson and Gilmore 1996: 343.) Gradually, the baby learns to prefer human faces to teddy-bear faces, and eventually to individuate them—normally starting with recognition of the mother.

Presumably, detailed facial-feature-detectors, such as those identified in monkeys by Perrett (Section iv.d), develop as a result of this brain–environment interaction. These may even include cells specialized to recognize expressions of disgust (Richard M. Young *et al*. 1997). But if so, these work only on human, or human-like, faces.

Facial-feature-detectors are typically species-relevant, because the infant is normally surrounded by members of its own species. (This adds a new dimension to Ludwig Wittgenstein's famous remark, "If a lion could speak, we would not understand him"—see Chapter 16.ii.b.) But the developing brain can be fooled by abnormal experience. For instance, if a horned sheep is reared with sheep without horns, it doesn't develop horn-detector cells—as it does if reared naturally, with other horned sheep (Kendrick and Baldwin 1987).

If one must use the term "innate", then what's innate here is the *predisposition* to orient towards crudely facelike stimuli. "Knowledge" of faces-as-such, or of their individual features, certainly isn't innate. By contrast, there's no innate predisposition to look at telephones. To be sure, some of the feature-detectors that will later be involved in learning to recognize telephones are present at birth. They aren't "learnt by experience" (although they are later tuned by experience). But as we saw in subsection a, they aren't specified by "heredity" either.

Granted, certain aspects of brain circuitry do appear to be genetically controlled. These include the shapes of the neurones' dendritic trees; how much these trees branch; where, and to which cell classes, a neurone's axon projects to; how strong the initial connections are; and what neurotransmitters are effective (J. A. Anderson *et al.* 1990*a*: 296). So there's no question of the brain's starting out as a randomly wired system, as in Linsker's work, or von der Malsburg's. But that's a far cry from saying that observable behaviours are innate.

In short (and as we've already seen in Chapter 7.vi.g), nativism and environmentalism are equally misleading. The adult mind/brain is formed by an epigenetic interplay, on many successive (bootstrapping) levels, of brain, behaviour, and environment.

The "environment", of course, includes the *cultural* environment. This provides cognitive technologies (6.ii.c) ranging from language and writing to shipboard instruments and navy rituals (8.iii). These don't merely *aid* the mind but, to a large extent, come to *constitute* it (see A. J. Clark 2003*a*). They become internalized within the brain, so that the brains of two adults from different cultures will be more different from each other than are the brains of any two newborn babies.

Various examples of behavioural "scaffolding" have been reviewed by Horst Hendriks-Jansen (1996), within a wide-ranging critique of GOFAI cognitivism. Although neural epigenesis can't be captured by GOFAI, or even by most connectionism, it has been simulated in more 'realistic' computer models. Some of these focus on neuroscientific details such as orientation detectors, but others deal with socially significant human behaviour (A. W. Young and Burton 1999). (For a very different, non-epigenetic, model of face recognition, see Duvdevani-Bar *et al.* 1998.)

One caveat remains. Oyama's critique of the developmental sciences applied to most epigenetic theories too (1985, ch. 3). The "heart" of the theories she was rejecting is the assumption that

> form, or its modern agent, information, exists before the interactions in which it appears and must be transmitted to the organism either through the genes or by the environment. (1985: 25)

"Compromises", she said, "don't help because they don't alter this basic assumption." We should abandon the nature/nurture duality and concentrate on *how the system creates form (order, structure, information) by its own spontaneous activities*. To be sure, it's sometimes convenient to regard genes, or feature-detectors, or interneurones . . . as simply *there*. But they weren't put there by some pre-existing force, nor even by two such forces interacting. They emerged within the living system, as a result of general principles and specific biological/ecological constraints.

d. Neural selection

In the 1950s, the UCL-based anatomist J. Z. Young questioned the widespread assumption—shared from Hartley to Hebb—that learning happens by facilitating the neural pathway that's just been excited. Instead, it might happen "by reducing the effectiveness of the other" (J. Z. Young 1964: 282).

If so, then "learning occurs by elimination of the unused pathways", involving "a reduction of the initial redundancy of connexions". Like Darwinian evolution, learning produces "adaptation by random small changes and shuffling demand selection among large numbers" (p. 288). But it's less random, being guided by "rapid and precise feedbacks [providing] precise information about the results of each action".

The "mechanism" (he continued) was an enigma, calling for "inquiry into the fundamental nature of the information-gathering circuits and the types of models [in Craik's sense] that they produce" (p. 298). The functional aspects, he said, had been illuminated by the learning machine built by his UCL colleague Wilfred Taylor (Chapter 12.i.d). But the molecules were a mystery.

Over the next thirty years, this idea was taken up in a number of fields. By the late 1980s, neurochemists had clarified the mechanism, in terms of various neurotransmitters and other molecules. Anatomists had shown that synapses continue to proliferate immediately after birth, but soon become fewer—sometimes, they're reduced to under 50 per cent.

Psychological experiments in the 1960s had implied that this pruning results from non-use (e.g. C. Blakemore and Cooper 1970). It was later confirmed that if brain circuitry is deprived of its normal input it will degenerate and/or be taken over for some other function. So, for instance, auditory cortex may develop systematically structured *visual*-feature-detectors (Sur *et al.* 1988, 1990). And (as remarked in Chapter 7.vi.i) the auditory cortex of congenitally deaf children becomes organized so as to compute visual input for linguistic purposes. (Much the same thing happens in A-Life evolutionary robots, where unused neural 'whisker drivers' can get taken over for visual purposes: Chapter 16.vi.c.)

Several neuroscientists integrated these results by explaining the brain's plasticity in terms of "neural selection". Foremost among them were Jean-Pierre Changeux (1936–), of the Institut Pasteur and Collège de France, and Gerald Edelman (1929–), initially at Rockefeller University, then UC San Diego.

Changeux did pioneering work on the molecular mechanism of neural selection (Changeux *et al.* 1973; Changeux and Danchin 1976), and later discussed the development of various neuropsychological "levels", including language (Changeux 1980, 1985; Changeux and Dehaene 1989). Edelman was interested in the synaptic chemistry too, but his main goal was to explain cognition—and consciousness (G. M. Edelman 1978, 1987, 1989; Edelman and Tononi 2000). Already a Nobel prizewinner (in 1972) for his work in immunology, his neuroscience attracted great interest—and withering criticism too, as we'll see.

Neither man shared McCulloch's 'informational' worry about genetic coding: Changeux, for instance, said it was only an "*apparent* paradox" (Changeux and Dehaene 1989). His reason was the huge number of *combinations* of sets of genes: "On strictly theoretical grounds, no opposition thus exists to a full genetic coding of brain organization" (Changeux *et al.* 1984: 125). Nevertheless, neither believed in a pre-set genetic coding of specific connectivities. *Selection*, not *instruction*, was the name of the game. A profusion of connectivities is initially available, only some of which will be stabilized during development or learning.

Young hadn't been able to outline a plausible mechanism. Now, advances in immunology offered a powerful analogy. Edelman himself had shown that all possible antibodies are potentially present at birth, but that only those which match—as he put it, "recognize"—the antigens happening to invade the body are "selected" for clonal reproduction (G. M. Edelman 1992: 74–8).

Applying these ideas to the brain: the hugely diverse "pre-representations" (Changeux's term), or items in the "primary repertoire" (Edelman's), are selectively stabilized or destroyed/damped down by the specific input. And as in Grossberg's ART, this happens by some sort of resonance, or reverberation, between percept and pre-representation. Feedback (for Edelman: "re-entrant connections", influenced by "values" which modulate the Hebbian rule being used) leads to the loss of unused connections and the strengthening of the others. Moreover, Hebb would be happy: besides single connections, *groups* of co-acting neurones (particularly stressed by Edelman) are formed. These are organized in systematic ways—often, as topographical maps.

What's of special interest here is what these neuroscientists said about computational views of the mind/brain. Both rejected functionalism, classical cognitive science, and mainstream connectionism. Yet Changeux looked forward to more realistic connectionist models, and Edelman produced some of the most complex neurocognitive models so far.

Changeux located his work in a long philosophical tradition (epigenetic theory: Chapter 7.vi.g–i), and related it to recent philosophy of mind and cognitive science (Changeux *et al.* 1973; Changeux 1985, ch. 7). Like Piaget, he believed that one can't understand adult cognition unless one understands how it developed. So he had no time for GOFAI, nor for most connectionism, because—in both cases—the instructions/structure are provided 'externally' by the modeller.

Moreover, he rejected the dogma of orthodox cognitive science: multiple realizability (Chapter 16.iii and iv.c–d). For Changeux, the molecular mechanisms at the synapse put functional constraints on development at higher levels, so even cognitive psychologists shouldn't ignore them (Changeux and Dehaene 1989; cf. M. H. Johnson and Karmiloff-Smith 1992).

He explicitly dismissed Fodor's vision of psychology as a theoretically autonomous "special science" (Chapter 16.iv.c), and rebutted Philip Johnson-Laird's assertion that "the physical nature [of the brain] places no constraints on the pattern of thought . . . any future themes of the mind [being] completely expressible within computational terms" (Changeux and Dehaene 1989: 63). His aim, by contrast, was "to *reconstruct* (rather than reduce) a function from (rather than to) its neural components"—and to do this by recognizing the brain's inherent powers of organization.

If most of the then current cognitive science was on the wrong track, Changeux said, suitably realistic computer systems wouldn't be. Connectionist models of highly evolved functions, such as NetTalk or the past-tense learner (Chapter 12.vi.e–f), were "far too simple and even naive compared to what the human brain actually uses for . . . multimodal performances with deep cultural impregnation" (Changeux and Dehaene 1989: 99). Instead, we needed "brain-style computers based on the actual architectural principles of the human brain and possessing some of its authentic [self-organizing] competences rather than simply mimicking some of its surface performances". Hopfield's cooperative networks (12.v.f) were interesting, he allowed, but didn't include selection; von der Malsburg's work was more biologically oriented, so more promising.

Changeux himself went some way towards producing "brain-style" simulations. Besides modelling his wetware ideas (Gouze *et al.* 1983), he implemented a selective network for learning temporal patterns, such as birdsong (Dehaene *et al.* 1987). But

Edelman tried to go much further, modelling "multimodal performances" if not "deep cultural impregnation".

From 1980 on, Edelman's team implemented a still-ongoing series of computer models called Darwin-I, Darwin-II, and so on, plus various 'spin-off' systems (Reeke *et al.* 1990; Krichmar and Edelman 2002). These models focused on perceptual categorization, and on the integration of perception and action. Some included neuronal group selection and/or re-entrant circuitry, but others didn't. Similarly, some had "values" modulating the Hebbian rules, while others didn't. And whereas some were 'pure' simulations, others were robots (the NOMADs: Neurally Organized Multiply/Mobile Adaptive Devices).

Darwin-I, in 1981, was a pure simulation, and focused on pattern categorization. Darwin-III, nine years later, simulated the development of sensori-motor coordination in reaching behaviour (Edelman and Reeke 1990: 47–61). The first incarnation of NOMAD—alias Darwin-IV—appeared in 1992, and added visual tracking, conditioning, and pattern categorization (G. M. Edelman 1992: 91 ff., 192–3). Darwin-VII was completed by 2002, and by mid-2004 Darwin-IX was well under way, adding artificial whiskers (simulating rat neurology) which can both learn and discriminate different textures. (As this book goes to press, the most recent published account describes Darwin-X; this uses a simulated hippocampus to aid navigation and spatial exploration: Krichmar *et al.* 2005.)

Even the relatively early models drew heavily on neuroscientific data. For instance, one simulated the innervation of the back and palm of a monkey's hand, and the way in which their different tactile 'experiences' lead to the formation of differently organized groups of receptive cells (cortical maps) in the monkey's brain (Pearson *et al.* 1987).

The most recent systems are comparable to Grossberg's in size and complexity—and run similar risks of opacity. As some fellow neuroscientists have said:

> One reason that many feel uncomfortable with learning by selection is that it makes a proclaimed virtue of complexity and imprecision. There is no sense at all of elegance, proportion, and abstract beauties of simple systems, well understood. Therefore the whole modeling approach sometimes seems slightly mystical. It is difficult to see what is actually going on in the simulations, that is, to see what the mechanisms assumed are doing to the behavior of the network. However, there is no requirement that nature is necessarily easy to understand. (J. A. Anderson *et al.* 1990*a*: 299)

To put the point in another way, it is as though we can get only so far by using what Marr called Type-I theories (Chapter 7.iii.b). The post-selection model itself is, to a large extent, a Type-II theory.

The current NOMAD (as I write), alias Darwin-VII, which isn't 'evolutionary', has about 20,000 units and 450,000 synapses, and models eighteen cortical and subcortical brain regions (Krichmar and Edelman 2002: 819). It attempts the "multimodal processing" requested by Changeux, for it integrates visual and auditory signals in categorizing the objects in its environment. The team is planning to add tactile whiskers, and probably a 'hippocampus' too (A. Seth, personal communication, June 2004; see Krichmar *et al.* 2005). Other plans are afoot to add re-entrant connections *between* neural regions, as well as within them; to explore the spiking dynamics of *individual* neurones, instead of merely averaging over small groups; and—for practical, not theoretical, purposes—to construct *hybrid* systems in which a NOMAD is linked to a conventional digital computer (Krichmar and Edelman 2002: 827).

The NOMAD of 2002 has a gripper that picks up visually distinguishable cubes and "tastes" their electrical conductivity. It "values" high conductivity, so can be conditioned to pick up striped cubes and avoid spotted ones (only the striped cubes have high conductivity); and it shows higher-order learning, by chaining conditioned stimuli. This NOMAD-ic creature learns to integrate auditory and visual signals in locating the cubes, since the striped cubes emit high tones and the spotted cubes low ones. It has horizontal- and vertical-feature-detectors, which influence categorization differently according to the temporal order of its 'experience'.

I just said that the NOMADs were robots. But Edelman didn't say that. For him, they were "noetic" (perceptual) devices, quite "unlike" the more familiar cybernetic and robotic artefacts (1992: 192). His caption of a diagram showing what is clearly a wheeled robot was this:

> While NOMAD looks like a robot, it does not operate like a robot under the strict control of a program. It operates like a noetic device, one that is neurally organized and works according to selectionist principles. (1992: 193)

The implication was that anything properly termed a robot is a GOFAI system of the sort described in Chapter 10.iii.c. He simply ignored the fact that some robots were already being based on very different principles, from Arbib's *Rana computatrix* to evolved robot cockroaches and fish (see Chapter 15.vi.c, vii, and viii.a).

Similarly, he repeatedly denied that his computer models were "computational", or even "connectionist". Darwin-VII, for instance, was said to promise "the development of intelligent machines that follow neurobiological rather than computational principles in their construction" (Krichmar and Edelman 2002: 818).

His models were presented as being based on new principles, originated by him. For instance, when he reported the model of cortical maps of the hand (Pearson *et al.* 1987), his contemporaries—his potential rivals—were ignored. Von der Malsburg wasn't mentioned, and nor were Grossberg, Arbib, Longuet-Higgins, Kohonen, or any other brain-modeller (although one survey was cited: Meinhardt 1982). The great Turing was acknowledged, for his work on morphology (Chapter 15.iv); and so was the luminary Hebb. All the other references were to experimental data from neuroscience (plus one to a computer model of crystallography by one of Edelman's colleagues).

Yet, in the judgement of three neuroscientific experts, "It is likely that the assumptions made in [Edelman's] complex models contain the essential core analyzed by Amari and by Willshaw and von der Malsburg" (J. A. Anderson *et al.* 1990*a*: 125). In short, whereas Changeux made a point of locating his own ideas in their intellectual context (both scientific and philosophical), Edelman didn't. When he mentioned that context at all it was usually to contrast, or even to scorn, not to give credit. As Daniel Dennett put it, "he seems to have a low opinion of everyone else in cognitive science" (1993*a*: 285).

This insistence on his own heroic creativity (Chapter 1.iii.e) is part of the reason why Edelman was criticized with such acerbity. For instance, Barlow's review of *Neural Darwinism* opened by noting that Darwinian theories were "much in the air these days", and had been used to good effect in neuroscience (he cited Changeux's work on birdsong). After this coded snub, the review went into high gear. Edelman's version of these by now familiar ideas was described as obscure, incomplete, one-sided, and mistaken on crucial facts—and his suggested selection process "would probably wreck the function of the whole brain". The piece ended with a gentlemanly caveat carrying a vicious sting in its tail:

> But epoch-making books are often panned unfairly by bigoted reviewers, so readers are strongly urged to study "this magisterial work" (as the publisher's blurb calls it) and decide for themselves whether it ushers in a new era in neuroscience, or whether it's just a hopeless muddle. (Barlow 1988)

Other stings were in store. Crick (1989*b*) soon complained that the theory should be called "Neural Edelmanism", since it bore no significant resemblance to Darwin's theory—and nor could he see any real benefit in applying evolutionary theory to self-organization in the brain. These were clashes of Titans: two great names infuriated by another. (Edelman cited both reviews in a popular book, crying "Vive le sport!": 1992: 94–7, 257.) But other people, too, were offended by Edelman's self-serving style. For instance, Dennett—having already complained of Edelman's "low opinion of everyone else" (see above)—tartly remarked that his work "would be a nicer try if he didn't present it as if it were such a saltation in the wilderness" (Dennett 1995*a*: 397 n.).

Edelman's self-congratulatory rhetoric reached its zenith in his trade books (1989, 1992), whose core messages were that he'd pretty well solved the problem of consciousness, and that "The brain is not a computer." Only members of his own trade unions, biochemists and neuroscientists, were allowed any authority or credited with any common sense. He recycled familiar criticisms of classical cognitive science and early connectionism—so ungenerously, that several readers of my acquaintance were led to defend positions they'd rejected long before.

In particular, he belittled the philosophers at length and en masse (1992, ch. 15). And he quoted an anonymous university president thus:

> Why is it that you physicists always require so much expensive equipment? Now, the Department of Mathematics requires nothing but money for paper, pencils, and waste paper baskets, and the Department of Philosophy is better still. It doesn't even ask for waste paper baskets. (G. M. Edelman 1992: 159)

Just good knockabout stuff? We all like a good fight. (And the story about the university president is genuinely funny.) Remember "Vive le sport!", and forget that Wittgenstein, for instance, consigned his entire previous œuvre to the waste-paper basket. If Chomsky could famously get away with mocking his opponents (9.vii.b), why reproach Edelman?

The short answer is that whereas Chomsky's mockery was an amusing frill tacked onto a careful argument, Edelman's was riddled with unexamined assumptions, misattributions, and crude misjudgements of the views he was ridiculing. For instance, when triumphantly noting (1992: 263; see also Edelman and Reeke 1990: 68) that Hilary Putnam had abandoned his own baby, functionalism, he failed to mention—even failed to realize?—that *in the very same book* Putnam had also given up on realism (see Chapter 16.vi).

The long answer is given in the discussion of consciousness below (Sections x–xi) and in Chapter 16 throughout. We'll see that Edelman's brisk adoption of three basic assumptions—realism, evolution of mind, and naturalism—was too easy (1992, chs. 12, 15). Certainly, these are accepted by virtually all neuroscientists (though not Maturana), and by most cognitive scientists too—myself included. But they're problematic nonetheless. Adopting them without argument, or dismissing opposing positions as mere "cotton candy" (as Edward Feigenbaum does: Chapter 11.ii.f), isn't good enough.

e. Grandmother cells

"It is with a sense of proud shame that I accept fathership of the 'grandmother' cell"—so wrote Lettvin (1991), recounting a bizarre story he'd made up in 1969 for an undergraduate lecture. Too complicated to summarize here, it featured an imaginary Russian neurosurgeon and the mother-obsessed Mr Portnoy of Philip Roth's just-published novel *Portnoy's Complaint*. It also featured imaginary cells (not just one, but "18,000") in Portnoy's brain which fired whenever he thought of his mother, and others which fired in respect only of his grandmother.

His terminology had caught on so quickly that Barlow used it a few years later without even bothering to define it (Barlow 1972). Later, however, he did define it: talk of grandmother cells describes

> the notion that there are cells in the brain that become active when and only when a grandmother, or some other arbitrary but specific feature, is present to the senses. (Barlow 1995: 421)

The idea was already familiar when Lettvin gave his lecture, if the memorable terminology wasn't. (Konorski, as we've seen, had called them "gnostic" units—although Lettvin hadn't heard of Konorski's work at the time—C. G. Gross 2002: 84.) And its popularity has waxed and waned over the years.

In the 1920s, Lashley argued that "It is very doubtful that the same neurons or synapses are involved even in two similar reactions for the same stimulus", and that his experimental results (on maze learning in rats) were "incompatible with . . . any theories which assume that particular neural integrations are dependent upon definite anatomical paths specialized for them" (Lashley 1929*a*: 3). Twenty years later, Hebb (1949) muddied the water by positing specific "cell assemblies" *as well as* broadly ranging "phase sequences" (Chapter 5.iv.c). But Lashley reiterated his earlier opinion:

> All of the cells of the brain are constantly active and are participating, by a sort of algebraic summation, in every activity. There are no special cells reserved for special memories. (Lashley 1950: 477)

Pitts and McCulloch (1947) didn't go quite that far. Indeed, even Lashley had admitted some specialization in the visual system: "[Equipotentiality] probably holds only for the association areas and for functions more complex than simple sensory or motor coordination" (1929*a*: 25). But they did contrast their mosaic theory with the "specialized neuron" earlier posited by "the school of Hughlings Jackson" (see Section iii.a).

Yet only ten years later, they helped describe the frog's bug-detectors. And a plethora of increasingly exotic feature-detectors soon followed, as we've seen (iv.b). By 1970, the grandmothers were flourishing: it was widely believed that there may be cells which respond to faces, perhaps even cells which respond to one's grandmother. (Not just one, but many: remember Lettvin's "18,000".)

They were flourishing in the computer labs, too. Many modellers in the 1950s–1970s thought in terms of computerized grandmother cells, and Uhr and Vossler compared their version of Pandemonium to the cells newly described by Hubel and Wiesel (Section iv). Those GOFAI programs were connectionist in spirit, as we've seen (12.ii.d). But they were localist in nature (one unit, one concept), as most early neural network models were.

However, the numbers didn't add up. Lettvin's original story had envisaged 18,000 grandmother cells per grandmother. Yet Mayhew's remark at the opening of this chapter implies there may be only one. Of course, he was speaking informally—but the point stands. The 'Frog's Eye' findings (about the numbers of retinal bug-detectors per bug, and the four correlated sheets of collicular cells) clearly didn't imply *just one* brain cell per bug. However, most neuroscientists who believed in grandmother cells didn't think there were thousands of them, even if there were more than one. But it was soon pointed out—in 1968 (see Page 2000: 445)—that there wouldn't be room in the brain for even *one* neurone devoted to *every* arbitrary combination of features, such as a yellow Volkswagen (C. S. Harris 1980) or a purple Rolls-Royce.

This point was trumpeted to neuroscientists in 1972 (see below), but didn't spread to AI modellers until later. James Anderson remembers "one of the high points" of the first connectionist conference (in 1979) as

> Jerry Feldman [an AI pioneer of localist networks] standing up in front of the group and computing how many cells you'd need to have enough grandmother cells to do vision. The numbers became astronomical extremely quickly. He realized he might have to rethink the problem. (J. A. Anderson and Rosenfeld 1998: 371)

Feldman wasn't the only one. The impossible numbers helped buttress the notion of distributed representation, in which each unit contributes to *many* representations—and, in the ideal case, *every* unit contributes to each representation. That too was an old idea, which went to ground in the late 1960s but later hit the headlines (see Chapter 12). Its sudden popularity seemed to ring the grandmother cells' death-knell: drowned by the 'D' in PDP.

A less extreme version (describing 'sparse' distributed representation) had appeared in 1972, in a paper Barlow wrote for the first volume of *Perception*, newly founded by his long-time colleague Gregory. Although hugely influential, its effect was less to promote interest in distributed representation than to feed the "virtual obsession with unit recording" about which Freeman would complain later. It drew heavily on recent experimental data (feature-detectors, for example), but was primarily devoted to abstract arguments about computational efficiency—Barlow's main concern ever since his Ratio Club days.

His revolutionary paper laid down five "dogmas" for perceptual neuroscience. The first was that theories should be couched at the level of individual cells, not "globalist" EEG potentials or holographic memories (Barlow 1972, sect. 6.1). Despite Lashley's (1950) evidence for mass action (as he'd put it: "every instance of recall requires the activity of literally millions of neurons"), experimenters should concentrate on single cells, rather than averaging over many.

The "unreliability" inferred from recent work on stochastic activity in the nervous system (Chapter 2.viii.f) had been overestimated. Although there is some intrinsic noise, its level is "extraordinarily low":

> Individual nerve cells were formerly thought to be unreliable, idiosyncratic, and incapable of performing complex tasks without acting in concert and thus overcoming their individual errors. This was quite wrong, and we now realise their apparently erratic behaviour was caused by our ignorance, not the neuron's incompetence. (Barlow 1972, sect. 3.5)

A single neurone, he argued, could code a complex reality (compute a complex decision). But there was a hierarchy here: "at the higher levels, fewer and fewer cells are active, but each represents a more and more specific happening in the sensory environment" (sect. 8). The entire visual scene may be represented by as few as 1,000 neurones. Each of these codes, or corresponds to, "a pattern of external events of the order of complexity of the events symbolized by a word" (he recalled the adage that "A picture is worth a thousand words"—p. 371 and sect. 8.3).

Nevertheless, Barlow spurned grandmother cells. He called them "pontifical cells", a term borrowed from Sherrington (1940), who in turn had taken it from William James. James had spoken of "one central or pontifical [cell] to which our consciousness is attached," in which the physical activities of all other brain cells are "combined" (1890: 179). In his Gifford Lectures,

> [Sherrington] introduced the notion of "one ultimate pontifical nerve-cell . . . the climax of the whole system of integration" and immediately rejected the idea in favour of the concept of mind as a "million-fold democracy whose each unit is a cell". (Barlow 1972, sect. 12.4)

(The imagery is telling: it's no accident that a book published in England in 1940 should show an unargued preference for "democracy".) Barlow's rejection of pontifical cells was more carefully reasoned.

He allowed that people who see perception as "a cooperative or emergent activity of many cells" would question his first dogma, saying that "carried to its logical conclusion" it implies there must be a single brain cell corresponding to "each and every recognizable object or scene". And he agreed that this is implausible. That was partly because (as noted above) there aren't enough cells, and partly because a single cell's activity couldn't convey the "richness" of any given perception:

> The "grandmother cell" might respond to all views of grandmother's face, but how would that indicate that it shares features in common with other human faces, and that, on a particular occasion, it occurs in a specific position surrounded by other recognizable objects? (Barlow 1972, sect. 12.4)

Instead, we must posit many "cardinal cells", of whom only a few speak at once: "each makes a complicated statement, but not, of course, as complicated as that of the pontiff if he were to express the whole of perception in one utterance". (Remember the intermediate-level demons in Pandemonium.)

But the neuronal hierarchy is very different from the Catholic Church, since the cardinals outnumber the worshippers in the pews. In other words, there are more cortical neurones capable of being influenced by vision than there are receptors in the retina. Far from there being a *single* cell that recognizes one's grandmother, "the college of these cardinals . . . must include a substantial fraction of the 10^{10} cells of the human brain".

In short, Barlow was recommending 'sparse' distributed representations, in which *only some* of the system's units are active. This was consistent with his second dogma: "The sensory system is organized to achieve as complete a representation of the sensory stimulus as possible with the *minimum number* of active neurons" (italics added).

The paper closed with a frank admission, a telling comparison, and a tacit obeisance to Craik:

> But clever neurons are not enough. The simplest computer program with its recursive routines and branch points has more subtlety than the simple hierarchy of clever neurons that I have here proposed as the substrate of perception.
>
> I think one can actually point to the main element that is lacking. [What is needed is] a corresponding model . . . for our own motor actions and their consequences. Such motor and sensory models could then interact and play exploratory games with each other, providing an internal model for the attempts of our ever-inquisitive perceptions to grasp the world around us. A higher-level language than that of neuronal firing might be required to describe and conceptualize such games, but its elements would have to be reducible to, or constructible from, the interactions of neurons.

Even tensor geometry and dynamical approaches, then, wouldn't undermine Barlow's first dogma—for they study systems composed, at base, of individual units.

Although experimental neuroscientists read Barlow's paper avidly, computer modellers—especially those from an engineering background—didn't. As we saw in Chapter 12.v–vii, a variety of people in the 1970s worked on 'whole-network' distributed representations—including PDP, which grabbed the spotlight in the 1980s. Barlow's sparse theory was sidelined, and grandmother cells apparently forgotten.

But could that really be right? After all, those feature-detectors *had* been found in visual cortex. Perhaps the most basic sensory features had cells all to themselves, while more complex and/or ecologically arbitrary patterns didn't? (Lettvin's story had actually started by imagining the discovery of *mother* cells, which are biologically plausible in a way that grandmother cells—and "yellow Volkswagen cells"—are not.)

The PDP group themselves, when talking about *the brain*, had steered a mid-course between Lashley and Lettvin:

> Clearly, there is specificity. Cells do not respond to all conceivable stimuli or even a small subset of them but are quite specific in their responses. At the same time they are not, in our opinion, so specific as to be what Barlow's dogmas would lead one to expect . . .
>
> We suggest that truth lies somewhere in the middle of the two extreme views and that there is a moderate amount of distribution in the cortex, so that any single cell responds to many things but nowhere near all things. [Both experiments and informational considerations point to] a considerable range of specificities from quite specific to quite broad. (Hinton and Anderson 1981: 43–4)

Geoffrey Hinton (1981) had even proved that features are most efficiently coded by a few very coarsely tuned units, not a multitude of finely tuned ones (12.iv.h). In short, the brain isn't a fully distributed system (as their computer models were)—but it doesn't contain 'pure' grandmother cells either. (Anderson still holds that "single-unit responses report only the dimmest shadows of the real mechanisms of neural computation"—J. A. Anderson and Rosenfeld 1998: 262.)

At the millennium, grandmother made her comeback. *Behavioral and Brain Sciences* published a spirited "localist manifesto", plus thirty-eight pages of peer commentary and response (Page 2000). Mike Page (at Cambridge's Cognition and Brain Sciences Unit) complained that localist representations "have acquired a bad reputation in some quarters" largely because "PDP/distributed" and "localist" had come to be seen as mutually exclusive. As he used the terms, however, "Localist models are characterized by the presence of localist representations rather than the absence of distributed representations" (2000: 443). (Compare Minsky's K-line theory, which combined single-unit significance and distributed processing: 12.iii.d.)

Localism in that sense, Page argued, is more biologically plausible than pure localism—and pure PDP, too. Various tasks—including symbolic modelling and memory for serial order—are tractable only for a localist system, so that "in the domain of psychological modelling, localist modelling is to be preferred". And he offered mathematical arguments showing why, given our psychological abilities, neuroscientists should *expect* to find both grandmother cells and distributed cell assemblies.

One of the many peer reviewers was Barlow himself, who declared:

> Almost all representations have both distributed and localist aspects, depending upon what properties of the data are being considered. With noisy data, features represented in a localist way can be detected very efficiently, and in binary representations they can be counted more efficiently than those represented in a distributed way. Brains operate in noisy environments, so the localist representation of behaviourally important events is advantageous, and fits what has been found experimentally. Distributed representations require more neurons to perform as efficiently, but they do have greater versatility. (Barlow and Gardner-Medwin 2000: 467)

Barlow was now having second thoughts about just how sparse a sparse representation should be (Barlow 2001*a*,*b*; Gardner-Medwin and Barlow 2001). He'd originally emphasized *economy* in neural coding, having "eagerly stepped on the boat" of Shannon's and Fred Attneave's (1954, 1959) studies of redundancy. This approach was popular for a while, but then "information theory dropped out of the limelight in neuroscience" until a reawakening in the 1980s. His new, or newly revived, "take-home message for the neuroscientist" was "Think probabilities" (Barlow 2001*b*)—see Section iii.b, above.

He now argued (against Shannon and Attneave) that coding should convert the hidden redundancy into an explicit, immediately recognizable, form rather than reducing or eliminating it. Fast behavioural response needs cortical representations with minimum overlap (i.e. very few elements activated by both inputs) when two inputs need to be distinguished, but not when they don't—in learning to respond similarly to both, for instance. So the second dogma bit the dust:

> Economy in the number of neurons used for the representation of sensory information is a bad idea, and the reverse is what actually seems to happen. On the other hand economy in the number of *active* neurons would make redundancy explicit rather than hidden, and would make each impulse represent an important, informative, event. (2001*b*, sect. 4)

Thinking probabilities, he said, can help us to understand *why* representations in the cortex "appear to use extravagant numbers of cells" (Gardner-Medwin and Barlow 2001: 477). In other words, we should drop the assumption that the more patterns a memory can hold, the better (see 12.v.c).

The truth about grandmother cells, whatever it turns out to be, will help decide which 'brainlike' models we favour. But it can't undermine computationalism as such. Much of the argument has concerned the computational power of different information-processing systems, and both 'unit-based' and distributed models have been implemented. Computational neuroscience can love its grandmothers or leave them.

f. Modelling modulation

For the first half-century of brain modelling, the general assumption was that a neurone can affect only those others which are connected to it, either directly or indirectly. To be sure, chemicals were involved: neurotransmitters at the synapse enabled one neurone to excite or inhibit the next. But these were thought of as mechanistic nuts and bolts, theoretically invisible at the functional (psychological) level. At that level, it was thought, linkage is all.

Or almost all: neural excitability *in general* might be affected—in changes of mood, for instance—by hormones diffusing throughout the brain. (As Norbert Wiener had put it, hormonal influences were messages "to whom it may concern"—Dupuy 2000: 116; Wiener 1948: 129–30.) Indeed, this fact led to complaints that AI can't model moods or emotions, because it can't model diffuse hormonal influences (Haugeland 1978: see Chapter 7.i.d). But *specific* neuronal functions—feature-detectors, for instance—were thought to depend on connections, not chemicals.

The first nail in this assumptive coffin was driven by the discovery of neuromodulators in the 1970s–1980s. These substances can temporarily alter a neurone's properties: in effect, they substitute one broadly Hebbian rule for another. They inspired various computer models (Fellous and Linster 1998). But, like neurotransmitters, they were thought to function only *locally*. All the then known neuromodulators were large organic molecules. Because they can diffuse only slowly inside the cell, and can't pass through cell membranes, they're stored and released near the synapse and can act only at the synapse itself. And "synapse", after all, is just Sherrington's word for "connection".

Around 1990, however, it was found that at least one neuromodulator is a very small inorganic molecule: nitric oxide, or NO (Garthwaite *et al.* 1988; Holscher 1997; O'Shea *et al.* 1998). This is generated, given the right enzymatic trigger, by (the whole cell body of) specialized neurones. But because it's so readily diffusible, even across cell membranes, NO can't be localized (or stored: it has to be synthesized 'on the spot', when needed).

It diffuses in all directions, and its effects—which depend on the concentration at the point concerned—endure until it decays. (The rate of decay can be varied by enzymes.) Consequently, NO works on all the cells within a given volume of cortex, *whether they're synaptically connected or not*. The resulting functional dynamics of the system (network) are highly complex, and very different from those of 'pure' connectionist systems, for volume signalling replaces point-to-point signalling.

This finding (later repeated for carbon monoxide and hydrogen sulphide) inspired researchers at Sussex's interdisciplinary Centre for Computational Neuroscience and Robotics to design artificial networks of a radically new type, where linkage is *not* all. For instance, the size of the diffusion volume matters, and so does the shape of the source (simulated as a hollow sphere, not a point source). Some of their models were kept as close to the biological data as possible, thanks to Michael O'Shea, a leading researcher on NO in invertebrate nervous systems (Philippides *et al.* 1998, 2005*a*). Others were more abstract, defining a general class of connectionist system called a GasNet.

In GasNets, some nodes scattered across the network can release diffusible 'gases', which modulate the intrinsic properties of other nodes and connections in various ways, depending on concentration. So one and the same node behaves differently at different times. Given certain gaseous conditions, a particular node will affect another despite there being no direct synaptic link. In other words, it's the *interaction* between the gas and the electrical connectivities in the system which is crucial. And, since the gas is emitted only on certain occasions, and diffuses and decays at varying rates, this interaction is dynamically complex.

General properties of neuromodulation could be explored using these systems. Indeed, the 'Gas' could be switched off, leaving the 'Net' unmodulated. When that was done, the resulting ("NoGas") dynamics were less subtle, the sensory morphology less efficient, and evolution (using the techniques described in Chapter 15.vi.c) much slower.

A specific behaviour might involve two *unconnected* sub-nets, which 'worked together' because of the modulatory effects. For instance, a variety of oscillator circuits, with various spiking frequencies and behavioural functions, were generated when GasNets were evolved to function as controllers for autonomous robots (Husbands 1998; Husbands *et al.* 1998; T. Smith *et al.* 2002; for the GasNet group's most recent paper, see Philippides *et al.* 2005*b*).

Feature-detectors (implemented as partially *unconnected* 'networks') arose which could recognize a triangle and use it as a navigation aid. As we'll see in Chapter 15.vi.c, the Sussex A-Life group had already evolved a wholly connective network to do this. Now, they were using neuromodulation to evolve such mechanisms faster, and to make them function more efficiently. *Post hoc* dynamic analysis showed that the modulated feature-detector involved a motor-node with a 2-cycle oscillation, which stimulated gas emission from two other nodes (T. Smith *et al.* 2002, sect. 7). Without the gas, the connectivities in that particular network couldn't do the job.

Space and time, as well as connectivities, affected the behaviour of GasNets. In that sense, even the highly abstract versions were more 'realistic' than conventional connectionist systems—for the brain, too, isn't just circuitry. But they were also highly unrealistic. In current GasNets, the modelled diffusion is instantaneous, not gradual (still less, carefully timed). And there's no interaction between different 'gases', as considered by Turing in his work on embryology (Chapter 15.iv.a). In principle, however, the physics and pharmacology could be modelled much more faithfully (cf. Wood and Garthwaite 1994).

By the time you read this, there will surely be many more simulations of neuromodulation. For, having long avoided neurochemistry, 'psychological' modellers had finally woken up to it.

Arbib was an example. After years of considering only connections (see Section vii, above), he confessed in 1993:

> [Until] recently, there's been a burgeoning world of neurochemistry which I've tried to stay away from, quite distinct from the world of relatively large-scale neural networks. Now, suddenly, we're seeing that we need to tailor the learning rules. Now, if you tailor the learning rules, you have to get into the biochemistry and understand how the playing off of the different mechanisms can change the time parameters . . . I now for the first time really have an integrated view in my work which shows the need to unify the neurochemistry with the systems modelling. (J. A. Anderson and Rosenfeld 1998: 235)

Similarly, David Rumelhart abandoned the 'pure' PDP that he'd helped to popularize in the 1980s (see Chapter 12.vi). Interviewed in the same year as Arbib, he said:

> [One] of the things I've been working on lately is trying to factor neurochemistry into my models, neuromodulators and things like that, which I take to be much more important than we've realized. I have a paper on the role of neuromodulators. It's a generalization of our conventional [PDP] networks, but which have neuromodulators included. (J. A. Anderson and Rosenfeld 1998: 289)

In short, there'd been a sea change in computational neuroscience. Connections had been married to chemicals, understood not as invisible nuts and bolts but as dynamic functions within neural networks.

At the turn of the millennium, an even more exciting change was in sight, as these ideas moved from pure simulation into the 'wet' world. For instance, in January 2005 a UK team started trying to evolve non-linear computers combining both wetware (diffusing chemicals and/or cultured neurones) and silicon (initially, up to sixty-four miniature electrodes arranged in grids/circuits). If successful, these systems would be capable of reliably achieving a user-defined computation.

This highly interdisciplinary project drew on several sources. One was the Sussex work on the evolution of GasNets, another Sussex's experience in culturing neurones *in vitro*. A third source was research by the physical chemist Annette Taylor, of the University of Leeds, on the dynamical properties of diffusing chemical waves (Chapter 15.iv). And fourth and fifth, previous work by AI scientists and toxicologists at the University of the West of England in Bristol—focused respectively on non-linear computing and the biochemistry of cell culture.

The general aim was to use GA techniques to evolve networks of chemicals and/or neurones which would compute a particular logical function. For instance, when electrodes X and Y were both stimulated artificially, the resulting activity in the final-generation 'wet' network should reliably result in the firing of some other electrode, Z—thus implementing an and-gate.

During the GA evolutionary process, several factors are randomly varied. They include the nature and concentration of various chemicals (e.g. NO, dopamine, and serotonin); the location, at different nodes in the neural network, of the release of neuromodulators; and the amount/timing of growth factor provided while the cells were being cultured. (Both vertebrate and invertebrate neurones are being studied.)

It's too early (as of June 2005) to report any firm results. But you can check up on what's happened by accessing the team's web site (<http://www.informatics.sussex.ac.uk/ccnr/research.html>). Meanwhile, the hope is that this research will throw light on non-linear computation in both engineered and organic machines, as well as teaching us more about neurones, neuromodulators, reinforcement learning, brain development, and medical prosthetics. ("Watch this space!", as they say.)

g. Time blindness—and glimmers of light

Rumelhart continued the conversation just quoted by mentioning the importance of *time*:

> If you are interested in dynamics, it turns out that there's a whole host of timescales involved. Different neuromodulators have different temporal properties; the neurons have different temporal properties, and learning has still others. In the nervous system, these things are all overlapping timescales, not independent ones like in physics. (J. A. Anderson and Rosenfeld 1998: 289)

The GasNet modellers, too, stressed the importance of different timescales in their systems. Indeed, they were among those 'A-Lifers' who had claimed for some years that conventional connectionism was hugely unrealistic—perhaps even biologically irrelevant—because it ignored temporal constraints on neural coding (I. Harvey 1992*b*). (As we've seen, this time blindness was found only in *conventional* connectionism; it didn't apply, for instance, to Grossberg's work.)

Timing matters not merely at the level of neural spikes, but at grosser levels too. For instance, if someone tries to learn two different movements in quick succession, they interfere; if separated by a few hours, they don't (Wolpert and Ghahramani 2000). From about 1970 on, experiments on conditioning showed repeatedly that timing (the onset and offset of the conditioned and unconditioned stimulus) was crucial.

Accordingly, some neuropsychologists even claimed that *associationism itself* was unrealistic, largely because of its 'timelessness'. Charles (Randy) Gallistel, a psychophysicist at UCLA, went so far as to call the associative bond "the phlogiston of psychology" (1997: 85). He not only claimed that *some* learning (e.g. gauging one's position by dead-reckoning, which many insects can do, or learning the centre of rotation of the night sky) isn't associative. He even insisted that "the process of association formation—as traditionally understood—is not involved in *any* form of learning that has been experimentally investigated, including classical and instrumental conditioning" (1997: 81; italics added).

Gallistel linked this claim with a commitment to Chomskyan modules (see Chapters 7.vi.d–e and 16.c–d). In his words: "A bird's gotta learn what a bird's gotta learn, and ditto [as regards language] for humans" (1997: 88). So, bearing in mind the findings of CNE (Chapter 15.vii), he said:

> [There] is no unitary learning process at the computational level of analysis. There are many different learning mechanisms or modules . . . different problem-specific learning mechanisms [which we may call] "instincts to learn". Each such mechanism has a structure that enables it to compute certain facts about the world. This specialization of computational structure renders the mechanism hopelessly ill-suited for computing other facts about the world. For that, one needs other mechanisms, with a different computational structure. (1997: 82)

So, much as GOFAI had moved from general-purpose mechanisms to expert knowledge (Chapter 10.iv), neuroscience should do so too:

> Despite long-standing and deeply entrenched views to the contrary, the brain can no longer be viewed as an amorphous plastic tissue that acquires its distinctive competencies from the environment acting on general-purpose cellular-level learning mechanisms. Cognitive neuroscientists, as they trace out the functional circuitry of the brain, should be prepared to identify adaptive specializations as the most likely functional units they will find. *At the circuit level*, special-purpose circuitry is to be expected everywhere in the brain, just as it is now routinely expected in the analysis of sensory and motor function. (Gallistel 1995: 1266; italics added)

He did allow that generality at the *cellular* level is "possible". All specialist learning mechanisms may employ the same set of elementary computational operations. But they may not: "At a time when we cannot specify the instruction set underlying any computation of any substantial complexity, we are in no position to say whether different complex computations use the same elementary computational operations" (1997: 83).

Even classical conditioning, which links *arbitrary* stimulus–response pairs, can't be explained by associationism. For Hebbian rules can't handle the "fascinating" results found in the last quarter-century, the "golden age" of experimental conditioning:

> [It appears that *all*] learning involves computing and storing the values of variables. In the case of conditioning, the crucial remembered variables are *the temporal intervals between events* [CS and US onsets and offsets]. But this conception of conditioning is as different from the traditional associative conception as the oxygen theory is different from the phlogiston theory. If this conception prevails, then the associative bond will indeed prove to have been the phlogiston of psychology. (Gallistel 1997: 85; italics added)

In a word, associative theories should be replaced by cognitive theories (Gallistel and Gibbon 2002). These assume that "the crucial remembered variables" are represented in the animal's brain, and that representations and decision rules together determine whether, and when, a response will occur.

No golden age had been needed to persuade neuroscientists that timing was often crucial. They'd known this since before mid-century (and one of Barlow's five dogmas concerned "high impulse frequency"). However, McCulloch in the early 1940s had deliberately ignored temporal properties he knew to be important: his "temporal propositional expressions" concerned temporal sequence, not time as such. His example was followed by virtually all connectionist modellers thereafter. (Early exceptions included Joseph Licklider 1951, 1959, and Braitenberg 1961.)

A few people had remarked that time could be incorporated in principle. Marr, for example, said in the 1960s:

> There is no reason why a context dependent system should not be run at different speeds, and if the extra postulate were made of some general intensity control acting uniformly over the effector circuits, a movement learnt at one speed could be performed at another. (D. C. Marr 1969: 466)

Moreover, Marr had inferred specific hypotheses about time intervals from his formal model of the cerebellum (see Section v.c). But most computer modellers ignored time entirely. Even 'temporal' connectionism, aka recurrent networks, considered temporal order rather than measurable time.

This wasn't inevitable: there's no principled reason why time can't be taken seriously in computational work. Although von Neumann computers operate on a 'clock' of uniform time-steps, it's not difficult to simulate real time in most practical circumstances. The block that prevented this was more psychological than computational.

In the early 1990s, Inman Harvey (1992*b*) urged network modellers to stop ignoring the real-value time lags on signals passing from one node to another. And in the late 1990s, he pointed out that models of *asynchronous* networks behave very differently from their synchronous cousins (Harvey and Bossomaier 1997). Some connectionists combined recurrent networks with simple models of synchronous neural oscillations (e.g. Lane and Henderson 1998). Others took time lags into account by experimenting with 'pulsed' networks. Here, the significance of a signal is coded by its timing; for instance, two pulses separated by a particular time interval may excite a certain unit, whereas pulses separated by any other time interval may inhibit it (Maass and Bishop 1999). But these weren't intended as serious models of real brains.

There were some exceptions (all in the last quarter-century), mostly coming from the neuroscientific stable. These included Grossberg, von der Malsburg, Arbib, Freeman, Changeux, and Edelman.

For instance, Grossberg modelled real-time perceptual processes, and used codes based on the frequency of unit firing. Arbib did so too, and simulated a number of interacting rhythms and arhythmias defined at the single-cell, correlated-cell, network, and (various) brain-regional levels (Arbib *et al.* 1997, ch. 6). His model hippocampus was one of the most time-informed, as well as one of the most complex, 'brainlike' systems of the period (see Section vii.c). By the new century, enough general interest had been raised to justify a special (double) number of *Adaptive Behavior* devoted to timing issues (Di Paolo 2002*a*).

There are technical obstacles if one wants to *emulate* time. Whereas one can if necessary take months to *simulate* a millisecond, emulation—where the computer generates real-time events at real moments in time—requires "a millisecond" to mean a millisecond. Some computer operating systems don't allow the real-time precision that would be needed to emulate highly time-sensitive processes. But others can already implement robot controllers driven by spike-timing measured to a few tens of milliseconds (Di Paolo 2002*b*: 143). So even emulation isn't always impossible.

As a critique of past work, then, this arrow meets its mark. Most modellers have ignored time, even including the biologists among them. This wasn't because they knew no better. Connections are clearly important, and people were focusing on those: one can't do everything at once.

By the turn of the century, however, it was clear to everyone—not just to the neuroscientists—that if one wants to model the brain, this couldn't continue. As Sejnowski had put it in 1993, "the real problem in the next five, ten years is coming to grips with real time signals [and imperfections too]" (J. A. Anderson and Rosenberg 1998: 331). Seven years later, one of the striking features of the models described by O'Reilly and Munakata (2000) was that many displayed close attention to time. As one would expect, given the authors' commitment to biological realism, the temporal features involved were based on the spiking times of real neurones (see ii.d, above). It was time, at last, for time.

14.x. Cartesian Correlations

This section outlines some theories of consciousness developed within cognitive science. Only *some*: as we'll see, there was an explosion of work on consciousness in the last two decades of the century. This happened quite suddenly. As late as 1979, the person who first gave cognitive psychology its name (Chapter 6.v.b) declared that psychology wasn't "ready" for consciousness (Neisser 1979). And Ernest Hilgard, who'd pioneered work on attention and hypnosis (7.i.h), said in the mid-1980s that most experimental psychologists were still "hostile" to the topic (Hilgard 1977/1986: 294).

At this point, the philosophical health warning given in Chapter 2.iii.a bears repeating. References to conscious experiences, or sensations, trip easily off the tongue—even the tongue of the man on the Clapham omnibus. "And why not? What could be more familiar? We've all had more experiences than we've had hot dinners."

Well, perhaps . . . In Section xi, we'll ask whether this common-sense notion is for scientific purposes better avoided. Why? Not because questions about the brain's role in consciousness can't be definitively answered (subjectivity, and all that). But because, given the usual interpretation of *experience*, certain 'obvious' questions about mind and brain *can't even be sensibly asked*.

Meanwhile, I'll continue to use our everyday vocabulary as though it were unproblematic. This is appropriate, for nearly all neuroscientists (like the passengers on the omnibus) do so too.

a. Consciousness comes in from the cold

Ever since the seventeenth century (specifically, ever since Descartes), philosophers discussed conscious experience and its relation to events in the brain: causal? parallel? epiphenomenal? identical . . .? And in the years surrounding the rise of cognitive science, they devoted countless pages to this topic (see Chapter 16.i–vi). But neuroscientists didn't.

Admittedly, neuroscientists asked just what types of consciousness occur when the brain is affected in various ways. In the late nineteenth and early twentieth centuries, they had only clinical evidence to go on. Later (starting with the invention of the EEG: Chapter 4.vi–vii), they could do systematic experiments of various kinds. With the rise of computational ideas, they looked at consciousness in terms of the information processing going on—and the ways in which this might break down. And when brain scanning became possible, various abnormalities of consciousness—including those seen in schizophrenia, multiple personality, and hypnosis—were studied by them accordingly (see references in subsection c, below).

Moreover, they realized that there's no such thing as *the* problem of consciousness. On the contrary—and as the philosophers were pointing out at length (16.iv.a–b and ix.c)—there are many such problems. For the words 'conscious' and 'consciousness' are used to refer to various phenomena, ranging from minimal alertness, through selective attention (6.i.a–c), to self-awareness via higher-order thoughts, or HOTs (7.i.g–i) and sensory experience.

So neuroscientists in the first three-quarters of the century experimented extensively on sleep and waking, various levels of anaesthesia, attention and orientation, conscious memory-recall, and perception—normal, illusory, and subliminal. They studied the brain's role in pain, anxiety, hallucination, and depression. And they described clinical syndromes involving various types of breakdown in conscious unity, such as 'multiple personality' (Chapters 5.ii.a and 7.i.h) and hemi-neglect—in which brain-damaged patients ignore one half of their body, even attributing it to someone else.

The Montreal neurosurgeon Wilder Penfield (1891–1976), an ex-student of Sherrington, studied brain–consciousness correlations in a relatively direct way. In around 1950 he discovered, unexpectedly, that he could elicit memory-like experiences by stimulating his patients' brains during surgery for temporal lobe epilepsy. (Only memory-*like*: the normal associative penumbra, they said, was missing.) One person, for instance, reported: "I heard my mother talking on the phone, telling my aunt to come over that night," and another remembered seeing her nephew and niece in her dining-room: "they were getting ready to go home, putting on their coats and hats . . . [and] my mother was talking to them" (Penfield and Perot 1963; see also Penfield 1952; Penfield and Rasmussen 1957; Penfield 1958). But he couldn't do this systematically: the stimulations served surgery, not curiosity.

With the advent of single-cell recording, researchers occasionally came up with results that tempted interpretation in terms of conscious experience. As early as the mid-1950s, for example, it was found that cells in the cat's auditory system (the cochlear nucleus) that are responding to 'meaningless' clicks will immediately stop responding if the cat is shown a mouse, allowed to smell a fish, or shocked on its paw (Galambos *et al.* 1956). The explicit inference was that the cat's *attention* had been captured by the new stimulus. But the tacit implication was that the cat stopped *consciously hearing* the clicks when it had more important fish to fry—or anyway, to *smell*. (That's why this experiment was sometimes cited by New Look psychologists as a support for "perceptual defense": e.g. Bruner and Klein 1960—see Chapter 6.ii.a.)

However, this experiment had been designed to study conditioning, not consciousness. It was found that the auditory cells would eventually stop responding (habituate) if the clicks continued—*unless* the clicks were 'meaningful', having been used as conditioned stimuli warning the animal of an impending electric shock.

The emphasis, in the click experiment, on matters other than consciousness was typical of its time. Conditioning, and even attention, could be studied, for both could be defined in objective terms. What neuroscientists didn't do, until relatively recently, was to consider the origin of conscious experience, or sensations, as such: what philosophers called 'raw feels' or 'sense data' around mid-century, and '*qualia*' today. (Remember that health warning!) They might ask *when* conscious experience occurs, relative to events happening in the brain. After mid-century, they started to ask *what computations* were involved in its construction. But they fought shy of asking *how it's generated by the stuff inside our skulls*.

Occasionally, an acclaimed neuroscientific guru—such as Sherrington (1940) or Eccles (1953, ch. 8)—would dare to speculate on this issue. Their discussion would be self-confessedly bemused and/or embarrassingly naive from the philosophical point of view (see Chapter 16.i.a). But their colossal reputations couldn't be harmed by sniggers behind the reader's hand. Neuroscientists in a more vulnerable professional position—and psychologists, too—tended to avoid the topic entirely.

As late as 1981, John Haugeland remarked that "the term itself is almost a dirty word in the technical literature" of cognitive science (Haugeland 1981*a*: 32). Even the maverick McCulloch, when he'd declared contra Sherrington that "Mind no longer goes 'more ghostly than a ghost'" (see Chapter 4.iii.e), hadn't grasped this particular nettle firmly.

A few courageous souls tried to fling the nettle onto the bonfire. So Barlow, in his 'five dogmas' paper, declared robustly that

> Thinking is brought about by neurons, and we should not use phrases like "unit activity reflects, reveals, or monitors thought processes", because the activities of neurons, quite simply, *are* thought processes. (1972, sect. 5)

But the nettle was slippery—maybe even fireproof. A few pages later, Barlow referred to "the activity of nerve cells accompanying [the personal, subjective, aspect of my] experience", which last is "something that one must be content to leave on one side for the moment" (1972, sect. 10.1). And in the next paragraph, having granted that not all aspects of visual perception are conscious, he insisted—in defence of his fourth "dogma"—that "an element of [conscious] perception can possess a simple neural cause without it necessarily being the case that all simple neural events cause perception". He didn't stop to ask how, if X is *identical* with Y, it can also be said to *accompany* Y, or to *cause* (or *bring about*) Y. We'll pick up this fire-resistant nettle in Chapter 16.i.d.

Much as Barlow was happy to talk about "cause" in this context, so neuroscientists in general were happy to talk about "correlations". However, there were a few intriguing experiments suggesting that mind–brain correlations are much less straightforward than Descartes—and our own contemporaries—imagined.

Most of these were done by Benjamin Libet, who started work on the neuronal basis of specific experiences in humans in the early 1960s (Libet *et al.* 1964, 1967; Libet 1965). For instance, he placed electrodes on the surface of people's sensory cortex during brain surgery, and asked them what—if anything—they felt when he delivered a stimulus; and he measured the brain waves elicited when they experienced (or thought of) something. He discovered that as much as half a second of neuronal activity is required before an experience can occur, although perceptual information is registered subliminally in half that time. Apparently, then, *qualia* are *constructed* by the brain.

This was already known by experimental psychologists. For instance, Paul Kolers—at Harvard's Center for Cognitive Studies—had been working since the late 1950s on "metacontrast", in which presentation of one visual stimulus very soon after another can block or even transform conscious awareness of the first (Kolers and Rosner 1960; Kolers 1972; Kolers and Grnau 1976; Kahneman 1968). But psychologists' experiments on visual masking had nothing to say about the neural mechanisms involved (see subsection b, below).

Libet's results (and Kolers's) didn't arouse widespread interest at the time—still less, heated discussion of their implications for the philosophy of mind (but see P. S. Churchland 1981 and Libet 1981). By the end of the 1980s, however, that had changed.

Suddenly, the neural basis of experience was a hot topic for scientists, as well as for philosophers. Indeed, the two communities started interacting much more than they'd done before, and contributed jointly to many collections of papers on the various aspects of consciousness (e.g. Pope and Singer 1978; Marcel and Bisiach 1988; B. Milner and Rugg 1992; Bock and Marsh 1993; Posner and Raichle 1994).

Discussion was further boosted, for the general reader as well as the professionals, by the publication in 1991 of two best-selling books: Tor Nørretranders's *The User Illusion: Cutting Consciousness Down to Size* and—especially—Dennett's provocatively titled *Consciousness Explained*. As we'll see in Section xi.b, this solved, or rather dissolved, the problem of mind–body correlations by giving a computational/behavioural analysis of consciousness, *including qualia*. But, like Nørretranders's book too, it also leant heavily on neuroscience—including recent work by Libet and by Marcel Kinsbourne (a co-author with Dennett in 1992) that cast further doubt on the *timing* of consciousness.

A biennial interdisciplinary conference entitled 'Toward a Science of Consciousness' was instituted by the newly formed Center for Consciousness Studies in Tucson (Arizona) in 1994. It attracted huge attention, and soon prompted the formation of the Association for the Scientific Study of Consciousness. Journals such as *Cognition and Consciousness* and the *Journal of Consciousness Studies* (tellingly subtitled *Controversies in Science and the Humanities*), and various 'consciousness' email discussion groups, were founded—and flourished. Quantity didn't guarantee quality: many of the papers were weak, to put it politely. By century's end, however, there was a wide variety of more 'respectable' work, both philosophical and neuroscientific (for a taster, see Dehaene 2001).

In the new century, robotics and AI got into the act in a big way (Haikonen 2003; Torrance 2003; Chrisley *et al.* 2005*a*,*b*). Of course, people had been asking philosophical questions about robot consciousness for years—not least, as a result of Turing's 1950 paper. But now things seemingly became more serious.

Between 2001 and 2005, there was a flurry of international meetings on "machine consciousness": in Cold Spring Harbor, Skövde (Sweden), Memphis, Birmingham, Turin, Antwerp, and London. An increasing number of papers on this topic graced the pages of the *Journal of Consciousness Studies*, which then decided to devote a double-number special issue to it (O. Holland 2003). Conferences named for other topics, such as 'Adaptation in Artificial and Biological Systems', ran symposia on machine consciousness. And a dedicated web site was established (<http://www.machineconsciousness.org>).

Some of this interest was purely philosophical. But much of it was linked to practically oriented work on "robot companions" (see Chapter 13.vi.d) and/or the evolution of linguistic communication in robots (Steels 2003). AI/A-Life researchers were now receiving research grants to develop "conscious robots" (Owen Holland, personal communication). And a commercial company, Nokia, was providing funds for this goal too.

Or at least, Nokia were happy to have the project described in that way. Just what they—or anyone else—really understood by the term "machine consciousness" was obscure, and philosophically up for grabs. Often, people tried to avoid the philosophical problems by defining "machine consciousness" in a non-committal way. For instance, the Call for Papers for AISB's symposium at Bristol in 2006 defined "MC" as "the study and creation of artefacts which have mental characteristics *typically associated with* consciousness such as (self-)awareness, emotion, affect, phenomenal states, imagination, etc." (italics added).

Some researchers, such as Igor Aleksander, were even describing their laptops as conscious. However, when challenged he'd retreat into objectivity, saying that he was studying the mechanisms underlying attention, choice, discrimination, and reflexive monitoring—i.e. a large part of what we mean by consciousness, but *not* "consciousness as it is in us" (personal communication). Aleksander's (2000) five criteria of consciousness were: having a sense of place; imagination; focusing of attention; planning future actions; and being guided by emotions. Given the discussion of Chapter 7.d–f, it's clear that the last criterion didn't necessarily include "experiencing feelings of emotion". In short, whether or not people were hoping/intending to attribute *qualia* to their future robots and/or laptops was ambiguous. (As for whether this would have been a nonsensical hope, see Section xi below, and Chapter 16.v.b.)

But that sudden surge of work on machine consciousness was a very late development. Meanwhile, from the late 1980s, the public interest in *human and animal* consciousness grew. By the early 1990s it had become so widespread that the Royal Society in London organized a brief press conference—*not* an academic meeting—on 'Consciousness—Its Place in Contemporary Science' in February 1995. Various recent findings and theories were described to the visiting journalists, with some pride: these were fascinating matters. But the Royal Society's scientists rang loud warning bells:

> [The] remarkable consensus of the speakers [was] that, despite all the recent books, TV programmes and other hype, science really did not understand *anything* about consciousness—what it is, how it evolved, how it is generated by the brain, or even what it is for! (K. Sutherland 1994: 285)

We'll return to this point in subsection c. First, let's look briefly at some of the neuroscientific findings that had contributed to this intellectual feeding frenzy.

b. Cognitive neuroscience

The key contributions had come from the discipline dubbed "cognitive neuroscience" by George Miller in the late 1970s (Gazzaniga 1988: 230). He'd realized the need for this after seeing the bewildering display of cognitive deficits and dissociations suffered by Gazzaniga's clinical patients at Cornell Medical College.

To be sure, he was already aware that there were relevant questions to be asked. For instance, he—and many other cognitive psychologists in the West—knew of the pioneering work on cerebral control and aphasias done by the Russian neuropsychologist Alexander Luria. The first English translation had appeared in the 1930s, and—after a long gap—by 1970 there were several more, including Luria's first best-selling trade book *The Mind of a Mnemonist* (Luria 1932, 1960, 1966*a*,*b*, 1968, 1970; Luria and Yudovich 1959). Miller had actually cited Luria's work on language development in *Plans and the Structure of Behavior* (p. 140 n.), and his MGP co-author Pribram had written a preface to *Higher Cortical Functions in Man* (Luria 1966*a*) a few years later. But he'd never actually seen for himself the phenomena that Luria was describing.

On visiting Gazzaniga's clinic, Miller was surprised, as well as bewildered. One reason was that his previous knowledge of clinical deficits was very general. Even Luria's professionally oriented books, like the papers in the clinical journals, were descriptive rather than analytic. And in those days, clinicians and theoreticians rarely mixed (i.a above).

Psychological studies of memory, for instance, typically ignored clinical amnesias. As late as 1980, the second edition of Roberta Klatzky's (1980) widely used textbook on *human* memory said nothing about the topic (although it did give brief discussions of "mnemonists" and of the effects of alcohol and drugs: pp. 307–10, 321–5). The experimental psychologist Brenda Milner (1959) was an exception: she'd described one such case (but in psychiatric/medical journals), and her research was followed up in the 1960s by a handful of her peers. In general, however, clinical work—as William Hirst recalls—was "treated lightly" by them:

Cognitive psychologists clearly felt more comfortable writing about laboratory experiments than about experiments with brain-damaged patients and did not feel compelled to account for neuropsychological results if they contradicted their theoretical position. (Hirst 1988*b*: 250)

Miller now tried to make amends. With Gazzaniga's help, he soon founded the Cognitive Neuroscience Institute (at Rockefeller University) to focus on the theoretical issues raised by clinical syndromes, and by neuroscience in general.

He made no apologies for asking psychologists to consider the brain—which Fodor and Putnam, and most early cognitive psychologists, had declared to be unnecessary (16.iii–iv). Nor did he worry about being called a reductionist. As he wrote in a letter to Gazzaniga in 1978, psychology needed neuroscience:

Since I have always thought of scientific psychology as a branch of biology, this objection [reductionism] carries little weight with me. It would carry greater weight, however, with such distinguished scientists as [the behaviourist] B. F. Skinner or [the functionalist] H. A. Simon. (Gazzaniga 1988: 239)

Gazzaniga was equally unapologetic, but in the opposite direction:

[The] idea that *neuroscience needed cognitive science* has prevailed. I put it that way because that, after all, is what is at stake. The molecular approach in the absence of the cognitive context limited the fashionable neuroscientist to pursuing answers to biologic questions in a manner not unlike that of the kidney physiologist. Although such approaches represent an admirable enterprise, they do, when put in that light, make it impossible for the neuroscientist to attack the central integrative questions of mind–brain research. (Gazzaniga 1988: 241; italics added)

Miller was still a cognitivist, of course. But, twenty years after his manifesto and mission station (6.iv.c–d), his enthusiasm for computers and AI had waned. Writing to Fritz Machlup in January 1983, he said:

I find it difficult to communicate clearly my enormous debt to people like Simon, Newell, and Minsky for helping cognitive psychology take a great leap forward, yet at the same time to communicate with equal clarity that the human brain/mind system is enormously more complicated than, and different from, any contemporary computational system. (G. A. Miller 1983*a*: 57)

Contemporary computers manipulate symbols, and symbol manipulation is certainly one kind of intelligence. But whether that kind of intelligence is the only kind remains an open question. (p. 57)

[As] the difficulties become more and more apparent, the tendency for the computer exploration to expunge psychologism (just as logic did a century earlier [see Chapter 2.ix.b]) and move off on its own seems stronger and more attractive. That might be a good development, but it would spell the doom of cognitive science as a new discipline encompassing both artificial intelligence and psychology. (p. 58)

The newly named discipline grew quickly. Initially based in clinical neurology (e.g. Shallice 1982, 1988*a*,*b*; Weiskrantz 1986, 1988; Vallar and Shallice 1990), it soon embraced non-patients too. At first, the focus was on vision, motor control, and language. By century's end, motivation and emotion—and their intimate links with cognition—were included also (Rolls 1990; Damasio 1994, 1999, 2001; LeDoux 1996, 2002; Gazzaniga 1995, pt. IX). (So "cognitive" neuroscience, like "cognitive" science itself, is *not* limited to cognition: 1.ii.a.)

The field soon spawned its own communication channels, the *Journal of Cognitive Neuroscience* and *Neuropsychologia*. Besides, hefty review volumes started appearing in the early 1990s (Marcel 1993; Bisiach 1993; Gazzaniga 1995, 1999, 2000; M. H. Johnson 1993*a*; Squire and Kosslyn 1998; O'Reilly and Munakata 2000; Parker *et al.* 2002). In the late 1990s, the interdisciplinary study of development in normal and brain-damaged children was flying (see Chapter 7.vi.i and Section ix.c above). By the turn of the century, then, cognitive neuroscience had made its mark.

According to its name-bestower, the central goal was to understand consciousness:

> I consider consciousness to be the constitutive problem for psychology, just as life is the constitutive problem for biology . . . Psychologists want to discover the molecular logic of the conscious state. [That is to say]: the set of principles that, in addition to the principles of physics, chemistry, and biology, operate to govern the behavior of inanimate matter in conscious systems. (G. A. Miller 1978: 233)

Whether this "set of principles" includes anything over and above abstract (functional, computational) principles of brain and behaviour will be discussed in Section xi. But it's worth noting that Miller's examples here did *not* include experience (*qualia*), and that—in the same letter—he swiftly substituted first "knowledge" and then "epistemic system" for the troublesome "consciousness" (1978: 235–6).

Cognitive neuroscience didn't start with Miller, for the name was newer than the activity. Arbib's schema theory (see Section vii.c, above), Eric Lenneberg's (1967) survey of neural-anatomical specializations for language, and Libet's 1960s research had all been early exercises in the genre. Indeed, so had the late 1960s neurophysiological studies of visual masking in cats (P. H. Schiller 1968). In this and later single-cell work on visual masking (Felsten and Wasserman 1980; Keysers and Perrett 2002), the assumption was that the underlying mechanisms in cats, monkeys, and people might be broadly similar—and that the consciousness was similar too.

Miller, citing Minsky and Marr, stressed the need to pass from purely correlational (brain–behaviour) studies to theories of cerebral information processing and representation (Gazzaniga 1988: 240). Accordingly, many brain researchers now adopted the computational approach he'd pioneered twenty years earlier (Chapter 6.iv.c), analysing behaviour and thinking into distinct functional components.

Clinicians had long noticed that brain damage often leads to some very specific loss: trouble with producing (though not with understanding) abstract nouns, for instance, or 'blindness' to and/or neglect of one side of one's own body. Charles Darwin had remarked the puzzling case of a man who, after suffering a stroke, could tell the time by looking at a clock-face but not by reading the words. Over 100 years later, in the

1980s, some curious cases of mental dissociation—and of abnormal memory—were familiar even to the general reader, thanks to fascinating trade books written by clinical neurologists or psychologists (Luria 1968, 1972; Sacks 1985, 1989).

As for the 1980s professionals, they no longer spoke merely of aphasia, amnesia, ataxia, or apraxia (i.e. disturbances of speech, memory, movement, or action). Instead, they distinguished many different *kinds* of disability previously lumped together under these terms. For instance, they looked out for the various types of action error distinguished by Timothy Shallice and Donald Norman (Chapter 12.ix.b), or for the wide variety of memory disorders (e.g. Cermak 1982). And besides trying to match these with particular brain lesions, they tried to explain and systematize them in terms of (formal or informal) theories of the information processing going on.

Some people took these functional dissociations as proof of the existence of 'modules', inborn mechanisms specialized for the relevant types of information processing. They were wrong: modules-in-the-adult don't necessarily imply modules-in-the-developing-brain (Section ix.c–d above, and Chapter 7.vi.i). However, this wasn't widely recognized at the time—except by *developmental* neuroscientists.

By the 1980s, too, Libet's research programme had delivered some even more intriguing results. In 1979 he reported (1) that the subjective time-of-occurrence of a sensory experience was shifted backwards, so that someone might experience something *as* happening at time-of-stimulation, even though the experience itself occurred half a second later (Libet *et al.* 1979). Yet more startling, his group did work on voluntary action that showed (2) not only that 'spontaneous', 'instantaneous', conscious decisions (like sensory *qualia*) take time to be constructed, but that the relevant motor areas of the brain are *already* being activated before the decision is experienced (Libet *et al.* 1983).

The first finding cast yet more doubt on the common-sense notion of temporal 'correlations'. Prompted by a critique from the British philosopher Ted Honderich (1984), Libet (1985*a*) wrote a paper for the *Journal of Theoretical Biology* specifically relating it to "mind–brain theories" (for Honderich's response, see his 1986, 2005). Eccles—with Karl Popper—argued that the result was inexplicable by any neurophysiological process, so provided further evidence for his long-held dualism (K. R. Popper and Eccles 1977: 364).

The second finding threatened popular notions of free will. Libet was immediately invited to write a paper for *Brain and Behavior Sciences*. This attracted huge attention—and an unusually large number of peer reviews accompanying it in the journal (Libet 1985*b*). By the end of the century, the *Journal of Consciousness Studies* had published a special issue on "the neuroscience of free will" (Libet 1999). Because of the general interest in the topic, this was made available also as a stand-alone book.

Most late twentieth-century neuroscientists still concerned themselves with only one of the many problems of consciousness indicated above. But a few developed comprehensive theories interrelating them all (e.g. Baars 1988; Cotterill 1998; Velmans 1996, 2000; Weiskrantz 1997; G. M. Edelman 1989; Edelman and Tononi 2000; Damasio 1999).

These writers usually took pains to distance "the brain" from "the computer". Nevertheless, most of them used computational ideas—even if they protested (like Edelman) that they weren't doing so.

They all agreed that a huge amount of cognitive processing occurs without consciousness. This had long been known, of course. But new technologies, including brain scanning, now provided further evidence. For instance, manual responses resulting from highly complex operations (integrating perceptual, semantic, and motor processes, plus the interpretation of verbal instructions) show up in motor cortex before the person is aware of them (Dehaene *et al.* 1998*b*). Similarly, they all agreed that attention is necessary for consciousness (although 'blindsight' showed that it's not sufficient: see subsection c), and that certain—ill-specified—types of task apparently can't be achieved unconsciously.

Their theories relating the different levels or aspects of consciousness, and explaining the 'need' for consciousness in certain cases, varied. However, certain key ideas cropped up repeatedly. One of these was the concept of a general workspace, explored at length by Bernard Baars (1988, esp. ch. 2; 2001) and adopted by others too (e.g. Dennett 1991, ch. 9; Dehaene and Naccache 2001).

The core notion here was that 'higher' (including deliberative) consciousness requires a *global* mechanism—broadly comparable to a GOFAI blackboard: Chapter 10.v.e—making information from many different areas simultaneously available. Fodor (1983) had implied as much in respect of the "higher mental processes", but had despaired of explaining such non-modular effects (see Chapters 7.iii.d and 16.iv.d). However, he was interested in why *this* person arrives at *this* belief on *this* occasion. The neuroscientists, by contrast, wanted to know how conscious thought in general is possible. Stanislas Dehaene and Lionel Naccache put it like this:

> [Various recent theories suggest that] besides specialized processors, the architecture of the human brain also comprises *a distributed neural system or "workspace" with long-distance connectivity that can potentially interconnect multiple specialized brain areas in a coordinated, though variable manner* . . . Through the workspace, modular systems that do not directly exchange information in an automatic mode can nevertheless gain access to each other's content . . .
>
> If the workspace hypothesis is correct, it becomes an empirical issue to determine which modular systems make their contents globally available to others through the workspace. Computations performed by modules that are not interconnected through the workspace would never be able to participate in a conscious content, regardless of the amount of introspective effort. (Dehaene and Naccache 2001: 13)

Significantly, their term "architecture" was ambiguous: it was primarily computational, and only secondarily neural.

In short, computational ideas were guiding neuroscientific experiments on the many aspects of consciousness, and informing the interpretation of the results.

c. The $64,000 question

The $64,000 question concerned the brain's role in generating conscious experience. Among the topics most discussed by *fin de siècle* thinkers interested in this problem were experiments on alternating perceptions, perceptual binding, and blindsight.

Alternating perceptual experiences seemed to be correlated with specific processes in the brain. It was already known that if a pattern of vertical bars is continuously presented to one eye, and a pattern of horizontal bars to the other, what a human subject actually sees isn't a vertical/horizontal grid, but a regular alternation between the two (simultaneously presented) patterns. When Nikos Logothetis and Jeff Schall (1989) put a monkey in the same experimental situation, its discriminatory behaviour—raising its left or right paw—suggested that it, too, saw first the one pattern and then the other.

Moreover, a group of cells in the monkey's visual cortex was active only when its behaviour implied that it was *aware* of the vertical pattern. A different group was continuously active while the vertical pattern *was being presented as a stimulus* to the eye. The same applied in respect of the horizontal patterns. This implied that a distinct group of cortical neurones is active *only when a particular type of visual phenomenology is being experienced*.

'Binding' is an aspect of conscious unity—remarked on, for instance, by Descartes—whereby a multifaceted object is experienced as 'one' thing. How do auditory, tactile, and visual features get to be attributed to one cat, for instance? And how are the many different visual features integrated, given that each is computed in a different part of visual cortex (Zeki 1993)?

Crick (with Christof Koch) suggested that distinct perceptual features will be attributed to one and the same thing (one and the same Gestalt) if the relevant neurone groups are not only simultaneously activated but are also resonating at the same frequency—perhaps 40 Hertz (Crick and Koch 1990). Von der Malsburg had already suggested something similar as the basis of the cocktail-party effect: hearing one's own name stand out within a confusing buzz of conversation (von der Malsburg and Schneider 1986). But now there seemed to be experimental confirmation. A recent issue of *Nature* had reported that the neurones in different visual-feature-detector columns in cats oscillate synchronously when responding to the same object (Gray *et al.* 1989).

These results had led others to ask whether the researchers had "uncovered the cellular basis of consciousness" (Baringa 1990: 856)—a question which Crick and Koch answered with a firm "Yes!" (The firmness soon became a wobble, as they weren't able to replicate these findings in monkeys: Nørretranders 1991: 432 n. 46.)

As for blindsight, this was first discovered in monkeys (Weiskrantz 1972). Animals with certain lesions in the visual cortex lost much of their discriminatory capacity, but not all of it. Soon, the condition was seen in humans too (Poppel *et al.* 1973; Weiskrantz *et al.* 1974; Weiskrantz 1986, 1997; Moore *et al.* 1998). But here, there was a further surprise. Patients with similarly located brain lesions claimed to be blind—*to have no conscious experience*—with respect to a particular part of their visual field. Asked to point to an object, or to move their eyes in its direction, they'd protest that this was ridiculous: they couldn't see it, so how could they point to it? Nevertheless, if they could be persuaded to 'guess', they usually indicated the right place—sometimes, even positioning their fingers to match the object's shape.

Apparently, much of the sensori-motor processing that Arbib tried to describe (Section vii.c) was going on. But the sensory information wasn't getting through to the 'higher' brain centres so as to become introspectively accessible. (It became clear later that blindsight isn't normal vision near the threshold of consciousness, but involves non-normal processing: Azzopardi and Cowey 1997.)

In the 1990s, an extraordinary clinical case of blindsight was reported (Goodale and Milner 1992; A. D. Milner and Goodale 1993, 1995), which reached the general public early in the new century (Goodale and Milner 2003). The unfortunate woman concerned, who'd suffered carbon monoxide poisoning, appeared to be blind. She couldn't recognize familiar faces, nor identify simple geometrical shapes. Nevertheless, she could put her fingers into the correct attitude and position when reaching out to pick something up. The key demonstration of her visual agnosia involved a plastic card and a narrow rotating slit in a box. She couldn't match the position of the slit perceptually; that is, she couldn't hold the card in the same orientation as the slit. However, if asked to "post" the card through the slit (in many different orientations), she had no problems at all.

In short, she was apparently able to see (see-for-action) things unconsciously which she couldn't see (see-for-perception) consciously. (Her clinicians used this as just one piece of evidence in arguing that there are two anatomically and functionally distinct visual pathways in the brain: one for perception, one for action—see 10.iv.b.)

When the new millennium dawned, then, 'consciousness' was no longer a dirty word in neuroscience. On the contrary, it was the acme of trendiness. In 2000 the British neuroscientist Jeffrey Gray (1934–2004) was asked to review no fewer than three recent books on consciousness at the same time—with several others being reviewed elsewhere in the same publication.

But Gray knew the difference between trendiness and intellectual progress. Despite having been a guest editor for the *Journal of Consciousness Studies* a few years earlier (J. A. Gray 1995), he didn't welcome these three new volumes unreservedly:

> There is a great deal of fuss these days about consciousness. Yet, 10 years ago or so, the fussometer reading would have hovered around the zero mark, where it had been stuck for most of the past century. Just a few philosophers worried about a problem that was totally ignored by the scientists. (J. A. Gray 2000: 36)

Why the vaulting fussometer reading? In Gray's opinion, it wasn't due to any scientific or philosophical advance. (Given that he'd introduced the cautionary Royal Society press conference mentioned above, this judgement was only to be expected—cf. J. A. Gray 1995.) Rather, he said, it was due to the recent technologies of brain imaging.

If the technologies were recent, the idea wasn't. James (1890: i. 97) mentioned the Italian physiologist Angelo Mosso, who'd noticed regional pulsations of the cortex, in patients with bits of their skulls missing after operations, which seemed to depend on active thinking. He'd suggested, and James agreed, that this was caused by changes in blood circulation. But studying such changes in subjects with intact skulls wasn't possible before the 1980s.

From 1982, it became possible to measure activity in specific parts of the brain—as opposed to EEGs taken across the whole brain (Frith 1992; Frackowiak *et al.* 1997; Raichle 1998; Frith *et al.* 1999). PET scanning (positron emission tomography) and fMRI (functional magnetic resonance imaging) identified the areas—perhaps only a few millimetres across—with the highest level of glucose metabolism or, what comes to much the same thing, the greatest increase in blood flow. These methods depicted the brain *in action*, for they showed (in some cases, several times a second) how the brain's energy consumption varies while someone thinks about or perceives something, or performs a motor act. What action the energy was being consumed *for*, however, wasn't as clear as it was usually assumed to be (see below).

(For the record, it was taken for granted at that time that most of the brain's energy consumption is for information processing at the synapses. We now know that this takes only 40 per cent of the energy, while another 40 per cent is consumed simply in passing messages along the axons. The rest is used for housekeeping/maintenance: Attwell and Laughlin 2001; Laughlin 2004.)

Cognitive psychologists and clinicians—and the USA's science administrators who named the 1990s "The Decade of the Brain"—were enthused. Questions previously way beyond the reach of neuroscience now seemed to be answerable. For instance:

* Brain scans done when people were asked to think about beliefs and desires supported the early 1980s claim that autism and Asperger's syndrome involve failings in "theory of mind" (Chapter 7.vi.f).

* Studies of schizophrenics implied that their hallucinations of 'inner voices' are due to a failure or delay of communication between different parts of the brain (Cahill *et al.* 1996; Silbersweig *et al.* 1996).

* Schizophrenic, and experimentally induced, delusions about alien control of one's own body were explained in a similar way (Frith *et al.* 2000; S.-J. Blakemore *et al.* 2003; cf. Chapter 7.i.i).

* Hypnotic states and multiple personality were correlated with changes in brain activation (Aikens and Ray 2001; Reinders *et al.* 2003; cf. 7.i.h–i).

* 'Oceanic feelings' and intimations of the numinous, described long before by James (1902), were associated with a certain area in cerebral cortex (Alper 1996; Saver and Rabin 1997; Cook and Persinger 1997; cf. 7.i.i).

* Brain-imagers even managed to explain why one can't tickle oneself (S.-J. Blakemore *et al.* 1998).

A host of other examples had been described, all linking conscious experiences (and voluntary movements) of various kinds with cerebral activity. Similar effects were observed in non-human mammals—but using implanted electrodes rather than brain-scanners. In one widely reported study on rats, signals from motor cortex which normally cause the rat to press a lever attached to a water-dispensing robot were transmitted directly to the robot after the lever had been disconnected (Chapin *et al.* 1999). Because the robot arm responded more quickly than the paw did, the animal soon learned that it needn't actually press the lever any more. In short, the rats had learnt to move robot arms 'by thought alone'.

This caused huge excitement, because of the potential for helping paralysed people. A few months later, the same experimenters (at Duke University, North Carolina) sent brain signals over the Internet to enable an owl monkey to control a 3D robot arm 600 miles away, at MIT (Nicolelis 2001). They planned to include visual and tactile feedback, to see whether closed-loop 'circular causation' could integrate the monkey's real and virtual worlds. And very soon after that, another group used similar techniques to enable a rhesus monkey to learn to play a video game controlled by a joystick—without actually touching the joystick (Serruya *et al.* 2002). (These experiments raise interesting questions regarding 'cognitive technology' and the concept of self: see 16.vii.d.)

Linking rats or monkeys to robots is a major exercise, not undertaken lightly. But brain-scanning studies on humans are less tricky, and are multiplying merrily. Emails reporting some new example reach me several times a week. One that arrived when I was first drafting this chapter announced an fMRI study that used John R. Anderson's computational model of goal-directed problem solving (Chapter 7.iv.iii) to predict blood-oxygen levels "in brain areas involved in the manipulation and planning of goals" (Fincham *et al.* 2002). Since then, many others have followed it (although very few are related to specific computational models, as that one was). The journalists have learnt to keep an eye out for them: brain-scan studies of 'religious' experience (see 8.vi.b, list-item 2), for instance, were widely featured in the media. As for the professional journals, by the time you read this book they will have carried thousands of PET/fMRI reports.

Their theoretical significance, however, is debatable. Brain imaging has even been dubbed "a neo-phrenological fad", because of the difficulty of interpreting it in terms of psychological functions (Uttal 2001). There are four main problems.

One is that such studies are only correlational: *causal* hypotheses have to be inferred from them, and this is a risky business. For instance, a neurone may be using energy to *excite* another cell, or to *inhibit* it. How can we decide? Recently, Logothetis's team at Tübingen's Max Planck Institute for Biological Cybernetics have combined fMRI with single-neurone recording and/or local injections of neurotransmitters (Logothetis 2002). Such studies can tell us whether what's going on is excitatory or inhibitory. But they're technically very difficult, and can't be done on human beings. They're therefore irrelevant to the 'sexy' discoveries reported in the journals—and in the newspapers.

Another difficulty recalls Gregory's complaint about "howling centres" (see Section iii.a, above). If a part of the brain increases its activity when the person thinks about X, that doesn't mean it's a "centre"—still less, *the* "centre"—for thinking about X: many other things will be going on elsewhere. In short, Gregory's critique applies to PET and MRI no less than to classic ablation experiments.

Third, brain-imaging results (unlike the results of brain lesions) aren't stable. They're highly sensitive to context, such as the order in which stimuli are presented and perhaps what the person was thinking about beforehand.

And fourth, one can't sensibly suggest *just what's being done* by the high activity (even if one knew it was excitatory activity) without a theory at the cognitive/psychological level, specifying just what computations might be involved when the thought in question occurs. Usually, no such theory is available. (The research programme described in Chapter 7.vi.i is an exception: there, a significant effort is made to relate neurological details to a specific theory of cognitive processing.) In short, most brain imaging is an a-theoretical fishing expedition: more natural history than science. As Gazzaniga had put it, before this new 'industry' burgeoned, neuroscience *needs* cognitive science.

Responsible researchers know all this, of course, and are careful. But the irresponsible ones—and a fortiori the journalists—seemingly don't, and aren't.

Gray, however, was less worried by such theoretical difficulties than by the naive optimism that brain scanning had banished the mind–body problem. These new gadgets, he declared, had gone to the neuroscientists' heads:

> The power of this method has convinced scientists that now they can watch the brain in action, they can forget the hoary old issues raised by philosophers and get on with the *real* job by the simple expedient of describing what the brain does. (J. A. Gray 2000)

But the hoary old issues hadn't gone away. What he'd described some years earlier as "the most basic issue—the theoretical link between the occurrence of conscious experience and the neural substrate of the brain" (J. A. Gray 1993: 263) was still unresolved.

As Gray remarked, the philosophers had been way ahead of the scientists on this one. Or anyway, they'd spent incalculably more hours discussing it. Whether they'd got much nearer to solving it was another matter.

They'd long ago considered what it would mean for our understanding of consciousness if we knew in detail every correlation between events in the brain and conscious events. And they'd (mostly) concluded that this alone would tell us nothing fundamental about the nature of consciousness, or about *how it's possible* for the brain to generate it (see 16.i). In a word, or three: correlation isn't causation.

Moreover, functionalism—or so it was widely believed (Chapter 16.v.b)—hadn't helped. Most people felt that an experiential quality, such as redness or sourness, can't be the same as an abstract computational or causal function (important exceptions are discussed in Section xi, below). Even the arch-functionalist Fodor had washed his hands of consciousness:

> Nobody has the slightest idea how anything material could be conscious. Nobody even knows what it would be like to have the slightest idea how anything material could be conscious. So much for the philosophy of consciousness. (Fodor 1992)

Gray agreed. He concluded that modern neuroscience has no idea of how neuronal firing *can* cause conscious thoughts or percepts. Nor can it explain why these evolved at all: given the closure of physics, it's hard to see how conscious states could possibly affect behaviour. In short, this was Princess Elizabeth all over again (see 2.iii.b).

If Gray was so sceptical, why were other neuroscientists so hopeful? What experimental evidence, *over and above* the discovery of many previously unknown mind–brain correlations, had persuaded them that they were about to solve the problem?

The most persuasive examples came not from human brain imaging but from single-unit recording in animals. For instance, experiments on rhesus monkeys (Newsome and Salzman 1993) showed a remarkably systematic correlation between activity in certain orientation-selective cells in the animal's visual cortex and its perceptual discriminations of movement—*and*, common sense would have us say, its experiences of seeing movement.

Before the experiment proper, the monkey was trained to move its eyes in the direction of the perceived movement. Then, stimulating a certain cell circuit caused the monkey to behave as though it saw motion in a certain direction. Moreover, these results were predictable. In other words, the relevant cells are spatially organized in a way that corresponds to the geometry of the monkey's discriminatory behaviour. Assuming that the monkey has conscious states, this evidence suggested not only a causal relationship between individual cells and experiences, but also a systematic mapping from spatial structures in the brain to perceived phenomenal structure. It even enabled the neuroscientists to predict that if such-and-such a cell group were to be stimulated, then such-and-such an experience *must* ensue.

This hypothetico-deductive reasoning is typical of scientific explanation. So, surely, this constituted a scientific explanation of (certain aspects of) the monkey's visual experiences?

Well, yes and no. This experiment couldn't have assuaged Gray's worry. What it showed was that, *given* that certain neurone groups give rise to (cause, generate, are correlated with . . .) visual experiences, *these* neurones lead to *those* experiences, whereas others lead to others. This, of course, was a lot better than nothing. But it didn't answer Gray's question about how it's possible for *any* neuronal activity to lead to *any* conscious experience. It confirmed the previous belief (the common-sense hunch, inherited from Descartes) that there are systematic mind–brain correlations there to be found. But it didn't explain how this can be so.

Moreover, it was (and is) still impossible—or anyway, deeply problematic—to understand causal relations going in the opposite direction. To be sure, some cognitive scientists claimed to explain how conscious experiences can have neuromuscular effects (Velmans 2002). These accounts were intelligible if interpreted functionally in informational, computational, terms. But if some extra (correlated) realm of conscious mental events was posited, Princess Elizabeth's problem remained.

In brief, work on consciousness was riddled with "paradox and cross purposes" (N. Block 2001).

d. Philosophical contortions

Gray wasn't the only one to be worried by the mind–brain problem. Several neuroscientists, and philosophers sympathetic to neuroscience, suggested more or less radical 'solutions' to it.

Crick (1994), for instance, proffered the "astonishing" hypothesis that conscious states are processes in the brain—or, as he put it, that " 'You', your joys and your sorrows . . . , your sense of personal identity and free will, are in fact no more than the behaviour of a vast assembly of nerve cells and their associated molecules." He claimed, for example, that "freewill is located in or near the anterior cingulate sulcus" (p. 268).

However, whether we take "freewill" to connote a conscious act of choice or a control mechanism for scheduling potentially conflicting motives (see Chapter 7.i.g), it's a category mistake to describe it as being "located" anywhere. What was truly astonishing, at least to the philosophers, was that Crick thought this hypothesis was either new or scientifically straightforward. In fact, it was deeply problematic—like the 'identity theory' of the 1950s (see Chapter 16.i.d), or the more recent 'eliminative materialism' (16.iv.e).

Eliminative materialism had been presaged by Willard Quine in the 1950s (Quine 1953*b*; 1960: 264), but was developed further by Paul Churchland (1979). In the 1970s, he'd formulated his theory without any knowledge of neuroscience or connectionism (see Chapter 12.x.a). Ten years later, he was a colleague of Crick's in San Diego, a devotee of PDP modelling, and—even more to the point—an admirer of Pellionisz and Llinas.

He adapted their theory of coordinate transformations in the cerebellum to define his concept of the "state-space sandwich", which he speculatively applied to the discrimination of tastes—and, he suggested, also to smells, sounds, and colours

(P. M. Churchland 1986*a*,*b*). He admitted that the last three seemed to be much more complex than tastes, but pointed out that they'd each been described in terms broadly comparable to those of Pellionisz and Llinas. That is, they'd been theorized by appeal to coordinate transformations, "variously called 'multivariate analysis', 'multidimensional scaling', or 'across-fibre pattern coding', and so forth" (1986*b*: 303).

Churchland wasn't assuming a mere collection of unrelated correlations between individual neural events and experiences. For his abstract state-space (like tensor geometry) depicted systematic metrical and similarity relations between the individual points within it. He posited a four-dimensional "taste-space", based on the four types of taste-receptor found in the tongue. The points in the space represented specific distributions of four neuronal spiking frequencies, in a system of four distinct sets of nerve fibres. Crucially, they also represented specific tastes *as experienced*: they could be interpreted *either* as specific neural events *or* as specific tastes.

The *empirical* hypothesis was that people's introspective reports on the similarities and dissimilarities between different tastes would map onto the similarity metric defined by the neural taste-space. (Or anyway, onto something broadly like it: for simplicity's sake, Churchland was ignoring the multidimensional contribution of smell to what we normally regard as the subjective experience of "taste".) In that case, we'd be able to predict that a newly discovered (never-tasted) substance, having such-and-such observable effects on the relevant neural mechanisms, will taste very like *x*, something like *y*, and not at all like *z*—indeed, we could say that it *must* taste like this. Other discriminatory spaces, perhaps with many more than four dimensions, could (he suggested) be similarly defined, and the relevant phenomenology mapped accordingly.

The *philosophical* claim—a highly provocative one—was that to have a sensory experience *simply is* to have one's brain visit a particular point in the relevant sensory hyperspace. We should stop thinking of 'experiences' as separately existing events, in some subjective mental space—what Dennett (1991) later called "the Cartesian theatre". Experiences (as commonly understood) were *eliminated*, the only truly existing things/events being brain states. If neuroscience ever progressed as far as he'd imagined, said Churchland, we'd interpret our taste-language as referring not to mysterious 'inner' events but to the material, neuroscientific, reality (this claim is spelt out further in Chapter 16.iv.e).

Some philosophers were highly sympathetic, and developed their own naturalistic theories broadly on Churchland's model (e.g. Flanagan 1992). But others regarded it as—literally—absurd. Churchland had anticipated their arguments in his first book (see 16.iv.e). Now, he offered the taste-space sandwich as a neurologically plausible example illustrating how his 'absurdities' could be understood.

In other words, Churchland—unlike Crick, who also identified conscious experiences with brain states—realized that eliminative materialism wasn't a straightforward scientific theory. It required careful philosophical argument and scene setting *even to make sense*.

Crick wasn't the only neuroscientist to treat eliminative materialism as a straightforward scientific hypothesis. Edelman did so too. His account of *qualia* was similar in spirit to Churchland's (G. M. Edelman and Tononi 2000, ch. 13). But, true to rhetorical form (see ix.d above), he scorned discussions of *qualia* as "ridiculous", generating "esoteric exertions" from philosophers arguing "unnecessarily" about zombies. He failed to see that his own position was comparable with that of Dennett or Sloman, for whom zombies are—necessarily—*non-sense* (Chapter 16.iv.b). His subtle neurophysiology may have answered the question "Why *this quale* rather than *that* one?" But, despite his assertion to the contrary, it didn't explain why *any* experience should be either "associated with", "represented by", "produced/generated by", or "defined as" (expressions he used interchangeably) the neural mechanisms concerned.

Another quasi-scientific account of experience was sketched by the mathematical physicist Penrose. He suggested that the brain's generation of consciousness could be explained by CQG: a new theory of "complete quantum gravity". This theory, he said, was needed to explain certain fundamental puzzles in quantum physics. In addition, however, it would show how *non-random* quantum events could happen, and how these could implement information processing that's *not* describable as Turing-computation (see Chapter 16.v.a and ix). This, in turn, he believed to be involved in human creativity (Penrose 1989) and in consciousness (1994*a*,*b*).

Penrose admitted that he had no idea what this imaginary theory might be. Understandably, then, he was widely accused of trying to solve one utter mystery by twinning it with another. (For an excellent rebuttal based on other grounds, see Sloman 1992.) Moreover, CQG—if we ever achieved it—would apply to all matter indiscriminately: to mud, just as to neuroprotein. So what's special about the brain? His answer, in a word, was *microtubules*. These are very tiny tubes in the neurone's protoplasm, described by the neurologist Stuart Hameroff (1994).

At first, Penrose said merely that neurones have microtubules, and that CQG quantum effects isolated within them might underlie consciousness. (MacKay (1957) had argued long before that quantum effects would be swamped by a combination of neurone size and redundancy. So perhaps the microtubules would prevent the swamping?) When it was pointed out that virtually all nucleated cells have microtubules—so are oak trees conscious, too?—Penrose replied that those within neurones are different (Grush and Churchland 1995; Penrose 1994*a*,*b*; Penrose and Hameroff 1995).

Specifically, they're arranged in parallel, not radially from centrioles. They're relatively stable. There are more of them, arranged in more complex networks, than in other cells. They show greater genetic variability. They transport chemical vesicles along the axon and dendritic processes. And there are neuron-specific proteins associated with them. There's even some evidence, he said, that they transmit "complicated signals" and "act rather like a cellular automaton", and that they're responsible for learning in paramaecium (Penrose 1994*b*: 248).

Even supposing all that to be true, however, the question remained how these facts relate to consciousness as such. Certainly, the "stability" of neuronal microtubules might make one think of enduring memories. But memory storage isn't consciousness. Neither is learning, whether in paramaecium or people.

Another argument put forward by Penrose was that the "curious relationship between conscious events and time" (in meta-contrast, for instance: Chapter 6.ii.c) might be explained if the relevant quantum events took about half a second—in which case "about 1,000 to 10,000" neurones might be involved in one conscious event (which "more or less agrees with other estimates"). But this begged the question. Taking for granted that conscious experiences happen *at some time*, it focused on specifying *which* time. But why they should happen *at all* remained unclear, not to say unintelligible.

Penrose had said that mysterious quantum effects might be relevant—which they might: who knows? And he'd said that microtubules might isolate and guide these effects—which, again, they might (though he gave no good reasons to believe this). But, as two Alice fans put it, his theory was "no better supported than any one of a gazillion caterpillar-with-hookah hypotheses" (Grush and Churchland 1995).

In short, Gray's "hoary old issues" were left untouched. Penrose was trying to blind people with (dodgy) science much as Eccles had done fifty years earlier, when he spoke of the will acting through "critically poised neurones" (see Chapters 2.viii.f and 16.i.a), and as Descartes—in his talk about the pineal gland—had done earlier still (2.iii.b).

The same could be said, perhaps even more strongly, with respect to Evan Walker's (2000) account of "the physics of consciousness"—another of the many quantum-based 'explanations' published around that time. Starting from the unpredictability of single neurone-firings, Walker suggested that quantum tunnelling at the synapses could integrate many such firings into "a single quantum mechanical conscious existence" (p. 228). This happens, he said, by means of the electrons travelling from one synapse to another via RNA molecules—and guided by free will. I can't comment on his theory as *physics*—although the Cavendish Laboratory's Matthew Donald (2001) was far from impressed. But Walker was begging crucial philosophical questions, just as Eccles and Penrose had done before him.

A very different scientific (and philosophical) revolution was envisaged by David Chalmers (1966–). Chalmers allowed that near-millennium neuroscience was well on the way to solving all the problems of consciousness—except one (Chalmers 1995, 1996*a*). "The hard problem" (how conscious experience can arise from the brain), he said, hadn't been touched.

The crux of Chalmers's "prototheory" of consciousness was Shannon's concept of information. As we saw in Chapter 4.v.d, this was defined not semantically, as a meaning or intentional content, but as one of a set of possibilities. For the telephone engineer Shannon, information was a transmittable state. For Chalmers, too, "physically realized information is only information in so far as it can be *processed*" (1996*a*: 181). But for him, information had a dual aspect:

> Physical realization is the most common way to think about information embedded in the world, but it is not the only way information can be found. We can also find information realized in our *phenomenology*. States of experience fall directly into information spaces in a natural way. There are natural patterns of similarity and difference between phenomenal states, and these patterns yield the difference structure of an information space. Thus we can see phenomenal states as realizing information states within those spaces. (1996*a*: 283–4)
>
> [So we can state "the double-aspect principle":] Whenever we find an information space realized phenomenally, we find the same information space realized physically. And when an experience realizes an information state, the same information state is realized in the experience's physical substrate. (p. 284)

This was reminiscent of Churchland's emphasis on structured phenomenal spaces, related to neural mechanisms by state-space sandwiches. But whereas Churchland thought that an adequate scientific theory would eliminate experiences from the furniture of the world, Chalmers didn't. He insisted that phenomenal qualities are "irreducible".

As for whether information is a metaphysically basic concept, underlying both physics and phenomenology, or simply "a useful construct in characterizing the psychophysical laws", this question was left open (Chalmers 1996*a*: 286). So too was the question whether it's "a *primitive* feature of the physical world in the way that mass and charge are primitive". Possibly, those physicists who'd already suggested that physics ultimately deals in pure information were correct: "It could be that in some way the physical is derivative on the informational, and the ontology of this view could be worked out very neatly" (p. 287). It could even be that experience is "ubiquitous": that the very simplest systems—not just slugs or thermostats, but atoms too—have a phenomenal aspect (p. 293).

This speculative panpsychism was trumped by a gesture towards a thoroughgoing idealism: perhaps the phenomenal isn't just one of two equal-status "aspects", but the ultimate *basis* of reality. If so, then

> Every time a feature such as mass or charge is realized, there is an intrinsic property behind it: a phenomenal or protophenomenal property, or a *microphenomenal* property for short. We will have a set of basic microphenomenal spaces, one for each fundamental physical property, and it is these spaces that will ground the information spaces that physics requires. The *ultimate* differences are these microphenomenal differences. (p. 305; second italics added)

Chalmers discussed all these seemingly "outrageous, or even crazy" ideas, arguing that it's not *obvious* that they're misguided (pp. 293–310). But he didn't commit himself to any one of them.

Chalmers's book drew much attention, not least because he'd refused to sweep the hard problem under the carpet. (Health warning, again: perhaps there's no hard problem to be swept? See Section xi.) But his theory was hardly better received than Penrose's. His speculations about panpsychism and the metaphysics of information didn't help. They were even weirder than Brian Smith's views on computation and intentionality (Chapter 16.ix.e). In most people's opinion, Chalmers's quasi-psychic account of information was mere mystificatory hand-waving, analogous to the preceding *fin de siècle* myth: *élan vital* (see Chapter 2.vii.b).

Searle—unlike Penrose, Walker, or Chalmers—didn't try to sketch a new scientific theory of consciousness. However, he repeatedly stated, "to the point of tedium" (Searle 2001: 513), that there must be some scientific explanation to be found.

He'd already said this about intentionality (Searle 1980). But his comments about the brain's "causal role" in generating meaning had been scientifically empty (Chapter 16.v.d), and so were his comments about how brains cause consciousness—"the central mental notion", without which concepts like meaning, subjectivity, and intelligence can't be understood (Searle 1992, ch. 4).

One might agree with him that "Consciousness . . . is caused by neurobiological processes and is as much a part of the natural biological order as any other biological features such as photosynthesis, digestion, or mitosis" (1992: 90). But where does this get us? We're still "very far" from having an adequate biological theory of consciousness (p. 91). Probably, he said, its neurobiology is at least as restricted as that of digestion—but we can't be sure. Perhaps, on other planets, non-carbon-based molecules (though not silicon) underlie conscious experience.

Ten years later, he was still bemused: perhaps even more so, since he was now stressing the paradoxes involved in "the neurobiology of free will" (Searle 2001). But he argued that even if consciousness is based in quantum indeterminacy, conscious thought and decisions needn't be random too—and they clearly aren't. With respect to all three puzzles (free will, consciousness, and intentionality), he said:

> [We] *know* that the causal features of the system level phenomena are entirely explainable by the behaviour of the micro phenomena [in the brain] . . . [The] causal relations have the same *formal* structure as the causal relations between molecular movements and solidity. (Searle 2001: 513; first italics added)

This "knowledge", however, amounted to no more than the fact that we now have even more evidence than Descartes did to believe that the brain causes consciousness. What we want to know is *How?* Searle offered no new scientific ideas, dodgy or not: no microtubules, no dual-aspect information, no special types of computation . . . nothing. He simply said that the problem of consciousness is a scientific problem, and encouraged the scientists to get on with it.

Some pessimists agreed with the diagnosis but withheld the encouragement. The philosopher Colin McGinn (1950–) had said in the early 1980s that "We should persist in the hope that some day philosophy (or perhaps science) will find the answer [to the mind–body problem]" (1981: 36). Now, in the early 1990s, he saw any such hope as doomed (McGinn 1989, 1991).

He argued that a scientific theory of mind–brain would be *so* radically different from all known science as to be inconceivable by human beings. Neither our (perceptual) concepts of physical matter nor our (introspective) concepts of consciousness can describe any intelligible *union* of them. Moreover, these are the only conceptual realms open to us. Any third-type concepts that did explain the mind–body relation would *necessarily* be so different that we couldn't entertain them. We simply don't have the cognitive capacity to understand these matters—much as dogs can't understand arithmetic or physics:

> We know that brains are the *de facto* causal basis of consciousness . . . [But] we are cut off by our very cognitive constitution from achieving a conception of that natural property of the brain (or of consciousness) that accounts for the psychophysical link. (McGinn 1989: 350)

In a God's eye view, said McGinn, there's no ultimate scientific or metaphysical mystery here. For us, however, there is. We can glimpse the link between brain and consciousness only superficially, as temporal correlations. Interpreting those correlations causally is forever beyond us.

Most readers admitted that McGinn might, conceivably, be right. To deny that would be hubris. But cognitive scientists felt that we've no convincing reason to think he was. Our knowledge of brain mechanisms is so scanty, and the history of neuroscience so short, that it would be defeatist to give up now. McGinn's intellectual pessimism was scornfully termed "the new mysterianism"—as opposed to the "old" (neo-Kantian) mysterianism, which *denied* that consciousness is naturalistic (Flanagan 1992: 8–9).

These valiant—or hopeless—attempts to explain mind–body correlations all came up against a long-familiar problem, memorably posed by Thomas Nagel (1937–) in his paper 'What Is It Like To Be a Bat?' (Nagel 1974). In a nutshell, science is objective whereas consciousness is subjective.

We all know, said Nagel, "what it is like" to be conscious, and this—subjective, inner—experience is inaccessible to science *in principle*. Neurones, neurotransmitters, microtubules, quantum events, computation, information . . . you can forget them all. These objectively describable matters may be necessary conditions for consciousness, but they simply *cannot* provide adequate explanations of it. At best, he said, science might offer an "objective phenomenology" describing the structural aspects of subjective experiences, including those (of bats, for instance) incomprehensible to human beings. (Nagel offered no examples: possibly, one might include AI work showing that identity can be computed without computing shape, which implies that a creature might be able to experience object-identity without being able to recognize shape: Ullman 1979.)

In light of these difficulties, some philosophers—and the occasional neuroscientist, such as Maturana—tried to renegotiate the central concept at issue here. We'll see that some of these negotiators still hoped for a scientific theory of consciousness, whereas others declared this to be impossible in principle—even (*pace* McGinn) for God.

14.xi. Descartes to the Tumbrils?

Now's the time, at last, to consider the anti-Cartesian heresy that *the very idea of mind–body correlations* is so deeply confused that neuroscientists can't be required to explain it. They're off the hook because, as this idea is commonly understood, *there's nothing there to be explained*.

Dennett, having discussed conscious experience ('*qualia*') with various neuroscientists for years, recently exclaimed: "To put it bluntly, nobody outside of philosophy should take a stand on the reality of *qualia* under the assumption that they know what they're saying" (in Gazzaniga 1997: 178). I agree, for reasons outlined below.

But I'd add (and he'd concur) that people *inside* philosophy usually don't know what they're saying either. The difference is that they're well aware that the very notion of conscious experiences—without which, there can be no talk of Cartesian correlations—is radically problematic. They may use the notion, of course. But they cross their fingers behind their backs while doing so.

Cognitive scientists also cross their fingers while speaking of introspection—the way in which (so it's normally said) we gain access to our conscious experiences. For "introspection" is a weasel word. That's been evident since the late nineteenth century, when experimental psychologists following Wilhelm Wundt, James Titchener, or the Würzburg school inspected their own consciousness in very different ways (2.x). Indeed, disagreements about *what counts* as introspection largely account for the phenomenally rapid rise of behaviourism after 1913 (Chapter 5, preamble). Now, it's even clearer that there are various kinds of introspection, involving different underlying mechanisms (Prinz 2004*c*).

In short, the common assumptions that we all understand what's meant by "experience", and how to gain access to it, are much too quick.

a. Describing the mind, or inventing it?

You'll have noticed that the neuroscientists we've been considering spoke of conscious experiences in animals as well as humans. Even their paper titles sometimes made this explicit (Logothetis 1998). They may have crossed their fingers sometimes, when ascribing *specific* experiences to cats or monkeys. But they saw no problem of principle in saying that some animals have conscious sensations. (You probably agree—although we'll see in Chapter 16.viii.b that some philosophers writing today do not.) A fortiori, they saw no problem of principle in speaking about experiences occurring in adult human minds.

Admittedly, cognitive psychologists had long ago discovered that sincere introspective reports—of visual imagery, for example—sometimes have to be taken with a pinch of salt (see Chapter 7.v.a). And Paul Churchland (1979) had argued that introspection is just as "theory-laden", just as prone to top-down conceptual influence, as ordinary perception is. This was troubling to people who took seriously Descartes's view that we have infallible direct access to our own consciousness. However, *that we do have* introspectible conscious experiences was taken for granted.

We open our eyes and have visual experiences, run our hands over our bodies and have sensations of touch . . . and so on. The experiences may sometimes be surprising, as they are in cases of illusion or meta-contrast. But they occur. Who could deny *that*? It's just common sense.

"Common sense", however, may consist largely of old wives' tales—or old philosophers' tales. If so, we need to be clear about just which tales the old philosophers were telling, and whether they were fact or fiction.

Descartes's *originality* in discussing mind–brain correlations (Chapter 2.iii.a) can be glossed in two very different ways:

* On the one hand, he might have been the first to say that conscious experiences (understood as inner mental states accessible only to the subject concerned), *already* a familiar topic of conversation, are correlated with specific states of the brain—as opposed to the heart, or the liver, or even some supernatural realm.

* On the other hand, he might have been the first to say that *there are conscious experiences* (*in the sense just defined*)—adding, for good measure, that they're closely related to the brain. In that case, the newly minted notion of experiences wouldn't have been part of common sense at the time, even though it became part of common sense very soon afterwards.

The question arises, then, as to which of these two readings is correct. In other words, did Descartes *describe* the conscious mind? Or did he rather *invent* it—and if the latter, would neuroscience profit by abandoning his invention?

b. A computational analysis

Virtually all twentieth-century neuroscientists—though not Maturana (see Chapter 15.vii.b)—tacitly opted for the first interpretation of Descartes's position. To be sure, they didn't posit mental *substance*. Indeed, most of them probably hadn't even read Descartes. But they didn't need to: their common sense (deeply imbued with Cartesian ideas) told them that there are conscious experiences. Moreover, the recent experimental advances sketched in Section x had persuaded them that these experiences could at last be studied by neuroscience. That is, they could be correlated with specific brain events, considered either as their causal basis or as identical with them.

One philosopher who agreed with them wholeheartedly was Chalmers:

> [We must] *take consciousness seriously* . . . [I assume] that consciousness exists, and that *to redefine the problem as that of explaining how certain cognitive or behavioural functions are performed* is unacceptable. This is what I mean by taking consciousness seriously.
>
> Some say that consciousness is an "illusion", but I have little idea what this could even mean. It seems to me that we are surer of the existence of conscious experience than we are of anything else in the world . . . I find myself absorbed in an orange sensation, and *something is going on*. There is something that needs explaining, even after we have explained the processes of discrimination and action: there is the *experience*. (Chalmers 1996*a*, p. xii; second italics added)

Among the views Chalmers was rejecting here were those of the computationalist philosophers Dennett (1988; 1991, ch. 12; 1993*b*) and, by implication, the less well-known Sloman (1999; Sloman and Chrisley 2003). Although Dennett wished to outlaw talk of *qualia* and Sloman didn't, their analyses were similar in spirit.

Each of them had argued that the notion of 'experience' can be cashed out *completely* in terms of discriminatory computations and behaviour, both actual and potential. (Having been influenced in their youth by Gilbert Ryle, they were well aware of the relevance of *dispositional* concepts: Chapter 16.i.c.) They both allowed that these matters are grounded in neurophysiology. But they analysed the concept of experience at the level of the computational architecture involved. Sloman, for instance, saw *qualia* as states in the virtual machine that constitutes the mind.

'Zombies'—creatures looking and behaving exactly like us, but having no conscious experiences—were therefore said by them to be logically impossible (see Chapter 16.v.b). More to the point, the traditional question of mind–brain correlations *simply doesn't arise*, for there are no ontologically distinct experiences over and above bodily/cerebral events (Chapter 16.iv.b).

Both Dennett and Sloman glossed *qualia* as self-reports generated by an information-processing system with a complex, and reflexive, computational architecture. 'Subjectivity' was interpreted as the fact that these reports are directly accessible to the highest level of the system itself. They may sometimes be betrayed by involuntary movements, such as facial expressions; and they may be deliberately communicated, by words or body language, to observers. In essence, however, they are reflexive reports: the system talking *to* itself, *about* itself. The directness, or lack of 'evidence', of first-person experiential statements is due to the particular kind of (reflexive) computation involved. It's *not* due to any 'privileged access' to a mysterious inner realm of mental being (or Cartesian theatre).

The "Cartesian theatre", with its lonely audience of one, was repeatedly criticized by Dennett, whose 1991 book was hugely influential. That's not to say that it was hugely endorsed: as we'll see below, many—probably most—of his readers couldn't swallow his denial of *qualia*. That is, they couldn't accept his *interpretation* of *qualia*-talk.

They might be willing to accept his theory of "multiple drafts", in which conscious experiences are continuously (re)constructed from many computational sources (hence their paradoxical timing properties: Dennett and Kinsbourne 1992). They might even be willing to accept his account of the self as a "center of narrative gravity", an intentionalist-stance projection *of* the system *to* the system—which, once constructed, can be used to further voluntary action and moral choice (cf. Chapters 7.i.g and 16.iv.b). But that was a far cry from accepting his account of *qualia*.

Like Nagel (1974), they thought it obvious that there's *something that it's like to be* a bat, and that this experience—grounded in the bat's sensory and behavioural skills and informed by its (language-free) concepts—can't possibly be understood by us. Or like Frank Jackson (1982, 1986), they felt that a scientist (Mary) encaged from birth in a windowless black-and-white room might know everything there is to know about the physical aspects of vision, but she'd *learn something quite new* if she opened the door and stepped out into the garden.

Dennett's response (1991: 398–401) was to pour scorn on the easy assumption that we know what we mean when we say that Mary could know *everything* about the physical aspects of vision. (If she really did, she wouldn't be at all surprised that she was now able to make discriminations, and utter sentences, that she'd never made/uttered before.) He compared this easy assumption to the careless notion that imagining that someone is "filthy rich" enables one to work out the implications of asserting that *she owns everything*. Like the infamous Chinese Room (Chapter 16.v.c–d)—and, for that matter, Nagel's bat (Dennett 1991: 441–8; Akins 1993)—Jackson's Mary is "a classic provoker of Philosophers' Syndrome: mistaking a failure of imagination for an insight into necessity".

Dennett expected no easy victories: "I know that this will not satisfy many of Mary's philosophical fans, and that there is a lot more to be said" (p. 401). Indeed, he foresaw that many (most?) of his readers would feel that consciousness hadn't so much been explained, as explained away. (Several reviewers would remark that his book title invited prosecution under the Trade Descriptions Act.)

So he constructed a fictional fall guy called Otto, who made all the obvious, common-sense objections—only to be answered, not to say mocked, in computational–behavioural terms. For example:

[OTTO:] It seems to me that you've denied the existence of the most indubitably real phenomena there are: the real seemings that even Descartes in his *Meditations* couldn't doubt.

[DENNETT:] In a sense, you're right: that's what I'm denying exist. Let's [consider] the neon color-spreading phenomenon. There seems to be a pinkish glowing ring on the dust jacket. [This refers to a visual illusion, the diagram printed on the shiny white dust jacket of Dennett's book. There's a grid of vertical/horizontal black lines. Red part-lines (in place of black) form a circle around the middle. The viewer 'sees' a glowing pink ring, half an inch wide, bounded by the inner and outer ends of the red part-lines.]

[OTTO:] There sure does.

[D.C.D.:] But there isn't any pinkish glowing ring. Not really.

[OTTO:] Right. But there sure seems to be!

[D.C.D.:] Right.

[OTTO:] So where is it, then?

[D.C.D.:] Where's what?

[OTTO:] The pinkish glowing ring.

[D.C.D.:] There isn't any; I thought you'd just acknowledged that.

[OTTO:] Well yes, there isn't any pinkish ring out there on the page, but there sure seems to be.

[D.C.D.:] Right. There seems to be a pinkish glowing ring.

[OTTO:] So let's talk about *that* ring.
[D.C.D.:] Which one?
[OTTO:] The one that *seems to be*.
[D.C.D.:] There is no such thing as a pink ring that merely seems to be.
[OTTO:] Look, I don't just *say* that there seems to be a pinkish glowing ring; *there really does seem* to be a pinkish glowing ring!
[D.C.D.:] I hasten to agree. I never would accuse you of speaking disingenuously! You really mean it when you say there seems to be a pinkish glowing ring.
[OTTO:] Look. I don't just mean it. I don't just *think* there seems to be a pinkish glowing ring; *there really* seems to be a pinkish glowing ring!
[D.C.D.:] Now you've done it. You've fallen in a trap, along with a lot of others. You seem to think there's a difference between thinking (judging, deciding, being of the firm opinion that) something seems pink to you and something *really seeming* pink to you. But there is no difference. There is no such phenomenon as really seeming—over and above the phenomenon of judging in one way or another that something is the case. (Dennett 1991: 363–4)

As this book goes to press, Otto still lives. But so does Dennett, and he's unabashed. His briefer account of consciousness (Dennett 2005) takes note of his earlier critics, but gives essentially the same answer: *qualia* don't need to be explained, since there are no *qualia*. (For Sloman, there are: they exist as states in virtual machines of a complex kind—see 16.ix.c.)

c. The other side of the river

Computationalists such as Dennett (and Churchland, and Sloman) weren't the only people to criticize the very notion of '*qualia*'. The critics also included thinkers from a very different philosophical tradition—so different, indeed, that many neuroscientists were unaware of them.

These radical voices were mostly neo-Kantian, or 'Continental', philosophers (see Chapters 2.vi and 16.vi–viii). However, they also included 'ordinary language' philosophers such as John Austin (1962*b*) and the later Wittgenstein (1953). And by the end of the century they even included Putnam, who'd provided the philosophical base for functionalist cognitive science in the 1960s but who'd changed his mind fundamentally thereafter (see Chapter 16.iii and vi).

Like Dennett, but on very different (non-computationalist) grounds, such people argued that the concept of conscious experiences, *considered as private, inner, events utterly distinct from physical events*, is unintelligible. They saw it as so fundamentally confused as to be nonsense: that is, non-sense.

They blamed Descartes, whom (as remarked in Chapter 2.iii.a) they saw as having *invented* the conscious mind. Aristotle and the medieval philosophers had never mentioned it—and neither had the Renaissance humanist Michel de Montaigne. To be sure, Montaigne used French words (*l'âme*, *l'esprit*) which Descartes would use too: but he didn't use them in the same—post-*cogito*—sense. In some languages, moreover, no equivalents exist. There's no vocabulary in Ancient Greek—or in Chinese or Croatian either—that maps onto Cartesian concepts of mind and consciousness (K. V. Wilkes 1988). The familiar notion (familiar, that is, to you and to me) that anyone with any common sense, anywhere, must *know* that conscious minds exist, and that conscious experiences happen, is therefore suspect.

In short, it's no accident that Descartes is famed for tussling with the mind–body problem, for it was he who was responsible for it—*not* "he who noticed it"—in the first place. Our common-sense notions of the mind and conscious experience date back to Descartes. They weren't part of common sense before him, and (on this view) they shouldn't be part of common sense today—nor of science, either. Moreover, racking one's brains over mind–body correlations is a waste of time: *there are no mind–body correlations*, as this notion is normally understood.

Nor, for the neo-Kantian, is there any 'identity' between brain states and experiences. On this view, experience (and mind) isn't a product of brain processes but a feature of certain interactions between an agent and its surroundings. These interactions—such as speaking to one's daughter, or sorting apples and oranges into two heaps—are largely due to the internal physical structure of the agent's whole body, and especially of the brain. (So it's no surprise to the non-Cartesian that 'correlations' are found, if people are so philosophically misguided as to look for them.) But brain processes *enable* these interactions, they aren't *constitutive* of them.

Let's take Putnam as our example here, because (unlike some others in this philosophical camp) he's relatively tough-minded. Quite apart from his pivotal role in orthodox functionalism (Chapter 16.iii), he can't be accused of ignorance of cognitive science, nor of lack of sympathy with science in general. The fact that he, of all people, eventually reached this unorthodox position shows (at least) that it deserves to be considered seriously *even by the Ottos of this world*—which, I'd wager, includes most readers of this book.

By the turn of the century, Putnam was saying that "neither the standard problems in the philosophy of mind, nor the 'philosophical positions' they give rise to are really intelligible" (Putnam 1999: 112). This applied also to concepts like "internal phenomenal state" and "sense datum" (and, from his own earlier writings, "functional state").

He wasn't asking, he said,

> whether the phrase "internal psychological condition" or "internal psychological state" *ever* has an intelligible use—of course it has!—*but whether we understand what is being claimed when it is said that, e.g.* believing that there are churches in Vienna *is an internal psychological state with the same causal-explanatory role [with respect to behaviour] as the noninternal state* of knowing that there are churches in Vienna. (Putnam 1999: 113)

Similarly, he wasn't denying that we have (as we say) experiences of *yellow*. (Much as Dennett wasn't denying that we have, as we say, experiences of a pinkish glowing ring.) But, whether we're looking at a yellow door or merely hallucinating one, there's no yellow *experience*, *sense datum*, or *quale*:

> Yellow isn't a property something we experience *has* (or a property the experience *is*) as talk of qualia suggests; it is a property the experience *ascribes* to the door. The experience *portrays the environment as pertaining yellow* (it [intentionally] "refers to" yellow, as it were); it isn't a yellow (or "subjectively yellow") particular or universal. As William James put it, the quality is "in" the experience "intentionally", but the experience doesn't have it "as an attribute". Confusing having redness or hotness "intentionally" with being red or hot "adjectively" (i.e. as attributes) is [a common philosophical fallacy]. (Putnam 1999: 154)

Of course, sometimes we seem to see a yellow door when there isn't one there. In general, we're subject to perceptual illusions, and even to hallucinations. Positing (illusory) "experiences" appears, prima facie, to explain this. But—according to Putnam—this assumption, too, is mistaken. We don't see an experience, we see real things. That is, our perception is *direct*, not mediated by inner experiences. When we see mistakenly, the explanation lies in the causal transactions between the real thing and the brain. Illusory aspects of the world are, for Putnam, in a sense "veridical". But that's just to say that they are the natural effects on our perceptual system of real things, having certain physical properties and perceived in certain physical/biological conditions.

In the Müller-Lyer illusion, for example (see Figure 6.3), the real-lines-drawn-on-real-paper cause processes in visual cortex that resemble those which occur when we're presented with really unequal lines. And in schizophrenic hallucinations, the misperceptions are caused by chemical imbalances and/or learnt patterns in the brain. Those patterns, in turn, can be traced back to earlier causal transactions with real things—including pictures and printed text in real books, and real words spoken by real storytellers (remember Arbib's hierarchy of schemas).

Certainly, then, we may say that the brain constructs the illusory interpretation. What—on this view—we must *not* say is that it constructs, or causes, or correlates with . . . some mysterious mental something-or-other, some inner 'experience'. In short, none of the experimental or neurophysiological facts is denied by Putnam. What's denied is that they are to be explained by positing *qualia*, somehow interposed between the brain and the thing being (mis)perceived.

This may strike you (as it would Otto) as crazy. You may want to echo Chalmers's remark, quoted above: "It seems to me that we are surer of the existence of conscious experience than we are of anything else in the world." Is Putnam mad? And is Dennett mad, too? *What on earth* are they up to?

d. Lions and lines

As an analogy, imagine that a great scientist–philosopher on his deathbed was heard to say, just before his last gasp, that navigators would benefit from considering the lions running around the earth.

His mourners found, to their delight, that he'd already drawn their pathways on the globe in his study. Evidently, the lions were quite convivial, for they met regularly (the best-attended gatherings took place at the poles). Sure enough, over the next few centuries the navigators—and eventually also the tourists—found it very helpful to consider the lions. They were even recognized as individuals: four were given special names, and the rest were named by numbers.

Field expeditions aimed at capturing one of these animals, however, always failed. Perhaps the lions were very shy, or very small, or running unseen in microtunnels . . . or perhaps (because of some unsuspected glitch of quantum physics?) forever invisible. The arguments raged on and on. But no one doubted that the lions were there. After all, their pathways had been measured precisely, and they were mentioned every day—in conversations that undeniably helped people to reach their intended destinations. *Of course* the lions existed!

But, of course, they didn't. The dying man had been misheard: he'd said "lines", not "lions". Moreover, he hadn't meant *real* lines, such as might be made by paw marks. No, these were imaginary lines, of latitude and longitude (what Dennett would call *abstracta*, or "exquisitely useful fictions"—1991: 367; see Chapter 16.iv.b).

There was no harm in his followers' speaking about "lions", if this language was used purely *geographically*. But if it was interpreted as referring to actual lions (perhaps very small ones!), with paws, whiskers, and purrs, it was highly misleading—not to say false. In Ryle's (1949) terms, belief in such lions was a category mistake (Chapter 16.i.c).

The mistake was by now so entrenched, however, that the few people who questioned the lions' existence (as *lions*) were accused of denying the facts underlying map-making and navigation. In truth, they were doing no such thing. But they were undercutting every single one of the ingenious theories (shy, small, quantum-invisible . . .) constructed to answer questions about the elusive lions' real nature. More: they were showing why *no such questions need arise*, and why *no such theory could ever be successful*.—And all without denying *any* of the facts that made lion talk so useful, and which had led the long-dead philosopher to posit the lines/lions in the first place.

One of the points at which this analogy (like all analogies) breaks down is that Descartes himself had *not* been misheard. He did believe in 'lions'—that is, in mental states considered as aspects of a special type of existence, just as real (indeed, just as substantial) as physical matter.

By the twentieth century, his followers had abandoned his belief in mental substance. (The lions could leave no paw marks.) But they still assumed the metaphysically distinct existence of conscious mental states, as events within a distinct level of reality. (The lions' purrs could be heard.) They called them experiences, sensations, raw feels, sense data, *qualia* . . . and woe betide anyone who questioned their existence *as so conceptualized*. The brave people who did question them were wrongly supposed to be denying the facts that had led to such talk in the first place—such as the fact that we sometimes think we're seeing a yellow door, or a pinkish glowing ring, when there isn't one.

Putnam, and Dennett too, is on the side of the *lines*. For both of them, although for somewhat different reasons, the claims of Crick and Churchland that so-called conscious experiences are in truth *the very same thing as brain states* are literally nonsensical. (Churchland, then, had been quite right to say that this wasn't a straightforward scientific theory, inviting tests rather than philosophical analysis.)

What's more, for Putnam (and Dennett) the question of mind–brain correlations, *as it's normally understood*, simply doesn't arise. There are no such correlations. There couldn't be any such correlations, because there are no *qualia* or inner conscious 'experiences' (again, *as these are normally understood*) that might be correlated, or not, with specific brain events. There's no need to puzzle over how to explain mind–brain correlations, or how to 'strengthen' them—pressed, perhaps, by Princess Elizabeth?—into physics-defying *causes*. For there's no correlation there to be explained.

Certainly, Putnam admitted, we need to explain the huge variety of behavioural discriminations displayed by people and animals. And he allowed that neuroscience—indeed, *computational* neuroscience—will be needed to do so (Putnam

1999: 48). Unlike Dennett, however, he didn't try to say what the neurocomputational architecture must be like. His interest was simply to show that the neo-Cartesian assumption shared by virtually all neuroscientists, *that there are mental (conscious) events and physical (brain) states, and that we should try to explain the correlations between them*, must be rejected.

If Putnam (or Dennett) is right, it's no wonder that neuroscientists face huge difficulties in explaining how the brain causes conscious experiences—and that increasingly bizarre 'scientific' hypotheses are dreamt up accordingly. This is just what one would expect, if their basic Cartesian assumption (italicized above) is philosophically confused.

If we decide to reject this assumption, none of the intriguing discoveries of neuroscience (nor of cognitive psychology) need be denied. But they must be interpreted in a very different way.

We can still say that rhesus monkeys—and, perhaps, humans—discriminate motion perception by cortical cells arranged around the compass, and that these discriminations are nicely predictable in neuroscientific terms. What we can't say is that the monkeys, or the humans, *have inner visual experiences* of motion-in-a-certain-direction.

Again, we can still say that the blindsight patient can make certain visual discriminations without being able to report them, and that this is because their information processing doesn't include reflexive computations of the kind necessary for self-report. We can even say that their common-sense belief system leads them to protest at the 'absurdity' of being asked to *guess*. What we can't say is that they lack what the normal person possesses: *inner experiences* (*qualia*) of objects seen in 3D space.

Last (to take an example discussed in Chapter 7.v.a), we can still say that when people imagine seeing landscapes or elephants, they're able to answer certain questions about them. We can also say that this capacity may involve such-and-such parts of, and/or such-and-such computational processes in, the brain. But we can't say that this behaviour involves *inner mental pictures*, *or conscious experiences (images)*.

The fundamental problem, then, is whether the neuroscience of consciousness should concern itself with *lions*, or with *lines*.

Despite neuroscience's huge intellectual debt to Descartes, who first defined it as a respectable activity (see Chapter 2.iii and viii), perhaps it should dismiss him as the storyteller of consciousness? Admittedly, lifting Descartes onto the philosophical tumbrils would be just as revolutionary as what his compatriots did in 1789—perhaps even more so. For our common sense (and Otto) cries out: "Rubbish! *Of course* neuroscience studies lions!" But the stubborn persistence of Gray's hoary old problems, not to mention the respect due to serious thinkers (albeit some of a very different philosophical persuasion), should at least give us pause.

e. Hung jury

My own view is that *if* we are ever to understand mind–brain correlations, some radical change in both neuroscience and the philosophy of mind will be required. So it's no accident that the end-of-century presses hummed with strange theories such as those of Penrose, Walker, and Chalmers—and others I've not had space to discuss, including various forms of panpsychism.

Some years ago, I argued that the conceptual change concerned would need to be comparable in depth to Maxwell's field theory (Boden 1998*b*). This theory reinterpreted physicists' seemingly contradictory talk of "waves" and "particles". These utterly different, even mutually exclusive, phenomena had been needed to account for different sets of experiments. Maxwell explained both in terms of an underlying theory mentioning neither, and also showed why they'd been used in distinct types of experimental situation. An analogous advance, I said, would be required to explain how the brain can generate *any* conscious experience. (Perhaps mind-as-virtual-machine is the core of the solution?)

However, I also said that this is a big "if". And I asked whether a fundamentally non-Cartesian neo-Kantian (as opposed to a Dennettian) approach might be better.

Then, I answered that it wouldn't. Not only would it mean that the 'mind–body correlations' we all talk about so confidently would have to be systematically redescribed (lines, not lions), but the nature of science in general would be redefined—not to say undermined. Instead of being a *realistic* enterprise, it would be a construction of human minds (and societies), no more 'truthful' than any other. As I said in the brief remarks on postmodernism in Chapter 1.iii.b, I regard this neo-Kantian view as fundamentally irrational. Even in the hands of a skilled analytic philosopher like John McDowell, or the middle Putnam, it's unconvincing (see Chapter 16.viii.b and vi, respectively).

But the late Putnam is different, for he now insists on the "natural realism" of science. He even defends the "direct realism" of perception—where, as we saw above, direct doesn't mean infallible. So—for him—*that* troubling philosophical bird is scotched.

Significant problems remain, however, about whether intentionality (meaning)—which is a crucial aspect of consciousness—can ever be naturalized. One can't responsibly offer an answer to our question about *qualia* without considering this question also.

For my part, if I were confident that intentionality can be scientifically explained—perhaps by Ruth Millikan's (1984) evolutionary approach: see Chapter 16.x.d—I'd gladly abandon the lions, or locate them in virtual reality. We've seen, after all, what trouble they cause. But intentionality is a huge, and far-reaching, philosophical problem—to be considered at length in Chapter 16.

Here, let me just say that my own preference—I have no knock-down argument—is for an evolutionary–computational account of these issues, not a neo-Kantian one (see Boden 1972). Any such account takes science to be a realist enterprise, an assumption I cannot bring myself to drop. One well-developed example, here, is Dennett's. He sketched an early version of Millikan's approach in his first book (1969), and holds that intentionality is something we *ascribe* to certain sorts of complex computational system. We do so because it helps us to predict, manage, and understand their behaviour (16.iv.a–b).

For Putnam, both middle and late, and for other neo-Kantians too, intentionality is a real property. Moreover, for them it is *prior* to science—not something that can be explained by it (Chapter 16.vi–viii). It follows, on that view, that neuroscience can never explain meaning. At most, it can describe what goes on in our brains when we have meaningful thoughts.

In sum, the existence of *qualia*—and therefore of mind–body correlations, *as normally understood*—isn't as "obvious" as it's typically assumed to be. And if their existence is in doubt, their explanation is necessarily problematic. The jury's still out. The discussion is often bedevilled by disagreements rooted in a clash of intuitions wholly impervious to argument (a fact noted by Dennett: see Chapter 16.iv.b). But one thing's sure: mind–brain correlations aren't a purely *scientific* problem. The philosophy has to be sorted out too.

15

A-LIFE IN EMBRYO

Artificial life is widely assumed to be excitingly new. Exciting, it is. But new, it isn't.

It was born in the 1940s, fathered by 'the two Williams': Grey Walter and Ross Ashby (Chapter 4.viii). It developed healthily in the 1950s, nurtured (as we'll see) by Alan Turing and John von Neumann. By 1960, the core ideas—situated behaviour, self-organization, adaptation, and evolution—had been sketched, and all but the last had even been simulated.

Then, A-Life (like connectionism) lapsed into a Sleeping Beauty phase. Nothing much happened for a while. Or rather, it did—but few people noticed. Even Herbert Simon's ant walked largely unseen (Chapter 7.iv.a). In the early 1980s, the sleeper stirred. The highly public awakening happened in 1987, at an interdisciplinary naming party that introduced "A-Life" not only to science but to the outside world. Today, the outside world accepts A-Life in a spirit both more mystified (S. R. L. Clark 1995) and more welcoming (Kember 2003; Whitelaw 2004) than the public perception of classical AI (see 13.vii.b). Even the postmodernists had learnt to love A-Life (see 1.iii.d).

The cyberneticists in general had assimilated life to mind. They believed that the life–mind gap could be bridged by a single type of explanation. Ashby, for example, held that his dynamical theories—and his artefacts—could advance both biology and psychology. Self-organization and adaptation, discrimination and teleology, were seen as equally central concerns.

But their explanatory monism went underground with the breakaway of GOFAI (see 4.ix.b). Most early computational psychologists focused on logical-symbolic modelling. Propositional contents ruled the day, while metabolism, adaptation, and self-organization were forgotten—or, in the latter case, assimilated to learning. Psychology, it seemed, had nothing to do with biology. Indeed, functionalist philosophy made this explicit as "multiple realizability" (16.iii.b). Cybernetics itself, meanwhile, became more closely associated with control engineering than with psychology or biology.

Later, things changed. By the end of the century, computer modelling was focused increasingly on life, and (in some cases) on the unification of life with mind. Ideas from many different sources were used in explaining the structural changes in biological (embryonic and evolutionary) and psychological development.

The biochemical origins of life were discussed too, sometimes in highly abstract, functional, terms (e.g. Drexler 1989). And people tried to model, and/or to build, chemical analogues of the origins of life at the molecular level (e.g. Luisi and Varela

1989; Szostak *et al*. 2001; Luisi *et al*. 2004). Apart from a few brief remarks at the close of Section x.b, I'll ignore these chemical discussions.

The theoretical focus of A-Life is the central feature of living things, namely self-organization. So to define self-organization is to identify the basic themes of this chapter:

* Self-organization is the spontaneous emergence (and maintenance) of order, out of an origin that's ordered to a lesser degree.
* It concerns not mere superficial change, but fundamental structural development.
* The development is spontaneous, or autonomous, in that it results from the intrinsic character of the system (often in interaction with the environment), rather than being imposed on it by some external force or designer.
* In self-organizing systems, higher-level properties result from interactions between simpler ones—and there may be many different levels of organization involved.

The phrase "spontaneous emergence" in that definition may sound like magic. It may even *feel* like magic:

> When I wrote the program [i.e. Biomorph: see vi.b, below], I never thought that it would evolve anything more than a variety of tree-like shapes . . . Nothing in my biologist's intuition, nothing in my 20 years' experience of programming computers, and nothing in my wildest dreams, prepared me for what actually emerged on the screen. . . . I distinctly heard the triumphal chords of *Also Sprach Zarathustra* (the "2001 theme") in my mind. I couldn't eat, and that night "my" insects swarmed behind my eyelids as I tried to sleep. (Dawkins 1986: 60)

If even the hard-headed Richard Dawkins reacted in this way to something unexpected on his utterly unmagical computer, how much more have people wondered at the examples of self-organization in the biological realm.

Emergence isn't imaginary: surprising phenomena, even radically *new* phenomena, do happen. In particular, unexpected high-level patterns can result from interactions between very simple lower-level processes (A. J. Clark 2001: 112–17). But it isn't magic, either—even though "emergent" is sometimes used as a buzzword with near-mystical overtones. (For a wide range of definitions, see Stephan 1998, 2003.) The aim of A-Life, with respect to emergence, is to provide the explanation without losing the wonder.

This chapter outlines the diverse origins of A-Life, and recounts how they were eventually woven together. It starts with a brief sketch of the historical links between the concepts of life, mind, and self-organization. Then, Section ii distinguishes A-Life from biomimetics. Section iii relates it to early mathematical biology, and to neo-Kantian biology too.

The story of A-Life as such begins with Section iv. (More accurately, it began in Chapter 4.viii, as remarked above.) Sections iv and v outline the relevance of reaction–diffusion equations and self-replicating automata, respectively. Evolutionary networks are discussed in Section vi.

The sensori-motor integration of the whole animal is the topic of Section vii, which outlines research in computational neuro-ethology (CNE), much of which appears in A-Life journals. Sections viii and ix describe a wide range of work on complex systems, including some done by physicists and computer scientists, and some done in a neo-Kantian spirit. The way in which A-Life was eventually recognized as a single field is described in Section x. Finally, Section xi discusses two state-of-the-art examples that are potentially relevant to cognitive science in general.

15.i. Life, Mind, Self-Organization

The historical roots of cognitive science are highly diverse, as we've seen. In particular, questions about mental processes and living things have long been intertwined. Recently, that intertwining has become even more closely tangled. For it's now clear that self-organization—the core feature of life—is an important concept in neuroscience and psychology too (see Chapters 12 and 14—especially 12.ii and v, and 14.vi and viii.c–d).

a. Life and mind versus life-and-mind

It's widely assumed—though rarely explicitly argued—that life is *necessary* for mind. This assumption, and the closely related dispute about the possibility of "strong A-Life", will be explored at length in Chapter 16.x. Meanwhile, let's merely acknowledge that all the minds we know of are found in living things. That's why "life" and "mind" are so commonly associated.

René Descartes didn't make the 'necessity' assumption (Chapter 2.ii–iii). He didn't believe in life-and-mind. Rather, he thought that the association between minds and living (human) bodies is fundamentally unintelligible, arranged by the whim of God. On his view, life and mind are radically different: living organisms, including human bodies, can be described in scientific (mechanistic) terms whereas minds can't. But as we saw in Chapter 2.v–vii, his successors didn't all agree with him.

Some disagreed by doubting the possibility of a physicalist biology. The chemist Justus von Liebig, for instance, held that chemical processes are "altered" by a vital force so as to produce compounds "altogether different" from those in inanimate matter. Others disagreed by claiming that life and mind can be explained in essentially similar ways—perhaps mechanistic (e.g. Julien de La Mettrie), perhaps not (e.g. Johann von Goethe and the Naturphilosophen).

The late nineteenth-century advances in general physiology and neurophysiology didn't settle the dispute. Non-physicalist accounts of both life and mind were still proposed after the turn of the century. It was said, for instance, that embryonic development is directed by vitalist entelechies, that adaptive evolution results from a creative life force, and that purposive behaviour involves a specifically psychic energy (see Chapter 2.vii.b and 2.x.b).

In short, in the early twentieth century life and mind were still thought by many people to lie beyond the bounds of empirical science. And life-and-mind was still a highly controversial idea.

b. Self-organization, in and out of focus

The four concepts just mentioned—embryogenesis, adaptation, evolution, and purpose—are fundamentally akin. Indeed, the word "evolution" used to mean embryogenesis—which is why Charles Darwin wrote of "descent with modification" in *The*

Origin (Bowler 1975). All four are examples of self-organization. So another way of putting the point made above is to say that, well into the twentieth century, self-organization—whether biological or psychological—was felt to lie outside science. A fortiori, it was out of reach of machine-based theories.

By the mid-twentieth century, the cybernetic movement had made more people willing to believe that these phenomena could be scientifically explained. Cybernetic explanations weren't mechanistic in the Cartesian sense outlined in Chapter 2.ii.a. They focused not on matter or energy, but on abstractions such as information, computation, adaptation, or equifinality (see Chapter 4.v–viii). These were assumed to be instantiated in physical systems, notably in organisms.

The cyberneticians, then, saw no essential mystery in self-organization. Moreover, they discussed its *origin*, as well as its *maintenance*. Ross Ashby's "ultrastable" Homeostat, for instance, showed how randomness could give way to order. And Norbert Wiener, in discussing quantum physics at the fifth Macy seminar, spoke of order arising from chaos. So whereas Claude Bernard and Walter Cannon had focused on the body's self-maintenance (see Chapter 2.vii.a), their followers in the 1940s–1950s were interested also in the generation of new order, whether in adaptation or (more rarely) in development.

Nevertheless, they weren't all happy with the term "self-organization". Ashby sometimes used it, and "self-coordinating" too (Ashby 1960: 10). But he also complained that such phrases were "fundamentally confused and inconsistent" and "probably better allowed to die out" (Ashby 1962: 269). He saw them as potentially mystifying because they imply that there's an organizer when in fact there isn't. Some modern researchers agree, carefully avoiding 'self-organization' and referring instead to *organization*: the ability to act as a unified whole (see Chapter 14.viii.c).

Yet the concept of self-organization hasn't died out. It's often mentioned in relation to neural networks—which Marvin Minsky and Seymour Papert (1969) saw as potentially related to "how the genetic program computes organisms" (see 12.iii–v). Neuroscientists use it in explaining the development of topographical maps in the brain (14.vi.b and ix.a). And it's employed by many scientists in A-Life—not to imply some mysterious 'inner organizer', but to focus on *the spontaneous origin and development* of organization at least as much as on its maintenance. As I use it in this chapter, the term carries that bias.

Self-organization is the central feature of life (see Section ii.b, below). It's no accident, then, that it's especially prominent in A-Life—as opposed to AI, psychology, or neuroscience. Those three disciplines focus on particular examples of behaviour/cognition, which they occasionally explain in terms of self-organization. By contrast, A-Life tends to focus on self-organization *as such*, using particular behaviours (such as flocking, ant trails, walking, or bodily control via perceptuo-motor mechanisms) as illustrations of it. (Similarly, the cyberneticists treated reflexes as illustrations of circular causation, rather than behavioural problems to be studied in their own right.)

The initial excitement about cybernetics in biology was soon swamped. It lost out to another way of mapping abstractions onto physical reality: the genetic code. This was hypothesized by Erwin Schrödinger in the 1940s, and attributed to DNA's double helix by Francis Crick and James Watson in 1953. It was finally decrypted, as amino-acid triplets coding for proteins, in the 1960s. As a result, the holism of cybernetics was swiftly overshadowed by a strongly reductionist molecular biology (Judson 1979).

This approach soon detailed many specific mechanisms involved in self-organization. These included gene regulation, immune reactions, and the 'programming' of neurones to make connections of specific types. But self-organization *as such* wasn't a concept of molecular biology.

It was to be born again, in a new guise, towards the end of the century. (Ironically, some of these revivalist ideas drew on the molecular biology of the immune system: Chapter 14.ix.d.) At that time, too, the cyberneticists' faith that similar types of explanation apply to both life and mind was renewed. Whether that faith was *justified* will be discussed in Chapter 16.x.

15.ii. Biomimetics and Artificial Life

Not every physical artefact that mimics living things is an example of A-Life. To show why, let's consider two examples of artificial fish—one ancient, one modern.

a. Artificial fish

In 1776 Henry Cavendish (1731–1810) nominated Captain James Cook for election to the Royal Society. Having just completed his second great voyage of discovery, Cook had exciting tales to tell of exotic fish and alien seas. But so did Cavendish. For, in the very same year, he had built an artificial electric fish and lain it in an artificial sea (Wu 1984; Hackman 1989).

Its body was made of wood and sheepskin, and its electric organ was two pewter discs, connected by a brass chain to a large Leyden battery; its habitat was a trough of salt water. Cavendish's aim was to prove that "animal electricity" is the same as the physicist's electricity, not an essentially different (vital) phenomenon. His immobile 'fish' wouldn't have fooled anyone into thinking it was a real fish, despite its fish-shaped leather 'body'. But, and this was the point, it did deliver a real electric shock, indistinguishable from that sent out by a real torpedo fish.

A hundred years later, a latter-day Cavendish might have interpreted his fish's electric organs (sensors and effectors) as Darwinian adaptations, with specific functions in the organism's biology. Today's neo-Darwinians are happy to do the same.

(However, some of them see no possibility of a *determinate* answer to the question "What is it for?" Daniel Dennett argues that attributions of biological function can *never* be wholly closed, wholly cut and dried: "It is not just that I can't tell, and they can't tell; *there is nothing to tell*"—1987: 312; italics added. His view on this matter is a biological version of his non-realist stance on psychological intentionality, outlined in Chapter 16.iv.b. It certainly doesn't match the practice of working biologists—neither in general (Kitcher and Kitcher 1988; Amundson 1988), nor in the particular case of electric fish (Keeley 1999). I'll take it for granted in this chapter, then, that biological/adaptive function can often be assigned with confidence, even if there are some difficult cases.)

Just over 200 years later, the fourth international conference on A-Life opened with a paper—and an uncannily lifelike demonstration—on the computer simulation of fish (Terzopoulos *et al*. 1994).

Whereas Cavendish's 'fish' had been a solitary object lying inert in a dish of water, these denizens of the VDU were constantly in motion, sometimes forming hunter–hunted pairs or co-moving schools. Each one, swimming around constantly, was an autonomous (independently acting) creature, with simple perceptual abilities that enabled it to respond to the world and to its fellows. Unlike the crickets and cockroaches discussed in Section vii below, or Jacques de Vaucanson's anatomically detailed duck (2.iv.a), they weren't robots: they were software creatures existing in a computer-generated virtual world.

To achieve these lifelike simulations, the modern authors started with digitized still photographs of real fish representing shape, colour, and texture. They converted these into movies not by hand-crafted image-by-image animation (as in Walt Disney's *Snow White*) but by defining rules enabling a computer to change the images automatically. These rules were based on the anatomy, mechanics, and ethology of various species of real fish, and also on real-world hydrodynamics.

The major bodily movements of the animations, with their associated changes in body shape, resulted from twelve internal muscles (conceptualized as springs). The computerized fish learned to control these in order to ride the (simulated) hydrodynamics of the surrounding sea water. A host of minor movements arose from the definitions of seventy-nine other springs and twenty-three nodal point masses, whose (virtual) physics resulted in subtly lifelike locomotion.

But realistic bodily movement doesn't suffice for realistic behaviour: where should the (animated) fish move to, how fast, how urgently, and when? These questions were answered by ethologically credible rules defining the movement trajectories and environmental conditions appropriate for various behaviours. These included feeding, hunting, fleeing, nuzzling, and reproducing. Interactive aspects, such as predator–prey behaviour, resulted from rules defining the mutual responses of two or more autonomous creatures.

Cavendish had intended his artificial fish to deliver an intellectual shock, as well as a real one. His aim was to demystify a vital phenomenon, to show the continuity between the physical and the organic—and, of course, to display the physical principle underlying the living behaviour.

He thought this shocking hypothesis to be so important that he invited some colleagues into his laboratory to observe the experiment—so far as we know, the only occasion on which he did so (Wu 1984: 602). Certainly, such an invitation from the taciturn Cavendish was a remarkable event: an acquaintance said that he "probably uttered fewer words in the course of his life than any man who ever lived to fourscore years, not at all excepting the monks of la Trappe" (Lord Brougham, quoted in *Encyclopaedia Britannica* 1990: 975). (It's been suggested that Cavendish's unsociability was due to Asperger's syndrome; the same posthumous 'diagnosis' has been made of Albert Einstein and Isaac Newton: Sacks 2001; Baron-Cohen and James 2003.)

Our contemporary fish-makers had a similar intellectual aim. Their digitized fish weren't intended as mere toys, or tools for Hollywood animators—although similar techniques are now being used for both home entertainment and commercial cinema.

Rather, they were intended to clarify "the interplay of physics, locomotion, perception, behavior, and learning in higher animals" (Terzopoulos *et al.* 1994: 17). That is, they were examples of research in A-Life.

Should we say, then, that A-Life originated with Cavendish, two centuries ago?—No. Cavendish's work was an early foray into biomimetics, not A-Life.

b. What is A-Life?

Biomimetics studies physical artefacts that mimic the material stuff of life, putting these studies to scientific or engineering use. (The term "biomimesis" also has another meaning: as defined by Warren McCulloch in 1961, it is "the imitation of one form of life by another"—for instance, a stick insect that looks just like a leaf: Bensaude-Vincent forthcoming. That meaning isn't relevant here.)

For instance, biomimetics explores the irritability and excitability of (non-biological) membranes. Or it builds iron-wire-in-nitric-acid models of nervous transmission (Lillie 1936). Or it analyses living structures for purposes of architectural design: water lily leaves for Joseph Paxton's magnificent Crystal Palace, perhaps. Or it models artificial sensors on sensors in plants and, especially, animals (Barth *et al.* 2003). Specific material properties are taken seriously, so that if some chemical element were missing, or some physical measure different, the biomimetic model would ideally be correspondingly altered.

A-Life is more abstract than this, even though the virtual-fish world does include data about actual fish and does attempt precise simulation of hydrodynamics. It draws its distinctive ideas from computer science and complex dynamics (see Sections v–viii). It uses computer modelling—including robotics—as its methodology. And it aims to explain not only particular vital phenomena but also the properties of life in general. As Christopher Langton (1949–) said when he first defined it in 1986, it studies "life as it could be" rather than merely "life as we know it" (Langton 1989*b*: 2).

The core of A-Life is self-organization, which (as remarked in the preamble) can involve interactions occurring on several levels. In living organisms, the relevant interactions include chemical diffusion, perception and communication, adaptation, and evolution.

The emergent properties are also of many different kinds. They include universal characteristics of life, such as autonomy, reproduction, and metabolism. They also cover distinct lifestyles, such as parasitism, and particular behaviours, such as flocking, hunting, or evasion. Bodily morphology is included: for instance, the anatomy of sense organs, motor organs (such as fins), and control mechanisms. So, too, are widespread developmental processes, such as cell differentiation.

The formation of single cells, the simplest living things, is a fundamental example of biotic self-organization. Many would say it's *the* fundamental example (see Section vii.b). But they'd allow that the spontaneous formation of new chemical compounds in prebiotic 'soups' is also relevant to biology.

Self-organization *tout court* doesn't suffice for life. It occurs in some purely chemical systems—such as the Belousov–Zhabotinsky diffusion reaction, wherein organized ring patterns of different colours arise within an initially homogeneous fluid. Life requires some or all of the types of self-organization just mentioned. ("Some or all", because there's no universally agreed definition of the concept of life (Boden 1996, pt. IV): see also 16.x.b–c.) Accordingly, work in A-Life has ranged across all these aspects of living organisms.

The aim of A-Life is to understand life, not to construct new life forms. Admittedly, a tiny handful of A-Life researchers hope to synthesize new life, even *virtual* life (see Section ix.b). In general, however, A-Life doesn't try to go one better than biomimetics. Its late twentieth-century artefacts, like Cavendish's leather fish, are meant to exemplify *theories about life*—not life itself.

15.iii. Mathematical Biology Begins

Someone might seek to distance A-Life still further from Cavendish's research, by suggesting another sense in which it is "more abstract".

Cavendish's experiment couldn't have been done without the artificial fish in its bath of conducting fluid, because his aim was to reproduce the same physical phenomenon (electrical conductivity) that occurs in some living things. Biomimetics requires physical mimesis. But—so someone might argue—A-Life's artefacts, namely computers, are dispensable. If artefacts are needed at all, then just three are enough: pencil, paper, and armchair. For A-Life is a recent variety of mathematical biology, and mathematics is an abstract science.

Our imaginary interlocutor is right in saying that A-Life is a form of mathematical biology. That is, it uses (broadly) mathematical concepts and techniques to analyse and explain properties of living things. But it doesn't follow that A-Life's artefacts are dispensable, as we'll see.

a. Of growth and form

Isolated examples of mathematically expressed biological research were scattered in the pre-twentieth-century literature. But mathematical biology as an all-encompassing and systematic approach was attempted only after the turn of the century. Its instigator was the zoologist Sir D'Arcy Thompson (1860–1948) of the University of St Andrews, whose visionary work *On Growth and Form* was first published in 1917. Richly packed with fascinating examples, it ran to nearly 800 pages. A much enlarged (1,116 pages) second edition appeared in 1942, six years before the author's death.

D'Arcy Thompson—he's hardly ever referred to merely as "Thompson"—was born only a year after the publication of *On the Origin of Species*, and was already middle-aged when Queen Victoria died in 1901. He survived through both world wars, dying at almost 90 years old in 1948. That was the year in which the Manchester MADM computer, for which Turing was the first programmer, became operational.

If he had an exceptional span in life years, he also had an extraordinary span in intellectual skills. He was a highly honoured classical scholar, who translated *Historia Animalium* for the authoritative edition of Aristotle (D. W. Thompson 1910). In addition, he was a biologist and mathematician, and was offered chairs in Classics and Mathematics as well as in Zoology.

While still a teenager (if 'teenagers' existed in Victorian Scotland), he edited a brief book of essays from the Museum of Zoology in Dundee (D. W. Thompson 1880). But he soon graduated to larger tomes. In his early twenties, he edited and translated a German biologist's scattered writings on how flowers of different types are pollinated by insects—in a 670-page volume for which Darwin himself wrote the Preface (D. W. Thompson 1883).

Forty years later, he was commenting on ancient Egyptian mathematics in *Nature* (D. W. Thompson 1925), and analysing the catches made by fishermen trawling off Aberdeen (D. W. Thompson 1931). His essays ran from classical biology and astronomy, through poetry and medicine, to 'Games and Playthings' from Greece and Rome, and included popular pieces written for *Country Life*, *Strand Magazine*, and *Blackwood's Magazine* (D. W. Thompson 1940). His last book, out a few months before he died, was *A Glossary of Greek Fishes*: a "sequel" to his volume on all the birds mentioned in ancient Greek texts (D. W. Thompson 1895, 1947). Clearly, then, D'Arcy Thompson was a man of parts.

He was no mere list-maker, as some of the titles above might suggest. On the contrary, he was a great intellect and a superb wordsmith. His major book has been described by the biologist Peter Medawar as "beyond comparison the finest work of literature in all the annals of science that have been recorded in the English tongue" (Medawar 1958: 232). And his intoxicating literary prose was matched by his imaginative scientific vision.

Although Darwin had written the Preface for his first 'real' book, D'Arcy Thompson became increasingly critical of Darwinian theory. An early intimation of this was in his paper 'Some Difficulties of Darwinism', given in 1894 to an Oxford meeting of the British Association for the Advancement of Science (one of Babbage's many brainchildren: Chapter 3.i.a).

His book, over twenty years later, explained at length why he felt Darwinism to be inadequate as an explanation of the living creatures we see around us. Like some maverick modern biologists (see Section viii), he regarded natural selection as strictly secondary to the origin of biological form—which must be explained in a different way.

He integrated a host of individual biological facts within a systematic vision of the order implicit in living organisms. That is, he used various ideas from mathematics not only to describe, but also to explain, fundamental features of biological form. He wasn't content, for example, to note that patterns of leaf sprouting on plants may often be described by a Fibonacci number series (such as 0, 1, 1, 2, 3, 5, 8, 13, 21, . . .). He converted this finding from a mathematical curiosity into a biologically intelligible fact, by pointing out that this is the most efficient way of using the space available.

Significantly, he often combined 'pure' mathematical analysis with the equations of theoretical physics. In this way, he tried to explain not only specific anatomical facts (such as the width and branching patterns of arteries, relative to the amount of blood to be transported), but also why certain forms appear repeatedly in the living world.

D'Arcy Thompson referred to countless examples of actual organisms, but he had in mind also *all possible* life forms. As he put it:

> [I] have tried in comparatively simple cases to use mathematical methods and mathematical terminology to describe and define the forms of organisms . . . [My] study of organic form, which [I] call by Goethe's name of Morphology, is but a portion of that wider Science of Form which deals with the forms assumed by matter under all aspects and conditions, and, in a still wider sense, with forms which are theoretically imaginable. (1917/1942: 1026)

For D'Arcy Thompson, then, the shapes of animals and plants aren't purely random: we can't say "Anything goes". To the contrary, developmental and evolutionary changes in morphology are constrained by underlying general principles of physical and mathematical order.

As his own acknowledgement made clear, D'Arcy Thompson's work was closely related to Goethe's rational morphology (see Chapter 2.vi.e). Like Goethe, whom he quoted with approval several times in his book, he sought an abstract description of the anatomical structures and transformations found in living things—indeed, in all possible things. So he discussed the reasons for the spherical shape of soap bubbles, for instance.

His reference to "forms which are theoretically imaginable" recalls Goethe's remark (quoted in 2.vi.e) that

> With such a model [of the archetypal plant and its transformations] . . . one will be able to contrive an infinite variety of plants. They will be strictly logical plants—in other words, even though they may not actually exist, they could exist. [Compare: "life as it could be".] They will not be mere picturesque and imaginative projects. They will be imbued with inner truth and necessity. And the same will be applicable to all that lives. (quoted in Nisbet 1972: 45)

And like Goethe, he believed that certain forms were more natural, more likely, than others. In some sense, he thought, there are "primal phenomena".

Also like Goethe—though here, the analogy becomes more strained—he asked questions about the physical mechanisms involved in bodily growth. But his philosophical motivation for those questions was importantly different. Although D'Arcy Thompson was sympathetic to some of the claims of the Naturphilosophen, he wasn't a fully paid-up member of their club. Indeed, he opened his book by criticizing Immanuel Kant and Goethe, complaining that they had ruled mathematics out of natural history (Thompson 1917/1942: 2).

In part, he was here expressing his conviction that "the harmony of the world is made manifest in Form and Number, and the heart and soul and all the poetry of Natural Philosophy are embodied in the concept of mathematical beauty" (pp. 1096–7). This conviction wasn't shared by his professional colleagues: "Even now, the zoologist has scarce begun to dream of defining in mathematical language even the simplest organic forms" (p. 2). But in part, he was saying that physics—real physics—is crucially relevant for understanding "Form".

The idealist Goethe had seen different kinds of sap as effecting the growth of sepal or petal, but for him those abstract possibilities had been generated by the divine intelligence self-creatively immanent in Nature. D'Arcy Thompson, by contrast, argued that it is real physical processes, instantiating strictly physical laws, which generate the range of morphological possibilities. Certainly, those laws conform to abstract mathematical relationships—to projective geometry, for example. But biological forms are made possible by underlying material–energetic relations.

Accordingly, D'Arcy Thompson tried to relate morphology to physics, and to the dynamical processes involved in bodily growth. He suggested that very general physical (as opposed to specific chemical or genetic) constraints could interact to make some biological forms possible, or even necessary, while others are impossible.

Had he lived today, D'Arcy Thompson would doubtless have relished the work on the self-organization of feature-detectors described in Chapter 14.vi.b and ix.a. For this explains why we should expect to find systematic neuro-anatomical structure in the brain, as opposed to a random ragbag of individually effective detector cells. Moreover, the "why" isn't a matter of selection pressures, but of spontaneous self-organization. But that recent research required computational concepts and computing power (not to mention anatomical data) that he simply didn't have. He could use only the mathematics and physics available in the early years of the century.

Although D'Arcy Thompson wasn't the first biologist to study bodies, he might be described as the first biologist who took *embodiment* seriously. The physical phenomena he discussed included diffusion, surface forces, elasticity, hydrodynamics, gravity, and many others. And he related these to specific aspects of bodily form.

His chapter 'On Magnitude', for example, argued both that size can be limited by physical forces and that the size of the organism determines which forces will be the most important. Gravity is crucial for mice, men, and mammoths, but the form and behaviour of a water beetle may be conditioned more by surface tension than by gravity. A bacillus can in effect ignore both, being subject rather to Brownian motion and fluid viscosity. Again, his discussion of 'The Forms of Cells' suggested, among many other things, that the shape and function of cilia follow naturally from the physics of their molecular constitution.

(A very recent discovery about axon sizes would have delighted his heart: Faisal *et al.* 2005. The thinner the axons are, the more neurones can be packed into a given volume. But no axons thinner than about 0.1 of a micron have ever been found, even in species with tiny bodies and tinier brains. Computer simulations show that the molecular 'noise' involved in the opening and shutting of sodium/potassium ion channels becomes overwhelming below that point, causing random spontaneous action potentials. In brief, the *biophysics* constrains the minimal diameter of an axon. A copper wire measuring 0.001 of a micron could transmit currents efficiently. But equally tiny axons, if they are to transmit information reliably, are *impossible*.)

Perhaps the best-known chapter of *On Growth and Form*, and the one which had the clearest direct influence, was entitled 'On the Theory of Transformations, or the Comparison of Related Forms'. This employed a set of two-dimensional Cartesian grids to show how differently shaped skulls, limb bones, leaves, and body forms are mathematically related. One form could generate many others, by enlargement, skewing, and rotation.

So, instead of a host of detailed comparisons of individual body parts bearing no theoretical relation with each other, anatomists were now being offered descriptions having some analytical unity.

To be sure, these purely topological transformations couldn't answer questions about more radical alterations in form. The gastrulation (self-invagination) of an embryo, for example, couldn't be explained in this way (see Section iv.a, below). And only very few zoologists—of whom Medawar was one—tried to use D'Arcy Thompson's specific method of analysis. But his discussion inspired modern-day allometrics: the study of the ratios of growth rates of different structures, in embryology and taxonomy.

b. More admiration than influence

One didn't need to be doing allometrics to admire D'Arcy Thompson. By mid-century, he was widely revered as a scientist of exceptional vision (Hutchinson 1948; Le Gros Clark and Medawar 1945). The second edition of *On Growth and Form* was received with excitement in 1942, the first edition (of only 500 copies) having sold out twenty years before. Reprints had been forbidden by D'Arcy Thompson himself, while he worked on the revisions, and second-hand copies had been fetching ten times their original price.

However, only a decade after the long-awaited second edition, the advent of molecular biology turned him overnight into a minority taste. Ironically, much the same had happened to his muse Goethe, whose still-unanswered biological questions simply stopped being asked when Charles Darwin's theory of evolution came off the press in 1859 (see Chapter 2.vi.f). By the end of the 1960s, only a few biologists regarded D'Arcy Thompson as more than a historical curiosity.

One of these was Conrad Waddington (1905–75), a developmental biologist at the University of Edinburgh (whose theory of "epigenesis" influenced Jean Piaget: see Chapter 7.vi.g). Waddington continually questioned the reductionist assumption that molecular biology can—or rather, will—explain the many-levelled self-organization of living creatures. It's hardly surprising, then, that D'Arcy Thompson was often mentioned in his 'invitation only' seminars on theoretical biology, held in the late 1960s at the Rockefeller Foundation's Villa Serbelloni on Lake Como (Waddington 1966–72). (The seminars gathered together a fascinating group of people, including several mentioned in this book: Michael Arbib, Ted Bastin, David Bohm, Brian Goodwin, Christopher Longuet-Higgins, John Maynard Smith, and Howard Pattee.)

But Waddington, too, was a maverick, more admired than believed. His theory of epigenesis couldn't be backed up by convincing empirical evidence, whether in the developing brain or in the embryo as a whole. Only after his death did his ideas gain ground. Significantly, the proceedings of the first A-Life conference were dedicated to him (Langton 1989*a*, p. xiii).

D'Arcy Thompson's most devoted admirers, however, had to concede that it was difficult to turn his vision into robust theoretical reality. Despite his seeding of allometrics, his direct influence on biology was less strong than one might expect, given the excitement (still) experienced on reading his book.

Even subsequent attempts to outline a mathematical biology eschewed his methods. Joseph Woodger's (1929, 1937) axiomatic biology, for instance, owed more to mathematical logic and the positivists' goal of unifying science (see Chapter 9.v.a) than to D'Arcy Thompson. And Turing's mathematical morphology employed numerically precise differential equations, not geometrical transformations—even though *Of Growth and Form* was cited at the end of Turing's paper (see Section iv.a). In short, D'Arcy Thompson figured more as inspirational muse than as purveyor of specific biological theory or fact.

The reason why his influence on other biologists, although "very great", was only "intangible and indirect" (Medawar 1958: 232) is implied by his own summary comment.

At the close of his final chapter, he recalled the intriguing work of a naval engineer who, in 1888, had described the contours and proportions of fish "from the shipbuilder's point of view". He suggested that hydrodynamics must limit the form and structure of swimming creatures. But he admitted that he could give no more than a hint of what this means, in practice. In general, he said:

> Our simple, or simplified, illustrations carry us but a little way, and only half prepare us for much harder things . . . *If the difficulties of description and representation could be overcome*, it is by means of such co-ordinates in space that we should at last obtain an adequate and satisfying picture of the processes of deformation and the directions of growth. (1917/1942: 1090; italics added)

c. Difficulties of description

The "difficulties of description and representation" remained insuperable for more than half a century after the publication of those first 500 copies of D'Arcy Thompson's book.

Glimpses of how they might be overcome arose (in the early 1950s) a few years after his death. Actually overcoming them took even longer. Or perhaps one should rather say it *is taking* even longer. We're now in a position to appreciate the potential of his ideas better than his contemporaries could, and to put more computational flesh onto the bones he sketched so many years ago (Chaplain *et al.* 1999). For this early exercise in mathematical biology resembled current work in A-Life in various ways.

Were D'Arcy Thompson alive today, he'd be very interested in A-Life:

* He'd be fascinated by the exhibition of the virtual swimming fish, with its detailed interplay of hydrodynamics and bodily form.
* He'd be intrigued by the A-Life evolution of decidedly unlifelike behaviour, as a result of a specific mistake in the simulated physics (Sims 1994).
* He'd recognize the potential relevance for morphology of computational work on diffusion gradients (see Section iv),
* and he'd sympathize with those who see evolution as grounded in general principles of order (Section viii).
* He'd appreciate the artificial evolution of a range of networks controlling lamprey swimming (Section vii.d).
* As remarked above, he'd appreciate the recent work on self-organization in the brain (14.vi.b and ix.a).
* He'd agree with A-Lifers who stress the dynamical dialectic between environmental forces and bodily form and behaviour.
* He might have embarked on a *virtual biomimetics*: a systematic exploration of the effects of (simulated) physical principles on (simulated) anatomies.
* And he'd certainly share A-Life's concern with life as it could be—his "theoretically imaginable forms"—rather than life as we know it.

Nevertheless, there are three important, and closely related, differences between D'Arcy Thompson's work and research in A-Life. Each of these reflects his historical situation—specifically, the fact that his work was done before the invention of computers. One difference concerns the practical usefulness of computer technology, and shows why (contrary to the suggestion noted above) A-Life's artefacts are not, in fact, dispensable. The other two concern limitations on the mathematical concepts available when D'Arcy Thompson was writing: in his words, the difficulties of description and representation that needed to be overcome.

First, D'Arcy Thompson was able to consider only broad outlines, largely because he had to calculate the implications of his theories using hand and brain alone. Today, theories with richly detailed implications can be stated and tested with the help of superhuman computational power. The relevant theories concern (for instance) the hydrodynamics of fish; the interactions between various combinations of diffusion gradients; and processes of evolution and co-evolution, occurring over many thousands of generations.

In addition, we can now study chaotic phenomena (which include many aspects of living organisms), where tiny alterations to the initial conditions of a fully deterministic system may have results utterly different from those in the non-altered case. These results can't be predicted by approximation, or by mathematical analysis. The only way to find out what they are is to watch the system—or some computer specification of it—run, and see what happens. In all these cases, the "help" A-Life gets from computers isn't an optional extra, but a practical necessity.

Second, D'Arcy Thompson's theory, though relatively wide in scope, didn't encompass the most general feature of life: self-organization as such. Instead, it considered many specific examples of self-organization. This isn't surprising. Prior to computer science and information theory, no precise language was available in which this could be discussed.

And third, although he did consider deformations produced by physical forces, D'Arcy Thompson focused more on structure than on process. This is characteristic of pre-computational theories in general. Prior to computer science, with its emphasis on the exact results of precisely specified procedures, scientists lacked ways of expressing—still less, of accurately modelling (and tracking)—the details of change.

Uniform physical changes could be described by linear differential equations, to be sure. And Charles Babbage could lay down rules, or programs, determining indefinitely many "miraculous" discontinuities (see Chapter 3.i.b). But much as Babbage (as he admitted) couldn't program the transformation of caterpillar into butterfly, so D'Arcy Thompson's mathematics couldn't describe the morphological changes and dynamical bifurcations that occur in biological development.

One might have expected that cybernetics would provide some of the necessary advances in descriptive ability. Not only was it a form of mathematical biology, but it used computer modelling as a research technique (see Chapter 4.v–vii). As the study of "circular causal systems", it drew on mainstream ideas about metabolism and reflexology, not on the morphological questions that interested D'Arcy Thompson. But it considered some central biological concerns now at the core of A-Life: adaptive self-organization, the close coupling of action and perception, and the autonomy of embodied agents.

It even made some progress. For instance, Ashby's (1952) "design for a brain", and his Homeostat, depicted brain and body as dynamical physical systems (see section xi, below). And Grey Walter's (1950*b*) tortoises, explicitly intended as "an imitation of life", showed that lifelike behavioural control can be generated by a very simple system (see Chapter 4.vii).

However, the cybernetics of the 1950s was hampered by lack of computational power, and by the diversionary rise of symbolic AI. Only much later—and partly because of lessons learned by symbolic AI—could cybernetic ideas be implemented more convincingly. Even so, some recent (dynamical) approaches suffer the limitation remarked in Chapter 4.vi.a with respect to cybernetics: they can't easily represent hierarchical structure, or detailed structural change.

As it turned out, it was physics and computer science—not cybernetics—which, very soon after D'Arcy Thompson's death in 1948, produced mathematical concepts describing the generation of biological form. Indeed, two of the founding fathers of computer science and AI, Turing and von Neumann, were also the two founding fathers of A-Life. (Von Neumann's intellectual range was even greater than Turing's, including chemical engineering for example: Ulam 1958.)

Around mid-century, they each developed accounts of self-organization, showing how simple processes could generate complex systems involving emergent order. They might have done this during D'Arcy Thompson's lifetime, had they not been preoccupied with defence research. While Turing was code breaking at Bletchley Park, von Neumann was in Los Alamos, cooperating in the Manhattan Project to design the atom bomb.

The end of the war freed some of their time for more speculative activities. Both turned to abstract studies of self-organization. Their new theoretical ideas eventually led to a wide-ranging mathematical biology, which could benefit from the increasingly powerful technology that their earlier work had made possible.

15.iv. Turing's Biological Turn

Turing's towering presence in the history of cognitive science is without parallel. He pioneered the theory of computer science and the design of digital computers, and outlined the research programme of AI—including connectionism (Chapters 4.i–ii, 10.i.f, and 12.i.b). In addition, his tongue-in-cheek challenge that came to be known as the Turing Test provoked a huge philosophical response, and still prompts attention today (Chapter 16.ii.c).

What's been less widely recognized, until recently, is his important contribution to mathematical biology—and, indirectly, to neuroscience.

a. A mathematical theory of embryology

The origin of biological form was still hugely mysterious at mid-century. Babbage's suggestion (Chapter 3.i.b) that metamorphosis might be due to some predetermined change in the laws of physics wasn't satisfactory. Scientists wanted to be able to explain the emergence of new forms *without* positing any change in the underlying physics. Better still, they wanted to do this by reference to specific aspects of the known laws of physics. But how was that to be done? Despite D'Arcy Thompson's provocative writings, no one had any clear idea. It was Turing who sketched a preliminary answer.

For the last few years of his life, Turing's energy went primarily into what he called "my mathematical theory of embryology". Indeed, after writing the first Manchester programming manual in 1950, he neglected his duties in the computing laboratory there as a result of his new interest.

His attitude perplexed and irritated his university colleagues, and the engineers and government officials charged with improving and applying the novel technology. For them, this was an exciting time. The world's first commercially available electronic computer (the Ferranti Mark I), which had been largely designed by Turing himself, was delivered to the Manchester laboratory early in 1951 (see Chapter 3.v.b). But he took little interest in it. His concentration was directed instead on his biological ideas. In 1952, when his Manchester colleagues were enjoying their new toy, he published a mathematical paper on morphogenesis (A. M. Turing 1952).

That was only two years before his untimely death: he committed suicide in 1954 (see 4.i.a). He was still working on these ideas when he died, and Max Newman's brief summary written for the Royal Society's memoir appeared in his mother's book (S. S. Turing 1959: 139–44). Drafts of, and extensive notes for, three further mathematical papers on 'The Morphogen Theory of Phyllotaxis' were found in his rooms. (They were partly corrected/prepared by N. E. Hoskin and B. Richards, with notes by Robin Gandy; details are available online in the Turing archive, <http://www.turingarchive.org>, AMT/C/8–10 and 24–7.) Generally, however, when people today refer to "Turing on morphogenesis" they mean his 1952 paper.

In his published account of morphogenesis, Turing followed the path pioneered by D'Arcy Thompson. Indeed, Thompson's book, which he had read before the war, was one of only six references he cited. This paper, in which he discussed the role of fundamental physical processes in the generation of biological form, is now recognized as an early essay in A-Life.

It is also, in principle, an early essay in neural dynamics—and is seen as such by Jack Cowan and Walter Freeman, for instance (see 12.ii.b and 14.x.a–b). The reason is that the crux of the 1952 paper was the problem of how self-organization (pattern development) *in general* is possible. Turing (1947*b*) had already asked how organization could arise in unorganized neural networks, but there he'd assumed some outside interference, or training procedure (12.i.b). Now, he considered the origin of organization without outside interference.

In particular, he asked how homogeneous cells can develop into differentiated tissues, and how these tissues can arrange themselves in regular patterns on a large scale, such as stripes or segments.

Embryologists of the 1950s knew well enough that ordered complexity arises from the undifferentiated egg. But how this is possible was a mystery. They appealed to vaguely conceptualized "morphogenetic fields", controlled by hypothetical, presumably biochemical, forces called "organizers". But what an organizer was, and how it could produce novel structure, they couldn't say.

Turing didn't claim to know the chemical details either. His achievement was to prove, in mathematical terms, that relatively simple chemical processes could, in principle, generate order from homogeneous tissue. The processes concerned involve chemicals whose mutual interactions as they diffuse throughout the system can (sometimes) destroy or build each other.

Since no one knew just which chemicals these might be, Turing referred to them simply as morphogens (from the Greek: form originators). He showed that the interactions between two or more morphogens, each initially distributed uniformly across the system, could eventually produce waves of differing concentrations. This can happen in non-living systems (chemicals diffusing in a bowl, for instance) as well as living creatures. But Turing suggested that in an embryo or developing organism, a succession of these processes might prompt the appearance of ordered structures such as spots, stripes, tentacles, or segments.

This may seem like magic: how can difference arise from homogeneity? Turing allowed that a perfectly homogeneous system in stable equilibrium would never differentiate. But if the equilibrium is unstable, even very slight disturbances could trigger differentiation.

Some disturbances, he pointed out, are inevitable, given that—as D'Arcy Thompson had insisted—living matter is subject to the laws of physics. For example, random Brownian motion within the cell fluids must vary the pairwise interactions between the molecules. And molecules will be slightly deformed as they pass through the cell wall. Even minute disturbances like these could upset the initial (unstable) equilibrium.

Turing gave simple differential equations defining possible interactions between two morphogens. Various terms specified the initial concentrations of the two substances, their rates of diffusion, and the speed at which one could destroy (or build up) the other. He showed that certain numerical values of these terms would result in ordered structures with biological plausibility.

For instance, irregular dappling or spot patterns could result from two morphogens diffusing on a plane surface (see Figure 15.1). Diffusion waves within a twenty-cell ring could give rise to regularly spaced structure, reminiscent of the embryonic beginnings of circular patterns of cilia, tentacles, leaf buds, or petals—or segments, if the ring were broken. (Such a ring is, in effect, a cellular automaton: see Section v.a.)

Turing suggested that order could be generated in three dimensions also. For example, diffusion waves could cause embryonic gastrulation, in which a sphere of homogeneous cells develops a hollow (which eventually becomes a tube). And interactions between

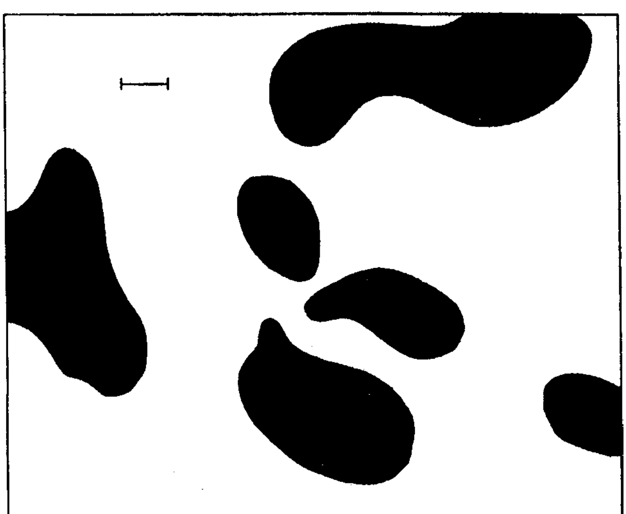

FIG. 15.1. Dappling produced by diffusion equations. Reprinted with permission from A. M. Turing (1952: 60)

more than two morphogens could produce travelling waves, such as might underlie the movements of a spermatozoon's tail.

b. History's verdict

Turing's imaginative paper was read with excitement by embryologists. It proved beyond doubt what D'Arcy Thompson had suggested: that self-organization of a biologically plausible kind could, in principle, result from relatively simple chemical processes. But it didn't, and couldn't, prove that real biological structures actually do emerge in this way. Only experimental developmental biology can show that. (Compare the point made in Chapter 7.iii.c, that only psychological experiments can confirm the psychological reality of a computer model of mind.)

This question couldn't be experimentally addressed at mid-century, because the necessary biochemical techniques weren't yet available. Today, it's still being debated.

For instance, the biologist Maynard Smith (1920–2004), who'd hoped to find that Turing waves underlie the segmentation of the fruit fly *Drosophila*, later admitted that this seems not to be the case: apparently, a different gene controls each segment (personal communication). However, he allowed that Turing waves may be responsible for segmentation in those animals, such as earthworms, in which most of the segments are identical, and/or that they were crucial at an earlier stage of evolution, before specialized segment genes appeared. Moreover, he said, the *numbers* of petals in flowers, for example, may be specified by wavelength ratios of Turing waves (though as yet there's no evidence for this).

Again, the geneticist Gabriel Dover (personal communication) argues that even in earthworms the generation of iterated segments is driven by strictly *local* processes. On his view, it's like adding yet another square at the end of a toilet roll, as opposed to taking a sheet of flimsy paper and spreading waves across it to generate stripes of perforation. And finally, the embryologist Lewis Wolpert (personal communication) denies that Turing waves can explain the development of fingers (an example of repeated structure).

In developmental neuroscience, however, recent work (described in Chapter 14.x.a) suggests that self-organization in the brain—of feature-detectors, for instance—does occur by means of mechanisms like those which Turing described. Cowan, for example, sees "a very close relationship" between Turing's ideas and the brain (J. A. Anderson and Rosenfeld 1998: 118). And this, he says, is no accident:

> The same epigenetic mechanism for pattern formation, the tendency to make stripes and blobs, is ubiquitous in nature. Cloud patterns, animal coat markings, hallucination patterns [in migraine, for example], maps—all that is sitting there. The brain is no different in many respects from any other physical organization. There's a tendency for pattern formation to occur because it's got all the same kinds of machinery in it. (J. A. Anderson and Rosenfeld 1998: 121)

D'Arcy Thompson would surely have agreed.

If Turing's paper didn't immediately affect embryology, nor did it spawn A-Life as a computational discipline. For he faced a methodological obstacle comparable to one facing D'Arcy Thompson before him.

Turing had access to the Manchester University computer, and used it (or, occasionally, a desk calculator) to calculate the successive steps of interaction between the morphogens. But this was a time-consuming and tedious matter. Moreover, in the absence of computer graphics, the computer's numerical results had to be laboriously converted to a (more easily intelligible) visual representation by hand. Turing himself remarked that much better machines would be needed to follow up his ideas.

Now, half a century later, such machines exist. Powerful computers have recently been used to vary the numerical parameters in Turing's own equations, to calculate the results, (often) to apply two or more equations successively, and to convert all these numerical results into graphical form (Turk 1991). In this way, Turing's equations have generated spot patterns, stripes, and reticulations resembling those seen in various living creatures.

Some of the structures produced in these computational experiments are shown in Figures 15.2–15.4. The large and small spots in the upper half of Figure 15.2 result from changing the size parameter in Turing's reaction–diffusion equation. If the large-spot pattern is frozen, and the small-spot equations then run over it, we get the 'cheetah spots' at bottom left. The 'leopard spots' at bottom right are generated by a similar two-step process, except that the numbers representing the concentrations of chemicals in the large spots are altered before the small-spot equation is run.

These cascades of reaction–diffusion systems kicking in at different times (reminiscent of the switching on and off of genes: see Section viii.b) result in more naturalistic patterns than does a simultaneous superposition of the two equations. Similar cascades of a 5-morphogen system generate the lifelike patterns of Figure 15.3. And the addition of rules linking stripe equations to 3D contours produces the moulded zebra stripes of Figure 15.4. This work was done for the purposes of computer graphics, not theoretical biology. But it shows that simple rules can produce lifelike complexity.

Other A-Life work on the physical principles underlying morphogenesis combines computer simulation with biomimetics. For example, chemical experiments (first done by Stéphane Leduc, soon after 1900) show that osmosis can produce lifelike forms, even in inorganic solutions. If pieces of calcium chloride are dropped into a saturated solution of sodium phosphate, the surface film of calcium chloride molecules functions as a 'membrane' separating a growing form (made of calcium chloride plus water) from the surrounding phosphate solution. This happens because osmotic pressure (more water molecules outside than inside) causes water to pass through the surface film, which increases in area as a result.

Computer simulations of osmosis show that, if the rates of production and disintegration of molecules are in balance, it will in general produce persisting (dynamically self-maintaining) topological unities (Zeleny *et al.* 1989). Because these are regarded as possible precursors of autonomous cells bounded by cell walls, this type of research is sometimes called "synthetic biology" (see Section x.b, below).

Some A-Life research has explored the morphological implications of differential cell growth, but without specifying actual physical mechanisms such as diffusion. For instance, the Dutch biologist Aristid Lindenmayer (1925–89) and others have followed up D'Arcy Thompson's ideas by defining various algorithms (known as L-systems) for describing cell growth in plants (Lindenmayer 1968, 1977; Jean 1984).

A Fibonacci number series, for example, may be employed without asking how it's instantiated in chemistry. When L-systems are expressed as computer graphics, a wide range of lifelike plant forms results. These can aid biologists by showing which forms can or can't be generated by certain types of rule, applied in one order or another. (L-systems are also widely used in computer animation.)

The focus on morphogenesis as a result of bottom-up, localized, physical processes is very much in the spirit of Turing, and D'Arcy Thompson too. Now, it's respectable. Early in the century, it wasn't. Indeed, in 1907 the French Académie des sciences refused to publish Leduc's account of osmotic precipitation, because it "touched too closely on the then-discredited notion of spontaneous generation" (Zeleny *et al.* 1989: 126). Self-organization, apparently, was seen by the Académie as either myth or magic.

Finally, exciting work (outlined in Chapter 14.ix.f) has recently begun on using A-Life techniques to evolve computers partly composed of diffusing waves of chemicals. The hope is that logical functions, such as *and-gates*, can be implemented in this way—and that these non-linear machines may be able to do other things which today's digital computers cannot.

So history's verdict on Turing's biological paper is one of approval. The editor of a collection of Turing's work has even stated that this paper has been cited more often "than the rest of his works taken together" (P. T. Saunders 1992).

I suspect that that isn't true, since the Turing Test paper has been cited countless times by philosophers and computer scientists—not to mention members of the general public. But there's no way of knowing for sure, because citation indices don't normally search the bibliographies given in books, often omit non-scientific journals, and never search the 'public' media.

What is true, however, is that by the time that statement was made, many more people were aware of the biological paper than was the case even ten years earlier. I'd noticed this myself. Having greatly admired it when I came across it as a medical student in the mid-1950s, I was surprised to find over the next twenty-five years that knowledge of it was pretty limited even among my scientific colleagues. (As for philosophers, they'd very rarely heard of it, never mind read it.) Now, references to this mid-century paper are ten a penny.

15.v. Self-Replicating Automata

Self-organization, and its biological relevance, interested von Neumann (1903–57) no less than Turing.

His work on this topic was even wider in scope than Turing's. For it included the problems of reproduction and evolution—including the puzzles of how complex a system must be in order to be able to replicate itself, and how a self-replicator could generate descendants more complex than itself. (Turing (1950) had mentioned the possibility of a child machine inheriting features from its parents, but hadn't detailed how this might be possible.)

a. Self-organization as computation

Von Neumann's approach differed from Turing's in treating self-organization in terms of information, not physics. His aim was to define the necessary conditions for self-replication in general: reproduction as it could be, not merely reproduction as we know it.

That "merely", however, may be misleading. The biological mechanism of heredity was still a mystery when von Neumann first described it in informational terms. When the double helix was discovered five years later (in 1953), and the genetic code decrypted some years after that, it turned out that biological reproduction did indeed fit von Neumann's abstract description.

He thought of replication as a computational process, requiring a minimal level of computational complexity. Specifically, he realized that part of the self-replicating system must function both as instructions and as data—namely, as a self-description. Turing had noted in 1936 that one and the same tape state could be interpreted sometimes as data and sometimes as instructions, but he didn't apply this insight to self-replication (see Chapter 4.i.d).

Von Neumann even defined a universal replicator, a computational system capable of reproducing any system, itself included. (Biological organisms aren't universal replicators: cats give birth only to kittens.) He also remarked that errors in copying the self-description could lead to evolution, which might thus be studied computationally.

In other words, "evolution" was being seen as an abstract principle. It could be applied not only to genes and/or species but to computational structures too—and, as eventually became clear, to the immune system and neural development (Chapter 14.ix.d). Formulated by Donald Campbell as BVSR, or Blind Variation and Selective Retention, it was even applied to concepts and cultural practices too (8.v.b). However, all that was in the future. In von Neumann's day, evolution was mostly thought of as strictly biological.

In the 1930s, von Neumann was already sharing his fascination with these topics with the mathematician Stanislaw Ulam (1909–84), who had raised them in coffee-house conversations as early as 1929. And they continued to discuss them after the war, when they were both working at Los Alamos.

Ulam has been described by a colleague as "probably the only close friend von Neumann ever had", and also as "the more original mathematician of the two—but notorious for not doing the detailed work" (Rota 1989). He published almost nothing throughout his life, but had many seminal ideas for which others (who went off and did the detailed work) got the credit.

One of these was a pioneering chess program (for a 6×6 board: no bishops) that took an average of twelve minutes per move, but which spent that time on a comprehensive two-move lookahead (McCorduck 1979: 157). Another earned him the dubious distinction of being joint patent-holder with Edward Teller for a crucial process in the production of the H-bomb—and the same colleague, Gian-Carlo Rota (1989), judges that Ulam's ideas were the more important contribution.

It's entirely possible, then, that Ulam seeded von Neumann's mind with the problem of self-reproduction and/or its outline solution. Certainly, they discussed these matters repeatedly:

> Our usual conversations [in about 1954] were either about mathematics or about his new interest in a theory of automata. These conversations had started in a sporadic and superficial way before the war at a time when such subjects hardly existed. After the war and before his illness [in 1955] we held many discussions on these problems. I proposed to him some of my own ideas about automata consisting of cells in a crystal-like arrangement. (Ulam 1989: 19; cf. Ulam 1962)

However, Ulam went on to say that von Neumann's "more concrete ideas developed [only] after his involvement with electronic machines".

In the 1930s, von Neumann couldn't formulate the problems clearly—still less, solve them. In 1943, however, he read McCulloch and Walter Pitts' "neural logic" paper and was introduced to computing on a visit to England (see Chapters 4.iv.a and 3.v.e, respectively). Thus inspired by the likely biological relevance of Turing machines, he claimed in 1946 to have formulated the problem of self-replication rigorously.

Two years later, he had the outlines of a solution—and of a general theory of automata, which he took to include both natural and artificial systems. That theory underlies much of what is now called A-Life.

He presented his outline in a talk at the Hixon symposium in 1948. This was the same interdisciplinary meeting at which Karl Lashley described his ideas on serial order in behaviour (Chapter 5.iv.a), and it was largely thanks to Lashley's urging that von Neumann later wrote up his talk for publication (von Neumann 1951). The Hixon paper sketched the general form of a self-reproductive system, and pointed out the possibility of heritable copy errors, or "mutations". It also described an (imaginary) mechanical system capable of self-assembly from physical parts.

This "kinematic" model caught some people's imagination, inspiring a simple mechanical model of self-replication that used interlocking tiles (L. S. Penrose 1959) and speculations by NASA scientists about robotic self-assembly in space (Levy 1992: 32–42). Von Neumann himself, however, was dissatisfied with it. It was limited to a specific type of physical system, and it left crucial processes unexplained (for example, recognizing, picking up, and welding the parts): "By axiomatising automata in this manner, one has thrown half of the problem out of the window, and it may be the more important half" (quoted in Burks 1970, p. xv).

He therefore turned (at Ulam's suggestion) to study systems defined not by physics, but by logic. Because Ulam had compared them to crystal growth in two dimensions, von Neumann called them crystalline regularities, or tessellations (tilings). Now, they are known as cellular automata, or CAs.

A CA is a computational "space" made up of many discrete cells, each of which can be in one of several states, and each of which changes (or retains) its state according to specific rules. More strictly: a CA is a space plus a specification of an initial space state. The same space may give very different results, given different initial states. CAs are artificial constructs, products of the logical imagination. But (as von Neumann foresaw) they can be used to simulate natural systems, if these involve equivalent principles of change.

Before the initial state can be specified, randomly or otherwise, the CA space itself must be defined. This requires decisions on many different options. The person defining the space must specify the number of dimensions; the size (sometimes infinite) of the space; the set of possible states per cell; the 'shape' (boundaries) and 'neighbours' of each cell; the timing (synchronous or asynchronous) of the cells' state changes; and the rules governing those state changes.

These rules are expressed in logical terms. For instance, a cell in state 6 (out of 12 possible states) must change to state 8 if and only if at least two of its neighbours are in state 10, and/or at least one is in state 3. The rules may apply universally across the space, or they may (in effect) vary according to region. And they can be of various general types. For instance, they may be fixed or mutable (changing systematically with time and/or subject to random mutation). And they may be deterministic, indeterministic, or probabilistic. On top of all this, a CA may be 'pure', or it may be subject to a certain amount of noise, or error.

Clearly, the potential variety of CAs is vast. Among the myriad possibilities are some systems with immense computational power. Indeed, as von Neumann suggested (but couldn't prove), his universal constructor is equivalent to a universal Turing machine, which can in principle perform any possible computation (Chapter 4.i.c).

Correlatively, CAs can in principle be used to simulate any natural system governed by local laws (as opposed to action at a distance), and having no essential discontinuities that can't be approximated discretely (as in the differential calculus). In short, CAs can be used to model dynamical systems describable by the laws of physics.

As usual, practicalities fall short of possibilities. For one thing, a natural system that could in principle be simulated by a CA may be so complex that such a simulation can never be found. Even if the CA rules can be specified, the initial state cannot. Putting this point in David Marr's terminology (Chapter 7.iii.b), many natural phenomena may be explicable only by Type 2 theories, which are extremely difficult to find. Von Neumann himself, for example, suggested that:

> [It] is futile to look for a precise logical concept, that is, for a precise verbal description, of "visual analogy". It is possible that the connection pattern of the visual brain itself is the simplest logical expression of this principle. (von Neumann 1951)

For another thing, most CAs that have actually been studied are relatively simple—although "simple", here, is a relative term. In practice, CAs normally have only a few dimensions: a 1D line, a 2D grid (as in von Neumann's case), or a 3D volume. Even CAs modelling hyper-dimensional fitness landscapes (see Section viii.b), or the networks called CTRNs (Section xi.b), don't approach the number of possible dimensions. (Whether they're large enough, nevertheless, to represent all the relevant evolutionary factors is an empirical question.)

Many CAs have an initial state defined by only a few cells. Von Neumann's universal replicator was an exception. It had a "body" (the central construction unit) of 32,000 cells, plus a "tail" (the instruction tape) 150,000 cells long.

Similarly, many spaces assume a strictly limited number of neighbours per cell, each located immediately adjacent to the cell. For von Neumann, each cell had four neighbours: those sharing square boundaries with it. For John Conway (1937–), whose three-rule game of Life was the first A-Life entertainment to hit the popular scientific press (M. Gardner 1970), cells have eight neighbours: the four boundary-sharers, plus the cells touching the four diagonals. (Conway's Life is not to be sneezed at: in principle, it can generate a Universal Turing Machine.) However, some CAs allow *any* cell in the space to count as a neighbour, thus allowing for large-scale parallel processing (see Section vi.a).

In practice, too, the state-change rules also are relatively simple. Most CA rules are both deterministic and unvarying. The rules are usually applied across all regions of the space, each cell deciding its next state according to the same rule set. (Again, some recent work discussed below is an exception.) As for the number of possible states per cell, von Neumann specified twenty-nine when defining his universal replicator (these were based on the logical functions used in his design for the EDVAC computer). But many CAs, Life included, use only two.

Finally, most CAs are defined with respect to distinct time steps. That is, all the cells change (or not) simultaneously. Asynchronous CAs, in which the rules may be identical but the cells have independent "clocks", can produce very different behaviour (Ingerson and Buvel 1984; Bersini and Detours 1994).

Not all CAs can self-replicate, for many lack the necessary complexity. But self-replication isn't the only lifelike property that makes CAs interesting. Even highly restricted systems can generate unpredictable order, which sometimes emerges only after hundreds of iterations. In general, the bottom-up (cell-by-cell) parallel processing characteristic of CAs can give rise to higher-level order which the GOFAI approach outlined in Chapter 10 would have tried to impose top-down.

For example, the fascination of Life is its ability to generate unexpected, and sometimes systematically repeated, 2D forms such as "gliders". A simple 1D system (a single line of cells, generating another line below it . . . and so on) may produce lifelike patterns reminiscent of the markings on cone shells (Wolfram 1984*a*). A set of three simple rules can enable computer-animated creatures (bats, dinosaurs, or milk bottles) to "flock" realistically (Reynolds 1987). And some recent A-Life models show complexities of co-evolutionary behaviour that are still more intriguing (see Section vi.c).

b. Why the delay?

Given the intellectual power of von Neumann's pioneering research, why wasn't it followed up immediately? D'Arcy Thompson's vision of a systematic mathematical biology had been reinforced. But where was the rush to turn vision into reality?

A few unorthodox biologists saw the point—McCulloch, of course, included. Automata theory was discussed at Waddington's ground-breaking meetings on theoretical biology (where D'Arcy Thompson was explicitly remembered). At one of these, the young Arbib presented a pencil-and-paper definition of a self-replicating program

(Arbib 1966, 1969). At another, Longuet-Higgins presented his ideas about the mathematics of associative memory (see Chapter 12.iv.c). And Gordon Pask, ahead of the pack as usual, experimented with simple evolutionary machines—not programmed as abstract cellular automata, but implemented as solutions of chemical salts (Pask 1961: 105–8).

But such experiments couldn't then be taken much further, and most computer scientists remained unimpressed. Almost all mid-century computer modellers focused their attention on other forms of cybernetics, or on GOFAI, or on simple neural networks. A-Life wasn't identified as a scientific endeavour until many years later (see Section x.a). It was later still that "chemical" computing, broadly anticipated by Pask, became a hot topic (Adamatzky *et al.* 2003; Sienko *et al.* 2003).

There are three reasons for this. One is the lack of computer power at the time. Von Neumann's A-Life research, like Turing's (and D'Arcy Thompson's), was a pencil-and-paper exercise, an abstract study in computational logic. He couldn't explore its implications by computer modelling, because the necessary technological advances were still far in the future. Accordingly, the first people to take up his ideas were logicians or mathematicians.

Even they were—for the second reason—very few in number. Von Neumann's CA research didn't immediately excite widespread attention because most of it remained unpublished until well after his death (he died of cancer early in 1957). A few brief hints were included in his (unfinished) lectures on *The Computer and the Brain*, published soon after he died (von Neumann 1958). And an account of the main ideas (written by the originator of BASIC) appeared in *Scientific American* (Kemeny 1955). However, this paper on 'Man Viewed as a Machine' contained very little detail. And Ulam, who had suggested CAs to von Neumann in the first place, published a relevant paper in the early 1960s (Ulam 1962)—but this, too, was very sketchy as compared with von Neumann's still-unpublished writings.

Von Neumann's major manuscript on automata, begun in 1952, was never finished. In 1949, a year after his Hixon talk, he lectured on 'The Theory and Organization of Complicated Automata' to an audience of mathematicians and computer scientists at the University of Illinois. There, he discussed various general types of automata. These included not only CAs, but also continuous systems—such as might be used to model the physical diffusion processes discussed by Turing. Others were quasi-neurological automata inspired by McCulloch and Pitts, involving thresholds, excitation/inhibition, and refractory periods, or fatigue. (He also revised his mid-1940s estimate of the number of individual units needed for self-replication, from the high 10,000s to about a million.) But these lectures, too, remained unpublished at the time.

The person most responsible for disseminating—and, initially, for developing—von Neumann's work on self-organization after he died was the philosopher and logician Arthur Burks (1915–). He did many years of editorial work to bring von Neumann's papers to public view. He circulated mimeographed notes of the 1949 Illinois lectures to those who asked for them, and in 1961 tried to interest behavioural scientists in general (Burks 1961). But von Neumann's own manuscripts weren't made widely available until a decade after his death (Burks 1966, 1970).

Burks was an ex-colleague of von Neumann's, having worked with him since the mid-1940s. They had cooperated on the design of the EDVAC, the ENIAC, and the Princeton computer (and jointly originated flow diagrams as a tool for program design: Aspray 1990). And, although he never discussed CAs personally with von Neumann (Levy 1992: 60), Burks had been thinking along similar lines for a long time. Indeed, it was he who coined the term "cellular automata".

His 'Logic of Computers' group at the University of Michigan was the first place where CAs were actually run on computers. Some of these runs were simulations of physical or biological processes (such as heart fibrillation), while others aimed to advance the theory of CAs in general. He developed, and even corrected, some of von Neumann's ideas while editing the manuscripts. For example, he proved his suggestion that a universal constructor, equivalent to a universal Turing machine, is possible; and he improved on his ("double-path") design for constructing instruction loops of arbitrary length within the CA space. In short, his intellectual contribution to the field was considerably more than the term "editor" normally implies.

Burks tried to interest the AI community in von Neumann's work, but he came up against the third reason why it was neglected. The fundamental difference in approach—bottom-up rather than top-down, and largely abstract to boot—was a formidable barrier.

Add the fact that MIT and Stanford (and later Yale) were recognized, not least by their own inhabitants, as the main centres of AI, and Michigan stood very little chance. It probably didn't help, in meetings dominated by ex-physicists and AI hackers, that Burks described himself as a philosopher. I remember attending several AI meetings in the early 1970s where he made an effort to talk about CAs and von Neumann to others, including people he hadn't met before. But it was obvious, and quite distressing in human terms, that he wasn't being taken seriously.

Inside Michigan, it was a different matter. Burks's students were introduced to von Neumann's ideas some years before they were published. They, too, helped to advance the field (Burks 1970).

In the early 1960s, one (James Thatcher) completed an alternative design for a universal constructor. Another, Edgar Codd (who would pioneer relational databases in the late 1970s), showed that a universal replicator could be axiomatized with only eight cell states instead of von Neumann's twenty-nine (Codd 1968, ch. 4). He did this by modelling candidate CAs on computers, iteratively redefining them when the computer tests failed—a methodology foreseen by von Neumann, but not available to him.

Later, another Michigan student, Richard Laing (1977), showed that a self-replicating machine needn't be 'magically' provided with a self-description, but could build one by inspecting itself. (It was Laing who'd been so critical of Mortimer Taube's anti-AI *Computers and Common Sense* in the early 1960s, and who'd been simulating large neural networks at that time too: see Chapter 11.ii.b and Richard Laing 1961*a*.) And later still, Langton (1984)—an ex-student of Burks's—would produce the first functioning implementation of a self-replicating automaton (see Section ix.a).

15.vi. Evolution Enters the Field

The most important work done in Burks's department was John Holland's (1929–). In his early twenties, Holland (1929–) had co-authored a model of Donald Hebb's theory of self-organizing cell assemblies (Rochester *et al.* 1956), which discovered unexpected difficulties in the theory (see Chapters 5.iv.b and 12.ii.d). But his prime inspiration came from von Neumann, not Hebb.

He turned towards automata theory as a very young man. Partly because von Neumann himself wasn't publishing on the topic, Holland's 'Survey' (1959) and two other general papers were cited in Minsky's bibliography of AI (Feigenbaum and Feldman 1963: 494). But Holland was much more than a competent surveyor, for he pushed the field forward in a very important way. Only a few years after von Neumann's death, he defined a new type of CA that answered the master's question of how an automaton could give rise to something more complex than itself (J. H. Holland 1962).

He did this by following up von Neumann's hint that a CA could support evolution, if it had an imperfect copying mechanism and some principle of selection. In other words, Holland was using biological ideas to extend CAs, rather than CAs to study biology.

His subsequent research elaborated these ideas. Eventually, they became highly influential. But this outcome was long delayed. The importance of Holland's approach wasn't widely recognized for over twenty years.

a. Holland, and mini-trips elsewhere

Holland's new systems, which he called iterative circuit computers, were more general than von Neumann's CAs. Not only did they allow neighbourhood relations and transition functions to change over time, but they weren't strictly localistic. Holland allowed for direct communication between *any* two cells (all cells could count as "neighbours"), so that his systems performed essentially parallel processing within a huge, and very noisy, space.

This meant that

* programs (of any length) stored in contiguous cells could be moved (or copied) to another set of cells in one step.
* In addition, they could be combined, by being located in adjacent cell sets.
* Or they could be split into two parts—
* which in turn could be combined with other programs or program parts.
* Specific types of noise, or copy error, were allowed to produce novel combinations of program parts.
* Moreover, given a measure of program efficiency, the best of the new combinations could be selected so as to generate programs better adapted to their task.

The analogy to biological genetics and evolution was intentional. Holland had first experienced self-improving computer programs in the late 1940s, when he worked with Arthur Samuel and John McCarthy on a neural-net simulation of IBM's first commercial calculator. Samuel, who "devoted his spare time to the subject of machine learning" (Samuel 1959), would soon (in 1952) complete a GOFAI checkers-player that learnt to play better than he did himself (see Chapter 10.i.e). The neural network he developed with Holland was much less impressive, but it did show a crude form of learning.

Holland's subsequent research benefited also from his Michigan-based familiarity with von Neumann's ideas. In particular, he was inspired by von Neumann's hints about evolution in automata.

By the early 1960s, Holland was already thinking in terms of concepts borrowed from biological genetics: crossover, linkage, and dominance (J. H. Holland 1962). By the late 1960s, he had developed a comprehensive logical theory of adaptive systems, and had formally defined the first genetic algorithm (GA) (J. H. Holland 1975). GAs enable a program to improve not by top-down hand coding, but by bottom-up evolution. (The program may or may not be capable also of individual learning.) They involve parallel search over a large number of candidates at each generation.

Even before Holland showed how these effects could be produced, several researchers (independently) had already raised the possibility of computerized—as opposed to mechanical (see L. S. Penrose 1959)—evolution (D. B. Fogel 1998). Most of them were inspired by Ashby and Grey Walter rather than von Neumann, whose work on CAs wasn't yet widely known (see Section v.b).

Perhaps the first was George Friedman at UCLA, who in the mid-1950s outlined how a "selective feedback computer" might evolve electrical circuits to maintain the internal temperature of a mobile robot (Friedman 1956). This goal was more taxing than it sounds. The robot's environment included not only hotter and colder areas, but areas where the temperature changed suddenly or slowly, and areas of very high temperature signalled by a flash of light (one of which changed position unpredictably). The parameters of the robot's circuits could be altered by a switchbox, and the most successful circuits at a given stage were selected and then randomly varied by instructions from the "Control".

At much the same time, Hans Bremermann (then at the University of Washington, Seattle, but later at Berkeley) began a series of theoretical studies of the evolution of "goal-seeking, self-organizing" systems (Bremermann 1962; Bremermann *et al.* 1966). He tried to analyse a range of evolutionary systems, showing how changing the variables would lead to different types of result. And in the early 1960s, Ingo Rechenberg in Germany actually evolved engineering designs based on wind-tunnel experiments (Rechenberg 1964).

These efforts had come out of the cybernetic stable, being focused on Shannon-type predictive systems. But others were influenced also by the nascent research on AI planning (Chapter 10.i.d).

For instance, the engineer Lawrence Fogel proposed the development of "goal-seeking" AI, in which artificial evolution looked after the tactics while artificial intelligence set the purposive strategy (L. J. Fogel *et al.* 1966). In the late 1960s, he joined with some central figures of the cybernetics–AI community—including Minsky, Allen Newell, McCarthy, and the ubiquitous McCulloch—in exploring the potential for evolving program-controlled sensory/motor prostheses for human patients and air pilots (Fogel and McCulloch 1970: 271–95). These instruments, he suggested, would autonomously adapt to their "experience" yet also be controllable by the human user. The user could thus concentrate on the higher-level goals, leaving the detailed execution—and eventually the setting of low-level sub-goals—to the machine.

This work, whether implemented or merely speculative, was less sophisticated—though more visible—than Holland's. Large-scale parallelism wasn't available; indeed, the current generation was sometimes restricted to only two programs or genotypes. And it relied on mutation rather than crossover (but see below). In other words, although it was termed "evolutionary programming", it didn't follow the biological analogy so closely as Holland's "genetic" method did. (The term "GAs" is sometimes used to cover all types of evolutionary computing, but is sometimes restricted to methods similar in spirit to Holland's.)

The early evolutionary programming didn't sweep the field. Besides its lack of power, it was sometimes associated with extravagant claims that invited hostility from other AI modellers. The proposal for evolutionary prosthetics, for instance, aroused scepticism from some discussants.

Thus Minsky commented: "The question is not, 'Is tree search better?,' because this is a tree search. The question is, 'Is the language of mutation and offspring as good as the language of subgoal, and so forth?' " (L. J. Fogel and McCulloch 1970: 284). His own answer (pp. 287, 288) appeared to be "No", since he doubted whether Fogel's evolutionary technique was an advance on Albert Uttley's conditional probability machine (Chapter 12.ii.c). Doubts were expressed also by McCarthy and Papert, both of whom saw random variation as a much less promising way of improving programs than the more 'rational' AI approach (pp. 292–4).

Nevertheless, AI work on evolutionary computing continued in a few places outside Michigan, from the early 1960s onwards. And some of this exemplified what would now be termed A-Life, since it was directed to biological concerns.

The Stanford biophysicist–philosopher Pattee (1926–), another regular Waddington invitee, had already applied automata theory to the origin of life (Pattee 1966). Now, he simulated evolution in an entire ecosystem (Conrad and Pattee 1970). But his model produced no significant results. Years later, he commented:

> [The] populational behavior of the biota appeared to be chaotic, although we did not know the significance of chaos at that time. However, in spite of biotic behavior that was unendingly novel in the chaotic sense, it was also clear that the environment was too simple to produce interesting emergent behavior. (Pattee 1989: 71)

Holland's (then unrecognized) achievement had been to show how "interesting emergent behaviour" could indeed be generated.

A GA program makes random changes (copy errors) in a specific batch of code (equivalent to the genotype), evaluates the results, and selects suitable candidates for breeding the next generation. As Holland pointed out, the "suitable" programs aren't always the "best": occasionally, his GA would select a low-performance program for breeding. This probabilistic approach enabled potentially useful program parts hidden within even highly inefficient programs to be (sometimes) preserved in the gene pool.

Von Neumann hadn't specified just which sorts of random copy error would be most evolutionarily fruitful. He appeared to assume that point mutations, wherein a genetic unit is substituted by another, suffice in an asexual population. By contrast, Holland stressed crossover or recombination between a pair of parents in a sexual population, wherein a set of adjacent units on one string—compare: adjacent genes on a chromosome—is swapped for a set of adjacent units on another string. Indeed, he allowed for multiple crossovers, wherein two or three gene sets are exchanged between the two strings.

Holland pointed out that crossover (as defined above) enables useful building blocks to be preserved during self-replication. A point mutation can affect any gene, anywhere. But this type of crossover is unlikely to make changes within small sets of adjacent units, because there are fewer potential breakage points within a short string than within a long one. Moreover, it can build up high-level blocks consisting of two or more lower-level blocks, and these hierarchical structures also can be preserved throughout evolution.

(It turned out later that Holland's restrictive definition of crossover was unnecessary. 'Uniform crossover'—wherein a coin is tossed at each locus in the paired gene strings, and either mother or father is chosen at random—makes widespread changes, yet can drive successful evolution: I. Harvey, personal communication.)

As Holland realized, however, strict adjacency is both improbable and unnecessary. It's unlikely that potentially cooperative lower-level blocks will always lie together. Even if they start out that way, some future crossover may separate them. For that matter, even a single block may contain functionally irrelevant units lying between the relevant ones. And the statistics are borne out by the biology: adaptively co-functional (sets of) genes needn't lie next to one another on the chromosome.

Accordingly, he specified building blocks (sub-strings within a program) as flexible "schemata" rather than fully determinate strings. And he defined a new type of GA to deal with them.

He represented schemata as fixed-length strings of "0s", "1s", and asterisks—where an asterisk means "it doesn't matter whether this unit is a 0 or a 1". For example, the schema "0010****" can be instantiated by any 8-unit string starting with 0010 (00101111, 00100000, 00101010, and so on); the schema "**0010**" is instantiated by 00001000, 11001010, 10001001, and so on. Holland's program could identify any string in which the relevant building block appears, and could manipulate sequences or hierarchies of building blocks while ignoring insertions of 'irrelevant' units. That was just as well, since such insertions would often be produced by the GA's own crossover activities. In short, his GA was efficient and highly robust.

Moreover, Holland proved the "Schema Theorem": that schemata, which enabled cooperation between different building blocks, would increase their representation within the population exponentially with time. Much later, it became clear that he should have stressed that they would do this *ceteris paribus*. This get-out clause is important, because as soon as schemata do start increasing, their relative fitness will change.

In other words, the conditions under which the Schema Theorem holds break down almost immediately. Partly for this reason, many now consider that the Schema Theorem didn't give a good picture of what was going on in Holland's models. Nevertheless, it was influential for a time, since it appeared to offer a mathematical proof of their evolutionary efficiency.

By the mid-1980s, Holland had found a way of making GAs even more powerful—and he'd applied them to classification, inductive reasoning, and philosophy of science (J. H. Holland *et al.* 1986). In artificial evolution, unlike the biological case, it's in principle possible to protect the most useful building blocks from being dropped, or damaged, during replication. But how is this to be done?

Given that many different strings (rules) are being searched in parallel, and that several contributory rules are acting together in performing the task, it's no trivial matter to discover which are especially useful. Holland devised an ingenious method for automatically advantaging the most adaptive rules within a complex evolved program. This was the bucket-brigade algorithm, whereby appropriate fractions of the overall "credit" are passed back to individual rules (J. H. Holland *et al.* 1986: 70–3).

b. Awaiting the computers

One might ask the same question about Holland's research as about von Neumann's. Why didn't it receive immediate recognition? Why have GAs been widely used in AI and A-Life only since the 1980s, given that they were first defined in the 1960s?—The answers are very similar.

Holland's interests in cellular automata, like von Neumann's, were more theoretical than technological. In his early work he did discuss the advantages and disadvantages of actually building machines as iterative circuit computers (Burks 1970). But he didn't implement his GA after he'd defined it. That was done by his student David Goldberg in 1983, to solve problems about controlling the flow of gas in pipelines (Goldberg 1987). (Other Michigan students had already used the ideas in theoretical studies—of adaptive game playing, for instance: Bagley 1967.) In any case, the computational power available before the 1980s hardly sufficed for interesting GA research.

Again, Holland—unlike some of his intellectual descendants—didn't initially seek to publicize his work, still less to turn it into the latest AI 'cult'. Although he published papers in the 1960s, his book on the formal theory of adaptive systems didn't appear until 1975.

Even that wasn't widely read. I recall being hugely impressed by the paper he gave at a twenty-person weekend meeting held on the edge of Dartmoor in 1981 (cf. Selfridge *et al.* 1984). I'd never heard of him, and when I got home from the Devon countryside I asked my AI colleagues in Sussex why they weren't shouting his name to the rooftops. Some replied that his work wasn't usable—and some had never heard of him either.

Finally, Holland's approach, like von Neumann's, was fundamentally at odds with the then dominant culture in AI. Burks had failed to persuade GOFAI researchers of the potential of CAs and bottom-up processing, but at least he'd focused on deterministic automata. Holland's programs, by contrast, relied crucially on rampant (and richly parallel) random change. It's perhaps not surprising that highly skilled GOFAI programmers, well aware that to omit a single LISP bracket was to crash their system, failed to see the intellectual promise of his work. (It probably didn't help that he was based in Michigan: theoretical linguistics wasn't the only discipline to exclude those outside the magic circle—see Chapter 9.viii.a.)

But that's not to say that mainstream AI was ignoring the possibility of evolving programs. As remarked above, such efforts had started in the early 1960s. Twenty years later, a number of people were using some sort of evolutionary method—variation plus selection—to evolve GOFAI programs.

John Koza (1943–) was a leading example (Koza 1989, 1992*a*). His technique enabled programs of increasing length and complexity to be generated, because larger program parts could be substituted for (and nested within) smaller ones. Besides applying this approach for optimizing AI problem solving, Koza used it to produce programs acting as sensori-motor controllers for simulated robots, which evolved the capacity to follow irregularly shaped "walls" (Koza 1992*b*).

However, Koza's method was less richly parallel than Holland's, and also less 'free'. Instead of allowing changes at any point in the code, it was constrained to swapping syntactically sensible LISP expressions. Koza therefore avoided the difficulty, which Holland had faced, of deciding how to identify and preserve useful mini-sequences—including 'interrupted' sequences containing blocks of non-relevant material.

Similar remarks apply to Karl Sims's (1962–) *interactively* evolved image-generating programs (developed on the Connection Machine at MIT's Media Lab: see 13.v.a), in which the selection is done by a human (Sims 1991). Although some variations can affect the very heart of the LISP code, the set of genetic operators ensures that only 'sensible' programs result.

Gradually, interest in evolutionary computation increased. By the mid-1980s, it had grown enough to support the first international conference on genetic algorithms (Grefenstette 1985). And this interest grew apace. A few years later, simple evolutionary programs such as Dawkins's Biomorph had even entered the home, influencing children's views on the concept of life (Dawkins 1986: 51–74; Turkle 1995).

By the late 1980s, AI work on evolutionary programming had burgeoned. Holland's ideas were better known, and huge computational power was becoming available. A number of interesting implementations of GAs—some directly inspired by Holland's work, some not—were appearing.

One was produced by Daniel Hillis (1956–) at MIT (Hillis 1992). To do so, he took advantage of the enormously powerful Connection Machine that he'd designed in the early 1980s, having been greatly influenced by Minsky's ideas on parallelism (12.iii.d). The first, quarter-sized, version had been bought by MIT's Media Lab in 1986, but the full-sized version was available soon afterwards. This had no fewer than 65,536 processors, with a maximum of sixteen 'steps' for any one to connect with any other (Hillis 1985).

Using that machine, Hillis was able to study populations of up to a million individuals, with up to 256 "chromosomes" per individual. For illustrative purposes, Hillis used his GAs to optimize sorting networks. Sorting algorithms put some set of elements into some rational order. For instance, they arrange a random set of numbers into an increasing series. In general, they are easy to test: their "fitness" can be readily assessed. Accordingly, Hillis was able to show a clear improvement as a result of applying GAs.

Other AI workers had used GAs to optimize computer programs. Hillis deliberately made the task—one might think—more difficult, by introducing "parasites", or "predators". These were sets of up to twenty test cases, which evolved to become more and more difficult as the sorting algorithms improved. Hillis found, as he expected (and as Darwinian theory predicted), that the parasites would make the improvement more rapid than it had been without them.

The reason is that competitors can dislodge a population from a local peak in its fitness landscape (see Section viii.b), so that it has the chance of finding a higher peak elsewhere. As Hillis remarked, this is similar in principle to the technique of simulated annealing used in connectionism to move a system away from a local minimum (Chapter 12.vi.b).

Whereas Hillis wasn't primarily interested in the biological relevance of co-evolution, others were. In the mid-1980s, people began to use GAs as experimental test beds for theoretical biology. The phenomena they studied would include parasitism, symbiosis, predator–prey behaviour, the evolution of sensori-motor anatomy, evolutionary change in fitness criteria, and the speeding-up of evolution by the introduction of competitors.

In some cases, mutation rates and population size were systematically varied, to investigate their effect on the pattern of evolution. Simulated species were tracked for thousands of generations, to see what types of order emerged, and why. In general, such GA work showed that very simple rules can give rise to richly ordered, and often unexpected, behaviour.

It was found, for instance, that the "punctuated" evolution posited by some biologists (Eldredge and Gould 1972; Gould and Eldredge 1993) can emerge in computer models—and can be explained in precise, and purely Darwinian, terms. Background mutations (ones not causing a change in the phenotype) would sometimes accumulate over many hundreds, even thousands, of generations—only to cause a sudden change in the phenotype when a few 'last-minute' mutations occurred and interacted with them. In short, hidden gradualism was producing observable saltations.

Early research of this type was done in the mid-1980s by Thomas Ray (1954–) at the University of Delaware. Ray was a botanist, specializing in the ecology of tropical rainforests (Ray 1992, 1994). Accordingly, his Tierra system was a virtual world of co-evolving "species", which competed and cooperated in ways broadly similar to biological species.

Ray's individual "creatures" were strings of self-replicating computer code, competing for space in computer memory. Some strings evolved the ability to borrow the self-replication facilities of other strings; and some host strings became resistant to these parasites, by evolving parts that prevented such attachments. After many generations, a variety of species, including parasites, hyper-parasites (outwitting the host's evolved resistance), and symbionts, usually emerged. Ray's work would eventually spawn a still-continuing worldwide experiment in computational ecology, in which virtual creatures are free to evolve in a "Digital Reserve" formed by pooling the idle time of computers linked by the Internet (Ray 1996; Ray and Hart 1998). (Ray himself is convinced that virtual creatures such as these can be genuinely alive: see Section ix.b, and Chapter 16.x.)

c. The saga of SAGA

GAs were developed in a new direction in the early 1990s, by Inman Harvey (1946–) at the University of Sussex (I. Harvey 1992*a*). Harvey extended GAs to cover open-ended, potentially indefinite evolution of increasingly complex artefacts, with genotypes of potentially unlimited length. ("Artefacts", because he didn't claim that his GA models were detailed theories of real life.)

Harvey's main aim (personal communication) was to discover how to set optimal mutation rates, given genotype spaces of different kinds. For example, some might involve "ridges" or "neutral" (*sic*) networks. In addition, he wanted to work with genomes that could vary in length.

From his point of view, Holland's approach had two drawbacks. First, Holland had considered only fixed-length genotypes, and his Schema Theorem guaranteed increasing fitness only for these. Second, he'd implicitly assumed that there was typically a large amount of genetic diversity within the population being evolved. Harvey argued that both these assumptions are inaccurate for natural evolution, and needn't apply to artificial evolution.

The use of fixed-length genotypes wasn't compatible with open-ended evolution (see subsection d, below). The search space of a fixed-length genome is finite—perhaps astronomical, but finite. Radically novel forms simply can't arise. Moreover, biological organisms that are more complex tend to have more genes. The reason is that a longer genome allows for more complex gene–gene interactions. It follows, said Harvey, that open-ended artificial evolution, too, requires variable-length genomes.

In relying on fixed-length genomes, Holland had supposed that the finite search space included some (relatively) optimal solution, which would eventually be found. For specific problems, this assumption is justified—in principle, if not always in practice.

But, as Harvey pointed out, biological evolution isn't like that. Species don't evolve in order to solve pre-given problems—although we sometimes speak as if they do, saying for example that blinking evolved "to protect the eye". Indeed, new fitness criteria arise as a result of evolution: no eyes, no 'need' for blinking. In other words, new 'problems' and new types of 'relevance' are spontaneously created by evolution.

This point had been implicit in Pask's early models of the emergence of new types of sensor: crystalline threads sensitive to auditory pitch or magnetic fields, for instance (see Chapter 4.v.e). But Pask hadn't specifically related it to evolutionary models, whereas Harvey did.

So, too, did Peter Cariani (1956–), a philosopher of A-Life in Pattee's group at SUNY Binghamton (and also an auditory neurophysiologist, now at the Massachusetts Eye and Ear Infirmary), and Peter Kugler and M. T. Turvey of the University of Connecticut's Ecological Psychology group (Cariani 1992; Kugler and Turvey 1987; Kugler *et al.* 1990). All of them insisted that biological evolution is open-ended—and, in general, leads to increasingly complex structures.

The second problematic assumption noted by Harvey concerned genetic diversity. Holland's Schema Theorem had implicitly presupposed wide genetic variation in the artificial population, but this doesn't apply to natural populations. The individuals within a biological species have very similar genotypes. In other words, the population is relatively *converged* within genotype space.

Further, Harvey argued, even if one were to begin with a highly diverse population, it would rapidly converge so that individual genotypes became more similar. The population genetics would then have settled down into a dynamic equilibrium between the forces of selection and variation. Thereafter, evolution must take place in the context of low genetic diversity. (Harvey's original argument focused on populations with variable-length genomes, but he later showed that it applies also to most fixed-length GA problems.)

The dynamic balance between selection and variation—and therefore the potential for further evolution—will be affected by altering the mutation rate. This in turn will depend on various factors, including the form of selection used, the shape of the fitness landscape, and—he realized later—whether crossover as well as mutation is allowed.

With these points in mind, Harvey developed the SAGA algorithm (Species Adaptation GA), to enable "hill-crawling" rather than hill climbing (I. Harvey 1992*a*, 1994). The technical arguments driving SAGA were tested out on Stuart Kauffman's models of fitness landscapes (see Section viii.b).

On rugged landscapes, sudden large-scale genetic change is likely to decrease fitness drastically. Fruitful interbreeding over many generations therefore requires not a ragbag of hugely different individuals but a genetically converged population: in other words, a species. SAGA's technical parameters were defined, and set, accordingly. Taking account of the three factors mentioned above, Harvey tried to determine the optimal mutation rates and set his models so as to approximate to them. For instance, it followed from Kauffman's point remarked above that, given a highly converged population, only small variations in length would tend to be viable. Similarly, crossover should result only in small variations in the genome.

In terms analogous to those used in Chapter 1.ii.b to categorize types of AI, Harvey's work counts as "technological"—not "biological"—A-Life. His work was done for engineering purposes, to make artificial evolution more powerful. Nevertheless, his ideas were potentially relevant to biology, for example to the question whether biological evolution has (sometimes? usually?) settled on near-optimal mutation rates.

In either case, the importance of SAGA was that it wasn't restricted to optimization on pre-defined problems. It could simulate the long-term incremental evolution of entire populations, and the generation of increasingly complex forms.

SAGA was used in the early 1990s by Harvey and his colleagues, and a few years later by others also, to evolve both virtual and physical 'species'. These were used to explore (for example) the rate of evolutionary improvement given varying mutation rates, the emergence of sensori-motor coupling between system and environment, and the effects of different levels of environmental noise. (Later, the Sussex group would evolve robot brains from GasNets, as well as from purely connectionist systems: Chapter 14.ix.f.)

For instance, a simulation of co-evolving predator and prey was used to measure evolutionary progress in strategies for hunting and escape (Cliff and Miller 1995). Evolutionary 'progress' is a problematic concept, not least because species evolve in complementary ways. As the Red Queen said to Alice, they have to run as fast as they can to stay in the same place. This causes difficulty: although an animal's speed can be directly measured, its efficiency cannot, because predator and prey are always in equilibrium. In a simulation, however, improvement can be measured by 'reviving' ancestor generations and pitting them against later ones.

As for physical artefacts, populations of robots embedded in specific environments evolved control mechanisms coupling them to those particular environments (see below).

Computer *hardware*, too, was developed by incremental (fixed-length) evolution using SAGA. Adrian Thompson (1970–) achieved the first evolved hardware robot controller in the mid-1990s. He worked with a reconfigurable home-made circuit on board a real robot, where the sonar echoes were simulated (during evolution) according to how the robot moved in a simulation of the corridor. After evolution the simulation was switched off, and the real sonar echoes in the real environment were used, to confirm that the robot did indeed work (A. Thompson 1995). Later, when suitable reconfigurable chips became available, he evolved circuits in simulation and then downloaded them into actual silicon chips (A. Thompson *et al.* 1996; Thompson 1998).

We noted in Section iii.c, when discussing D'Arcy Thompson, that a mistake in the simulated physics of a virtual environment may be picked up by the software creatures evolving in it (cf. Sims 1994). Similarly, contingent features of a laboratory task environment can become locked into evolving material artefacts—sometimes, bearing a startling resemblance to actual biological mechanisms. The Sussex work on evolutionary robotics showed that this can happen in negative or positive ways, decreasing or increasing complexity, respectively.

For instance, one of a robot's two 'eyes', and all of its 'whiskers', sometimes lost their connections to the controlling neural network (the 'brain'), if—in the environment provided—neither stereopsis nor touch was essential to perform the task (Cliff *et al.* 1993). (Compare the fact that auditory cortex in the congenitally deaf, or in laboratory animals deprived of auditory input, comes to be used for visual computation: Chapter 14.ix.d.)

More positively, the 'brains' of robots encountering a triangle of white cardboard sometimes evolved a 'feature-detector' analogous to those discovered in monkey brains in the 1960s by David Hubel and Torstein Wiesel (14.iv.a). This was a mini-network sensitive to a light–dark gradient at a particular orientation. It evolved as part of a visuo-motor mechanism, its connections to motor units enabling the robots to use the white triangle as a navigation aid (I. Harvey *et al.* 1994; P. Husbands *et al.* 1995).

In another experiment, the group evolved a neural circuit capable of controlling sixteen robot motors—two for each of the artificial octopod's legs—in coordination. As a result, the robot could move coherently and 'appropriately'. What's more, the evolved neural network took account of the signals from the robot's four infra-red sensors, ten light sensors, and various sensory bumpers and whiskers (Jacobi 1998).

Likewise, in the evolution of computer hardware at Sussex, circuits evolved to compensate for—and sometimes even to exploit—physical properties of the chip that were irrelevant to the chip fabricator's model of what was going on (A. Thompson 1997). Being irrelevant (in that sense), they were unknown, and not part of the chip specification.

Up to a point, such opportunistic noise tolerance is an advantage. But the exploitation of accidental details can be dangerous. In biological terms, a species that exploits a highly specialized niche is especially vulnerable to environmental change. Likewise, if the evolved logic circuit were to be copied into a different silicon chip, it might not work. And the robots' feature-detector would be useless if the triangle were black, or had sides sloping at a different angle.

Environmental 'noise' was therefore deliberately provided by the Sussex group, to prevent such overspecialization—and to follow up their intuition that evolution is easier in noisy environments. Biological evolution has noise provided anyway, in the sense that organisms live in variable environments. Even animals that eat only one type of food don't insist on its absolute purity. And many vertebrates have evolved comprehensive sets of feature-detectors, sensitive to both light–dark and dark–light gradients, in any orientation (Chapter 14.iv.b).

Evolution was modelled also by exploiting genetic drift across neutral (*sic*) networks. Some units in a genome may be irrelevant, in the sense that mutations have no effect on fitness. In the current genetic context, they have no causal influence on the phenotype. But, given mutations elsewhere in the genome, they might be useful in the future (see the discussion of "punctuated" evolution in Tierra, above).

Many organisms contain large amounts of 'junk DNA'. But it's hard to believe that evolution favours useless burdens—so perhaps junk DNA does convey some advantage? The molecular biologist Manfred Eigen suggested in the late 1980s that junk DNA could enable wider exploration of the genetic space, by providing fitness-neutral pathways that sometimes lead to high-fitness structures that would otherwise be inaccessible. In other words, neutral networks could prevent the species from getting stuck on a local optimum in the fitness landscape. Instead, it could move 'sideways' through the space, altering the genome without altering the fitness.

Harvey and Thompson (1996) combined Eigen's idea with (a fixed-length version of) SAGA, and with the recognition that the way of encoding the genome did indeed allow potentially useful "junk". Using GA parameters optimized to take advantage of this phenomenon, they evolved hardware circuits and also studied various abstract properties of evolution in general (see also Barnett 1998).

At much the same time as Harvey was working on SAGA, Steve Grand was independently developing a new type of computer world called Creatures, inhabited by evolving virtual organisms of various types (Grand *et al.* 1997; Grand and Cliff 1998; Cliff and Grand 1999). Although this was initially intended for home entertainment—and swept the world on its release in 1996—it could also be used as a test bed for theories of mental architecture, and for various commercially useful applications. For instance. it was used to simulate customers' behaviour in a bank, to enable the management to plan where to position the counters, advice tables, and automatic tellers (R. Saunders 2000).

The story of Creatures is told in Chapters 13.vi.d and 16.x.b. Here, its interest is that it was initiated outside academia, by someone who wasn't a trained computer scientist—and that it enthused a number of artists and cultural commentators. Artificial evolution had entered the real world.

d. Open-ended evolution

By the late 1990s, evolutionary computing was an established methodology in AI and A-Life:

* It merited a handbook of over 600 pages to describe the various techniques (Baeck *et al.* 2000).
* It could be used for systematic experiments concerning both life and mind.
* At the level of evolutionary biology, it could investigate the effects of different types and rates of mutation, on different types of fitness landscapes, given different amounts of environmental noise, and allowing for fitness-neutral genetic drift. (These were the questions driving SAGA, as we've seen.)
* And at the psychological level, simple relations between environment, neural mechanisms, and movement and behavioural strategies could be explored in evolutionary terms.

All very well . . . However, a significant problem remained, one which had been highlighted by Harvey and by the Pattee group mentioned above—namely, the open-endedness of biological evolution.

They'd pointed out, for example, that phylogenetic evolution has seen the appearance of novel types of sensory organ. As well as producing *improved* eyes, ears, or noses, it has produced *first-time* eyes, ears, or noses. How can that be?

The new sensory organs don't spring out of nothing, of course. They are adaptations of pre-existing structures, which may or may not have had some other function (e.g. the bones of the inner ear evolved from jaw parts, which in turn evolved from gill slits). Because novel forms of perception afford novel problems/challenges and novel solutions, they can't be generated by a GA with a fixed set of parameters—not even by a length-variable SAGA system. If the parameters foreseen by the programmer as potentially relevant don't happen to include (e.g.) light, then no eye can possibly emerge in the simulation.

In the new century, two of Harvey's younger colleagues managed to circumvent this problem—not by overturning the logic of the argument, but by bypassing it. They did this by working with physical hardware as well as computer programs. In brief, Jon Bird (1968–) and Paul Layzell (1964–) used Thompson's SAGA-based technique to evolve oscillator circuits—and unexpectedly ended up with a novel sensor: a primitive radio receiver (Bird and Layzell 2002).

We encountered this research in Chapter 4.v.e, in the context of Pask's self-organizing artificial "ear". As explained there, the evolution of the radio wave sensor depended on unforeseen parameters, such as proximity to a PC monitor and the aerial-like properties of printed circuit boards. Bird and Layzell concluded:

> We have argued that there are three key properties that devices must embody in order for selection pressure to form them into novel sensors:
>
> * they are situated in the physical world;
> * they consist of primitives with no fixed functional roles;
> * and the primitives are sensitive to a wide range of environmental stimuli. (Bird and Layzell 2002: 1841)

The good news was that if those conditions are satisfied, it needn't matter if the A-Life programmer doesn't—and couldn't—foresee every physical factor required for a novel sensor to arise. (Which isn't to say, of course, that a novel sensor actually will arise.) The bad news was that simulations, i.e. programs running on computers, aren't enough: truly open-ended evolution can happen only in physical devices, situated in the physical world. (D'Arcy Thompson would have approved!)

As I write this (in early 2005), comparable experiments are virtually non-existent. The small proportion of A-Life workers who do deal with "hardware" issues are almost all concerned with biochemistry (see Section x.b, below). Although they plan/interpret their experiments in the context of biological evolution, they don't use evolution in the experiments themselves. One exciting exception is a just-initiated project on evolving organic–silicon computers (described in 14.ix.f). Besides relying on GAs, this work is exploiting—and investigating—the physical dynamics of diffusion reactions. In such (still rare) cases, Turing and von Neumann and Holland *and D'Arcy Thompson too* are all marching in step. Most current evolutionary A-Life, however, recalls only the first three.

Not surprisingly, then, open-ended evolution was recently identified by the A-Life community as *the* major challenge facing them in the new century. That judgement appeared in spring 2003, when the journal *Artificial Life* published a paper bravely titled 'Collective Intelligence of the Artificial Life Community on its Own Successes, Failures, and Future' (Rasmussen *et al.* 2003*b*).

In a sense, they'd done this already. For the paper was a report drawing on the 'A-Life VII' conference in Portland, Oregon, and an earlier report on that had appeared in the same journal three years before (Bedau *et al.* 2000). Indeed, that one had nine authors, whereas the new version listed only four (two appeared on both lists). So why bother? And why call the report of the *smaller* group a "Collective" opinion of the A-Life "Community"? The reason was that this 2003 paper was based on an analysis of an extensive Internet consultation of A-Life researchers. This was intended for conversion into a continuing presence on the Web. In Francis Bacon's terminology (Chapter 2.ii.b), it was an attempt to establish an electronic Solomon's House, to serve the A-Life community in a more disciplined way than an email list or bulletin board.

The 250 delegates to 'A-Life VII' had been asked to consider the "grand challenges" for the field. After discussion through questionnaires, and through meetings held in Portland, the final verdict listed fourteen "open problems" (Bedau *et al.* 2000). The more detailed email survey added an order of priority (i.e. number of votes). The most important issues were said to be: open-ended evolution; better theory, to underpin/unify ad hoc experimentation; the definition of life; creating life (see Section x.b); and understanding dynamical hierarchies. You'll have noticed which one was top of the list.

15.vii. From Vehicles to Lampreys

Evolutionary robotics, as we've just seen, might throw light on how neural mechanisms can evolve to generate ecologically appropriate behaviour. But how neural is "neural"?

It's one thing for a robot's control mechanism to be broadly analogous to real biology, as the artificial triangle-detector was analogous to the orientation cells in visual cortex. It's quite another for a robot (or a computer simulation), whether evolutionary or not, to model actual neurology in any detail. If that could be done, however, it should provide *both* more lifelike robots/simulations *and* a way of testing, and generating, specific biological hypotheses. In other words, robots or simulations produced with real animals firmly in mind could give us computational neuro-ethology, or CNE (Chapter 14.vii)—a term coined by one of the scientists responsible for the triangle-detecting robot (see subsection b, below).

One of the first people to realize this was Arbib, who took the whole animal—and its detailed neurology—into account when modelling integrated sensori-motor mechanisms. In the 1960s, he was doing this virtually alone: his *Rana computatrix* had no implemented CNE cousins. But as the years passed, the four obstacles remarked in Chapter 14.vii.a lessened. From the early 1980s, practical work in CNE flowered.

Frogs were joined, as subjects for computer modelling, by many other animals. And 'computer modelling' increasingly came to mean robots as well as simulations—with predictable disagreements about which methodology was superior. Some of these artificial animals, whether implemented as robots or as programs, weren't designed but evolved—with interesting implications for neuroscience.

Claims to be modelling the "whole" animal, of course, had to be taken with a pinch of salt. Even apparently 'simple' animals often turn out to be much more complex than they seem.

For example, every one of the hundreds of hairs found on a spider's leg (eight legs, remember) bears a number of sophisticated mechanoreceptors and chemoreceptors (Barth 2002; Humphrey *et al.* 2003). (I say "a spider", but that's shorthand: there are eight times as many species of spider as of mammals.) And whereas the nematode worm has 302 neurones (whose action and development have been individually mapped by Sydney Brenner's team at Cambridge: 14.v.b), ants have approximately half a million.

a. Valentino's vehicles

While Arbib was concentrating on increasingly realistic frogs and largely speculative humans, the MIT neuro-anatomist Valentino Braitenberg (1926–) was defining a whole family of imaginary animals (Braitenberg 1984). These were toys, in the sense that they were descriptions of possible mechanisms *stripped down to the bare essentials*. (They also part-inspired the design of actual toys, such as the robot dogs manufactured in end-of-century Japan: R. A. Brooks, personal communication.) However, the "essentials" were all drawn from neuroscience—including the work on feature-detectors discussed in Chapter 14.iv.

Braitenberg wasn't the first to imagine models of whole animals. Friedman, for example, had speculated on a homeostatic robot (see Section vi.a). Edward Tolman and Clark Hull had sketched the "schematic sowbug" and other notional robots (Chapter 5.iii.c). Grey Walter had not only imagined his tortoises, but built them (Chapter 4.viii.a–b). And McCulloch had helped program a controller for a Mars robot (Chapter 14.v.a). But Braitenberg's discussion was much more systematic, concerning not a single model animal but an increasingly complex series of them. He showed persuasively how a wide range of behaviours could be generated by a relatively simple set of basic (and neurologically plausible) mechanisms.

He'd been interested in physical simulations since the late 1950s, when he described systems of coupled oscillators as functional models of cell assemblies and correlation-based models of the cerebellum (1961). In the mid-1960s, he wrote a lively paper giving designs for simple creatures that would move around in response to smell and vision. The three key concepts were *taxis* (automatic movement whose direction and speed is determined by the position and intensity of the stimulus), *kinesis* (unoriented movement, whose speed depends on stimulus intensity), and *decussation* (wherein one side of the brain is connected to the opposite side of the body). It was this paper, together with Braitenberg's earlier theory of movement timing by the cerebellum, which had inspired Arbib to work on *Rana computatrix* in the first place (Arbib 2002*b*: 13).

By the early 1980s, neuroscientific work on learning, and on the integration of perception and action, had blossomed. In an intriguing and highly accessible book—which introduced many people to cognitive science—Braitenberg (1984) now defined a series of increasingly complex creatures, or "Vehicles".

Vehicles were described by Braitenberg himself as a "fantasy" (1984: 95). They weren't implemented: not as robots, and not as programs either. They count as a form of CNE nevertheless, because his book was an abstract exercise in comparative neuropsychology.

In effect, his Vehicles were paper-and-pencil designs for what are now called situated robots (see Section viii.a, below). They provided a phylogenetic scale, going from simple to complex and ending with robots supposedly capable of "running after a dream" (p. 83). Each chapter started from, and added to, the design achieved in the chapter before. So, like biological evolution, the sequence had no viability gaps.

The first Vehicle had (i.e. was imagined as having) one motor, and one sensor—for temperature, light, chemicals, or sound waves. Braitenberg pointed out that even this creature, which simply moved in the direction in which it happened to be pointing, with a speed proportional to the stimulus intensity, would in practice do things that weren't built into the rules. For it would encounter friction, which would affect both its speed and its direction. In general, the behaviour of an *implemented* (embodied) Vehicle would depend not only on its design but also on its dynamic interaction with the environment.

Vehicle 2, which had *two* motors and *two* sensors, was a combination of two instances of Vehicle 1. Although its motors, too, moved faster with increased stimulation of the sensors, its behaviour was more complex. Moreover, the behaviour differed according to just how the two component Vehicles were combined. Each sensor might be connected to the motor on its own side, or to the one on the opposite side (the simplest case of decussation). In the first case (Vehicle 2a), the creature would tend to avoid the source of stimulation. In the second (Vehicle 2b), it would turn towards the source and move forward until hitting it.

The other twelve designs, each with distinct varieties as in Vehicles 2a and 2b, were synthesized by adding a relatively simple computational feature to the one before. These features included inhibition, thresholds, lateral inhibition, association, and one-way facilitation. As Braitenberg remarked, the last of these—which an engineer would regard as "the main technical problem to be solved"—had been modelled by Uttley in the 1950s, and was now being used in many models of conditioning (p. 114).

Even Vehicle 1, Braitenberg had claimed, would be described by an observer as *alive*. If someone were to watch Vehicle 2 for a while, their descriptions would be psychological as well as biological:

> Let Vehicles 2a and 2b move around in their world for a while and watch them. Their characters are quite opposite. Both DISLIKE sources. But 2a [the same-sided version] becomes restless in their vicinity and tends to avoid them, escaping until it safely reaches a place where the influence of the source is scarcely felt. Vehicle 2a is a COWARD, you would say. Not so Vehicle 2b [the decussated version]. It, too, is excited by the presence of sources, but resolutely turns towards them and hits them with high velocity, as if it wanted to destroy them. Vehicle 2b is AGGRESSIVE, obviously. (Braitenberg 1984: 9)

As this passage shows, the Vehicles were mischievously described in psychological terms—such as LOVE (as early as Vehicle 3!), VALUES, LOGIC, CONCEPTS, IDEAS, FORESIGHT, EGOTISM, and OPTIMISM. These anthropomorphic properties were said to be just as "obvious" as AGGRESSION.

Clearly, Braitenberg's tongue was wedged firmly in his cheek. But there was method in his mischief. He was aiming not only to show how highly complex behaviour could be generated by fundamentally simple computational processes, but also to ground this fact in known neurological mechanisms.

Like Pitts and McCulloch (1947), but with the benefit of nearly forty more years of brain research, he related his abstract designs to the specifics of neuro-anatomy. He referred, for instance, to the pyramidal and stellate cells of the cerebellum, and to the orientation columns in visual cortex. He also referred to non-vertebrate examples, such as the compound eyes of insects (pp. 100 ff., 105 ff.).

He even offered computational explanations of some puzzling biological facts. For example, he argued that decussation hasn't evolved by chance as a selective advantage. Rather, it's a natural consequence of a mathematical fact: if each computational unit is connected to all the others then, given bilateral symmetry, there will be more connections crossing the median plane than staying on one side of it (pp. 95–9). Similarly, he suggested that the feature-detectors for orientation and direction that had so amazed their discoverers, Hubel and Wiesel, "may be just a special case of a general principle of the cortex" (p. 140).

Not surprisingly, Braitenberg's work later became highly influential in CNE, and in other areas of A-Life (see Section viii.a). But whereas he'd discussed different types of animal in highly general terms, most of this late-century research modelled the neurology and behaviour of particular species.

The animals chosen were many and various. Besides frogs, which Arbib had been simulating since the late 1960s, several types of fish were considered. Multi-finned fish were modelled by computer graphics programs that simulated how they swam, taking into account both muscle movements and detailed hydrodynamics (see Section ii.a, above). The "robotuna" was a swimming robot fish, whose tail propulsion depended on the production of (and interactions with) specific vortices in the water (Triantafyllou and Triantafyllou 1995). Lampreys were modelled also (see subsection d, below). So were rats: for example, how their navigation abilities depended on the spatial maps in the hippocampus (Mataric 1991).

b. Of hoverflies

Lest you think that only vertebrates were so honoured, insects were studied too. Indeed, the relative simplicity of insects' behaviour and neurology made them a prime focus for CNE. The many insect species involved included hoverflies, crickets, stick insects, and cockroaches—and the CNE methods used to study them differed significantly, as we'll now see.

A male hoverfly will track a female as she flies through the air. Once she settles on a flower, he shoots forward at a very high rate of acceleration, lands on the female, and mates with her. His change of direction, on seeing her settle, depends on the particular approach angle subtended by the target female at the time. If the flower suddenly moves in the breeze, too bad: the male's movement is ballistic. Like a bullet, its trajectory can't be adjusted in mid-flight. The reason is that, unlike the guided missiles developed by the early cyberneticians (see Chapter 4.vii), the fly has no internal mechanism enabling its mating path to be influenced by feedback from the target.

The male's tracking of the female while she's in flight does vary as her position changes. But it doesn't show the flexible selection and variation of pathways often seen in humans and other mammals. Instead, the male fly's tracking flight path is determined by a small set of simple and inflexible rules, hardwired into the insect's nervous system. These rules transform a specific visual signal into a specific muscular response.

One doesn't normally think of anatomical sex differences as including the eyes. But in hoverflies (more specifically, in *Syritta pipiens*), they do. The male has a specialized frontally directed high-resolution set of ommatidia (eyelets) in its compound eye that is functionally a fovea, like that in human eyes. The female doesn't. As she flies around, her eyes aren't good enough to tell her that, just beyond her visual range, lurks the male who is tracking her. In other words, whereas he's capable of a primitive form of visual *attention*, she isn't.

For the male to do the tracking, he needs to keep her foveated—i.e. in the centre of his visual field. Just like humans, the male *Syritta* uses a ballistic eye movement (a saccade) to foveate a target that appears in its peripheral vision. Once the target is in the fovea, it's kept there by means of smooth tracking movements (more precisely, by a succession of tiny ballistic movements, which are damped by the resistance of the air). The male regulates the distance to the female by keeping the vertical height of her image on his eye within a set range. He has feature-detectors in his retina that respond in an appropriate fashion: the closer the target image is to the right height, the more actively they fire.

The "right" height, of course, refers implicitly to the size of a female hoverfly. Just as a frog will snap at a moving object only if its radius of curvature lies within certain limits (14.iv.a), so a male hoverfly will accept as a target only something that happens to be much the same size as a female. But this is all that's needed to induce tracking: if an appropriately sized speck of ash happens to be floating in the air, it may be tracked instead.

These facts were discovered in the mid-1970s by biologists Michael Land and Thomas Collett at the University of Sussex (Land 1975; Collett and Land 1975; Collett 1980). They were later turned from NE into CNE by David Cliff (1966–), one of the Sussex 'A-Lifers' responsible for the triangle-detecting robot (Cliff 1991*a*).

Given the question raised in Chapter 1.i.a, whether the study of insects can teach us anything about human minds, it's worth noting that both Land (1975) and Cliff saw the hoverfly as a simple analogue of animate vision in humans. In "animate" vision, important perceptual information is provided by the creature's own movements (Ballard 1989, 1991). It's worth noting, too (with respect to the attacks on GOFAI described in Chapter 13.iii.b), that it was Cliff who suggested reading "AI" as "artificial insects".

Much as a human's gaze, or visual attention, is captured by certain visual stimuli (a phenomenon discussed in Pitts and McCulloch's 'Universals' paper: see Chapter 12.i.c), so is the hoverfly's. In both cases, behaviour—including eye movements—is influenced accordingly. But once the hoverfly's eyes have centred, its action selection is more rigidly constrained.

Because its eyes are fixed in its head and it has no neck movements, there's no distinction between direction of gaze and body orientation. Moreover, although it can fly in any direction—including sideways, backwards, and stationary hovering—its flight direction is generated by only three components. On top of all this its eyes are less complex, so more easily simulated, than human eyes. Each has about 30,000 photoreceptors, as against 127 million in the human case. In short, 'realistic' simulation of the hoverfly's visuo-motor system was a reasonable goal.

Cliff designed a neural network named *Syritta computatrix*, or SYCO, in homage to Grey Walter and Arbib—and Alfred Hitchcock. This modelled how the hoverfly uses image sampling to lock the most important stimulus onto the area of greatest visual acuity in its eyes; how it tracks that stimulus in motion; and how the visual information is used to determine its flight.

Things weren't made unnaturally easy for SYCO: varying air turbulence and cross-winds were simulated too. As Cliff pointed out, this form of computer vision was very different from that of GOFAI, which typically used toy worlds, static receptors with uniform resolution, and static images (see 10.iv.b).

To simulate the rigid flight control described above, Cliff relied not on exhaustive hand design but on training. SYCO used backprop (see 12.vi.c) to learn to match specific retinal images with specific flight directions. The intention was to compare the 'neurology' of the successful network (once it emerged) with the neurology of the real fly, and to choose between alternative explanations—or generate new ones—accordingly. Cliff constantly evaluated and improved his CNE model by comparing it with the NE data, and managed to answer some previously posed theoretical questions.

He pointed out that "Experiments impossible in living tissue or impracticable in robotics can routinely be performed on SYCO" (1991*a*: 95). But SYCO was just one system. So Cliff broadened his argument in a "provisional manifesto" for CNE in general (Cliff 1991*b*). He explicitly endorsed Humberto Maturana's whole-animal approach (see Section viii.b), including his argument that "the nervous system should not be treated as an input–output device" (1991*b*: 32). Unlike Maturana, however, Cliff was happy to describe his own project as a computational one:

> Computational neuroethology replaces the *in vacuo* approach of connectionism with a (simulated) *in vivo* approach; and in doing so, the semantics of the model are automatically grounded.
>
> So, computational neuroethology can be provisionally defined as the study of neuroethology using the techniques of computational neuroscience. (1991*b*: 34)

(He was happy to use the term *computational* because he thought of it then as fairly "neutral"—as it is in this book. Today, because of the later developments in A-Life, he'd prefer *synthetic*: personal communication.)

Although Cliff here described this definition as "provisional", he'd been using the term CNE in unpublished work since 1988 (1991*b*: 34). It first left the press in 1990, when Randall Beer used it in the subtitle of his book *Intelligence as Adaptive Behavior: An Experiment in Computational Neuroethology*. By the mid-1990s, the new coinage had been widely adopted.

Besides vaunting CNE as a way of using A-Life to do neuroscience, Cliff drew a moral for other areas of cognitive science. He criticized the biologically unrealistic assumptions of both GOFAI and connectionism. And he ended with this anti-anthropocentric flourish:

> All current connectionist models of language are wildly premature. Language will be best understood as a very high layer in a subsumption architecture: how it interacts with lower layers could be of vital importance, and we should study these lower layers first.
>
> If we are still yet to discover the subsymbolic or neural basis underlying the dance-language of bees, how then are we supposed to study such aspects of human language at anything but the

most gross level of neuroanatomy (i.e. studies of lesioned patients)? We simply do not know enough. (1991*b*: 37–8)

It didn't follow that the studies of language described in Chapter 7.ii and 9 were a waste of time, for they hadn't addressed the "neural basis" of language. But connectionist work on past-tense learning, for instance, was seen by Cliff as fundamentally wrong-headed (Chapter 12.vi.e).

As for Arbib's talk of linguistic schemas (Chapter 14.vii.c), this (by implication) was possibly on the right track—but highly untimely nevertheless. The message was that to understand language, we must first understand hoverflies.

c. Playing cricket

Cliff had defended *Syritta computatrix* partly by reference to the "impracticalities" of robotics (see above). Nevertheless, some influential CNE research relied on this methodology.

One example was Barbara Webb's (1965–) work on crickets, begun in Edinburgh's AI Department and continued under Psychology's flag at Stirling (and now back in Edinburgh again, in the School of Informatics). Like Cliff, she was offering not only a contribution to neuroscience but also a critique of symbolic and connectionist AI. Her theoretical focus was on "behaviour and physics" rather than "representation" or "general abilities" (1994: 52–3; 1996; 2001*a*,*b*).

Francis Crick pointed out that evolution employs "slick tricks" when it can (see Chapter 14.ii.a). Turning from Crick to crickets, it turns out that these creatures use an especially slick trick to manage their courting behaviour. The female finds the male by locating the source of his song (produced by drawing one wing across the other). *Good! So she can hear!* Well, yes and no.

A human Juliet hearing her Romeo can first recognize his song, distinguishing it from all the other sound patterns she can identify, and then decide in which direction she should go to meet him—or to avoid him, if they've had a tiff. She doesn't have to go straight there: if her ardour isn't overwhelming, she can run a few errands on the way. (The female cricket may not respond if she's already mated, or if there are predators around—but if she goes, she goes.) Moreover, if Romeo sings half an octave lower than he did yesterday, or half as fast, Juliet can still find him. She can even learn to appreciate a new song, should he decide to sing one.

Not so, the cricket. As remarked in Chapter 14.iv.d, insects can't learn new patterns. Even more to the point, the female cricket can recognize only one song, sung at only one speed and frequency—give or take . . . (cf. Webb and Scutt 2000: 247 ff.). What she takes as the "speed" of the song is the rate of repetition of the syllabic patterns within it—which varies for different species of cricket. When she hears her conspecific's song, she can do only one thing: move towards it. Unlike the hoverfly, however, she can walk *or* fly to meet her mate—and if she walks, she can do so more or less directly.

Her ears respond to many different sounds, but she doesn't rely on that fact to recognize the male's song. She doesn't need, and doesn't possess, a brain stuffed full of auditory-feature-detectors for coding a wide range of sounds. Instead, she has a custom-built mechanism—a single 'feature-detector'—sensitive to only one frequency. (She also has a simple mechanism for hearing and fleeing bat ultrasound: Webb, personal communication.)

Her automatic mate-finder isn't a *neural* feature-detector, like those described in Section iv. Instead, it's implemented as a fixed-length tube in her thorax (the trachea), which is connected to the ears on her front legs and to her spiracles.

When the male cricket sings, the sound waves travelling through the air in the tube interact with those in the air outside, resulting in phase shifts that produce vibrations of different intensity at each eardrum. But the length of the tubes in the female's body is an exact proportion of the physical wavelength of the sound emitted by the male. So the *physics* ensures that phase cancellation happens only for sounds having the frequency of the male cricket's chirp. Similarly, the *physics* ensures that the intensity difference depends wholly on the direction of the sound source. The female doesn't have to work that out, nor decide what to do about it: she's neurally hardwired to move in the direction concerned. (Notice that there's no need to assume she's 'conscious' of any sound.)

So much was suspected by the early 1980s. The cricket's sound-directed movement (phonotaxis) and its neural underpinnings were already "one of the insect systems most thoroughly studied in neuroethology" (Webb 1994: 45). Researchers knew, for instance, that there are about fifty auditory receptors (though they weren't yet individually identified), and several pairs of auditory interneurones in the pro-thoracic ganglion (Webb and Scutt 2000: 248). In 1985 the behaviour and neuro-anatomy were described for the public, in the *Scientific American* (Huber and Thorson 1985).

All very intriguing . . . But despite the congratulatory tone of the *Scientific American* article, the underlying mechanism still wasn't understood. Various sound cues had been suggested, but how they might be discriminated by the cricket was unclear. Equally, whether—and how—they interacted in the nervous system wasn't known. Another mystery was how the cricket's hearing could be integrated with any other modality, such as vision (this isn't too surprising, since most of the phonotaxis experiments were done in the dark).

It was generally assumed that the *recognition* of the song happened in the brain, and that the neural system representing the song was distinct from the *localization* system. Nevertheless, this wasn't certain. So a neurological paper published in the *Journal of Comparative Physiology* of 1988 admitted:

> It is still entirely unclear whether or how [the direction and the characteristic sound] of the calling song are processed independently of one another in the brain, or how the brain triggers and controls phonotactic walking. (quoted in Webb 1994: 45)

In the mid-1990s, the same journal published a paper (modelling the role of the pro-thoracic ganglion) which simply took recognition for granted, and which used spiking rates to predict the direction of movement without specifying how this correlation might be implemented (Webb and Scutt 2000: 248; Webb 2001*c*). In short, a great deal of neuro-ethological hand-waving was going on.

In the early 1990s, Webb decided to address these questions by devising "the simplest possible robotic mechanism that could support the observed behaviour of the cricket" (Webb 1994: 46). That is, she turned the NE into CNE—and she expressed the "C" as physical robots, not (like Cliff) as computer simulations.

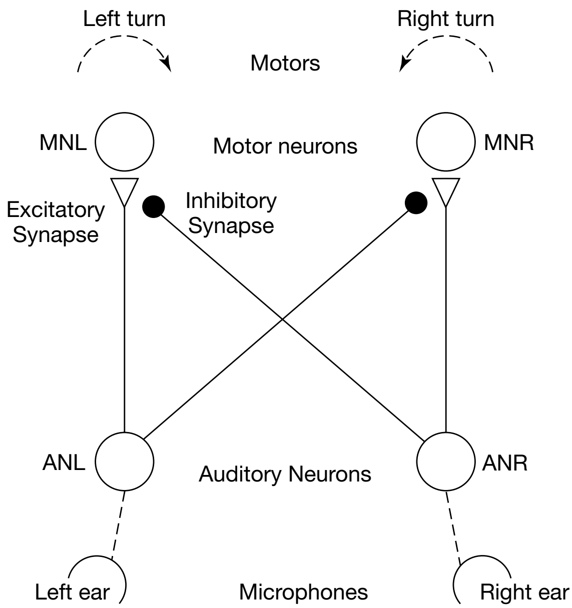

FIG. 15.5. The four-neurone system for phonotaxis. Auditory neurones (AN), modelling the AN1 pair in the cricket pro-thoracic ganglion, receive auditory input. They have a high recovery level, i.e. continue producing spikes over a raised membrane potential while the stimulus continues, and a relatively slow time constant. Each connects to a motor neurone (MN), which will be excited at the onset of firing, and to the opposite AN–MN synapse, which will be inhibited at the onset of firing. Thus, repeated onsets of one AN before the other are required to drive the respective MN above threshold, which causes a turn. Redrawn with permission from Webb and Scutt (2000: 251)

As for seeking the simplest possible mechanism, she was closely guided by the neuro-anatomy but didn't try to model every neurone that had been observed. Eventually, she got down to as few as four (see Figure 15.5).

Unlike the artificial cockroaches described below, Webb's early 1990s robots looked nothing like insects. They had wheels, not legs, and were built on a Lego base or a commercial Khepera robot. After all, the theoretical questions didn't concern the movements of the cricket's legs, but the sensori-motor circuitry making her move towards the song.

Like Arbib's *Rana computatrix* (see 14.vii), Webb's machines grew closer to the biological data as the series progressed. By the turn of the millennium, her robots modelled the neural processes of summation, firing latency, thresholding, recovery, decay, and comparison. Changes in membrane potential were simulated by a small set of state rules, defined in terms of above/below resting, above/below threshold, and above/below recovery (Webb and Scutt 2000: 250).

The neurones were connected to the motors on either side in such a way that recognition of the ideal signal would cause the robot to turn towards it (compare Braitenberg's Vehicles). And Webb tracked the activity levels of the individual neurones, as well as observing the whole robot's behaviour.

Most of these robots didn't move in a straight line—and nor do female crickets. The machines, like the insects, zigzagged within 60 degrees of the optimal direction, and weren't put off by obstacles unless the sound source was very close to the starting point. Later, Webb's group showed (with the help of specially designed VLSI chips from Caltech) that combining hearing with vision enabled the creature to move to the target more directly (Webb and Harrison 2000).

The internal parameters were systematically varied, to test the neural hypotheses involved. Significantly, it turned out that the robot's success was generated by a decision mechanism much simpler than had previously been thought necessary. That is, CNE had provided—and tested—a more elegant theory than straight NE. A-Life had advanced our knowledge of real life.

Webb's work showed conclusively (for example):

* that the various neurological theories which had assumed that there *must be* distinct systems for recognition and localization were mistaken;
* that this was so *even though* the female is able to choose the more attractive of two simultaneous songs (a fact that had previously been thought to support the distinct-systems hypothesis);
* that the neural firing rate was *not* (as had often been assumed) the crucial feature of the signal;
* and that one and the same mechanism could both compare latencies and identify the temporal patterning of the song.

In short, she had clarified many neuroscientific questions, answered some, and raised some more. Answering the unanswered questions, she said, would require work both in robotics and in 'wet' neuro-ethology—and, ideally, close cooperation between them.

To critics who sneered at the use of wheeled robots to model graceful crickets, Webb had an effective reply—a modern version of Vaucanson's remarks about what he'd learnt by building his flute-player (Chapter 2.iv.b). In general, she said, the practical weaknesses of robotic CNE could be seen as theoretical strengths:

> The precision of sensing and motor control is generally much worse in the robot than would be expected for the cricket, so the success of the mechanism is unlikely to be due to abilities that the cricket could not really have. The robot constitutes a *subset* of the capabilities of the cricket rather than an *abstraction* of them. (Webb 1994: 51)

By contrast, purely programmed simulations could be too powerful to be biologically convincing:

> Computer modelling of *realistic* physics of phonotaxis in a moving animal or robot is quite difficult. "Ideal" sound propagation can be described by fairly simple equations, but in any real situation, with a directed speaker, a floor surface, reflecting walls and so on, it becomes extremely difficult to calculate with any accuracy . . .
>
> Using a computer model rather than a robot would, in this case, substantially weaken the justification for extending the results of testing the hypothesis to the cricket. For example, it would be hard to claim that, insofar as sensors and motors differ, those in the model are substantially *worse* in accuracy than in the cricket: it would be more likely that the mechanism only works because of the idealised conditions. (p. 53)

In some studies, Webb's group worked backwards from robot to insect, instead of from insect to robot (Lund *et al.* 1997). In other words, they asked whether, and how, sensori-motor robots could be made to respond to the songs of *real* crickets.

In the earlier experiments, the "ideal" sound signal had been partly determined by parameters such as robot size, processing time in the circuitry and software, movement speed, and turning inertia. As a result, the robot had sought a signal very different from that preferred by biological crickets. For instance, the songs it responded to were ten to twenty times slower than those of the real animals, and the area that could be experimentally explored was only a fifth of the size (relative to the size of the creature) typically used in NE experiments on crickets.

By the mid-1990s, technological progress in robotics offered Webb speedier processing, and a more fast-moving creature. As well as confirming that her earlier neural hypotheses could indeed explain response to real cricket songs, these new experiments enabled her to test ideas about *why* crickets, given their sensory anatomy, prefer certain frequencies rather than others.

In effect, then, Webb was now in a position to say not only "The cricket behaves as it does because its neurology is what it is", but also "If the cricket's neurology were like *this*, she'd behave *thus and so*." Indeed, she could even have said "No cricket could have a neurology like *that*, because if she did she'd never find a mate." It's no surprise, then, that Webb's work was sometimes published in A-Life journals. For A-Life studies not only "life as we know it" but also "life as it could be".

Early in the new century, Webb's team reported a model of phonotaxis that included a much larger number of the known neural properties, and a wider behavioural repertoire (Reeve and Webb 2002). Drawing on biophysical theories of computation developed by Christof Koch (1999), they included (for instance) a variable exponential decay of membrane potential; a biologically plausible 'weight' determining the standard change of conductance in particular ion channels; and short-term mechanisms for facilitating or depressing this change. Whereas the earlier models had focused on one pair of auditory neurones (marked AN in Figure 15.5), they now included several other types. The speed of the cricket's movement was varied, as well as its direction, and these were integrated with both visual and auditory inputs. For example, in brighter light the robot was less likely to stop when it was moving towards the sound.

Webb's new robots included not only wheeled systems, but also six-legged creatures similar to those discussed below. Significantly, these insect-like robots can move across natural terrain, such as summertime and frost-covered grass, not just the unnaturally flat laboratory floor (Horchler *et al.* 2004; Reeve *et al.* 2005). As well as responding to real cricket songs, they rely on biologically based neural simulators (and specially crafted VLSI chips) which are even closer to the actual neurophysiology than in Webb's earlier experiments. (Her team hope to make them closer still, by feeding the spiking patterns from real cricket neurones into the model.) This example illustrates how far "neuromorphic engineering" had come since Carver Mead's pioneering VLSI retina (see 12.v.f).

We shouldn't look down our noses too hard at the cricket. For humans, too, sometimes rely on inbuilt anatomical tricks, and on 'quick-and-dirty' responses to limited aspects of the sensory information.

Indeed, one set of human responses probably involves another fixed-length physical mechanism for sound location. In cats, the time difference between the moments at which the signal arrives in the two ears is coded by the connection lengths of specific neural circuits in the brain, and this tiny (microsecond) delay is used as a cue in locating the source (Smith *et al.* 1993). The same is very likely true of people. However, the mammalian system—because it depends on a range of time differences rather than a specific phase interaction—isn't limited to a particular sound frequency, as the cricket is; and mammals have a series of delay lines of different lengths rather than just one fixed delay.

A closer analogy, perhaps, is the strong tendency people show to turn to face a sound source (Webb, personal communication). They don't need to recognize the sound, or to locate it accurately. They simply keep turning until the two ears have the same input. Whether or not this is done by dedicated neural circuitry, the point is that the information in the sensory signals doesn't have to be 'explicitly' decoded to enable the response.

So, much as William Harvey's studies of slugs, newts, and eels helped him understand the human blood system (Chapter 2.ii.a), CNE studies of crickets can help us think about our own psychology. But whereas blood circulation in newts is very similar to ours, although slower, perception and action selection in insects is profoundly different. Humans (Juliet, for instance) can do much, much more.

As for stick insects and cockroaches, their neuro-anatomy was simulated in six-legged robots modelled on NE findings about real beasts. The theoretical focus, here, was on walking *as such*.

These hexapod robots, using their multi-segmented legs, could clamber over obstacles rather than having to avoid them, and could even climb stairs. Some could recoil from an obstacle. They'd walk backwards steadily for a while before turning, instead of repeatedly colliding with the obstacle while edging along its surface as Grey Walter's *Machina speculatrix*, and the simplest Vehicles too, had done. (Beer sometimes referred to his cockroaches as *Periplaneta computatrix*, in homage to Grey Walter.)

Such results weren't trivial. The choice of the next movement—*which* leg should be moved, and *how*?—had to be just right. What was the correct placement, force, timing, and sequence? And how should the legs interact? They had to be largely independent, because there might well be a pebble near the 'foot' of the second leg and none near the sixth. But there had to be some degree of integration. If the second leg were lifted higher than usual, the balance of the insect's body would be affected—so the other legs would have to compensate. Moreover, each leg was jointed: how were the several segments to be coordinated?

Some of the most influential work of this type was done in the 1980s by Beer (1961–) and colleagues, including mechanical engineers (directed by Roger Quinn), at Case Western Reserve University, Cleveland. Initially, they were inspired by Braitenberg's Vehicles, by Rodney Brooks's situated robotics (viii.a, below), and by Phil Agre and David Chapman's Pengi (13.iii.b). (Later, they'd be enthused also by ideas about dynamical systems: see xi.b below.) Beer's group designed movement controllers for artificial cockroaches (R. D. Beer 1990; Beer and Chiel 1991). In the late 1980s, they began to experiment with GAs to *evolve* the controllers, rather than designing them by hand (Beer, personal communication).

Most of their robots were physical machines. Others, especially when they got into evolutionary robotics, were abstract simulations, functioning within a virtual environment. In both cases, their "neuro-anatomy" initially reflected NE data from several insect species, not just cockroaches. But they later studied the behaviour of the death-head cockroach in particular detail, and used their robot results to suggest further NE hypotheses (Quinn and Ritzmann 1998).

Beer's robots modelled the control of walking, on uneven terrain and with occasional obstacles. They had six pacemaker neurones, all of which automatically produced rhythmic bursts of activity, and each of which controlled the swing and stance of a single leg. Kinaesthetic feedback from leg-position sensors and local leg reflexes was included, and some models also had two sensory "antennae". In addition, the leg circuits were coupled together. The result was a family of robots with a range of physically stable gaits very like those seen in real cockroaches.

In the simulated creatures, walking was done with a purpose (Beer and Chiel 1991). That is, it was triggered and guided by several internal drives, or motives: eating, seeking food, edge following, and wandering. Some of these were mutually incompatible. After all, if a human nursemaid has only two hands (see Chapter 7.i.f), a cockroach has only six legs. Since it can't be everywhere at once, it must choose what to try to do next (as well as how to do it). In short, Beer's creatures faced the same fundamental problem as the Mars robot described in Chapter 14.v.a, but had a more advanced neural architecture with which to do so.

d. Evolving lampreys

The nervous systems of Beer's early cockroaches were hand-designed—as was the artificial stick insect, some of whose features Beer incorporated in his own work (Cruse *et al*. 1995). But some of his later creations were evolved, using GAs (R. D. Beer and Gallagher 1992). Starting with largely random networks—and therefore with paralysed cockroaches—he ended with happily perambulating creatures.

Cliff and his colleagues, as we've seen (Section vi.c), also did pioneering work in evolutionary robotics. Myriad 'neural' circuits were brought into existence at each generation. But only those which—like the artificial orientation detector—contributed to the robot's "fitness" (in this case, its navigational ability) had a high probability of surviving into the next.

Intriguing results such as these inspired some professional neuroscientists to start using GAs to study real animals. By the late 1990s, David Willshaw (some of whose earlier work was described in Chapters 12.v.c and 14.ix.a) was doing evolutionary CNE—though not evolutionary robotics.

With two AI researchers from Edinburgh, he compared the efficiency of artificially evolved neural networks with real ones, namely those used for controlling swimming in lampreys (Ijspeert *et al*. 1997). (These eel-like fish have a much earlier claim to fame: King Henry I of England is said to have died from "a surfeit of lampreys" in 1135.)

A lamprey doesn't have paired fins, but swims by rhythmic undulations of its long body. By 1990, biological NE had discovered a great deal about the neural circuitry, transmitters, and membrane properties involved. What it couldn't discover was what alternatives, if any, are biologically possible. What non-existent, but viable, lampreys might biological evolution have generated, had the genetic mutations been different? Even straightforward CNE simulation of the lamprey's neuromuscular system, which had been achieved in the early 1990s, couldn't answer that question.

Willshaw and his AI colleagues now used GAs to show that there are many network architectures capable of controlling this type of swimming. Moreover, they found that some of their artificial networks, *although* composed of 'neurones' closely based on the biological data, were much more efficient than those found in real lampreys. Some had a frequency range five times larger. Even when the connections (and their type: excitatory or inhibitory) were fixed to be identical with those in real lampreys, some networks evolved—within only 100 generations—with frequency ranges three times larger.

This was interesting, in view of Marr's earlier claim that biological evolution can be trusted to find the *optimal* solution for a given computational task (see Chapter 7.iv.g). It was also interesting as yet another description of "life as it could be". Evidently, CNE could provide both science and biologically plausible science fiction.

15.viii. Parallel Developments

Computer-based research on self-organization accumulated slowly. Most of it, including Holland's and the CNE examples described above, could be properly developed only when vast computational power became available in the 1980s.

The germinal ideas were growing, nevertheless. Some focused on the *results* of self-organization, some on the self-organizing *process*. In general, however, this research led to new ways of thinking about life and mind. Or rather, it used new theories and data to go back to pre-GOFAI days, building on Turing's and von Neumann's 'biological' writings and even revivifying ideas from the late eighteenth century.

These 'new' ideas were arising both within and outside cognitive science. Various people were engaged in fundamentally similar enterprises, often without realizing it. The potentially unifying themes were self-organization (emergent order), complex dynamics, distributed control, the close coupling of perception and action (and 'whole-animal' approaches in general), and autonomous systems embedded in their environment. But the unification still hadn't happened.

By 1986–7, when A-Life was first identified as a unitary field (see Section ix.a), relevant research lay scattered across mathematics, physics, and biology—and almost every discipline of cognitive science.

* In AI, for example, evolutionary modelling was studying the emergence of novel systems of increasing order (see Section vi, above), and work on agents was exploring the nature of distributed cognition (see Chapter 13.d).
* Researchers in AI and computational psychology, partly inspired by PDP connectionism (12.vi–viii), were focusing on self-organization in distributed systems (Rumelhart, McClelland, *et al*. 1986; Forrest 1991).
* Much of this work was drawing on the growing body of research in dynamical systems (see below, and Section xi).
* Neuroscientists, too, were looking at the origin and the functioning of integrated self-organized systems (Chapter 14.vi–ix, and Section vii above).

* And a few philosophers and/or biologists-turned-philosophers were exploring theories of life and mind very different in spirit from orthodox empiricism (Chapters 14.ix.b and 16.x.c, and subsection b below).
* Only theoretical linguistics, preoccupied by the "Linguistic Wars" (Chapter 9.ix.a), was immune.

This section, and the next, illustrates both the diversity and the commonality of this widespread work.

a. Artificial ants

Emergent order was being studied by a new approach in robotics, in which Herbert Simon's ant (Chapter 7.iv.i) was at last coming into its own.

As described by Simon twenty years earlier, the ant's apparently complex behaviour resulted from local interactions with its environment. Similarly, the newly built "situated" robots possessed a small number of simple reflexes, movements triggered by specific environmental cues (R. A. Brooks 1986; Beer and Gallagher 1992). These weren't movements of the entire creature, but of a single part, such as a leg. Distinct body parts would each have their own inbuilt reflex mechanism, triggered independently of the others. But these separate reflexes functioned in parallel, so that the creature as a whole 'walked' successfully.

The integrated behaviour of these biologically inspired robots, like Beer's artificial cockroaches (see Section vii.c, above), was organized bottom-up. At the lowest level of reflexes, there were no interconnections. (In the language of NK networks, N was small and K was zero: see Section ix.b, below.) But several levels of reflex mechanism might be provided, as in Brooks's "subsumption" architecture. The extra levels came from addition rather than reconstruction: the robot remained effective ('viable') at every stage.

Subsumption architectures were very different from GOFAI, and Brooks's insect-like robots not at all like SHAKEY (Chapters 10.iii.c and 13.iii.b). Earl Sacerdoti's (1974, 1975*a*,*b*) ingenious contingency planning and last-minute adjustments were given no place here. There was some flexibility, to be sure. Higher-level reflexes could inhibit lower-level ones in certain circumstances, given certain environmental cues. Apparently purposive behaviour could even emerge as a result (Mataric 1991; Maes 1991*a*,*b*). But there was no top-down behavioural control, still less any detailed modification of the execution of lower-level modules.

In short, these systems were very different from GOFAI robots. Arguably, they supported explanations of adaptive/purposive behaviour, even in animals (including humans), very different from what orthodox functionalism had recommended (Hendriks-Jansen 1996: 135–53).

Situated robots, and similarly conceived software "agents" (Riecken 1994), were proudly described by their builders as "autonomous" (e.g. Maes 1991*c*). What this actually meant was that their behaviour resulted from their own inner structure, not from any externally imposed program or plan. But there was a risk (dare one say "a hope"?) that people would read much more into it. This sort of autonomy is a far cry from human autonomy, or freedom—which, counter-intuitive though this may seem, is better modelled by GOFAI than by A-Life (Boden 1995*a*; see also Chapter 7.i.g).

These A-Life efforts, and their overly anthropomorphic interpretation, had been anticipated by Braitenberg. As we saw in Section vii.a, he'd discussed designs for "Vehicles" that were, in effect, unimplemented designs for situated robots. They'd also been anticipated by Grey Walter, though in a less neurologically explicit, and less systematic, fashion (see Chapter 4.viii.a–b).

As befitted the director of an institute of biological cybernetics, Braitenberg had acknowledged the influence of Wiener (Braitenberg 1984: 2). But his brief book didn't mention Grey Walter, whose tortoises were the first situated robots, and which generated approach–avoidance behaviour comparable to Braitenberg's LOVE and COWARDICE. Even Brooks, who did salute Grey Walter's work, criticized him for "the lack of mechanisms for abstractly describing behaviour at a level below the complete behaviour, so that an implementation could reflect those simpler components" (Brooks 1991*b*, sect. 3.3).

This criticism wasn't entirely merited: in a manuscript of 1961, Grey Walter had analysed his tortoises' behaviour in precisely this way (see Chapter 4.viii.b). But the piece had remained unpublished. It wasn't until the end of the century that Grey Walter was recognized in the A-Life conference Proceedings as "the pioneer of real artificial life" (O. Holland 1997). And it wasn't until the millennium had passed that an international A-Life meeting, on biologically based robotics, was explicitly dedicated to his memory (Damper and Cliff 2002).

Situated robots were compared by Brooks himself to Jacob von Uexküll's animal species, each with its own life-world (Chapter 5.ii.c). And—despite Brooks's disclaimer (1991*a*, sect. 7.3)—they might have been likened to Simon's Production Systems of the early 1970s (see 7.iv.b). For these, too, had relied on automatic responses to predefined cues. But Simon had focused on human reasoning, and had posited a rich internal environment of symbolic representations.

Simon had also stressed the role of the external environment, such as pencil marks on paper. But this aspect of his work was ignored by the situated roboticists of the 1980s. It was taken up (and much extended) later by philosophers and psychologists interested in situated cognition and embodiment, who recognized the importance of cultural artefacts for prompting human behaviour (see Chapters 8.iii.a and 16.vii.d).

The A-Life roboticists were inspired not by human reasoning or language, but by the world-driven behaviour of relatively simple animals. Many of their robots looked something like insects, having long bodies and six or eight jointed legs. A few, including those developed by Webb and Beer, even modelled insect neurology in some detail. Accordingly, some wags repeated Cliff's remark that "AI" now stood for "artificial insects".

The point of this remark, besides its power to raise a laugh, was tacitly to classify A-Life as a form of AI. In my view, that's correct: just as connectionism is a form of AI, so is A-Life. However, the jibe wasn't welcome in the A-Life community, most of whom went to great lengths to distance their work from "AI".

In part, this new AI methodology was driven by failure. It was trying to avoid the notorious failure of classical AI to solve the frame problem (see Chapters 10.iii.e and 13.i). But in part, it—and evolutionary robotics, too—was grounded in a different conception of intelligence, one which took seriously the fact that human and animal minds evolved in real-world environments.

This approach (outlined in 13.iii.b) insisted that advanced behavioural abilities emerge from simple ones, and that the path from simple to complex has no viability gaps (though it needn't appear continuous: see the comment on punctuated evolution in Section vi.b). The simple abilities are closely coupled with environmental conditions, so the frame problem can't arise.

Moreover, the view was that even advanced mental abilities function in similar sorts of ways, so that the concepts of computation and representation are irrelevant for explaining cognition. The leading evolutionary roboticists described their work in terms of dynamical systems (see subsections c–d, below, and Section xi), explicitly rejecting the types of explanation familiar in classical AI and (most) connectionism (Beer and Gallagher 1992; Husbands *et al.* 1995). Similarly, Brooks saw situated robotics as offering "intelligence without representation" (Brooks 1987/1991*a*) and also "without reason" (1991*b*).

Brooks wasn't speaking, here, only of insect intelligence. Despite some (ambiguous) backtracking with respect to linguistic and logical thinking, he was soon to initiate a long-term robotics project modelling the early development of human cognition—and, with Daniel Dennett's cooperation, even consciousness (Brooks and Stein 1994; Dennett 1994*a*). Dennett (1978*c*) had suggested many years before that AI researchers should try to build a *whole* cognitive system: now, here was his chance.

The Cog robot, which has already given rise to a commercially marketed baby doll, combined inbuilt reflexes with connectionist learning. It was an early exercise in what's now called "epigenetic robotics", in which a robot's control system and behaviour develop differently according to the particularities of its environment.

So Cog incorporated some of the findings in developmental psychology, linguistics, and cognitive neuroscience described in previous chapters. For example, psychologists had shown in the mid-1970s that joint attention develops by mutual gaze, gaze following, and pointing (6.ii.c). Brooks's team used these features to model the development of joint attention—not mother–baby this time, but human–robot—in Cog (Scassellati 1996, 2001).

In this still ongoing project, now directed by Brooks's students Cynthia Breazeal (Ferrell) and Brian Scassellati, the artificial denizens of "The Cog Shop" became ever more "human" (for the most recent reports, see the web site at <http://www.ai.mit.edu/projects/humanoid-robotics-group/cog/cog.html>). This was true not only of their appearance, but also of their behaviour—especially, their "social" interactions. The robot was not only given "needs" (drives, motivations) to induce caretaking responses on the part of the human interacting with it, but also babylike responses that signalled to the carer whether or not those needs had yet been met.

(More recently, the MIT group have worked on a puppy-like furry robot called Leonardo, which—up to a point—can imitate the facial expressions of the human being. Babies can do this too, probably by using the "mirror neurones" discovered in the 1990s: 14.vii.c. And Scassellati, now at Yale, is building Nico, a creature that will recognize and respond to gestures as well as speech. This is no mere trivial toy. Like his medical funders, Scassellati hopes to use Nico to identify, and perhaps even to cure, early childhood autism: see 7.vi.f. Indeed, he hopes eventually to be able to use humanoid robots to *test* theories in developmental psychology, much as computer simulations are so used today.)

Given that description, this work may sound reminiscent of the "social" AI described in Chapter 7.i.c. But its methodology was very different. For Brooks's team avoided top-down control, symbolic computation, planning, and objective world modelling. In short, the GOFAI approach was being turned on its head: *situated action*, including social interaction, was the buzz phrase (see 13.iii.b).

Predictably, there was resistance. That is, there was theoretical resistance (13.iii.c). Behavioural resistance was less predictable. On encountering Cog, and despite its highly *non-human* appearance, people tended to engage with it as though it were human—or anyway, animate. The key feature seemed to be the robot's ability to catch the human's eye and maintain mutual gaze and/or attention.

This animistic response was even stronger with respect to Kismet, a Cog-like creature equipped with floppy pink ears, large blue eyes, and an amazing set of eyelashes (Breazeal and Scassellati 2002). The robot's ears, eyes, and eyelashes could be put into different physical positions, spontaneously interpreted by people as sadness, anger, tiredness, interest, excitement, happiness, or even disgust. With the addition of "needs" and associated feedback signals to its carers, Kismet was able to trigger still more of the emotional responses normally elicited by (and evolved for) vulnerable fellow humans. The carers even lapsed into 'motherese', the syntactically and intonationally distinct dialect that mothers use when speaking to babies and infants (see 9.vii.c).

Even Sherry Turkle—not only a trained psychoanalyst, but a long-time colleague of the MIT AI community (and ex-wife of Papert)—reacted in that way. She didn't need Kismet or Leonardo to make her do so, for the more primitive Cog sufficed:

> Cog's mobile torso, neck, and head stand on a pedestal. Trained to track the largest moving object in its field (because this will usually be a human being), Cog "noticed" me soon after I entered its room. Its head turned to follow me and I was embarrassed to note that this made me happy. I found myself competing with another visitor for its attention. At one point, I felt sure that Cog's eyes had "caught" my own. My visit left me shaken—not by anything that Cog was able to accomplish but by my own reaction to "him". For years, whenever I had heard Rodney Brooks speak about his robotic "creatures", I had always been careful to mentally put quotation marks around the word. But now, with Cog, I had found that the quotation marks disappeared. Despite myself, and despite my continuing skepticism about this research project, I had behaved as though in the presence of another being. (Turkle 1995: 266)

Turkle's scepticism was based largely on postmodernist philosophical grounds. The same was true of her MIT colleague, the feminist philosopher of science Evelyn Fox Keller, who queried the "human" responses to Kismet (Fox Keller forthcoming). Others looked askance at Cog for different reasons.

Quite apart from scepticism over the "consciousness" of the humanoid robot envisaged by Brooks, many felt that he'd failed to learn the lesson that both Lashley (1951*a*) and Noam Chomsky (1959*b*) had tried to teach Burrhus Skinner: that S–R reflexology isn't enough. In particular, Brooks's claim that representations are unnecessary for intelligence—and especially for human intelligence—was soon challenged (13.iii.c). The disagreement eventually led to a better understanding of the diversity of mechanisms that can be called "representations" (14.viii).

The proof of the pudding . . . ? Some ten years after its start, Cog is now virtually on ice (for a recent account, see Brooks *et al.* 2000). It was always a 'spare-time' project, and most of the original team—then, graduate students—have left MIT to take jobs elsewhere. (Brooks himself has been swamped by administration since becoming director of the AI Lab.) A comparable project, well funded by Sony, has begun under the direction of Luc Steels (1952–) at the Free University of Brussels. Their pudding may turn out to have a more satisfying taste.

So, too, may the concoction due to Alan Mackworth's group, in their study of robot soccer (Sahota and Mackworth 1994). Unlike some workers in the area (Chapter 11.iii.b), they're guided by a generally important theoretical aim. Namely, they want to explore the need for, and the possibility of, an *integration* of classical and situated robotics. Describing the first as the Hegelian "thesis", and the second as its "antithesis", they offer an architecture for *reactive deliberation*—seemingly, an oxymoron. Their robots integrate sensory perception, real-time decision making, planning, plan recognition, learning, and coordination (11.iii.b).

Less 'sexy', but interesting nonetheless, is the recent robotics work based on insect navigation. To mention just one example (similar research is being done at Sussex), a team that includes Brooks's ex-student Maja Mataric (1965–) is modelling the way-finding strategies of desert ants, so that their robots will be able to return to 'base camp' after going out to explore unfamiliar territory (Roumeliotis *et al.* 2000). This project was inspired by Collett's discovery that desert ants, unlike their more familiar cousins, don't use pheromones to find their way home (Collett *et al.* 1998). Rather, they rely on path integration, backed up by visual landmarks. The landmarks are needed because if integration were used alone, tiny errors would accumulate and eventually lead the creatures astray.

In sum, the Brooksian dogma—though fruitful at its inception—is looking less and less persuasive. Nevertheless, his advice that roboticists should study insects is still being followed, if often interpreted in a broader sense.

b. New philosophies of biology

The 'biological' view of intelligence wasn't restricted to AI, for it had already developed within other areas of cognitive science.

In psychology, James Gibson's (1966) ecological theory was the outstanding example (see Chapters 5.ii.c and 7.v.e). Although it had been regarded, not least by Gibson himself, as radically opposed to AI, it was now beginning to influence AI research. Recent computational work on animate vision, for instance, had assumed that the creature's own movements through its environment provided crucial perceptual information (Ballard 1989, 1991).

Neuroscientists had discovered sensori-motor circuits illustrating the close coupling between animal and environment. And computer models of such systems had been developed since the late 1960s by CNE researchers, as we've seen. Moreover, sophisticated models of self-organization in mammalian brains had been developed by Stephen Grossberg, Christoph von der Malsburg, and Andras Pellionisz and Rodolfo Llinas (see Chapter 14.vi and viii.b–c).

Developmental psychology and cognitive neuroscience had indicated the close epigenetic interplay between inbuilt dispositions and experience (Chapters 12.viii.c–e and 14.viii.c). And some linguists had attributed fundamental aspects of both syntax and semantics to their grounding in our material embodiment (Boden 1981*a*).

Philosophy, too, was involved. Non-Cartesian accounts of mind, stressing embodiment and rejecting the representational theory of perception, had long been available within the neo-Kantian tradition (see Chapter 2.vi). And they'd featured in the philosophy of cognitive science since the 1960s, when Hubert Dreyfus first put forward his critique of GOFAI (11.ii.a and 16.vii.a). He'd drawn heavily on the ideas of the continental phenomenologists Maurice Merleau-Ponty and Martin Heidegger, and of the later Wittgenstein.

Dreyfus's critique had initially been dismissed by most cognitive scientists, whose work lay within the alternative, empiricist, tradition (see 11.ii.a–b). When Terry Winograd was converted by Dreyfus (and Fernando Flores) in the early 1980s, this was widely seen as a betrayal by one of the masters of GOFAI (11.ii.g). In the 1990s, these ideas were stirring again. Heidegger, for instance, was becoming prominent in certain philosophers' thoughts about cognitive science—including some highly sympathetic to situated and evolutionary robotics (van Gelder 1992/1995; M. W. Wheeler 1996, 2005).

For many years, Heidegger had been regarded by analytical philosophers with utter contempt. Hardly any of them bothered to say anything about him—although Anthony Quinton complained about his "ponderous and rubbishy woolgathering" (a judgement he still stands by: personal communication). At the millennium, however, the heat was turned up. Heidegger was called "a dismal windbag, whose influence has been completely disastrous" (Blackburn 2000), and "the greatest catastrophe in the history of philosophy" (Edwards 2004: 9).

Both those remarks were made by highly eminent analytic philosophers, disturbed (especially in Edwards's case) by the fact that by the end of the century, Heideggerian ideas had spread apace. Just why he was now thought by some respectable Anglo-Saxon philosophers, and by some cognitive scientists, to be relevant is discussed in Chapter 16.vii.

Besides downplaying the mind's embeddedness in the physical world, Cartesianism had encouraged analytic methods in biology (see Chapter 2). Not until after the mid-twentieth century was there a wide range of scientific studies providing ideas about self-organization. By the late 1980s, a number of people had developed holistic philosophies of life informed by these scientific advances.

Pattee, a participant at the first A-Life meeting (see Section x.a), was an influential case in point. He'd always drawn on both cybernetics and biology. In the 1960s he'd edited a collection of early papers on computer and mathematical models of life (Pattee *et al.* 1966), and soon simulated an ecosystem himself (see Section vi.b). But his main project was to articulate a philosophy of life.

He described organisms as self-organizing dynamical systems realized in a physical medium (Pattee 1985, 1989). And he was especially concerned to show how stable "symbols"—in particular, genes—could arise within dynamically changing physical systems (2001). He saw this symbolism as the necessary ground for the genotype–phenotype distinction, and indeed for the phenomenon of life itself.

Others with similar views included two of Pattee's students: Robert Rosen (1985, 1991) and Cariani (1992). (Rosen was initially a student of Nicholas Rashevsky, whose Chicago biophysics group gave him a lasting interest in metabolism as the basis of life.) All three rejected the Cartesian view of organisms as "mechanisms"—that is, as analytically decomposable systems. They allowed that computer simulations of the self-organizing dynamics involved can be useful. But they insisted that these must be very different from symbolic AI models. In particular, the emergence of new dynamical wholes, and of new types of function (such as new powers of perception), are problematic for traditional AI.

The emergence of new dynamical wholes was the key concept in an unorthodox philosophy of biology (and cognition) that had been maturing for thirty years. It was developed by the Chilean neuro-anatomist Maturana (1928–) and his student, a Chilean psychologist, Francisco Varela (1946–2001). Although originated by Maturana, the theory—and the A-Life work inspired by it—was eventually associated just as strongly with Varela (Di Paolo 2004; McMullin 2004).

Maturana had been a member of the cybernetics group in the 1950s, and co-authored the hugely influential 1959 paper 'What the Frog's Eye Tells the Frog's Brain'. In the 1960s, he defined both life and cognition in terms of "autopoiesis": the continuous self-production of an autonomous entity (Maturana 1969; see 16.x.c).

The word was coined from the Greek: *autos*, or self, and *poiein*, or creation. But the idea, as Varela acknowledged later (Weber and Varela 2002), had been largely inspired by Kant. Specifically, it was grounded in Kant's vision of organisms as systems in which the parts are formed for and from the others, giving a dynamic whole without which the existence of the parts would be meaningless (see Chapter 2.vi.b).

This 1960s biological approach advanced steadily, though always in the shadow of the mainstream. The 1970s saw an account of autopoiesis appear in the *International Journal of Man–Machine Studies*—hardly a neo-Kantian enterprise (Maturana 1975). And the same decade produced the first computer simulation of *the* fundamental autopoietic event: the spontaneous formation of the cell membrane (Zeleny 1977, 1981; McMullin and Varela 1997). Now, in the mid-1980s, Maturana's ideas had been included in a highly respected series on the philosophy of science (Maturana and Varela 1972/1980). (Soon, they would be applied to cognitive science as such: Varela *et al.* 1991.)

The theory of autopoiesis was fundamentally opposed to non-holistic, logical–computational accounts of life and mind. This may seem strange, for the 'Frog's Eye' paper had been prompted by computational ideas, and had led to their wider use in neurophysiology (Chapter 14.iv). But in his mature philosophy, Maturana regarded artefacts of any sort, and especially of the logical–computational variety, as misleading analogies of living things.

Even admittedly convenient terms such as *input, output*, and (ironically) *feature-detector* were discouraged. Talk of *representations*, too, was to be avoided. Instead, one should conceptualize the brain as a dynamical living system, wherein stimuli aren't "inputs" but "perturbations". As his colleague Varela put it:

> The LGN [lateral geniculate nucleus] is usually described as a "relay" station to the cortex. However . . . most of what the neurons in the LGN receive comes not from the retina (less than 20%), but from other centers inside the brain. . . . What reaches the brain from the retina is only a gentle perturbation on an ongoing internal activity, which can be modulated . . . but not instructed. This is the key. To understand the neural processes from a nonrepresentationist point of view, it is enough just to notice that whatever perturbation reaches from the medium will be informed according to the internal coherences of the system. (Varela 1987: 59–60)

Maturana wasn't the only neuroscientist to object to informational/computational terminology. Jean-Pierre Changeux, for instance, saw it as a mistake to describe brain processes as being determined by the sensory input:

> [Variations] in a physical parameter in the environment are translated into variations in nerve impulses . . . A chain of successive reactions, explicable in strictly physico-chemical terms, *regulates the spontaneous activity of the oscillator, which pre-exists all interaction with the outside world*. The impulses produced are therefore *independent from the physical stimulus* to which the organ is sensitive. The sense organs behave like *regulators* of molecular clocks. The stimulation that they receive from the outside world sets them forward or backward and corrects their timing. *There is no direct analogy, however, between the physical stimulus received from the environment and the nervous signal produced*. (1985: 82–3; italics added)

In other words, Changeux (like Maturana) favoured a dynamical, even 'non-mechanistic', account of the brain, while allowing that brain processes could be described at the physico-chemical level if one wished.

But Maturana went beyond neuroscience, to develop a philosophy of biology in general. He objected to descriptions of the nervous system as "mediating between perception and action". Instead, the living autopoietic unity—cell or organism—was conceptualized as a self-organizing dynamical system, closely coupled with its environment.

So closely coupled, indeed, that they could even be regarded as a single system. For Maturana, the "environment" isn't objectively present independently of the organism. Rather, it's constituted in opposition to and cooperation with the activity of the living thing. What the observer chooses to count as 'one' system is a matter of scientific convenience. In the 1990s, some philosophers of cognitive science would draw on such ideas to smear the boundaries of the 'mind'/'self' in a similar way (Chapter 16.vii.d).

As for the computer modelling of autopoiesis, this too became more prominent in the 1990s, though still a minority taste (McMullin 2004: 283–92). Increasingly, it was pursued in the context of biochemical theories.

For example, Naoki Ono and Takashi Ikegami in Japan developed an approach called LAC, or Lattice Artificial Chemistry. They employed abstract chemical schemas to generate "proto-cells" showing boundedness, self-maintenance, reproduction, and evolution. Initially, they could deal with only one or two dimensions (Ono and Ikegami 1999, 2000, 2001); later, they modelled a 3D lattice (Madina *et al.* 2003).

Their experiments would start from an assortment of randomly moving (abstract) molecules: some hydrophilic, some hydrophobic, and some autocatalytic. Given parameter values within a certain range, structures such as vesicles would emerge, and spontaneously split into two. The authors see this as a study of the origins of life, which must have involved molecules in the primeval soup coming together into "compartments" somehow separated from what was now the first "environment". This sort of self-organization is the crux of autopoietic theory.

c. Dynamical systems

It's not surprising that Maturana's work received a more sympathetic hearing in the late 1980s than it had done in the preceding years. For by that time, more people were avoiding talk of representations and/or studying self-organizing dynamical systems.

For instance, PDP-based connectionism ascribed meaning to holistic patterns of activation, not to individual units (Chapter 12.vi). A few neuroscientists and psychologists were starting to explain brain and behaviour in terms of dynamical attractors (14.ix.b). Some 'neurological' work in CNE (R. D. Beer 1995*a*,*b*) was interpreted using dynamical systems theory. The evolution of the robot orientation detector (Section vi.c, above) was described by the research team in terms of state space attractors, not input–output functions (P. Husbands *et al.* 1995). And some philosophers were arguing that dynamical, not computational, concepts are needed to explain cognition (van Gelder 1992/1995; Port and van Gelder 1995).

A dynamical system is one whose states change according to definite rules. The rules may be deterministic or probabilistic; linear or non-linear; fixed or alterable; uniform or region-/unit-specific; and time-sensitive or synchronously "clocked". A self-organizing dynamical system is one in which new forms of order spontaneously emerge.

A von Neumann computer is a dynamical system, although it's rarely described as such (Giunti 1997). So is a pendulum, whose system dynamics are relatively simple. In addition, the term is commonly applied to massively parallel systems, where it's easier to identify overall patterns of activity than to keep track of individual units. Often, these patterns are stable or recurrent, in which case they are described in terms of attractors. An attractor is a point, region, or state cycle within the phase space (the set of all possible states) of a dynamical system, such that the system tends to approach it from any randomly chosen starting point and to return to it when perturbed.

Dynamical systems go under various names. They're called circular causal systems, reaction–diffusion systems, neural networks, cellular automata, NK networks, and CTRNs (Continuous-Time Recurrent Networks). And they even include gases.

At the most fundamental level, all these are similar (although the defining rules are different):

* That's why von Neumann's CAs could be used to model the laws of physics (see Section v.a),
* why CTRNs can model any dynamical system (see xi.b, below),
* and why thermodynamics can be used to specify connectionist networks (see 12.v.f and vi.b).
* It's why Ashby could include plants growing, plants ageing, and machines moving—as well as brains living—as examples of dynamical systems (Chapter 4.viii.c).
* And it's why D'Arcy Thompson's and Turing's claims about the formative powers of physics and chemistry count as early studies of the dynamics of development.

By the late 1980s, dynamical systems were being studied by many different disciplines. Some of the authors were biological scientists trying to explain specific phenomena. Such phenomena included the brain's control of (and switching between) different bodily gaits (Thelen 1985; Thelen and Smith 1994), the coupling of organism and environment by way of movement (Kugler and Turvey 1987, 1988), and the evolution of new systems of perception, or "measurement" (Kugler *et al.* 1990; Turvey and Shaw 1995). Others were physicists, mathematicians, or computer scientists seeking abstract descriptions of dynamical systems in general. (Some interesting recent examples are discussed in the following subsection, and in Sections ix.a–b and xi.)

Whether the growing sympathy for dynamical systems was entirely merited is controversial. It's not clear, for example, that theories couched in terms of dynamical systems can explain all the specifics of human thinking. It's one thing to say that the mind/brain is a dynamical system (compare: made of atoms). It's quite another to say that dynamical concepts (compare: atomic theory) suffice to explain everything that it does.

This isn't a question of accepting magic, but of rejecting reductionism. Even chemistry requires concepts not needed in physics; and genetics, neurophysiology, and psychology require yet more (see Chapter 16.iv.c). Nor is it a question of the *philosophical* problem of meaning, or intentionality. Even if one takes for granted that a dynamical system could express meanings and/or behave meaningfully, it doesn't follow that the mathematical concepts of dynamical systems theory suffice to represent structured linguistic propositions or inferences.

In other words, this is a current version of the problem that mid-century cybernetics had with propositional content (see Chapters 4.v.d and ix.b, and 16.vii.c).

15.ix. Order and Complexity

The emergence of order in cellular automata had been investigated for many years before the naming of A-Life, both at Michigan (see Sections v–vi) and elsewhere. A group at MIT's computing laboratory, directed by Ed Fredkin, had been working on CAs since the 1970s, and an ex-Michigan member had recently outlined a dedicated CA machine (Toffoli 1984). But especially interesting work of this type had been done by Stephen Wolfram (1959–) and, in particular, Stuart Kauffman (1939–).

Both Wolfram and Kauffman used CAs to explore complexity—including life—*as such*. If it had any interest at all, then, their work was relevant to a huge range of topics, both within biology and outside it.

a. The four classes of CA

By the late 1980s, the computer scientist Wolfram was extending the study of cellular automata in various ways. He'd noted that even very simple CAs could generate lifelike visual patterns, such as shell markings (see Section v.a), so might be relevant in explaining specific biological phenomena. But he also used CAs as grounds for claiming that a certain level of complexity, involving both order and novelty, is needed for life in general—and for computation, too (Wolfram 1983, 1984*a*,*b*, 1986).

Taking advantage of the newly available computational power, Wolfram modelled many different CAs, and observed them in action. On the basis of these experiments—experiments, not theorems—he suggested a classification into four classes (a classification anticipated in outline by Turing in 1950: see 16.ii.a).

Wolfram's four classes of CA were: I—those which eventually reach stasis; II—those which settle into rigidly periodic behaviour; III—those which remain forever chaotic; and IV—those which achieve order that's stable without being rigid, so that the structural relations between consecutive states are varied yet intelligible. The final category, he said, included life.

Later, in the early 1990s, Langton would add numbers to this qualitative classification. He did extensive, and hugely tedious, CA modelling to explore the conditions in which each of Wolfram's four classes would in fact emerge. And he came up with an intriguing result.

His experiments led him to claim that life is possible only within a very narrowly restricted range of numerical values on a simple statistical measure of complexity, which he called the "lambda parameter". This type of complexity was located "at the edge of chaos": near the phase transition between Wolfram's Class IV and his Class III (Langton 1990, 1992). As Langton pointed out, this means that there's not only a lower limit to the complexity of living things—as von Neumann had argued in the 1940s—but an upper limit also (Langton 1990: 36–7).

Another person inspired by Wolfram's classification of CAs was Andrew Wuensche (1943–). Independently of Langton, Wuensche defined a different measure of complexity, the Z-parameter (Wuensche and Lesser 1992; Wuensche 1999). This was a natural extension of his remarkable "reverse algorithm", developed in the late 1980s for computing the *predecessors* of CA states—which in effect provided CA systems with "memory" (Wuensche 1997). (You may remember that McCulloch and Pitts had argued that it's in principle impossible to describe neural nets retrospectively: see 4.iii.f.) When the two complexity measures were compared, it turned out that there was a strong relationship between them. But the Z-parameter was the more general, being able to avoid certain exceptions to lambda.

Largely because Wolfram's qualitative classification of CAs had whetted people's appetite for quantitative measures of complexity, both Langton's work and Wuensche's attracted significant attention.

In fact, however, the cyberneticist Ashby had beaten them to it. He and a colleague, Crayton Walker, had defined a broadly comparable measure over twenty years earlier (Walker and Ashby 1966). Their concept of "internal homogeneity" was equivalent to Langton's lambda, for CAs having only two possible states. In the absence of a flourishing CA modelling community, however, this earlier theoretical approach hadn't been much noticed.

b. K for Kauffman

Even before Wolfram and Langton, Kauffman had investigated the nature and limits of complexity with various biological questions in mind. His first papers had appeared in the late 1960s, when he was a young member of the mathematical biology group in Chicago.

Twenty years later, his work was a provocative mix of mathematics, biochemistry, and biology—integrated by a highly unfashionable, though ancient, philosophical framework. For some readers, it was intoxicating. For others, infuriating. Mainstream biologists still rejected the general approach, especially the downplaying of natural selection (see below). They also questioned the fit between Kauffman's mathematics and biological fact.

Kauffman was originally trained in philosophy, physiology, and psychology (his teachers included Stuart Sutherland and McCulloch). He then entered medical school.

His interests at that time (the early 1960s) were in brain function and cell differentiation in the embryo.

The then current research on neural functioning was largely inspired by the 1940s models of McCulloch and Pitts, which represented neurones as Boolean on–off units (see Chapters 4.iii.e and 12.i–ii). As for cell differentiation, this still wasn't understood. Turing's ideas on diffusion reactions (see Section iv.a) remained speculative and non-specific. However, the recent discovery of regulatory genes (Jacob and Monod 1961) suggested the possibility that embryonic development might be directed by specific genes becoming active at successive stages. Since the role of regulatory genes is to 'switch' other genes on or off, Kauffman decided to use Boolean networks to model both kinds of activity.

He contacted McCulloch to discuss these ideas, and was introduced by him to the developmental biologist Goodwin (1931–), with whom he would later co-author several papers. Goodwin was a student of Waddington at the time, and through him Kauffman was invited to speak at Waddington's seminar (Kauffman 1969). There could have been no more suitable a context for using mathematical analysis to illuminate epigenesis.

In these studies of the metabolic base of cell differentiation, Kauffman was investigating the action of what Turing had called morphogens. But his questions, like Turing's, were very general ones. He didn't ask which protein causes a liver cell to develop, and which produces a neurone. Rather, he wanted to know (for example) why the morphogens, whatever they happen to be, generate 264 distinct human cell types—as opposed to 100, 1,000, or even millions. (Just how one can count "cell types" is a thorny question, to which we'll return.)

His (primitive) computer models explored the behaviour of randomly connected Boolean NK networks. Such a network has N units, each with K inputs. Each unit follows some (randomly assigned) rule, which determines its on–off activity according to the (binary) values of the K inputs.

Kauffman found that NK networks often settle into, or cycle between, a restricted number of stable patterns. That is, of the many—perhaps astronomically many—possible states of the system, only a small number can be reliably maintained. Moreover, when $K = 2$ there's a simple ratio between the value of N and the number of attractors: the latter is the square root of the former.

It was then thought that the number of genes in the human genome is about 100,000 (now, it's believed there are only 30,000–60,000). Kauffman pointed out that with $N = 100,000$, there would be 317 types of stability—which, he said, approximates the number of human cell-types. (With $N = 60,000$, the number of attractors would be about 245; with $N = 30,000$, it would be 173.) In other words, it was perhaps no accident (on this view) that Santiago Ramón y Cajal had been able to find more than one type of brain cell, but fewer than 100 (see 2.viii.c).

There were three intriguing implications. First, that there may be something special about networks where $K = 2$—or (more generally) that the numerical values of N and K may be significant in determining network behaviour. Second, that these abstract properties may be instantiated in a wide variety of contexts, wherever order emerges in systems of interconnected units. And third, that the power of natural selection may therefore be limited: the number of cell-types (for instance) may depend as much on the self-organizing properties of the embryo as on the *post hoc* effects of selection. Over the 1970s and 1980s, Kauffman explored all three implications.

As for the significance of $K = 2$, Kauffman soon proved that very richly interconnected networks, where K approaches $N - 1$, produce chaos (Wolfram's Class III), not order. More surprisingly, he showed that, in an NK network of this simple type, chaos will result if K is larger than 5. In general, the precise numerical values of N and K are crucial determinants of the overall dynamics of the system.

In one sense, he admitted, both N and K are irrelevant. *All* NK networks will achieve order eventually, because they have a finite number of states. So if any state reoccurs, the preceding trajectory through the phase space must be traversed again . . . and again. But "finite" can mean astronomical, and "eventually" can mean billions of years. So there's a real distinction between NK networks that will achieve order within some reasonable time and those which won't.

What counts as a "reasonable" time depends on the context, and in living organisms will involve many different constraints. But whatever the context, the numerical values of N and K affect the system's properties as a whole. Moreover, numerically tiny differences in N or K may result in huge system differences: either a phase transition into a different type of order (analogous to a new embryonic stage, for example), or a collapse into chaos.

In his later work, Kauffman supported Langton's suggestion that life exists "at the edge of chaos". And he proved, what had long been regarded as intuitively obvious, that with increasing complexity an organized system becomes more resistant to change. As he put it, selection becomes less able to alter the system's fundamental properties (see below).

As for generalizing this approach, Kauffman was nothing if not ambitious, seeing a wide range of phenomena as essentially comparable. He first applied his ideas to autocatalytic networks (in which various chemicals cooperate in generating each other), which he thought of as primitive metabolisms (Kauffman 1969, 1971). Later, he extended them to the functioning, and the evolution, of systems defined at many different levels.

These included enzymes and antibodies; genomes; embryos; neural networks; species; ant colonies; ecosystems—and even market economies and human cultures (Kauffman 1983, 1986*a*,*b*, 1989, 1993). For instance, he used NK networks to model fitness landscapes and co-evolution, and to define the circumstances in which genetic variation and natural selection would be most likely to lead to an increase in fitness.

Kauffman's ideas influenced various groups working in A-Life, including some who used NK networks for evolving artificial species (see Section vi.c). But his seminal claims weren't all well founded.

For instance, near the end of the century Harvey showed that Kauffmann's analysis of NK networks is false in the general case. It applies only to synchronously updated random Boolean networks, not to asynchronously updated ones. For these, the picture is so different that "there is no sense in which the behaviour of synchronous [NK networks] gives any clue towards [their] behaviour" (Harvey and Bossomaier 1997: 74).

In other words, Kauffmann's work provides yet another example of a mathematician ignoring real time. Von Neumann's CAs, too, were defined synchronously (see Section v.a). The Turing machine assumed a sequence of atemporal steps, defined in practice by the digital computer's—essentially arbitrary—clock (see Chapter 4.iv). And neural network theorists have—until very recently—typically ignored real-time properties, despite their importance in actual brains. Temporal *order* might be taken into account (by Uttley or Jeffrey Elman, for instance: see Chapter 12.ii.c and viii.b). But precise temporal intervals usually weren't (14.ix.g). Only at the turn of the millennium, for instance, did a connectionist textbook pay attention to them (O'Reilly and Munakata 2000, e.g. sects. 2.5 and 6.7).

One might argue that all these mathematical idealizations are necessary in the initial stages of research, and that their results will at least approximate those of the relevant real systems. Harvey allowed the first of these defences, but not—or not always—the second. He also showed that, contrary to what was widely assumed, asynchronous networks can be both analysed and simulated (pp. 74–5). In short, while his critique cast serious doubt on Kauffman's models of genetic regulation, for instance, it also showed how his ideas could be built on in unexpected ways.

c. Morphology revived

Kauffman's work on evolution had been initially prompted by Maynard Smith, a leading evolutionary biologist. In the early 1980s, Maynard Smith persuaded Kauffman that he should no longer ignore evolution, and suggested that he combine the mathematics of fitness landscapes with his own NK approach (Maynard Smith, personal communication). But the models of evolution that ensued merely confirmed Kauffman in his commitment to a highly unorthodox conclusion—one already held by Waddington and Goodwin.

Maynard Smith and Goodwin were colleagues for many years at the University of Sussex. Their relations were warm, friendly, and highly respectful on both sides. (We were members of a small dining club, so I witnessed them interacting many times.) Despite the mutual respect, however, their philosophical commitments were, and remained, fundamentally different.

Discussing the improbability of a species' settling on a high-but-narrow peak in the fitness landscape, Kauffman declared:

> Selection typically cannot reach and hold an adapting population in arbitrarily located or overprecise volumes of parameter space. Thus it is not foolish to suppose that the forms we see are largely those which are easily generated by the underlying developmental mechanisms. (Kauffman 1993: 642)

As for what is "easily generated" in development, he said:

> [My work, and Goodwin's, suggests that], contrary to intuition, morphogenesis may be deeply robust. Organisms, rather than being tinkered-together contraptions, may exhibit a nearly inevitable and stable order. Real morphogenesis is due not to the unfolding of any single developmental mechanism but to the beautifully ordered unfolding in time and space of some richly integrated combination of simpler mechanisms such as cell-sorting, sheet-folding, positional discontinuities, and reaction–diffusion mechanisms. . . . [These] *constrain* the morphologies which emerge to a small subset, each of which occupies a large volume of state space and parameter. Rather than causing complexity, integration of developmental mechanisms may generically yield simplicity and order. (Kauffman 1993: 637)

In short, natural selection is important, but not fundamental. If we want to know why certain imaginable morphologies have not appeared, even though they are represented at some point in the fitness landscape (the co-evolutionary phase space), the answer will sometimes be that fundamental developmental constraints prevent it. Like snowballs in hell, they are theoretically conceivable but dynamically impracticable.

This view was stated even more strongly in the concluding passages of Kauffman's *magnum opus*, *The Origins of Order* (1993):

> This book is an effort to continue in [D'Arcy] Thompson's tradition with the spirit now animating parts of physics. It seeks origins of order in the generic properties of complex systems. Those properties [I have] discussed have ranged [over many levels of biological self-regulation, including] the origins of spatial integration in multicellular systems when products of individual cells can reach their neighbours . . .
>
> I have tried [to characterize] the interaction of selection and self-organization. To some great extent, evolution is a complex combinatorial optimization process in each of the co-evolving species in a linked ecosystem, where the [fitness] landscape of each actor deforms as the other actors move . . . In sufficiently complex systems, much of the order seen in organisms is precisely the spontaneous order in the systems of which we are composed. Such order has beauty and elegance, casting an image of permanence and underlying law over biology. Evolution is not just "chance caught on the wing". It is not just a tinkering of the ad hoc, of bricolage, of contraption. It is emergent order honored and honed by selection. (Kauffman 1993: 644)

The reference to tinkering was a direct challenge to François Jacob, the co-discoverer of regulatory genes. He had famously described evolution as *bricolage*, or tinkering (Jacob 1977).

As if such downplaying of natural selection weren't maverick enough, Kauffman "continued in D'Arcy Thompson's tradition" even to the extent of paying homage to Goethe as well as to Kant. Many biologists had been entranced by D'Arcy Thompson's writing, as we've seen, but most readers had ignored his praise of Goethe and Kant. Even in the late eighteenth and nineteenth centuries, their holistic approach to biology had been scorned by most empiricists—though not, or not entirely, by Hermann von Helmholtz (see 2.vi.e). Now, Kauffman was resurrecting these long-dead philosophers.

His unfashionable remarks about them weren't mere fleeting asides. To the contrary, they were rhetorically prominent declarations of biological faith. The opening pages of his most important book expressed his kinship with the pre-Darwinian tradition of rational morphology; and the Epilogue began by praising Kant's philosophy of organisms (Kauffman 1993: 3–5, 643). As we saw in Chapter 2.vi.e–f, the rational morphologists had seen organisms as holistic self-organizing systems, shaped according to (unspecified) universal laws of form—an a-historical approach that was to be suddenly eclipsed by Darwinism.

Kauffman's appreciation of this outmoded theoretical tradition was largely due to his interactions with Waddington and Goodwin. Waddington had tried to combine D'Arcy Thompson's developmental approach with evolution and genetics. But his ideas about epigenetic landscapes were uncomfortably vague, and his concern with whole organisms was overshadowed by molecular biology. Eventually, his student Goodwin offered a theory (of developmental transformations within morphogenetic fields) that was better grounded in experimental data and more mathematically precise than Waddington's (Webster and Goodwin 1996, pt. II).

Goodwin identified even more strongly with the rationalist tradition in biology than Waddington had done. His major book took its motto from Goethe, and devoted many pages (written by his colleague Gerry Webster) to a philosophical discussion of these ideas (Webster and Goodwin 1996: vii, pt. I).

In his early research, Goodwin had used cognitive and informational concepts to try to capture some of the high-level, holistic features of organisms (Goodwin 1974, 1976; Boden 1981*b*). Later, and especially in his research with Kauffman, he relied more on dynamical mathematics. As an experimental biologist, he was closer to the actual data than Kauffman.

Kauffman's mathematical work on fitness landscapes, for example, showed that fundamental changes in body plan will become less probable as development or evolution proceeds, and that certain transformations will be possible (certain attractors available) only on certain trajectories. Consequently, certain types of organ will tend to be found together, in recognizable morphological groups (Kauffman 1993, ch. 6). But Goodwin asked just which transformations actually occur, and how they come about.

In an early discussion of slime moulds, for instance, he pointed out that a single chemical may have very different morphogenetic "meanings" in different developmental contexts (Goodwin 1976). And his later work hypothesized specific transformations and morphogenetic fields in a wide range of examples, from slime moulds to the pentadactyl limb (Webster and Goodwin 1996, pt. II).

Just as computational psychologists need to test their models against the empirical data, so mathematical biologists need to do this too. Accordingly, Kauffman sought evidence from various areas of biology to confirm his mathematical analyses. When discussing the significance of very low values of K, for example, he remarked that each gene or active molecule in living organisms (from bacteria to primates) appears to be directly regulated by only a few other molecules—often, as few as two. In general, his book referred to a large number of biological studies in support of his approach.

However, the evidence wasn't always available, nor even consistent. His remark just cited, for instance, is questionable: many genes can interact directly with at least ten others. If chaos theoretically ensues when K is greater than 5, this fact is an embarrassment. So is the fact that individual neurones may receive thousands of inputs from others, yet the brain generates highly ordered cognition. Again, his claim that *Drosophila* segmentation can be explained by reaction–diffusion models inspired by Turing (Kauffman 1993: 566–600) is disputed (see Section iv.b). And as for counting cell-types, it's not obvious that the best way to classify cells, as natural kinds, is by their morphological properties, as is done in histology textbooks (and by Ramón y Cajal): hidden properties, programmed in by the genes, may be just as important (Maynard Smith, personal communication).

Maynard Smith, for instance, allowed that Kauffman's work on autocatalytic protein networks perhaps throws light on the origin of life (Maynard Smith and Szathmáry 1995: 69–72). But he also argued that many questions about evolution call for more biological data, not more theoretical models. On his view, computer models of actual genetic systems are likely to be more useful than simulations of evolution in general (Maynard Smith 1996).

In short, sceptics often complained that Kauffman's models (and other A-Life abstractions, such as Ray's), though admittedly intriguing, were too far from the biological coalface to be really useful. This opposition was stoked by Kauffman's provocative views on natural selection, and his 'old-fashioned' philosophical holism.

d. Discussions in the desert

Not everyone was situated at the biological coalface, however. Many people remembered that, although a real neurone is very different from an abstractly defined McCulloch–Pitts unit (see Chapter 14.ii), McCulloch's simplification had inspired important empirical research. So, too, might Kauffman's. And for some readers, his dynamical approach seemed to offer a way of thinking about self-organization in many different disciplines besides biology.

That's why, in 1985, Kauffman was invited to join the Santa Fe Institute (SFI), in the research group on Complex Systems. SFI had been set up one year before, by a group of physicists and mathematicians at nearby Los Alamos. Their research focus was on non-linear dynamical systems.

Following in the footsteps of the physicists Schrödinger (1887–1961) and, especially, Ilya Prigogine (1917–2003), they asked how fundamental physical principles, concerning entropy and equilibrium, can allow—or even give rise to—self-sustaining order, especially biological order. Schrödinger (1944) had argued that living things survive not thanks to food, but thanks to negative entropy. And Prigogine himself had described his Nobel-winning work on "dissipative structures"—irreversible far-from-equilibrium processes—as a study of the "self-organization" of matter (Prigogine *et al.* 1969; Prigogine and Stengers 1984).

For instance, he'd shown that a heated liquid may form rotating "convection cells", patterns of physical activity that hugely outstrip the range of the intermolecular forces that cause them. It may be that he called this "self-organization" because he spent a good deal of time with the embryologists in Brussels (Dupuy 2000: 130). If so, biological morphology may have been close to his mind even when he was doing 'pure' thermodynamics.

The group at Los Alamos also worked on the theories of chaos and complexity. As Kauffman's work on NK networks had illustrated, these dynamical phenomena are intimately related. They'd been studied within mathematical physics since the mid-1960s, but had been recognized by the wider scientific community only recently—partly as a result of the activities of the Los Alamos group (Waldrop 1992; Kellert 1993). It was in light of this historical context that Kauffman had described his own work as "an effort to continue in [D'Arcy] Thompson's tradition *with the spirit now animating parts of physics*" (1993: 644; italics added).

The Los Alamos physicists encouraged a widely interdisciplinary approach. Their Center for Nonlinear Studies had initiated a series of conferences on various aspects of self-organization. One of these, focusing on emergent order and distributed computation, included non-physicists such as Holland, Kauffman, Hillis, Douglas Hofstadter, Stephanie Forrest, Stevan Harnad, and Paul Churchland (Forrest 1991). The new institute, SFI, was intended as a focus for interdisciplinary research concerned with complex systems *in general*.

One early SFI activity was a joint physics–economics workshop, held there in 1987. Two of the economists involved (Kenneth Arrow and Brian Arthur) had long stressed the non-linearity of economic systems—something ignored by classical economics. But that's not to say that all was plain sailing when these matters were discussed. The initial physics–economics culture clash has been tellingly described by Mitchell Waldrop (1992, ch. 4). Although this meeting ended fruitfully, even pleasantly, some later SFI workshops "degenerated into shouting matches and sulking" (p. 143). Interdisciplinarity isn't always easy—or good-tempered.

In short, the personnel at SFI were nothing if not open-minded. Over the next decade, they welcomed colleagues in physics, mathematics, computer science, AI, neuroscience, biology, psychology, economics, and philosophy. All were invited to discuss the emergence of order in complex systems. Many chose to focus on aspects of life and cognition.

As so often happens, the open-mindedness of the early days eventually became muted. By the end of the 1990s, both Kauffman and Langton had been sidelined by SFI, apparently for speculating too wildly (C. J. Langton, personal communication). The puzzle of life had been replaced in SFI's affections by puzzles about predicting the stock market.

15.x. Naming and Synthesis

A-Life was born healthy at mid-century, as we've seen. But the pattering of its tiny feet caused little disturbance. The infant field wasn't even mentioned for over thirty years. Some of its core *topics* were widely discussed, to be sure—for example, in Hofstadter's hugely popular *Gödel, Escher, Bach* (see Chapter 12.x.a). And the Media Lab's Vivarium (a simulated aquarium), alongside its work on animation, was attracting funding from Hollywood and computer manufacturers, and drawing huge numbers of visitors (13.v.a). But artificial life as such was invisible. Then, suddenly, it seemed to be everywhere.

The suddenness was due to a public act of naming in 1986, and a christening party in 1987. Before then, the term "A-Life" didn't exist. The seeming ubiquity was due to the wide range of disciplines represented at the party, and to media interest prompted by the infant's name—even more outrageous, evidently, than Fifi Trixibelle.

a. The party

Studies of self-organization prior to the 1990s had many underlying similarities, as we've seen. But most people at the time were aware of the links only dimly, if at all. Indeed, they were largely ignorant of each other's activities.

One wouldn't expect ethologists, for instance, to have come across Craig Reynolds's paper on flocking, published in the journal of *Computer Graphics* (Reynolds 1987). His model showed that the group behaviour typical of flocks of birds or schools of fish can emerge from three simple rules—so simple, that they might conceivably be 'hardwired' into animals' brains. Computer animation experts soon picked up on this work. It was used, for example, to generate the lifelike 'schools' of virtual fish described at the outset of this chapter, and to choreograph the flocks of bats in the film *Batman*. But people interested in real fish, and how they manage to do what they do, were hardly likely to have *Computer Graphics* on their reading lists.

This isn't an isolated example. Much of the relevant research was inaccessible to potentially interested readers, because of disciplinary boundaries.

The unification (such as it is) occurred in the late 1980s, when the term A-Life was coined by Langton. He first used it in print in 1986 (Langton 1986). But he'd thought of it in 1985, during a meeting organized at Los Alamos by the physicists Doyne Farmer and Norman Packard, and by the mathematicians Buton Wendroff and Alan Lapedes (Rasmussen *et al.* 2003*b*: 210). The official title of that meeting had been a mouthful: 'Evolution, Games, and Learning: Models for Adaptation in Machines and Nature'. The term *artificial life* was more pithy, more unifying—and, of course, much more provocative.

Langton was a Los Alamos physicist, especially interested in the relation between complexity and life. He had a wide intellectual background, and an iconoclastic attitude to disciplinary boundaries (Levy 1992: 93–103; Kelly 1994: 343–6). This would have counted against him in most academic institutions, but was no disadvantage in Los Alamos. The physicists there had highly interdisciplinary sympathies, as we've seen.

By 1986, Langton was embarking on his painstaking research involving the lambda parameter (see Section ix.a). But he'd already completed a number of important studies in what he now decided to call A-Life.

After working with Burks at Michigan, he'd recently achieved the first implementation of a self-replicator (Langton 1984). (Arbib's 1966 design for a self-replicating CA, mentioned in Section v.b, wasn't implemented.)

He'd also produced various models of ant trails (Langton 1986: 135–6). He showed that a disorganized group of ants, each one following a very simple rule, could give rise to many different trails (e.g. circles, spirals, straight lines . . .). Tiny rule changes could result in observably different larger-scale phenomena. And these phenomena were reminiscent of real insects. For instance, ants dropping pheromones as they walked could eventually converge on a small number of (relatively straight) paths leading to the best food sources.

This was a purely abstract study: Langton was no biologist. Later, however, others would use real-life data in modelling the effects on ant trails of different chemical concentrations, walking speeds, and antennae spans—another example of CNE (Sharpe and Webb 1998). Indeed, Langton's paper led A-Lifers to a general interest in "stigmergy", wherein social behaviour is mediated by individuals responding to environmental changes caused by other individuals (Bonabeau 1999). This phenomenon was named by a French biologist in the 1950s, and many empirical data had been collected. Now, biologists had the possibility of analysing it in rigorous terms.

Mathematicians were interested, too. The notion of "Langton's ant" was generalized in the CA/A-Life community, and led to many follow-up analyses(e.g. Gale and Propp 1994; Gale *et al.* 1995; Stewart 1994; Gajardo *et al.* 2002). In addition, AI work on agents and distributed cognition sometimes drew on Langton's ideas (e.g. O. Holland and Melhuish 1999: see 13.iii.d).

Already connected with the Santa Fe Institute, Langton helped found their A-Life research group. And it was he who organized "the first workshop on A-Life". This event took place in 1987, in Los Alamos. It's remembered by many who attended as a party, even a celebration, as much as a workshop.

The invitations had been issued by Langton, who sent them not only to a wide variety of selected individuals but also to Internet newsgroups in many different disciplines. He recalls this as an anxious period: he had no idea how many people would be intrigued by his invitation, nor how many would see the point if they actually came. After the event, he described it as producing "a growing sense of excitement and camaraderie—even profound relief—as previously isolated research efforts were opened up to one another for the first time" (Langton 1989*a*, p. xvi).

Langton's memory of the meeting is doubtless coloured by his own role in it. But the workshop did catalyse an increasing level of interest, and even cooperation, between scientists from different disciplines. Beer (personal communication), for instance, now remembers it as hugely important for consolidating his nascent interest in dynamical systems—first triggered by Hofstadter and Winograd, and recently strengthened by a best-seller on chaos theory (see xi.b, below). Many others today would tell similar stories. The general sense of excitement fostered by this meeting is clear from the many informal remarks of participants quoted by science journalists reporting on the new field (Levy 1992; Kelly 1994).

It also led to a great deal of 'hype'. Some of this was generated by the participating scientists themselves. Langton later admitted that there was "more good science and less 'gee-whiz' " in the second volume of A-Life Proceedings than in the first (Langton *et al.* 1992, p. xiv).

But much of the hype was generated by 'outsiders'. The people attending included a generous sprinkling of famous names, associated with a wide range of sciences. That was likely to be noticed. And Langton's vision of the future of the field was highly provocative: "The ultimate goal [of A-Life is] to create 'life' in some other medium, ideally a *virtual* medium" (see below). Such a claim was bound to—indeed, was intended to—attract attention. However, it also drew scepticism and scorn.

As for the name bestowed on the field, this too had its drawbacks. Irrespective of specific remarks made by Langton or anyone else, the term "artificial life", like "artificial intelligence" before it, invites literal interpretation from the media. I've encountered journalists from good newspapers who evidently think that the question "Does system X really use A-Life technology?" means the same as "Does system X contain creatures that are really alive?" In short, the meeting was a journalist's dream.

Langton was far from unhappy about that. And within a few years, A-Life had gained the attention of the counter-culture. For it exemplified a new image of science, more 'romantic' than the traditional image was.

The philosopher Stephen Clark (1995) contrasted "Faustean" and "Magean" science, the first being intelligible and largely predictable (though often bringing unwanted side effects) and the second opaque, almost like magic. Where GOFAI—and science in general—had been seen as dealing in preconceived plans and pre-defined goals, with "little use for spontaneity, trial-and-error, unplanned discovery, vaguely-defined ends, or informality" (Edwards 1996: 168), A-Life showed unpredictable evolution, emergence, and responsiveness to environmental details.

Stephen Clark cited it, accordingly, as an example of Magean science. Many professional artists apparently agreed with him. They were inspired by what they saw (often, wrongly) as the aims, and philosophical claims, of work in A-Life. By the turn of the century, hardly more than a decade after Langton's naming party, there was a still-growing body of art based broadly on these ideas (Whitelaw 2004). And students of contemporary culture, such as Sarah Kember, were making grand claims for A-Life as a cultural discourse describing "posthuman" ("cyborgian") life (2003, p. vii and *passim*).

But Clark saw Magean science as threatening, too. Just because of its opacity and unpredictability, it was unintelligible and beyond control—which is to say, it risked going out of control (cf. Kelly 1994). Soon, science-fiction novels/films such as Michael Crichton's (2002) *Prey* would give vivid expression to those cultural fears.

Worrying or not, however, A-Life became the talk of the town—much as Langton had hoped. The tone of "the talk of the town" wasn't always one of apocalyptic anxiety. Often, the *gee whiz* factor won out. Consider (for example) this University of Toronto press release of 2000, which describes the then latest version of the artificial fish mentioned in Section ii.a, above:

Surviving jaws: virtual merman 'thinks' his way to safety

Using a mythical merman and hungry sharks, a University of Toronto computer science professor and two former graduate students have pushed the notion of artificial intelligence and virtual life to a new level.

In his creation of a virtual underwater world, Professor Demetri Terzopoulos has fashioned more than just a cool screen saver—he has given his animated characters the ability to think. A hungry shark circles ominously, looking for a nice meal, while a nervous merman searches for a place to hide. When the shark swims away, the merman dashes from behind large rocks to open water with the shark in hot pursuit. Will his cleverly devised plan allow him to reach safety or not?

"This is more than artificial intelligence", says Terzopoulos. "It's artificial life. Computer graphics, animation and virtual reality have advanced dramatically over the past decade. We are now able to create characters that are self-animating with functional bodies and brains that have behaviour, perception, learning and cognition centres."

Terzopoulos and his former students have developed the cognitive modelling language that enables animated characters to reason. For example, it enabled the virtual merman to formulate a plan of action by reasoning about his situation given certain knowledge, such as the fact that he cannot outrun sharks but can use underwater rocks to hide. "With cognitively empowered graphical characters, the animator need only specify a behaviour outline and, through reasoning, the character will automatically work out a detailed sequence of actions."

The potential for future applications are immense, Terzopoulos says. Cognitive modelling and the cognitive modelling language can become powerful tools for scientists, animators and game developers. His paper, co-authored with John Funge and Xiaoyuan Tu, was published at the 1999 ACM SIGGRAPH conference, the premier forum for research in computer graphics. (University of Toronto web site, <http://www.utoronto.ca/>, 29 February 2000)

If this was the official, relatively restrained, account you can perhaps imagine the enthusiastically garbled versions that would appear in the less scrupulous newspapers.

(Excessive hype, from within and outside the field, is still a problem—and an embarrassing one, for those seeking professional legitimacy. In the A-Life community's turn-of-century self-assessment, the key failure was said to be "No rigor", and the greatest advantage of founding an International Society for A-Life—set up in 2003—was "reducing hype" by improving intellectual standards: Rasmussen *et al.* 2003*b*.)

Despite the hyperbole and misunderstandings, however, there was—and is—a serious intellectual core. The common scientific interest aroused at the workshop was afterwards described by Langton as

> an emerging consensus . . . of the "essence" of Artificial Life [based on] themes such as *bottom-up* rather than *top-down* modelling, *local* rather than *global* control, *simple* rather than *complex* specifications, *emergent* rather than *prespecified* behavior, *population* rather than *individual* simulation, and so forth. (Langton 1989*a*, p. xvi)

These themes are evident in the seminal work of Turing, von Neumann, Burks, and Holland (and in the wide range of later research mentioned in Sections vii–viii). And, if interpreted without reference to computer models, most of them can be seen in D'Arcy Thompson's writings, too.

Such people's pioneering work also fits the definition given in Langton's Call for Papers in 1986:

> Artificial life is the study of artificial systems that exhibit behavior characteristic of natural living systems. It is the quest to explain life in any of its possible manifestations, without restriction to the particular examples that have evolved on earth. This includes biological and chemical experiments, computer simulations, and purely theoretical endeavors. Processes occurring on molecular, social, and evolutionary scales are subject to investigation. The ultimate goal is to extract the logical form of living systems. (quoted in Levy 1992: 113)

D'Arcy Thompson and von Neumann, for instance, would have been quick to allow that the logical form of living systems isn't immediately evident. Discovering it might add something new to our accepted concept of life. In Langton's terms, we could come to see that "life as it could be" is a wider category than "life as it is".

For example, the crucial values of Langton's lambda parameter or Wuensche's Z (see Section ix.a) might come to be included within the definition of life.

Again, if reproduction is regarded as essential to life, then life might be defined as requiring von Neumann's dual (data/instructions) functionality. Von Neumann showed also that a universal replicator is possible: so perhaps some extra-terrestrial living organism could give birth to puppies as well as kittens—and to tadpoles and grass seeds, too? One might object that such a heredity-cheating creature could never have evolved. But that's relevant here only if one regards evolution itself as an essential criterion of life. Some biologists and philosophers do (Bedau 1996; Moreno and Ruiz-Mirazo 2004: 251–5; Luisi *et al.* forthcoming, 3). However, this decision isn't without drawbacks (see Chapter 16.x.d).

As for the logical form of living *bodies*, most biologists would probably say that there's no such thing. But not all: we've seen that recent work in D'Arcy Thompson's (and Goethe's) footsteps suggests that—given the laws of physics—only certain types of morphology are actually possible.

b. Simulation or realization?

For Langton, the logical form of living systems is such as to allow the possibility of *virtual* life. Contrary to D'Arcy Thompson, the constraints of physical embodiment are a distraction best avoided:

> The ultimate goal of the study of artificial life would be to create "life" in some other medium, ideally [*sic*] a *virtual* medium where the essence of life has been abstracted from the details of its implementation in any particular model. (Langton 1986)

Ray agrees. He argues that digitized creatures existing in cyberspace (very like his, described in Section vi) could be genuinely alive (Ray 1992, 1994).

This philosophical claim (discussed in Chapter 16.x) is called strong A-Life, in analogy to strong AI. Most A-Lifers reject it, believing that life in principle requires some sort of physical body and metabolism. Pattee, for instance, always insisted on a clear distinction between simulating life and realizing it, because he saw the laws of physics as crucial in explaining biological organization (Pattee 1972, 1976). So the journalists who excitedly reported that the production of cyberlife is the goal of A-Life *in general* were mistaken. So, too, were those who said that A-Life *in general* was aiming to produce "new forms of life", whether virtual or physical.

But their mistakes were understandable. For Langton, the instigator and organizer of the inaugural event, explicitly held both views. Moreover, as the official subtitle of the meeting he chose 'An Interdisciplinary Workshop on the Synthesis [*sic*] and Simulation of Living Systems' (Langton 1989*a*). And, in a paper published shortly before the first A-Life meeting, he'd said:

> We would like to build models that are so life-like that they cease to become *models* of life and become *examples* of life themselves. (Langton 1986)

Another point in mitigation was mentioned above: the likelihood that "artificial life" would be interpreted by outsiders to mean "life made artificially".

In fact, only a few insiders understood the term in this way. Indeed, some soon adopted less philosophically provocative (and somewhat less inclusive) language. They spoke of "adaptive systems", for example, or of "animats"—a conflation of "animal" and "robot" (Meyer and Wilson 1991). That enabled them to work on computer models of life without implying that simulation was intended as realization.

Because of the high profile of the 1987 meeting and its immediate successors, however, the term *artificial life*, like the term *artificial intelligence*, is here to stay. One must remember, therefore, that using artefacts to learn about life—even "life as it could be"—isn't the same thing as aiming to make life artificially.

Whether life could be made artificially remains an interesting question nevertheless. So does the question whether virtual life is in principle possible. So, too, do disputed claims about whether only life can support mind, whether adaptive autonomy (without representation) can suffice to do so, whether evolution is necessary for life and/or intelligence, and whether minds are distinct from living brains.

These are all partly philosophical questions (see Chapter 16.x), to which scientific work is dialectically relevant. That's why reports of experiments in this area often include discussions of the *definition* of life, and phrases like "the definition of life one wishes to use" (Luisi and Oberholzer 2001: 353).

If they were purely scientific questions then one, at least, would have been answered at the dawn of the new millennium. London's *Sunday Times* of 30 January 2000, under the headline 'First Artificial DNA Can Create New Forms of Life', reported that researchers in Texas "have made the world's first synthetic DNA [and] mapped out the exact way it will be configured to create synthetic organism one (SO1), the microbe destined to be the world's first man-made creature".

Three years later, the *New Scientist* excitedly reported that Craig Venter (director of the Human Genome project) is trying to build "the minimal genome" (by stripping down the genome of the simplest existing organism), and that the Harvard nanotechnologist George Church is aiming to do much the same thing (Ainsworth 2003). But the *New Scientist* had the philosophical edge over the *Sunday Times*, for its journalist acknowledged the controversial nature of the *concept of 'life'*. These matters aren't so straightforward as his *Sunday Times* rival had assumed.

That's evident from the conceptual arguments (i.e. not just the empirical disagreements) that arise within so-called "wet" A-Life. This form of A-Life *does* aim to create new life. Specifically, it aims to create living/lifelike systems out of chemical/biochemical substances. Sometimes, it even starts from what Kant would have termed "crude inorganic matter" (see 2.vi.b), although sometimes it starts from an already living thing.

The notion that this is in principle possible dates from the mid-1920s, in a paper by the Russian biochemist Alexander Oparin. Remaining untranslated, this had little impact at the time. But Oparin's late 1930s book caused huge excitement, not to say scandal (Oparin 1936/1938). The first Oparin-inspired experiments to succeed in synthesizing molecules characteristic of life, namely amino acids, from simple substances present on the primitive earth were done half a century ago (S. L. Miller 1953; Miller and Urey 1959), and sugars had followed by the late 1960s (Reid and Orgel 1967).

Today, such experiments continue. But most of them don't count as wet A-Life. For that, the aim must be not merely to synthesize unorganized biomolecules, but to create *entire, albeit simple, living things*. Several groups around the world are attempting this. And they're doing so in interestingly different ways, depending on their philosophical views about the nature of life as such.

Venter's team in Maryland—who drew the attention of the *New Scientist*—are working top-down. That is, they're starting from a living, independently replicating, cell (*Mycoplasma genitalium*) that has the smallest known genome: only 517 genes (Fraser *et al.* 1995; Hutchison *et al.* 1999). They aim to identify any non-essential genes (the so-called junk DNA), and to construct a new, stripped-down, genome that will generate a recognizably *living* organism. By the eve of the new century, they'd identified 480 protein-forming genes, of which between 265 and 350 seemed to be essential (including 100 of unknown function). If and when they achieve their aim, it's unlikely that there will be much disagreement over whether the result really is a living organism. After all, it will be a cleaned-up copy of a naturally evolved life form.

Things may be—indeed, they already are—rather different in cases where researchers aim (*à la* Oparin) to concoct life from the bottom up, as opposed to working top-down by removing redundant DNA. The problematic philosophical issues are more evident when people start from a non-biological base and try to build living systems anew. Such people often restrict themselves to molecules we already recognize as "biochemical".

But sometimes they don't, hoping to find very general biochemical principles which cover substances other than the ones found in terrestrial organisms. (Life as it could be.)

The biochemists who are seeking to model and/or produce physical analogues of the molecular origins of life don't always agree about just what molecules count as "biological" and what as "pre-biological", or about what is a "basically autonomous system" but *not* a living thing, or about how "biomolecules" can become sufficiently organized to merit the label of "full-fledged living beings" (Moreno and Ruiz-Mirazo 2004: 245–55).

Similarly, they disagree on just how the criterion of a *boundary* is to be interpreted, and what its philosophical significance is, when chemical compartments (micelles, vesicles . . .) arise within which specific chemical reactions can take place. For example, liposomes can form vesicles; if these contain an enzyme for replication, an RNA template, and ingredients for RNA synthesis, then the system may self-replicate (Biebricher *et al.* 1982). Some biochemists—notably Pier Luigi Luisi's group in Rome—interpret such chemical boundaries in terms of the philosophy of autopoiesis (Bachman *et al.* 1990, 1992; Walde *et al.* 1994; Luisi *et al.* 2004).

Luisi, a long-time friend and admirer of Varela, relates his experiments to an autopoietic interpretation of "the minimal cell" (Luisi and Varela 1989; Luisi and Oberholzer 2001: 349–50; Luisi 2002). This concept has been discussed for almost fifty years. For example, Harold Morowitz (1967) argued that the minimal cell need be no more than nine-tenths the size of *M. genitalium*. (For more recent estimates, see Islas *et al.* 2004; Szathmáry 2005.) But new biochemical techniques have led to a new spurt of interest, including two international conferences in 2004.

The minimal cell is the smallest possible living system, having "the minimal and sufficient number of components to be called alive" (Luisi *et al.* forthcoming, 3). It isn't thought to be a particular system, which *had to be* generated if life was to appear at all. Rather, the assumption is that there's a broad family of potential minimal cells. Which of these was/were actually realized is a question more for biological history than for abstract biological theory.

As for the term "living", this is usually understood in wet A-Life to mean: capable of self-maintenance (metabolism), self-reproduction, and evolution. Pre-cellular systems, or proto-life, may fulfil only one or two of these three criteria. And/or they may be reproducible for only a few generations, or they may be able to reproduce only part of themselves. Luisi calls such systems "limping life" (Luisi *et al.* forthcoming, 22). Workers in wet A-Life typically argue that they were essential stepping stones on the way to the emergence of fully fledged life.

Researchers differ in their commitment to what I just called biological history, as opposed to biological theory. So there's no consensus over whether we should be trying (like the Texas researchers who impressed the *Sunday Times*) to replicate the biomolecules already familiar to us. Some argue that wet A-Life may, or even should, attempt to build "chemical automata" made up of *alternative* chemical components (Drexler 1989; Bro 1997; Moreno and Ruiz-Mirazo 2004: 255).

In addition, of course, there are many empirical disagreements. These include one instigated at the University of Copenhagen by Peter Nielsen, the "inventor" of PNAs (polyamide-linked nucleic acids). PNAs are man-made "chimaera" molecules, having some of the structural properties of DNA and some of the chemical properties of proteins (Nielsen *et al.* 1991). Significantly, they follow the Watson–Crick base-pairing rules (Egholm *et al.* 1993). So the question arises whether PNA chemistry can replace RNA chemistry for the purposes of wet A-Life (Rasmussen *et al.* 2003*a*).

Here, as elsewhere, science and philosophy can interact. Work in wet A-Life often includes explicit discussion of how to define "life" (e.g. Moreno and Ruiz-Mirazo 2004: 254–7). And for those who believe that life and cognition are *essentially* linked, it may affect their philosophy of mind as well.

15.xi. After the Party

After the party was over, life went on. And A-Life went on, too. Only seventeen years have passed since Langton's epochal gathering. Nevertheless, a large body of work has been done.

A few examples drawn from the 1990s, or later, have already been mentioned. These include the evolutionary robots outlined in Section vi.c, the primitive open-ended evolution sensors of Section vi.d, the various models of neuro-ethology discussed in Section vii.b–d, and the biochemical A-Life briefly mentioned above. By and large, however, this chapter has followed the time-line, from the early work to the official founding/naming of the field. It may be appropriate, then, to end it by describing two more instances of *very* recent research.

These will bring things full circle, all the way back to mid-century cybernetics. But the circle is an ascending spiral, not a plane figure: besides lifting cybernetic understanding to a new level, these two examples open up exciting pathways for further study. Moreover, they raise fundamental issues that are relevant to cognitive science *in general*.

a. Resurrection of the Homeostat

Over a century ago, George Stratton (1896, 1897*a*,*b*) earned immortality by an experiment in which he wore inverting lenses for eighty-one hours, spread over eight days (see 14.viii.b). At first, his movements were utterly inappropriate to the physical environment around him. But his visuo-motor system gradually adapted until he was able to negotiate his world almost as successfully as before. Moreover, he no longer had to make allowances for the fact that the world looked upside down because, after the adaptation, the world *didn't* look upside down, but broadly "normal".

This phenomenon has intrigued psychologists and neurophysiologists ever since, and various similar experiments—some with left–right inverting spectacles—have been done. Now, further examples are cropping up in a wide range of VR applications (see 13.vi.b), including novel forms of motor and/or sensory prostheses (A. J. Clark 2003*a*).

Ashby's interest in it was mentioned in passing in Chapter 4.viii.c, and Andras Pellionisz's neurologically based explanation was described in Chapter 14.viii.b. Recently, another—more abstract—model of recovery from inversion has exploited Ashby's notion of a homeostatic dynamical system.

Ezequiel Di Paolo (2000*b*) evolved simulated light-seeking robots that could gradually recover phototaxis after their visual field was inverted. Putting it like that, however, may be misleading. For—like Stratton himself—they weren't evolved *to recover from* *visual inversion*. In other words, this adaptation didn't feature in the fitness function. Rather, they were evolved to perform phototaxis. But the 8-unit control network that enabled them to do this was of a type which *also* enabled them to recover when later subjected to the radical challenge of visual inversion.

Phototaxis was achieved by evolving the robots' control network, or "brain"—broadly, as described in Section vi.c, above. Two of the eight units ("neurones") in the network were attached to the left and right motors, and two to the sensors ("eyes"). In addition, every unit was connected to every other. But the excitatory/inhibitory nature of the connections could be varied by mutation, as could the numbers assigned to units and connections (see below). At each generation, six lights, of various intensities, were shown at different times and at different places. The robots that, on average, approached them most closely and most quickly, and that stayed by the light when they got there, were selected as parents for the next generation. (Noise was added to the system, to make the evolving circuits more robust.)

So far, so conventional (if such a still-recent approach can be called conventional). The difference from previous work was the nature of the units in the network. The key point is that each one of these was locally homeostatic. In other words, each artificial neurone had a permissible range of activation rates (not evolved, but assigned to it by Di Paolo). If it went above or below its limits, the weight on the incoming (presynaptic) connections would be changed so as to lower or increase its activity, respectively.

Unlike blood temperature then, where homeostasis restores a specific value, a neurone's acceptable activation rate could have various values—all lying within the relevant range. Given the numerical limits of each of the eight individual neurones, the numbers in the rule of presynaptic weight change were evolved. That is, the fitness function—besides measuring success in the behaviour of light seeking, as described above—measured success in homeostasis of all eight units.

In perfect homeostasis, no neurone would ever move outside its limits, so weight changes would never need to be made. But it turned out that neurones with very powerful homeostasis were bad news: they tended to do nothing, so that the robot hardly moved. For phototaxis to evolve, the unit homeostasis had to be less than perfect.

The result of 1,000–2,000 generations of evolution would be a light-seeking robot with a neural controller wherein each unit would recover its permissible activation rate if perturbed by some unusual input. An "unusual input" would normally be something like an especially strong (or weak, or distant) light source. But the robots' sensory anatomy enabled the malign roboticist to provide yet more unusual inputs.

Each robot had a left eye and a right eye. That is, its two sensors were placed relatively far apart on its body, so that the difference between the two visual inputs would depend on (in functionalist terms, would "encode") the specific location of the light source. A near-equivalent to Stratton's upside-down inversion, then, was to switch the anatomical positions of the two eyes, while leaving their neuronal connections intact.

As you might expect, each immediately post-operative robot was unable to approach the light. Indeed, it would move in the *opposite* direction. Di Paolo found, however, that about half of his robots eventually managed to adapt to their new situation, ending up with perfect phototaxis as before.

Although the behavioural outcome (reaching the light) was identical, the behavioural strategy wasn't. In one case, for instance, the pre-operative robot would begin by moving slightly to one side and then to the other, in order to centre the light in its visual field, and would then move directly towards it. After adaptation to inversion, the same robot moved in an arc of a circle to locate the source. (Di Paolo also found that the longer the period before inversion, the longer it took for adaptation to occur; he compared this to the "critical periods" for neural adaptation that have been observed in animals—2000*b*: 445.)

Senator Proxmire wouldn't have been impressed (see Chapter 6.iv.f). Granted, phototaxic robots could conceivably be useful. But if a researcher has managed to produce light-seeking robots, why waste the taxpayers' money in messing around with their sense organs so that they fall into confusion?

Put like that, the Proxmire complaint sounds persuasive. But, as was so often the case in his lifetime, the Senator would have been wrong. For the light-seeking robots were just an example. Famous though Stratton's experiment is, it wasn't Di Paolo's primary concern. What he was really engaged in was something even more interesting. Explicitly paying homage to Ashby, he was resurrecting the Homeostat (Chapter 4.viii.c). Specifically, he was demonstrating the sort of self-organization that Ashby had called ultrastability. Homeostasis of the system as a whole resulted from changes triggered by local homeostasis of its component units.

Moreover, his work was physiologically promising, in the sense that his general methodology allowed for the modelling of many other sorts of cerebral plasticity besides weight change (Di Paolo 2000*b*: 447–8). For instance, it could be used to model neuronal depression or potentiation, or modulatory synapses. It could even be used to simulate diffusive chemical neuromodulation—a phenomenon recently studied by his Sussex colleagues (cf. 14.ix.f).

Above all, for our purposes here, his chosen example was *psychologically* interesting, and highly relevant to cognitive science. Indeed, he sees his phototactic robots, like his earlier work on the evolution of communication (13.iii.e), as evidence supporting *a radical critique* of orthodox (functionalist) cognitive science (2000*b*: 448).

The reason is that his robots' behavioural homeostasis—that is, their successful adaptation to environmental perturbation—wasn't guided by any specific behavioural goals. Rather, it resulted from the underlying dynamical principles of the system. (This point was confirmed by the fact that adaptation also occurred when he made various "lesions" in one of the sensor or motor "organs"—2000*b*: 446.) In short, their behaviour was in effect *purposeful*, but wasn't directed by *purposes*.

b. Analysing dynamics

Di Paolo's work was experimental, not analytic. Each of his successfully adapting robots provided an existence proof of a homeostatic dynamical system with intriguing psychological overtones. (Only overtones: unlike the neurologist Pellionisz, he wasn't trying to say just how, in fact, Stratton's brain might have recovered from visual inversion.) But he didn't know just how many 8-unit networks were in principle capable of this adaptation. Nor did he know just what type, or types, they could be. He didn't even know whether as many as eight neurones were strictly necessary.

That's not unusual. In general, cognitive scientists who manage to get interesting behaviour out of a dynamical system typically don't know just why it occurred. (Up to a point, the same is true of GOFAI; but GOFAI researchers learnt long ago that they should try to analyse their programs, not just glory in them: see Chapter 11.iii.) Dynamicists rarely know just what it was about *this* dynamical system which made it capable of generating *that* behaviour.

Very recently, however, some elegant mathematical work has enabled researchers to say something along these lines, at least for very small networks of a certain general type. The systems concerned are called CTRNs, or CTRNNs: continuous-time recurrent (neural) networks.

This is a very broad class. (The "brains" controlling Di Paolo's robots were an extended version, as we'll see.) The first person to pay significant attention to them was the cockroach-building Beer (R. D. Beer 1995*c*). Beer first defined them in 1991 (he doesn't know whether anyone else had done so already: personal communication). He used the double-N label: CTRNNs.

When they're called CTRNs (by Di Paolo, for instance), the N for "neural" is omitted. Arguably, the single-N label is better (and I'll use it in what follows). For, as Beer himself pointed out when he defined the term in the first place, the units *need not* represent neurones, nor even neuronal cell assemblies. They can stand for *any* essential variable, *any* convenient dynamical building block, in the dynamical system being modelled.

In general physiology, these would be key aspects of metabolism. In neuroscience and psychology, they'd be features of neural function and behaviour, respectively. And in sociology or management studies, they'd be properties of the social communications concerned. Even Pask's ideas about the cybernetics of the criminal underworld (4.v.e) could be represented by a CTRN. (It's significant that his ambitious "conversation theory" was intended as a *general* account of feedback systems, in which the conversationalists identified by the rebarbative notation could be cells, people, or organizations.)

Today, CTRNs are increasingly used by people doing dynamical modelling in A-Life and neuroscience. One reason for this is a mathematical proof achieved in the early 1990s (Funahashi and Nakamura 1993). Much as a universal Turing machine can model any discrete computation, so these networks can in principle represent any dynamical phenomenon.

A CTRN is made up of units computing continuously in time. In effect, it's a cellular automaton in which the time-steps are infinitesimal in duration. (If it's implemented on a von Neumann computer, a CTRN will in fact involve *discrete* state transitions.) But each unit has its own numerical time-constant, which determines just how quickly/slowly it will give its output in response to a significant input. The units aren't binary, but sigmoidal. (Di Paolo's units are unusual in having a *range* of "permissible" activation rates that's smaller than the range of possible activation rates, and a homeostatic mechanism for bringing them back within the permissible range as appropriate.)

What counts as a significant input is determined by the unit's numerical "bias" parameter. This is broadly equivalent to the threshold of a McCulloch–Pitts neurone. But the bias (and the other numerical parameters of a CTRN) doesn't have to be an integer. Unlike McCulloch–Pitts thresholds, it can be defined to whatever degree of precision is required.

Each connection is either excitatory or inhibitory, and carries some numerical weight. The weights on the connections between any two units can be asymmetrical, in which case unit A will influence unit B more strongly than B influences A. (So a CTRN could model the asymmetrical communications between the various crew members aboard ship: see Chapter 8.iii.b.) Often, all the weights stay the same once they've been assigned. But sometimes, for instance in Di Paolo's phototaxic robots, the individual weights can change during the system's "lifetime".

Finally, the networks are completely connected. That is, each unit is connected to every other unit—and even to itself, by a recursive feedback loop. Because the network is completely connected, any change in one unit *directly* affects every other unit. (A CTRN is thus similar to a continuous Hopfield net, described in Chapter 12.v.f; but Hopfield units don't have self-loops, and Hopfield connections are all symmetrical.) Being completely connected makes a CTRN a dynamical system par excellence:

> Much of the unique flavor of dynamical systems is captured by the idea of *coupling*. [Two] variables are coupled when the way each *changes* at any given time depends directly on the way the other *is* at that time. In other words, coupled variables simultaneously, interdependently co-evolve, just like arm angle and engine speed in the centrifugal [Watt] governor. *Genuinely dynamical systems exhibit high degrees of coupling: every variable is changing all the time, and all pairs of variables are, either directly or indirectly, mutually determining the shapes of each other's changes*. (van Gelder 1997: 437; final italics added)

Complete connection is mathematically interesting, and it enables holistic study of dynamical systems in which every individual part influences every other. But it's rarely biologically plausible. For instance, the number of connections found in mammalian nervous systems scales roughly linearly as the number of neurones increases, instead of exploding as it does in fully connected networks (C. F. Stevens 1989).

Nevertheless, CTRNs can be used to model real biological circuits, for if a weight is set to zero then the connection concerned is in effect deleted. (Similarly, a huge bias parameter would deactivate the relevant unit.) So every conceivable network, whether fully connected or not, can be represented as a CTRN.

Beer's first artificial cockroaches, described in Section vii.c above, were situated robots inspired by Brooks and by Pengi. One might almost say that they were engineered rather than controlled. But Beer soon began to use dynamical system controllers to improve their walking.

His dynamical turn had been inspired by two near-simultaneous publications. One was James Gleick's (1987) popular book on chaos theory (personal communication), and the other was the Winograd–Flores book (see 11.ii.g)—which introduced Beer to the ideas of Maturana and Varela. From that time on, they were the major intellectual influences on his work.

Initially, Beer was most excited by how specific dynamical systems could help him build better robots. For example, he evolved a CTRN leg controller that repeatedly adapted its parameters to compensate for the fact that the (simulated) leg was *growing*, so changing the values of the physical constraints involved (J. G. Gallagher and Beer 1993, sect. 6). In 1991–2 he wrote his dynamicist's "manifesto" (personal communication) for the journal *Artificial Intelligence* (R. D. Beer 1995*a*). But he became increasingly interested in the abstract properties of his robot mechanisms *considered as dynamical systems*.

By the start of the new century, these general principles were his main focus. He now wanted to discover just which dynamical attractors were possible for different classes of CTRNs. This was a mathematical exercise (described below), but one with practical implications.

For instance, suppose he found that some class of CTRNs involved cyclic (oscillating) attractors. Intuitively, it seems that such networks would be specially apt for controlling rhythmic activities, like walking. If so, then one particular CTRN oscillator would need to be built into any actual robot. Of course, Beer could simply have picked out one example from the class of oscillators to use as the gait controller for an artificial cockroach leg. But his choice would have been largely arbitrary. So, instead, he picked a "parent" CTRN from this general class and then used GAs to evolve even more suitable descendants.

In other words, he was able to search the wide range of possibilities generated from the chosen seed by random mutation. (There was another advantage, too: biological evolution didn't have the luxury of picking something out of an explicitly analysed class, so Beer wanted to convince himself that these stable oscillators *could actually be evolved*.)

Beer's mathematics wasn't wholly a priori. As Gleick's book had pointed out at length, one can't predict (i.e. analytically prove) just how a complex dynamical system will behave. So Beer had to rely on experimental induction. That is, he defined/evolved a range of CTRNs, and studied their behaviour *post hoc* to see if he could find any regularities. Langton had done much the same thing when defining his "lambda" parameter in the mid-1980s, though using CAs rather than CTRNs (see ix.a, above). But whereas he'd looked at scores of different systems, Beer—with his students Sean Psujek and Jeffrey Ames—looked at several millions (Psujek *et al*. 2004).

Why so many? Well, the rich connectivity of CTRNs means that the range of possible architectures is huge. (An architecture is defined as a set of directed connections.) For a 3-unit network there are 64 architectures, for a 4-unit net there are 4,096, and 5 units surpass the half-million mark (to 528,384). Then, the numbers rapidly become unmanageable. Moreover, any one architecture has multifarious examples, because each parameter (the three connection weights, the bias, and the time constant) can have various numerical values.

Consequently, the Case Western team studied only CTRNs of up to five units. (For the 5-unit networks, they couldn't inspect every possibility so looked at a 1 per cent sample instead.)

In evolving CTRNs (with a population size of 100, and 250 generations), they soon discovered that convergence was common. In other words, CTRNs (like NK networks) are *apt* to fall into stable limit cycles—so are potentially promising as models of living/nervous systems. (Compare Wolfram's intuitions about which type of CA is capable of life and/or computation.) But they wanted to discover which architectures are most likely to converge to this or that stable oscillation.

For instance:

* What types of CTRN make oscillations possible?
* Or closed feedback loops?

* And when do these oscillators and/or loops involve connections to the "motor" neurones? (In their experiments, three units were "motor" neurones for the two opposing swing muscles and the foot, and the others—if any—were unassigned.)
* What classes will oscillate between three (or four . . .) states, rather than two?
* What's the minimum number of connections necessary to achieve successful walking?
* And what types of oscillator are best for achieving speed and stability in walking?
* Can any CTRNs produce several different oscillators?
* Or a combination of oscillator/s and point attractor/s?
* If so, what's needed for these oscillators to be smoothly coordinated?
* Last, but not least: for any given architecture, are there particular clusters of parameter-values that are especially promising?

They discovered, for example, which class of 3-unit CTRNs is best suited for controlling walking. There were three behaviourally distinct groups: 29 out of the 64 3-unit possibilities generated either no movement at all or only a single step; 8 produced slow, jerky, walking; and 27 resulted in fast, rhythmically smooth, stepping. On inspecting the connectivity patterns of the three groups, they found key differences in the existence and connectivity of feedback loops between the motor neurones for the foot and the two swing muscles. They then asked whether the same graph-theoretic properties could be used to *predict* similar classes of behavioural output in 4- and 5-unit nets.—Yes, they could. (There were some exceptions, but these could be explained: see 2004, sect. 4, paras. 7–8.)

In addition, some types of network were found to be *more easily evolvable* than others (2004, sect. 5). And qualitative descriptions like those mentioned above were supplemented by quantitative measures of fitness, distinguishing each individual motor neurone. These measures enabled the team to study an architecture's average results as well as its best ones. Some types were found to be more generally useful than others, even though their best performances were lower. (Di Paolo, you'll remember, had selected the robots which approached the lights most closely *on average*. But he couldn't say what type of controller was most likely to give a good performance-average.)

Even more recently, Beer's group have observed how the phase portrait of a dynamical system changes when the numerical value of one of the parameters is changed (R. D. Beer 2005). A "movie" of the effects of varying the bias in a 2- or 3-unit network, for example, shows how the system changes smoothly from one attractor to another, or diverges from any equilibrium. Plotted as a diagram of a two- or three-dimensional space, a particular region (or regions) can be identified where most of the "interesting" things happen, and others can be seen to be sterile. (Compare the pioneering fourfold classification of CAs mentioned in ix.a, above.)

This abstract analysis has intriguing biological and psychological implications. For example, given a specific CTRN, one can sometimes predict how its behaviour will change as the parameters are varied in certain ways. And Beer has recently used these ideas to explain the behaviour of a "minimally cognitive agent" with as many as fourteen artificial neurones (personal communication). Conceivably, such analysis might even help biologists to show why certain behaviours have evolved (i.e. are easily evolvable) from one origin rather than another.

However, "intriguing" and "conceivably" is as much as can be said, at present. And maybe you shouldn't hold your breath. The very recent (2005) analysis just described is certainly exciting, for it can be applied to CTRNs of *any* size. But readily intelligible 'Euclidean' diagrams can be drawn only for two or three dimensions. The larger CTRNs are like the multidimensional hyperspaces (including the imaginary scholarship rules) discussed in Chapter 14.viii.b: not beyond mathematical understanding, but fiendishly difficult.

As for Beer's *complete* descriptions of the space of architectures, these have been applied only to very tiny CTRNs. Even artificial CTRNs may have more units than can be dealt with in this way, and real organisms are huge by comparison: the minimalist. *C. elegans* has 302 neurones (14.v.b), and mammalian brains have many millions.

These biological facts may not be quite so devastating as they seem, for the Case Western researchers discovered that *more* need not be *better*: once there are five or more connections (connections, not units), the best fitness for the robot-walking task hardly alters (Psujek *et al*. 2004, sect. 3). That may be why, as remarked above, biological networks—even including the cerebral cortex—are very sparsely connected in comparison with full-blooded CTRNs. Nevertheless, the numbers remain awesome. (It's not clear that increased computer power will help much; but possibly quantum computers?—see 16.ix, preamble.)

In other words, the combinatorial explosion threatens work in dynamical systems just as it threatens GOFAI. So one shouldn't expect Beer to provide further exhaustive analyses of CTRNs: five units today, eight tomorrow, perhaps the elegant 302 next month . . . Rather, one should see his work—including the varying-parameter phase portraits—as a promising exploration of *the kinds of effects, properties, or concepts* that may be needed in thinking about realistic (i.e. larger) systems.

For example, rhythmic behaviour in general—not just walking, and not just cockroaches—depends on oscillator attractors, which in turn depend on there being closed loops in the architecture. With hindsight, that may be obvious. But it wasn't obvious, even to committed dynamical theorists (such as Di Paolo: personal communication), before Beer's analysis.

Much the same might be said about psychological AI. Consider, for instance, research on mental architecture (Chapter 7.i.e–f), on anxiety-ridden speech (7.ii.c), on the complex webs of relevance involved in everyday thinking (7.iii.d), or even on the development of the past tense (12.vi.e and x.d). The hope of the cognitive scientists concerned is not to map the computations involved in precise detail, but to understand *what sort of system* a personality (or a neurosis, or an associative memory, or an infant learning to speak) is, and *in what sorts of ways* it can be manifested, in *what sorts of circumstances*. Most computational psychologists believe that concepts drawn from classical and connectionist AI can answer those questions. By contrast, dynamicists believe that dynamical concepts and insights can best help us understand what sort of system an organism, or a mind, is. Similar bets, different horses.

In sum, dynamical systems are still more theoretically opaque than either GOFAI or orthodox connectionism. It's not clear how far Beer's analysis can be applied to the dynamics evolved by Nature. And, for all Di Paolo's 8-unit ingenuity, Ashby may have been right to fear that future Homeostats would be "too complex and subtle for the designer's understanding" (1948: 383). But some provocative beginnings have been made. If many open questions still remain, and others can't yet even be asked, that's par for the course in any creative science.

16

PHILOSOPHIES OF MIND AS MACHINE

Philosophies of mind and machine have been prominent since the 1630s. But for René Descartes and virtually all of his successors, that "and" really meant "not". Mind was contrasted with machines, not likened to them (see Chapter 2).

Philosophies of mind *as* machine didn't appear until over 200 years later (Chapter 4.ii and vi). Today, they still have many philosophical adversaries. And even those philosophers who are sympathetic to mind-as-machine disagree about *just which* machines these might be. Nor would they accept Herbert Simon's claim that, in writing the Logic Theorist (6.iii.c and 10.i.b), he and his colleagues had "solved the venerable problem of how a system composed of matter can have the properties of mind" (Simon 1991: 190).

Evidently, then, philosophical problems don't get solved in a hurry. One might even say that they don't get solved at all—for if they do, they're relabelled as "scientific" problems. AI often suffers a similar fate (see 13.vii.a). Having bravely located firm ground in unmapped and marshy territory, its successes are renamed "computer science" and what was once exploration becomes tourism. Moreover, some philosophers insist that their aim is not to solve problems but to *dissolve* them, "to show the fly the way out of the fly bottle" (Wittgenstein 1953, para. 309; cf. A. J. T. D. Wisdom 1952: 259).

Soluble or not, philosophical problems have already featured in our discussion. Chapter 2 outlined two broad philosophical movements with competing influences on the life sciences. And other chapters have included arguments on specific topics, such as:

* free will (Chapters 5.ii.a and 7.i.g);
* innate ideas and nativism (7.vi, 8.v–vi, 9.vii, 12.viii.c–e, 12.x.e, and 14.x.c);
* word meaning (4.iii.c, 7.ii.d, 9.iv and x.d);
* concepts (5.iv.c, 8.i.b, 9.x.d, and 12.x);
* non-conceptual content (12.x.f);
* representations (7.i.h, 7.v.a, 12.ix.e, and 14.viii–ix);
* scientific explanation (7.iii and 12.x.f);
* consciousness (7.i.g–h and 14.x–xi);
* relativism and scientific objectivity (1.iii.b);
* tacit knowledge (13.ii.b); and
* life (15.vii.b).

Some issues in the philosophy of religion were implicit in Chapter 8.vi, and even metaphysics has been mentioned (13.i.b–c and 7.iv.e—and see the discussion of computation in Section ix.e, below).

A fortiori, cognitive science is related to the philosophy of mind. That's the general topic of this chapter. Section i outlines the competing philosophies of mind dominant at the inception of cognitive science, and the various philosophical impasses involved. To understand those is to appreciate why, in the late 1950s and early 1960s, cognitive science seemed to be such a liberation.

Section ii considers the influence of the Turing Test on philosophy and AI. Various forms of functionalism are discussed in Sections iii and iv. Some objections to functionalism feature in Section v, and the founder's recantation in Section vi. Further neo-Kantian critiques are discussed in Sections vii and viii. Differing concepts of computation, and their relation to intentionality, are explored in Section ix. Finally, Section x deals with the relevance of life to mind.

Aperitif. Before starting, however, we need to ask why non-philosophers should bother with philosophy at all.

Many think they should not. For instance, one reviewer of an early outline of this book suggested that the proposed chapter on philosophy be entirely omitted. Cognitive science, he/she evidently believed, can get on very well without it. (And this *despite* the fact that most leaders in the field find it exciting largely because they believe that it solves the notorious mind–body problem.)

Even philosophers admit that "First-rate philosophy can be profoundly irritating, especially to non-philosophers" (Bringsjord and Zenzen 2002: 241). The slowness/insolubility mentioned above is one common source of irritation. But the authors just quoted were thinking of another:

> [Following Socrates' example, the philosopher] starts with innocent enquiry, pushes and probes, makes some seemingly innocuous inference . . . and boom!—suddenly she has shown that what scientists and engineers take for granted *shouldn't* be taken for granted. (ibid.)

Occasionally, to be sure, what was taken for granted is later confirmed by the philosopher concerned, with stronger arguments provided to buttress it. Even then, the common-sense belief may have been transformed in the process (see the discussion of free will in Chapter 7.i.g). That doesn't make for comfortable reading. But sometimes, what was previously assumed is rejected altogether. In that case, the question is left worryingly open. And there's no hope for a neat resolution in the next number of *Nature*.

Hard-headed scientists, as a result, are likely to agree that "There is nothing so absurd that it has not been said by some philosopher"—a remark of Cicero's, quoted by Descartes and by many others after him. (For Cicero and Descartes, of course, "philosophy" included what we would call science. It's ironic, then, that the biologist Lewis Wolpert, while repeatedly dismissing philosophy in the most contemptuous terms, celebrates the seeming absurdity, or "unnaturalness", of science: L. Wolpert 1992.)

Friedrich Nietzsche, some 2,000 years after Cicero, even remarked that a philosopher is "a terrible explosive, endangering everything" (Kauffmann 1969: 281). That wasn't a criticism, for he wasn't hoping for (epistemological) safety. Most practising scientists, by contrast, are.

Myriad beliefs normally taken for granted are questioned (*questioned*, not necessarily rejected) in the philosophy of cognitive science. For instance: that mind requires life; that zombies are logically possible; that human freedom can't be scientifically explained; and that dogs and monkeys have conscious experiences—and intentions, too. The list could go on, and on . . .

That's irritating enough, perhaps. But one challenge in particular annoys the "scientists and engineers": the denial that a real world exists independently of human minds, and that science can find out about it.

This counter-intuitive claim isn't new. It was lying in wait at the heart of Descartes's philosophy (he toyed with it himself, in suggesting that his whole life might be a dream: 2.iii.b), and was later forefronted by the neo-Kantians (2.vi and vii.c). Nor is it tucked away safely inside dusty philosophy books. To the contrary, it's often wheeled up to the scientists' front door. The "strong programme" in the sociology of knowledge defends this claim, and has led to vituperative "science wars" in which gallons of metaphorical blood have been angrily spilt (see 1.iii.b).

Scientists, however, have little patience for the anti-realist challenge. (That may not be true of quantum physicists, but in my experience it applies to most life scientists.) Even when they're discussing and/or dismissing philosophy as such, they often don't mention this aspect of it. Or if they do, they don't give it more than a glancing thought. Gerald Edelman is a case in point, as we've seen (14.ix.d).

Philosophers of cognitive science usually are willing to argue about realism (although sometimes they deliberately sidestep the question: see vii.d, below). But they almost always end by accepting it, *even while admitting that they can't decisively prove it*. That's what I did, provisionally, in Chapter 1.i.c and iii.b; and it's what Jerry (Jerrold) Fodor does too (see viii.b, below). Indeed, seven of the ten sections below ignore the realism/anti-realism dispute. It features only in Sections vi–viii.

So why ask non-philosopher readers to consider it at all? One reason is that some experimental cognitive scientists, the followers of Humberto Maturana and Francisco Varela (x.c, below), support views which—whether they realize it or not—are fundamentally anti-realist. (Occasionally they do realize it, and explicitly accept them: I. Harvey 2005.)

Another is that the counter-cultural opposition mentioned at various points in this book (e.g. 1.iii.b–d, 6.1.d, and 11.ii.f) is grounded not only in political suspicion of science's applications, but (often) also on neo-Kantian scepticism about its realist foundations. The counter-culture can be properly understood, and persuasively (if not definitively) rebutted, only if that is appreciated.

A third is that an interesting new twist on the realism/anti-realism debate is related to the recent AI technology of virtual reality, or VR (13.vi). Some philosophers' reactions to this draw on work in cognitive science (see viii.c, below).

The main reason, however, is that anti-realism is grounded in an alternative, and in non-scientific circles highly influential, philosophy of mind. If that philosophy is correct, then cognitive science is fundamentally wrong-headed—indeed, impossible. For to drop realism is to drop naturalism: the belief that there could, in principle, be a science of mind. "Cognitive science", on this alternative view, should be a very different kind of enterprise: hermeneutic, not naturalistic (Harré 2002). Intentionality is to be presupposed, not explained.

In sum, no serious consideration of cognitive science can ignore philosophy. Quite apart from the specific philosophical issues that arise *within* the field (concepts, representations, zombies, free will, self . . . and, of course, the mind–body problem), its very possibility, as a coherent intellectual enterprise, is in doubt. Those doubts must be understood, even if one ultimately rejects them—as I do myself. Moreover, the huge attraction of the field lies largely in its promise to help solve one of the greatest philosophical puzzles of all: the mind–body problem.

This chapter, then, explains why that promise seemed to many people to be convincing—and why many others are *still* not convinced.

16.i. Mid-Century Blues

In the 1940s and 1950s, four philosophies of mind competed for attention from English-language philosophers. ('Continental' philosophers favoured fundamentally different accounts, not taken seriously in analytic circles at the time: see Section vii.) Mind-as-machine wasn't one of them.

GOFAI, connectionist, and cybernetic approaches were already hovering in the wings, to be sure (see Chapters 4–15). But professional philosophers were looking straight ahead, on-stage.

There, the forerunners in the talent competition—in order of appearance—were epiphenomenalism, logical positivism, logical behaviourism, and identity theory. Alan Turing was cast as a support dancer for behaviourism's solo: not until the 1960s would he move onto centre-stage.

Each key contestant attracted many fans. But few onlookers sat comfortably in their seats. As we'll see, they had to admit to—or systematically repress (Feigl 1958/1967: 3)—worrying flaws in every performance.

a. Interactionist squibs

Besides these four, there was an also-ran: interactionism. This was dismissed out of hand by most mid-century thinkers, who shared Princess Elizabeth's scepticism about the mind's ability to move the brain (see Chapter 2.iii.b). An occasional philosopher, however, insisted that interactionism—and even substance dualism—hadn't actually been refuted (Ewing 1954: 114).

Some scientist–philosophers went even further. The chemist Michael Polanyi, for instance, suggested that "some enlarged laws of nature may make possible the realization of operational principles acting by consciousness", and that the mind might "exercise power over the body merely by sorting out the random impulses of the ambient thermal agitation" (Polanyi 1958: 397, 403 n.).

Similarly, the leading neuroscientist John Eccles (1903–97) argued that conscious choice is a matter of essentially mental influences causing changes in the brain (see Chapter 2.viii.f). This applied only to the cerebrum: as we saw in Chapter 14.v.c, Eccles was happy to describe the cerebellum as "a Neuronal Machine".

Eccles avoided speculations about the pineal gland, preferring to tell fairy stories in modern scientific language ("fields", "quantum effects", and "critically poised neurones"). But he encountered much the same logical difficulties that had bedevilled Descartes long before.

He said, for instance: "[My] hypothesis assumes that the 'will' or 'mind influence' has itself a spatio-temporal patterned character in order to allow it this operative effectiveness [on specific cells]" (Eccles 1953: 277–8). This was given almost as an aside: *how it is possible* for an essentially mental influence to be spatio-temporal wasn't discussed. Eccles's move, here, invites Peter Medawar's classic comment on Teilhard de Chardin's even woollier remarks about consciousness (especially how individual minds can be absorbed in the one Omega consciousness): "And so our hero escapes from his appalling predicament: with one bound, Jack was free" (Medawar 1961: 104).

Some twenty years later, a distinguished philosopher of science—one of the tiny handful of people elected to both the British Academy and the Royal Society (others are the cognitive scientists Uta Frith and Philip Johnson-Laird)—would join Eccles in promoting interactionism (Popper and Eccles 1977). Karl Popper's obituarist for the Academy, a close colleague for many years, said of him, "At heart he was a Cartesian interactionist" (Watkins 1997: 679), and mentioned his saying that he believed in what was then being dubbed "the ghost in the machine". This was at a talk given in Oxford, where Gilbert Ryle's ghost-denying approach was then dominant (see subsection c, below).

By the late 1970s, there were many other ghost-deniers besides Ryle. All of them upstaged Popper. Despite his high standing in the profession, the audience for his interactionist cameo was small, and the applause muted.

b. Puffs of smoke and nomological danglers

The first 'spot' in the contest was epiphenomenalism, singing a hymn to body–mind causation but trashing mind–body influence. This competitor had been ushered on stage by Thomas Huxley long before, in the 1870s (Chapter 2.viii.b). He'd costumed mental events as puffs of smoke from a steam-engine: unmissable, but ineffectual.

Now, eighty years later, many scientifically minded people—including most neurophysiologists—were still applauding it. Many expressed it in much the same (Cartesian) terms as Huxley had done. But the denial of mind-to-body—and even mind-to-mind—causation remained counter-intuitive, and the posited body-to-mind causation remained a metaphysical mystery.

Even when put less provocatively, in twentieth-century (phenomenalist) terms of lawful regularities rather than causal interaction, the doctrine was still problematic. Mental events are regularly connected with the physical story, but—given that the physical story is apparently seamless—they don't lead back into it. They don't even lead without interruption to each other, for the mental story isn't seamless. Nor is it regular: thought *x* is not predictably followed by thought *y*.

Herbert Feigl (1902–88) noted these difficulties:

Causality [i.e. regular succession] in the mental series is by far too spotty to constitute a "chain" of events sufficiently regular to be deterministic by itself. Epiphenomenalism in a value-neutral scientific sense may be understood as the hypothesis of a one-to-one correlation of [mental states] to (some, not all) [cerebral states], with determinism (or as much of it as is allowed by modern physics) holding for the [cerebral] series, and of course the "dangling" nomological relations connecting [the cerebral and mental events]. (Feigl 1958/1967: 15)

Feigl's nomological danglers were perhaps less puzzling than Huxley's body-to-mind causation, but they were a philosophical embarrassment nonetheless. They were especially problematic for those people—including many leading linguists and psychologists, as well as Feigl himself—who shared the logical positivists' faith in the unity of science (Chapter 9.v.a).

The logical positivists had bounded onto the boards in the 1930s. They saw their role not as cutting the mind–body Gordian knot, but as preventing it from being tied in the first place. They argued that the mind–body problem, like all metaphysical puzzles, is a "pseudo-problem" generated by misunderstanding of language. Although they held that all knowledge is based in sense experience, they insisted that their approach wasn't just another form of post-Cartesian idealism. And they briskly denied any fundamental difficulty in relating mind and body:

The answer to the question whether sense-contents are mental or physical is that they are neither; or rather, that the distinction between what is mental and what is physical does not apply to sense-contents. It applies only to objects which are logical constructions out of them. But what differentiates one such logical construction from another is the fact that it is constituted by different sense-contents or by sense-contents differently related . . . [There] is no philosophical problem concerning the relationship of mind and matter, other than the linguistic problems of defining certain symbols which denote logical constructions in terms of symbols which denote sense-contents . . . Being freed from metaphysics, we see that there can be no *a priori* objections to the existence of either causal [i.e. Humean] or of epistemological connections between minds and material things. (Ayer 1936: 123–4)

So far, so dismissive. Too dismissive, for many people. Even Feigl, who'd been involved with logical positivism since its inception in 1920s Vienna, refused to accept that mind–body is a mere pseudo-problem. (His own solution was a version of the identity theory: see below.)

c. Dispositions and category mistakes

A third philosophical contestant appeared in the late 1940s, eliciting both vociferous applause from the gallery and angry hisses from the stalls: logical behaviourism. This too, though for different reasons, saw the mind–body problem as an illusion based in misunderstandings of language.

The most well-known script used by this contender was Gilbert Ryle's book *The Concept of Mind* (1949), whose advance flyer had been posted a few years earlier (Ryle 1946). The book was immediately hailed in *Mind* as "probably one of the two or three most important and original works of general philosophy which have been published in English in the last twenty years"—*despite* (said this reviewer) its having fundamental flaws (Hampshire 1950: 237). Ryle's crisp sentences and humorous polemic were exceptionally widely read. There were five reprints within five years, and many more thereafter.

Ryle (1900–82) was an Oxford philosopher who often traversed the English countryside in the 1930s to hear Ludwig Wittgenstein (1889–1951) lecture in Cambridge.

Ryle was deeply influenced by him, and they became close friends. But the amity didn't last. Wittgenstein's 'later' work had circulated privately for some years (Chapter 9.x.d). To his annoyance, however, Ryle's book was published first and received enormous attention.

Wittgenstein's chagrin wasn't merely priority pique, nor simply plagiarism paranoia. (He was quick to accuse others of plagiarizing, and misrepresenting, his work: the young Richard Braithwaite, for example, was forced to write a letter to *Mind* 'apologizing' to him on this count: Wittgenstein 1933; Braithwaite 1933.) He felt that Ryle had not only benefited from his ideas, but also misrepresented—or anyway, altered—them. For instance, Ryle relied heavily on "dispositions", a term that Wittgenstein disliked (see below).

Their earlier friendship dissolved into thin air. Wittgenstein dismissed Ryle as not "serious". For his part, Ryle deplored Wittgenstein's "unhealthy" and "pedagogically disastrous" influence on his students (Monk 1990: 275, 495).

Ryle dismissed Descartes's dualistic "myth" of "the ghost in the machine" as radically incoherent and/or a source of countless examples of infinite regress. For example, it explained "intelligent" action in terms of "intelligent" thought—hardly a helpful move.

Descartes was cast as the villain in Ryle's script. However, the *Mind* reviewer pointed out that Descartes wasn't the only one to be blamed. As he put it, "the myth of the mind as a ghost within the body is one of the most primitive and natural" of all beliefs (Hampshire 1950: 239). Moreover, the words for mind, soul, or spirit in most European languages had the same etymology as the words for ghost "long before Descartes or modern mechanics". It was true, however, that Descartes's account had been especially clear, and especially influential.

But if Descartes had been talking nonsense, said Ryle, he hadn't been talking utter nonsense:

> A myth is of course not a fairy story. It is the presentation of facts belonging to one category in the idioms appropriate to another. To explode a myth is accordingly not to deny the facts but to re-allocate them. And this is what I am trying to do. (Ryle 1949: 8)

For Ryle, everyday psychological terms don't denote occurrences within some non-material world. (Compare Wittgenstein: "When I think in language, there aren't 'meanings' going through my mind in addition to the verbal expressions: the language is itself the vehicle of thought" and "Speech with and without thought is to be compared with the playing of a piece of music with and without thought"—1953, paras. 329, 341.)

Rather, such terms should be analysed as shorthand descriptions of actual *and possible* behaviour. That is, they concern behavioural "dispositions"—comparable to the brittleness of glass.

To say that glass is brittle is to say that it's disposed to break, in certain circumstances. A given piece of glass may never actually break, but it's brittle nonetheless. *If* it were dropped onto a hard surface, *then* it would break. Analogously, Ryle argued, to say that someone is jealous, or happy, or thinking about a problem . . . is to say that they are disposed to behave in certain ways, given certain circumstances. Even to say that someone is hot, or itchy, or seeing red (in either sense!) is to remark on their actual and/or potential behaviour.

He allowed that people can keep their thoughts and feelings to themselves. But he analysed this as a counterfactual claim. What it meant, he argued, was simply that *if* the circumstances had been different (if their interlocutor were less indiscreet and/or more trustworthy, or if they were on the point of death, or . . .), *then* they would have expressed them.

Words denoting "propositional attitudes" (Bertrand Russell's term: B. Russell 1918–19)—such as *know*, *believe*, *desire*, *prefer*, *fear*, and *hope*—were treated in the same way. To believe that *p* is to be disposed to say that *p*, and to behave in ways that would be appropriate (given the person's other beliefs and desires) if *p* were true. As in this example, psychological concepts are generally defined in terms of others. So this approach put a new gloss on what would previously have been thought of as mind–mind (or even mind–body) causation. Pity, for instance, is—among other things—the disposition to help and/or comfort ('behaviour') someone seen to be in distress ('circumstances'). So to say that Mary helped Jane "because" she pitied her is to mark a conceptual link, not a causal (contingent) one.

As for intelligence (said Ryle), this isn't some ghostly power causally responsible for behaviour, but rather a certain manner of behaving. Intelligent behaviour is carried out carefully, thoughtfully, skilfully, appropriately, and flexibly. Largely, the intelligence manifests itself only as tacit *knowledge how*. Sometimes, a person can comment on aspects of their behaviour, and answer questions or give advice, by verbal statements of *knowledge that*. Intelligence in general, however, isn't a matter of explicit reasoning—whether kept to oneself or shouted to the rooftops. In a nutshell:

> Overt intelligent performances are not clues to the workings of minds; they are those workings. Boswell described Johnson's mind when he described how he wrote, talked, ate, fidgeted and fumed. (Ryle 1949: 58)

In general, then, Ryle didn't try to forbid talk of mental states, but he gave an unfamiliar analysis of their nature. (Similarly, computational analyses of human freedom admit that people have a psychological characteristic which animals don't, but gloss this in an unorthodox way: see Chapter 7.i.g.)

All very plausible, possibly, for third-person remarks about mental states. But what about first-person statements? Surely these are reports of inner happenings?—Ryle was obdurate. He said (for instance) that first-person statements about one's feelings of emotion are "avowals" rather than reports:

> Avowing "I feel depressed" is doing one of the things, namely one of the conversational things, that depression is the mood to do. It is not a piece of scientific premiss providing, but a piece of conversational moping. That is why, if we are suspicious, we do not ask "Fact or fiction?", "True or false?", "Reliable or unreliable?", but "Sincere or shammed?" The conversational avowal of moods requires not acumen but openness. It comes from the heart, not the head. It is not discovery [by Cartesian direct access], but voluntary non-concealment. (Ryle 1949: 102)

(Compare Wittgenstein: " 'So you are saying that the word "pain" really means crying?'—On the contrary, the verbal expression of pain replaces crying and does not describe it"—1953, para. 244.)

For all his hard-headedness in rejecting the Ghost, Ryle had no interest in saving the Machine:

> [The] influence of the bogy of mechanism has for a century been dwindling because, among other reasons, during this period the biological sciences have established their title of "sciences". The Newtonian system is no longer the sole paradigm of natural science. Man need not be degraded to a machine by being denied to be a ghost in a machine. He might, after all, be a sort of animal, namely, a higher mammal. There has yet to be ventured the hazardous leap to the hypothesis that perhaps he is a man. (Ryle 1949: 328)

Ryle's reference, here, to a non-Newtonian paradigm in biology is puzzling. He may have been thinking of Claude Bernard's work on self-organization, or Walter Cannon's on homeostasis (Chapter 2.vii.a). Presumably, he wasn't referring to their 1940s equivalent, cybernetics. For his cybernetic contemporaries were arguing that all organisms are fundamentally like *some* machines, albeit machines unlike anything imagined by Descartes (see Chapter 4.v–vii).

Logical behaviourism was very different from the psychological variety discussed in Chapter 5.i and iii. Psychological behaviourists, in essence, were experimental epiphenomenalists. They claimed that mental (conscious) states are ontologically distinct from the body; that proper knowledge of mental states can be had only by the person whose states they are; and that, for scientific purposes, third-party concepts of mental states can be defined in the non-intentional terms of *stimulus* and *response*. As noted above, Ryle rejected every one of these claims.

So did Wittgenstein. He wrote:

> "Are you not really a behaviourist in disguise? Aren't you at bottom really saying that everything except human behaviour is a fiction?"—If I do speak of a fiction, then it is of a *grammatical* fiction.
>
> How does the philosophical problem about mental processes and states and about behaviourism arise?—The first step is the one that altogether escapes notice. We talk of processes and states and leave their nature undecided. Sometimes perhaps we shall know more about them—we think. But that is just what commits us to a particular way of looking at the matter. For we have a definite concept of what it means to know a process better. (The decisive movement in the conjuring trick has been made, and it was the very one we thought quite innocent.)—And now the analogy which was to make us understand our thoughts falls to pieces. So we have to deny the yet uncomprehended process in the yet unexplored medium. And now it looks as if we had denied mental processes. And naturally we don't want to deny them. (Wittgenstein 1953, paras. 307–8)

> And yet you again and again reach the conclusion that the sensation itself is a *nothing*.—Not at all. It is not a *something*, but not a *nothing* either! The conclusion was only that a nothing would serve just as well as a something about which nothing could be said. (para. 304)

Some cognitive scientists today, including Daniel Dennett and Aaron Sloman (both of whom encountered Ryle while studying at Oxford), see themselves as following in Ryle's footsteps (Dennett 1969, pp. xi, 2000; Sloman 1996*c*, Acknowledgements). This may seem strange. For his neo-Wittgensteinian assumption that talk of non-material processes can be understood only dualistically was very different from cognitive science—which is mentalistic, although not dualistic. However, there are two good reasons for arguing that Ryle should be seen as a precursor of cognitive science, not just a predecessor (see 9.ii).

First, Ryle's subtle analyses of psychological concepts, and of the rich interconnections between them, were highly illuminating as accounts of mental architecture. His account of emotions (1949: 83–115), for instance, was an inspiration for Sloman's work on the topic (Chapter 7.i.f). And in exhibiting the conceptual (rational) links between the many varieties of belief and desire, he prefigured Dennett's theory of intentional systems (see Section iv.b).

Second, Ryle's term "disposition" can be interpreted in a way that fits very well with cognitive science. Whether Ryle himself understood the term in this way is another matter.

Most talk of "dispositions" is systematically ambiguous, denoting behaviour and/or its underlying causes. This is why Wittgenstein preferred to avoid the term (1953, para. 149 and pp. 191–2). The psychologist William McDougall had explicitly defined the word in both these senses, and had kept them clearly distinct (McDougall 1923; see 5.ii.a). Ryle didn't.

His term is usually read *descriptively*, as denoting *an observable tendency to behave in a certain manner* (O'Shaughnessy 1970). This sense was dominant in the 1950s, partly because analytic philosophers of mind didn't see it as their role to offer explanations. That, Wittgenstein had taught them, was the business of brain scientists. However, Ryle's term was later read also as *explanatory*, denoting *the mechanism responsible for the relevant behaviour* (Squires 1970).

Whether Ryle himself understood it in this way is doubtful. But cognitive scientists in general favour the dual reading. And, while any "mechanism" which Ryle might have intended would have been neurophysiological, they allow computational explanations too. (Whether they all expect these to map neatly onto the propositional attitudes is another question: see Section iv.)

If Ryle's bravura performance was hailed by many of his contemporaries, it was fiercely criticized by others. Even the adulatory *Mind* reviewer was ambivalent. Quite apart from his analytic philosophical method in general (which he later confessed was the *real* topic of the book, mind–body being a "notorious and large-size Gordian knot" that he could use as an illustrative example—Ryle 1971: 12), there were two major problems.

First, it wasn't clear that dispositional analyses could be fully spelt out in practice, not least because so many psychological concepts are defined in terms of others. Moreover, many people felt that consciousness was still missing—or, to put it in linguistic terms, that philosophical behaviourism didn't give a satisfactory account of first-person psychological statements. Ryle's analyses of sensations, and Wittgenstein's dismissal of private languages (1953, paras. 243–76) and "the beetle in the box" (1953, para. 293), failed to persuade them that Cartesian mental processes are dispensable. On the contrary, they seemed—to many critics—to be recalcitrantly real. (A dialogue between Ryle/Wittgenstein and the obstinate "Otto" might have been very similar to that given in Chapter 14.xi.b.)

d. Questions of identity

In 1956 a fourth challenger entered the limelight—and, especially for scientific audiences, threatened to win the contest. This was mind–brain identity theory.

The new theory accepted dispositional analyses for most psychological predicates, adopting the dual interpretation that posits explanatory mechanisms in the brain. But sensations, or experiences, were not analysed in this way. Nor were they understood as epiphenomena. Denying any special realm of conscious events, identity theory held that sensations are *identical* with brain states. The brain state doesn't cause the sensation, nor is it correlated with it. Rather, it constitutes it. Ontologically there is only one thing. But it can be described, and known, in two ways.

Identity theory was first published in a scientific journal, the *British Journal of Psychology*, by Ullin Place (1924–2000). (As usual, there were precursors: Feigl, for instance, had been thinking along similar lines for some time.) Place insisted that the theory was "a reasonable scientific hypothesis, not to be dismissed on logical grounds alone" (Place 1956: 44). Only future work in neurophysiology could confirm its truth, he said, although suggestive empirical evidence was already available.

"Logical" objections were sure to be made, of course, and Place anticipated two. The first was that our introspective access to our conscious states proves that they are events of a different order. Place called this "the phenomenological fallacy". He argued that it rested on "the mistaken idea that descriptions of the appearances of things are descriptions of the actual state of affairs in a mysterious internal environment" (1956: 44).

The second was that mental and physical states are radically different, so can't possibly be identical. Or, expressed less 'metaphysically': the meanings of mental and physical terms are very different, which is why people can talk about their experiences without knowing that the brain is in any way involved.

Distinguishing "the 'is' of definition" from "the 'is' of composition", Place replied that things falling under very different concepts may in fact be compositionally identical. Some such identities are superficial and contingent (Mary's table *is* an old packing case). But some are deep and systematic, and discoverable only by science. People had talked about lightning for thousands of years, but scientists eventually discovered that lightning *is* electric charges in motion. It follows, Place argued, that the fact that our concepts of mental states are logically very different from our concepts of brain states doesn't prove that they pick out non-identical things.

Stated thus, Place was right. Feigl made the same point by appealing to Gottlob Frege's distinction between *sense* and *reference* (Chapter 2.ix.b). But even two "very different" concepts may share an important feature. All Place's examples relied on shared spatio-temporal dimensions. (Think of how one discovers that a table is a packing case, or that lightning is electric discharge.) And, *pace* Eccles, conscious states—notoriously—are not in space.

Accordingly, the identity theory was widely regarded as paradoxical. Even David Armstrong, who published the best-developed version of it—known as central-state materialism—ten years later, admitted: "Certainly I myself found the theory paradoxical when I first heard it expounded" (Armstrong 1968: 73).

The next move—taken by Jack Smart (1920–), in whose Adelaide department Place had written his paper—was intended to resolve the paradox. Smart suggested that we wield Occam's razor and *decide* to treat experiences and brain states as identical. In that case, an experience could be said to have the same location as the brain process which constitutes it. He even said:

> [We] may *easily* adopt a convention (which is not a change in our present rules for the use of experience words but an addition to them) whereby it would make sense to talk of an experience in terms appropriate to physical processes. (Smart 1959; italics added)

Many critics could hear Jack (the giant killer) bounding again. Norman Malcolm (1911–90), for instance, insisted that Smart *was* suggesting a change in usage, and one that would be fundamentally incoherent (Malcolm 1964). But at least Smart, unlike his successor Francis Crick (14.x.d), recognized that any such change would be a scientifically grounded philosophical decision, not a scientific discovery.

Whether the scientific grounding required could ever be delivered was unclear. The identity theorists held that each type of mental state is, as a matter of fact, identifiable with a certain type of brain state. Yet there were many reasons to doubt this—some scientific, some philosophical.

One was Karl Lashley's (1950) recent discovery that memories seem not to be located in any specific part of the cortex (Chapter 5.iv.a). Nowadays, the term "brain state" could include some highly distributed pattern of activity (see Chapters 12 and 14), making Lashley's findings less problematic. At mid-century, however, "brain state" usually intended the activity of a single neurone or localized cell assembly. In those terms, hardly any positive evidence was available. Single-cell feature-detectors were yet to be discovered (see Chapter 14.iv). It had recently been found that complex conscious states can be elicited by stimulating points in the temporal cortex. But their content was predictable only, if at all, in the individual concerned (Penfield 1952, 1958).

Natural language, too, presented a problem. Except on an extreme Humboldtian view (Chapter 9.iv.b), two people can sometimes express the same thought. But if they speak in different tongues (different phonemes, etc.), their brain states must differ in many ways. Even dogs gave pause for thought. Presumably dogs, and possibly Martians, can feel (non-conceptualized) pain, much as a baby can. But a dog's or Martian's brain is very different from a baby's—which would imply (according to the identity thesis) that it *cannot* feel pain (David Lewis 1980).

Besides 'scientific' hesitations such as these, more fundamental attacks were mounted by Wittgensteinian philosophers. Malcolm (1964), for instance, argued that only someone whose culture includes milkmen can have the sudden thought that they haven't put out the milk bottles. This thought therefore can't be identified with a brain state, for that could conceivably occur (perhaps due to microsurgery) in anybody's head. Any brain state could even happen, as Smart himself had pointed out (1963), in a brain *in vitro*. But for Malcolm, the notion that a brain—in a head or in a vat—can *think* is literally absurd. Thoughts can be sensibly ascribed only to embodied and enculturated persons.

At the end of the 1950s, then, none of the four main rivals had monopolized the applause, and all were receiving some highly critical reviews. Despite the near-universal rejection of mental substance, Descartes's mid-twentieth-century heirs faced much the same mind–body problems as he had done (see Chapter 2.iii.b).

Some voices off-stage—across the Channel—were arguing that "mind" and "body" are Cartesian illusions anyway (see Sections vii–viii below, and Chapter 14.xi). But most of the analytic audience wasn't listening. Those few—notably Ryle and Wittgenstein—who had heard them were expressing this view in different terms.

(About ten years later, at a meeting held in France, Ryle admitted that his book "could be described as a sustained essay in phenomenology, if you are at home with that label"—1962: 188. In the discussion, which also included A. J. Ayer and Willard Quine, one of the leading Continentals replied: "[What Mr Ryle] was saying was not so strange to us, and the distance, if there is a distance, is one that he puts between us rather than one I find there"—Merleau-Ponty 1960: 65. And the 'analytic' reviewer of the meeting's Proceedings apparently agreed: C. M. Taylor 1964*b*. All this isn't too surprising, for as a young man Ryle had been an exponent of Edmund Husserl, and had reviewed Martin Heidegger's *Being and Time* with respect. The respect was coloured with scepticism, however. Ryle's review opened with "This is a very difficult and important book . . . though . . . I suspect that this advance is an advance towards disaster," and closed by saying, "Phenomenology is at present heading for bankruptcy and disaster and will end either in self-ruinous Subjectivism or in a windy mysticism"—Ryle 1929: 355, 370.)

As for mind-as-machine, the topic had barely arisen. On the rare occasions when mind—or rather, adaptive behaviour—was likened to machine in the philosophical journals (Ashby 1947; J. O. Wisdom 1951), it was cybernetic machines which were in question (see Chapter 4.v–vii). Digital computers were hardly mentioned until 1950, when a provocative squib in *Mind* written by Alan Turing prompted a flurry of discussion about the possibility of machine intelligence.

16.ii. Turing Throws Down the Gauntlet

Turing himself was more interested in the machine than in the intelligence. In other words, his *Mind* paper was primarily intended as a sketch of a research programme for AI (see 10.i.f), not as a conceptual analysis of "intelligence". However, virtually all the philosophical authors who responded to it addressed what they saw as Turing's behaviourism, rather than his imagined machines.

Moreover, those who did mention his machines didn't do so sympathetically, or in detail. Not until the 1960s would philosophers of mind start to use computational ideas in a constructive manner (Sections iii–iv, below).

a. Sketch of a future AI

Well before mid-century, Turing had been considering mind in a very different way from the writers discussed above (see Chapters 3.v.b and 4.ii.b). From the late 1930s, he'd believed that many, perhaps all, thoughts were formal–computational in nature. And soon after the war, he wrote a technical report on how to make "thinking machinery"—and there outlined what was later called the Turing Test. But the Official Secrets Act prevented publication.

Some of Turing's philosopher contemporaries were aware of his general position. In October 1949 he took part in a Manchester seminar on 'The Mind and the Computing Machine', with the philosophers Dorothy Emmet and Wolfe Mays (1912–2005), and the chemist–philosopher Polanyi. But none of them was persuaded (Manchester Philosophy Seminar 1949; Polanyi 1958). Other discussants on this occasion included the mathematician Max Newman, the zoologist John Z. Young, and the psychologist Frederic Bartlett. They were more ready to consider his ideas seriously, and to try to relate them to what was known about the brain (he'd mentioned both logical and 'neurone-based' models: Chapter 10.i.a).

Many philosophers, however, still knew of Turing only as a mathematical logician and/or a slave of Manchester's newfangled calculating machine, vulgarly dubbed a "giant brain" by the newspapers. This was the world's first modern computer—but why should they be interested in *that*? Many more hadn't heard of him at all.

In 1950 Turing's philosophical profile suddenly became more prominent, when he published a paper in *Mind* on 'Computing Machinery and Intelligence'. It ignored all the mind–body 'isms' outlined in Section i—although it did rebut several potential objections, including the argument from Gödel's theorem. (For the record, that argument had originated with Emil Post some thirty years earlier, and had featured in a paper of 1941 rejected by the *American Journal of Mathematics* as too "historical": Post 1965.) Nevertheless, Turing's 1950 essay was rich fare. It served up two intellectually tasty dishes—one of which was left untouched by most of its philosophical readers.

Primarily, the *Mind* paper comprised an outline programme for AI research, based on Turing's still-secret report. It provided a tutorial on digital computers, describing programs in terms of "tables of instructions" (rules for linking Input plus Internal State to Output). And it suggested how these machines might be useful in thinking about thinking.

It said, for example, that if we want to find analogies between computers and brains, we should focus on "mathematical analyses of function", not superficial similarities such as using electricity. Charles Babbage, after all, had "all the essential ideas" but hadn't used electricity. And it suggested that intelligence could be modelled by these machines (even though Turing knew there are *some* questions they can't answer: Chapter 4.i.c).

The paper provided "recitations tending to produce belief", as opposed to "convincing arguments of a positive nature", about what practical advances might be made—and *how*. So in the august pages of *Mind*, Turing discussed possible AI work on game playing, perception, language, and learning, giving tantalizing hints about what had already been achieved (for details, see Chapter 10.i.a and f). He even envisaged cloning—which he said would *not* be regarded as "constructing a thinking machine".

Most philosophers at the time paid no serious attention to Turing's substantive argument about the possibility of AI. They focused, rather, on his tongue-in-cheek claim that it would be natural to attribute thought to a computer that succeeded in the "imitation game" (a chess version of which he'd already carried out on a "paper machine": A. M. Turing 1947*a*: 23).

The game (soon dubbed the Turing Test: see subsection c, below) had been proposed in order to avoid dismissive arguments based on the meanings of words. These were wheeled out, nonetheless, some citing the authority of the *OED* (Mays 1952: 149). Turing himself resolutely refused to define either "machine" or "thinking":

> I propose to consider the question, "Can machines think?" This should begin with definitions [framed to reflect] the normal use of the words, but this attitude is dangerous. [It implies that the meaning and the answer are] to be sought in a statistical survey such as a Gallup poll. But this is absurd. Instead of attempting such a definition I shall replace it by another [namely, the

Turing Test], which is closely related to it and is expressed in relatively unambiguous words. (A. M. Turing 1950: 433)

He added two provocative predictions, based on his expectation of practical advance in AI. The first was that "in about fifty years' time" machines would be able to play the imitation game with at least a 30 per cent probability of fooling "an average interrogator" for five minutes (p. 442). (What he actually wrote was: "[the] interrogator will not have more than 70 per cent chance of making the right identification". This is very often misread as predicting that the computer would *fool* the interrogator in 70 per cent of cases; but, as Blay Whitby pointed out to me, it means that the interrogator would be *correct* up to 70 per cent of the time.)

This prediction gave grounds for the second:

The original question, "Can machines think?" I believe to be too meaningless to deserve discussion. Nevertheless, I believe that at the end of the century the use of words and general educated opinion will have altered so much that one will be able to speak of machines thinking without expecting to be contradicted. (p. 455)

This was slippery. It could be read as a philosophical claim (an "educated opinion"), or as an empirical prediction about "the use of words". Moreover, the term "contradicted" was ambiguous. To allow someone—without reproof—to speak of computers thinking, or even to do so oneself, isn't necessarily to believe that computers actually think (see Sections v–vii, below).

By 1952, Turing's ideas had been featured in the newspapers, and he was debating them on BBC radio (for the BBC transcripts, see Copeland 1999). And the first philosophical replies had been published (Pinsky 1951; Mays 1951, 1952). One of these, written by Mays, would have appeared even earlier, had it not been censored by Ryle:

When Turing published his paper in *Mind* in 1950, Gilbert Ryle sent me the proofs and asked me to comment on them. I did, but Ryle rejected it on the ground that it was too polemical. (I used the word consciousness too many times, which in those days was heresy. It's now well-trodden ground by Searle, Dreyfus, and others.) Instead he asked Minsky to reply [who, in the end, didn't]. My reply got published in *Philosophy* some time later. (Mays, personal communication)

(Mays wasn't anti-machines: he'd co-designed an electrical logic device in the late 1940s—see Preface, ii. He'd also arranged for two digital computers to be shown at a 1950 philosophy conference, which could transform strings of up to 2,048 binary digits into logical symbolism: Mays *et al.* 1951. However, he *was* anti-formalist and anti-behaviourist with respect to the philosophy of mind. Indeed, he later founded the British Society for Phenomenology.)

Initially, these papers were a trickle, not a flood. In the 1950s, the attention of scientifically minded philosophers was largely captured by the identity theory (see Section i.d). One Cambridge apple orchard housed a group of philosophers, and others, deeply influenced by Turing. But they were more concerned to put his scientific ideas into effect than to publish philosophical papers about them (see Preface, ii, and Chapter 9.x.d).

It wasn't until the 1960s—thanks partly to functionalism and partly to results in early AI—that Turing began to be cited regularly by philosophers of mind. Usually, they ignored the main thrust of the piece and focused only on the Turing Test. But a few picked up Turing's gauntlet, by asking whether certain aspects of mind could, in fact, be simulated in computers.

Keith Gunderson, then at Princeton, was one of the first to pay Turing the compliment of disagreeing with him about his *main* point: that AI could (at least) simulate intelligence.

Gunderson had been alerted to AI/functionalism in the 1950s, even before either of those names existed. The first wake-up call was Turing's classic essay. The next was Michael Scriven's (1953) paper denying consciousness to robots (because they aren't alive: see Section x, below). The third was Paul Ziff's (1959) discussion of feelings in robots. And the last was a seminar given at Princeton by Hilary Putnam in 1959 (personal communication). Now, in the early 1960s, Gunderson published a paper on the imitation game (1964*b*), another touching on language in computers (1964a, sect. iii), and another—in reply to Ziff—on emotions in robots (1963).

With respect to Turing's core claim, Gunderson was sceptical. He distinguished various forms of "computerophily" (1964*a*: 211), in which philosophers claimed that this or that human capacity could be simulated, perhaps even instantiated, in computers. On the one hand, he shared Descartes's doubts about the provision of language and *general* intelligence to machines (see 2.iii.c), although he did consent to leave open the question of whether computers could ever use language successfully (1964*a*: 222). On the other, in thinking about feelings in robots he'd begun to develop the distinction between "program receptive" and "program resistant" properties—later spelt out at length (Gunderson 1971; cf. 1985: 166–247). Some psychological phenomena, he said, could never be understood in AI/functionalist terms, whereas others could: emotions and problem solving, respectively (see 7.i.d).

Computer scientists, by contrast, had appreciated the main point of Turing's piece in *Mind* immediately. By 1963 it was already "one of the best-known papers" on AI, and was included in the influential collection on *Computers and Thought* (Feigenbaum and Feldman 1963: 9). Interest in it continued to grow. By the century's end, it had been anthologized scores of times, and cited on countless occasions. It still features regularly, both in professional journals (of philosophy and cognitive science) and in the media.

b. The gauntlet spurned

For ten years or more, most philosophers (as opposed to computer scientists) considered Turing's paper as a version of behaviourism, not as a substantive claim about thought. (Honourable exceptions included Mays, Gunderson, Scriven, Ziff, and John Lucas: see Section v.a–c.) In that sense, the philosophical community declined to pick up the gauntlet he'd thrown down. Indeed, many of these early replies said nothing specific about computers—which were still fairly inaccessible (see 3.v).

Even after computers became familiar, anti-Turing arguments—for instance, that robots must be non-conscious "zombies"—usually focused on his approach in the abstract (Section v.b, below). Its detailed implementation was ignored.

Ned Block's (1942–) influential argument about the giant look-up table was seemingly an exception (N. Block 1982). "Seemingly", because it ignored the intractable problem of the combinatorial explosion—which no computer scientist would have done (Dennett 1988). Interpreted literally, the Turing Test allowed the possibility that the computer's individual answers had been pre-stored, each one directly triggered by a particular question. But that wouldn't count as intelligence, which as Descartes had pointed out (Chapter 2.iii.c) is able to generate new answers to new questions.

However, Block's objection was well aimed only at the letter of Turing's paper, not at its spirit. In his wartime work—trying to determine what coding machine could be responsible for the observed 'behaviour'—Turing had indeed been seeking look-up tables: *this* letter of the message alphabet corresponds to *that* letter of the code alphabet. (It had turned out that there were two successive look-up tables, not one.) But by 1950, when his paper appeared in *Mind*, computing had already moved on. Programs now defined internal computations and structured spaces of generative possibilities, not mere lists of input–output pairs. In other words, Turing had excluded look-up tables implicitly, if not explicitly.

Despite Turing's coyness about defining thought, his paper implied that some conceivable digital computers could actually think. It was one of his philosophical colleagues at Manchester who first published substantive reasons for denying this.

Mays argued—like John Searle, thirty years later—that computer programs are all syntax and no semantics (Mays 1951, 1952). Or, as he put it:

> But if we grant that logical machines are complex pieces of symbolism, a development of the visual aids to thinking which we have known for centuries, in order that the signs may acquire a significance they need to be given a specific logical or mathematical interpretation. As Whitehead [in his *Universal Algebra* of 1898, pp. 3–5] tells us, though we can study the art of practical manipulation of these signs without needing to assign any meaning to them, abstract calculi only possess a serious scientific value when they can be given an important interpretation.
>
> Neglect of the pragmatic or instrumental aspects of such machines, leads to the tendency to attribute to them a capacity for thinking which they have only by proxy. The transformation of formulae according to a fixed set of logical rules, is not, however, a sufficient criterion of thinking. Unless the resultant formulae or patterns of symbols are retranslated in terms of their referents, the transformation remains a meaningless array of marks. [We need a human] intelligence to programme the machine and interpret the end-result . . . (Mays 1952: 159)

He failed to point out that Turing himself had made the same point in his *Mind* contribution—not once, but twice. We can speak of computers making "mistakes", he said, only "when some meaning is attached to the output signals from the machine". Similarly: "[it needs to] be shown that the machine has *some* thought with *some* subject matter. Nevertheless, 'the subject matter of a machine's operations' does seem to mean something, at least to the people who deal with it" (1950: 445).

Mays added a scientific remark, citing Gestalt psychology and Lashley's psycho-physiology (Chapter 5.i.b and iv.a). Thinking is very unlike logic, he said, since "the nervous system operates as an organic whole". And he blamed Wittgenstein for putting AI on the wrong track:

> The basic assumption in applying the calculating machine analogy to the mind is that thinking operates in the form of an atomic system. It accepts Wittgenstein's view of the world as a structure of atomic facts . . . The progenitor is, of course, Wittgenstein [in the *Tractatus*] . . . Indeed one might say that modern digital computors [*sic*] are electrified pieces of Wittgensteinian logic. (Mays 1952: 161)

Here, Mays was right. It had been Warren McCulloch's youthful infatuation with logical atomism which eventually led him and Walter Pitts to propose AI, and influenced the design of the von Neumann computer (see Chapter 4.iii–iv).

But that was the early Wittgenstein. The later Wittgenstein saw those ideas as fundamentally misguided: thought was *not* a matter of atomistic logic (Chapter 9.x.d). Nor was language: on the contrary, it's part of our biology, one of our "forms of life"—so "If a lion could speak, we would not understand him" (1953: 223). As for machines, he said:

> Could a machine think?—Could it be in pain?—Well, is the human body to be called such a machine? It surely comes as close as possible to being such a machine.
>
> But a machine surely cannot think!—Is that an empirical statement? No. We only say of a human being and what is like one that it thinks. We also say it of dolls and no doubt of ghosts too. Look at the word "to think" as a tool. (Wittgenstein 1953, paras. 359, 360)

One might say that Turing agreed. For he was arguing that if a machine behaved like us, we would say it was thinking. But here the analogy ended. Wittgenstein was presupposing the presence of a human body and human "forms of life" as criteria for thinking, whereas Turing explicitly discounted these (see Section vii.a).

Mays was one of the very few commentators to pick up Turing's *main* philosophical challenge. Most philosophers were diverted by the Turing Test.

c. The Turing Test: Then and now

The phrase "Turing Test" wasn't used by Turing himself, and it suggests rather more philosophical weight than he'd intended. His friend Robin Gandy (1919–95) recalled the paper being written as lighthearted "propaganda", inviting giggles as much as serious philosophical critique (Gandy 1996: 125).

We saw, above, that Turing's teasing discussion of the imitation game had been aimed at avoiding endless definitions of intelligence. In fact, it spawned a minor—and still continuing—philosophical industry doing just that (e.g. Millican and Clark 1996). The lengthy entry in the online *Stanford Encyclopedia of Philosophy*, for example, lists over forty essential publications—and six Internet sources too.

Some saw the Test as indicating (if not *proving*) not intelligence *as such* but embodied, enculturated, human intelligence—which no computer could achieve, even though it might be genuinely intelligent in some other way (R. French 1990; Boden 1995*b*). And some elaborated it as the Total Turing Test (Harnad 1989), and even as the Total Total Turing Test (Harnad 1991, 1994; Bringsjord 1995). The TTT included full sensori-motor behaviour, or robotics. And the TTTT added "Turing indistinguishability right down to the neurons and molecules"—cloning, again? Most commentators, however, were content to discuss the original pen-pal version.

Despite this huge body of literature, one can't say briefly what the Turing Test *is*. The all-human version of the imitation game was clear enough: an interrogator exchanges written messages with a man and a woman, trying to distinguish them (only the man is allowed to lie). However, Turing's paper suggested three different 'machine' versions.

The first two involved a computer, an interrogator, and another human being—whose output text is compared with the computer's to decide which is which.

The computer plays the part of (1) a man pretending to be a woman, or (2) a man; the other human being is (1) a woman, or (2) a man. The third version involved only a computer and a human interrogator. The human knows that he/she is conversing with a computer, and must decide whether it is thinking. In discussions of the paper, the first definition was almost always forgotten. The second was often ignored. Usually, philosophers—like Turing himself—focused on the third.

Further confusion arose after AI started to achieve practical results. Then, people often considered a fourth case, where the interrogator does *not* know that a computer might be involved.

Sometimes, this situation arose accidentally. One famous example involved a prototype of the ELIZA program described in Chapter 10.iii.a, interacting with the NewFAI researcher Danny Bobrow. Slightly different reports of this dialogue have appeared in print. The version given in (Kaneff 1970: 32–3), and reproduced below, was personally confirmed to me by Bobrow. (However, as the editor of the *SIGART Newsletter* sagely remarked, "it's a good enough story that it probably deserves repetition even if there is not a word of truth in it!": *SIGART Newsletter* 1968.)

A computer salesman had a teletype interchange with Bobrow—or so he thought:

SALESMAN: DO YOU THINK THAT I CAN USE THE COMPUTER THIS MORNING?

TELETYPE RESPONSE: WHY DO YOU ASK?

SALESMAN: I MIGHT BE ABLE TO MAKE SOME ADDITIONAL TELCOMP SALES.

TELETYPE RESPONSE: WHY AREN´T YOU SURE?

SALESMAN: MY PROSPECTIVE CUSTOMERS HAVE NEVER SEEN A DEMONSTRATION OF THE SYSTEM.

TELETYPE RESPONSE: DOES THIS MEAN VERY MUCH TO YOU?

SALESMAN: OF COURSE IT DOES.

TELETYPE RESPONSE: YOU SEEM VERY POSITIVE ABOUT THAT.

SALESMAN: THIS IS RIDICULOUS.

TELETYPE RESPONSE: WHAT DO YOU MEAN THIS IS RIDICULOUS?

SALESMAN: IS THERE ANY REASON WHY I CAN´T USE THE COMPUTER NOW?

TELETYPE RESPONSE: TELL ME MORE ABOUT YOUR PROSPECTIVE CUSTOMERS.

SALESMAN: PLEASE DIAL ME UP ON 491–1850

At that point, no teletype response occurred. (The salesman hadn't put a full stop at the end of his curt request, and ELIZA always needed a full stop to trigger a response.) And, of course, no phone call was forthcoming either. Eventually, the furious salesman phoned Bobrow direct: "Why are you being so snotty to me?" Bobrow, still half-asleep, naturally asked: "What do you mean, why am I being so snotty to you?" The reply was unprintable.

Journalists and others, some of whom should have known better, celebrated this episode as ELIZA's having "passed the Turing Test". However, it didn't fit any of the definitions of the imitation game given in Turing's paper.

More to the point, the fourth-case situation sometimes arose by design. A few years after Bobrow was so rudely awakened, an experiment was carried out to "validate" Kenneth Colby's computer model of paranoia (Chapter 7.i.a). A random group of psychiatrists were asked to give diagnostic interviews by teletype, and some were connected not to a mental patient but to PARRY (Colby *et al.* 1972). Another group were asked to rate the transcripts for paranoia. And a third group were sent the transcripts, told that some had involved a computer, and asked to say which.

Sure enough, no one in the first group realized they were interviewing a program. The "weak" and "strong" versions of Colby's model were diagnosed, by the first two groups, as slightly and highly paranoid, respectively. (Occasionally, PARRY's linguistic limitations led to a diagnosis of physical brain damage.) And the *man or machine?* guesses of the third group achieved only chance level.

Colby himself had the wit to see that this wasn't a Turing Test as the master had defined it. He pointed out that, had the interviewers been warned, they would have asked different questions, designed to discover whether the interviewee was a program. In a follow-up experiment, he did warn the judges beforehand—and they were mistaken almost as often (Heiser *et al.* 1980). Again, however, this wasn't the unrestricted test imagined by Turing: the psychiatrists' freedom to question was limited by medical ethics (*one* communicant was a human patient) and professional focusing (on paranoia, and its simulation). And again, Colby was explicit about this, referring to "*Turing-Like* Tests" and stressing the *limitations* of such experiments in assessing simulations. Similarly, John Clippinger (1977, ch. 9) pointed out that the plausibility tests done on ERMA weren't reliable as validations of his psychological theory (Chapter 7.ii.c). Other commentators were often less careful, describing the programs in these (and similar) examples as having passed the Turing Test.

The high media profile given to this type of case not only brought the Turing Test into the layman's vocabulary, but also reinforced its presence in the vocabulary of AI. The early AI researchers had been inspired by the scientific vision of Turing's 1950 paper, and its many challenges to their ingenuity. In addition, most had read it as providing a criterion of their success. Especially in the 1960s and early 1970s, AI work was often judged in terms of some version of the Turing Test. Colby's experimental "validation" was a case in point. And most philosophers agreed that the Test was an appropriate criterion. Hubert Dreyfus, for instance, declared it to be "just what was needed" for evaluating AI (H. L. Dreyfus 1972, p. xxi).

Today, outsiders still use TT comparisons to evaluate AI's achievements—usually, to criticize them. By 1980 however, serious AI professionals were much less likely to judge their work in these terms. Bernard Meltzer, first Editor of the journal *Artificial Intelligence*, had already argued that the Turing Test was not only irrelevant but constraining, since it *limited* AI to considering human intelligence (Meltzer 1971). From 1980 onwards, AI researchers in general came to agree with him.

John McCarthy, in a presidential pep talk to his fellow AAAI members, specifically said that improving standards in AI research *did not* require passing, or even considering, the Turing Test: it was a "challenge", not a "scientific criterion" (1984: 8; see 11.iii.b). A few years later, when AI was no longer in its infancy and so-called "failures" had multiplied, several writers described evaluation by Turing Test as positively damaging to AI (Hayes and Ford 1995; Whitby 1996*a*; Sloman 2002). The main exception concerned people writing games and entertainments in the 1990s, who talked about "believable" agents and valued virtual-reality systems that could 'fool' the user to some extent (Chapter 13.vi).

To be sure, in 1991 the Boston Computer Society sponsored a public run of the Turing Test, the American Association for AI reported it in their magazine (R. Epstein 1992), and the event was subsidized by the National Science and Sloan Foundations. This was the first in an annual competition (visible live on the Web since 1999) funded by Hugh

Loebner. The yearly prize is $2,000, for the "best" entry. But the rules state that $25,000 awaits "the first computer whose responses [are] indistinguishable from a human's" (see the official web site: <http://www.loebner.net/prizef/loebner-prize.html>). And entrants at that level will also be able to compete for the Grand Prize of $100,000, which requires "audio-visual capabilities" too.

(One might regard this as somewhat niggardly. For Ed Fredkin had set the same sum aside in 1980 for the first program to beat a reigning world champion in chess—no audio-visuals required. The Fredkin prize was won in 1997, by IBM's Deep Blue: Hamilton and Hedberg 1997; Michie 1997. Then Deep Blue was disassembled, never to play again: Hsu 2002.)

By the end of the century, the Loebner competition had moved around the world, to be sponsored by Flinders University in South Australia and then by the London Science Museum. However, the event always was—and still is—more publicity than science.

The original planning committee involved philosophers as well as computer scientists (Shieber 1994). Early members included Dennett, Quine, and (initially) Bernard Cohen; and the philosopher Block was one of the first referees. (Quine might almost be an honorary computer scientist, for two of his papers on logic spawned a widely used method for minimizing the number of gates or interconnections in computer circuits and chips: Quine 1952, 1955.)

A genuine Turing Test being out of the question, the competition used a highly restricted version: only one topic per conversation, and a non-probing conversational style on the part of the human judge. The programs (and hidden humans) were rated on how "human-like" they were, as well as on whether or not they were human. It turned out, to the judges' surprise, that some programs were mistaken for people—and vice versa!

Dennett eventually resigned as chairman of the prize committee, because they couldn't (then) be persuaded to toughen the test—to include fancier syntax and pronominal reference, for instance (Dennett 1998: 27–9). A few years later, the restrictions on topic hopping and probing were lifted. And the judges now include experts in NLP and other areas of AI.

But the competition still attracts little interest from AI professionals (although the 1997 prize was won by a team led by Yorick Wilks, a leading NLP researcher whose "preference semantics" was mentioned in Chapter 9.x.d). It won't make anyone's fortune. Even the intermediate prize will probably remain forever unclaimed, and achieving apparently human performance *in the general case* is impossible in practice (and perhaps also in principle).

More important, it's now recognized, at least by insiders, that the Turing Test isn't an appropriate way of judging AI's progress. This was made crystal clear in Turing's suggested landmark year. The Loebner prizewinner in 2000 was a program much nearer to ELIZA than to SHRDLU or LUNAR. And NLP research had already progressed hugely since all of those (Chapter 9.x–xi). In any event, AI's aim isn't *épater les bourgeois*. Highly human-like performance is only rarely required, even in technological AI.

The exceptions include certain applications of speech processing. Someone needing an artificial voice will normally want one that sounds as human-like as possible—not to deceive their interlocutors, but to put them at their ease. (I say "normally" because there is at least one such person who's said he doesn't want a human-sounding speech synthesizer: see 9.xi.g.) These voices may be not only humanlike, but plausibly idiosyncratic: early-millennial speech-synthesizers can pronounce written text in many different local accents (9.xi.g). Similarly, someone wanting a computerized "companion" may well prefer to hear a pleasing human-like voice, and familiar regional pronunciation (see 13.vi.d). In the general case, however, the Turing Test is irrelevant for AI.

Or rather, the Turing Test *as philosophers normally understand it* is irrelevant. In a recent issue of the *AI Magazine* devoted to a twenty-five-year retrospective on AI, one of the invited articles did indeed discuss the Turing Test. It even declared that "the test still stands as a grand challenge for artificial intelligence, it is part of how we define ourselves as a field, it won't go away" (P. R. Cohen 2005: 61). But its title was a give-away: 'If Not [*sic*] Turing's Test, Then What?' For the writer was arguing that "Turing's test is not irrelevant, *though its role has changed over the years* . . . [Among] AI researchers, the question is no longer, 'What should we do to pass the test?' but, 'Why can't we pass it?' " (italics added). These shifting attitudes to the TT in AI's professional community, despite its unchanged role in the minds of the general public (and most philosophers), have been noted also by Whitby (1996*a*) and by Robert French (2000). In short: although the test "won't go away", passing it isn't regarded as AI's core goal, or as the key criterion of its success.

After AI programs had entered the public domain, the AI community asked whether passing the Turing Test—even in the attenuated sense of a program's evoking trust in the user—is actually desirable (cf. Boden 1977, ch. 15). Professional codes of practice were suggested, to prevent the production of deceptively 'human' systems and to limit marketing hype (Council for Science and Society 1989; Whitby 1988). Marketing hype continued, nonetheless.

But the potential for deception depends on the sophistication of the user. An early medical-assistant program (dealing with issues in medical ethics) explicitly reminded its users that they might have relevant knowledge which it didn't, and that only they could make the decision required (Sieghart and Dawson 1987). Whether such warnings are appropriate at any given point in AI's history depends on what the users (in this case, medics and paramedics in Great Britain) can be assumed to know about AI.

This is why Turing's prediction about the 30 per cent fooling of "the average interrogator" failed. It might, perhaps, have been borne out in the underdeveloped world. But, by the year 2000, people in technological societies already knew too much about what computers can and can't do. A computer salesman accidentally connected to ELIZA today wouldn't ever reach the stage of raging at Bobrow.

Admittedly, language generation—needed for the imitation game—is still the least impressive aspect of NLP research (see Chapter 9.xi.c). Deception in other modes is sometimes possible. A real-time jazz improvisation system can fool many people for much longer than five minutes (Paul Hodgson, personal communication). A program can compose music indistinguishable (by all but experts) from that of Bach, and other famous composers (see Chapter 13.iv.b). And I've found that a program that interprets marks of expression in musical scores (a more complex problem than one might think: Longuet-Higgins 1994) can play Chopin's romantic Fantaisie-Impromptu in C sharp minor—which lasts about four minutes—so convincingly that even musically experienced AI researchers often can't tell that a computer is 'at the keyboard'. To be sure, the Turing Test (*sic*) allows *any* comparison, other than bodily form. But Turing's imitation game (*sic*) allowed only comparisons made via teletyped language.

By contrast, Turing's prediction about changing word usage came true long before he expected. By the turn of the millennium, the new usages had spread far beyond science. People now speak about computers in psychological terms as a routine, everyday, matter.

For instance, as Scriven (1953: 235) foresaw, they speak about "consulting" the computer, not just "using" it. Indeed, changes have occurred in the opposite direction too, computing terminology being used to describe human thought. My own favourite example (you probably have yours) came from the mouth of a British Museum curator of Pacific artefacts—hardly a paradigm member of the computer culture. While talking about how to tell indigenous peoples about the ways in which Aids spreads, she said of one suggested approach that "People just can't compute it."

But was psychological language being understood literally, when applied to computers? Had spontaneous belief and/or educated opinion changed, along with the use of words?

The sociologist Sherry Turkle tried to find out. In the late 1970s, when some children had already had regular access to computers for some years, she found that these youngsters were happy to describe computers as (really) "thinking" and "intelligent", but not as having "feelings" or "emotions", nor as being "alive" (Turkle 1984).

Some years later, when A-Life technology was widely available, she found that both children and adults still insisted that computers aren't "really alive, as we are" (Turkle 1995). But they vacillated (as well as disagreeing) over whether robots, and/or VDU-screen creatures, are alive merely as ants are, sort of alive, or not alive (though admittedly in control of their own movement). Sometimes, these distinctions were brushed aside with the remark "It's just a machine".

That is, the people interviewed by Turkle tried to draw a principled distinction between computers and human beings—though not necessarily in terms of *thinking*. But they often did so by giving mutually inconsistent definitions in different cases. The rest of this chapter outlines how philosophers of cognitive science have tried to address the man–machine distinction more rigorously—whether to insist on it or to deny it.

16.iii. Functionalist Freedoms

Functionalism was first defined as such by Putnam (1926–), in 1960. (He didn't actually use that word, but he did define mental events in terms of causal–computational functions, as we'll see.) But it had been more or less explicit in other thinkers too—who weren't professional philosophers, and whose work was read hardly at all by the philosophical community.

One shouldn't assume, then, that there were no functionalists before Putnam. However, all self-styled philosophical "functionalists" were inspired by Putnam's early work.

That word "early" is important. Many years later, Putnam would roundly reject his earlier approach, as we'll see in Section vi. Here, and in Sections iv–v also, "Putnam" means early Putnam.

a. Just below the surface

Functionalist approaches to mind were sketched as early as 1943 by McCulloch and Pitts, and also by Craik (see Chapters 4.iii–iv and vi, and 14.viii). I don't mean merely that their psychological research was functionalist in spirit. In addition, all of them engaged in explicitly *philosophical* argument, relating their work to the views of Kant, for instance, and to the nature of universals, cause, and number.

Craik, for example, repeatedly described his book as offering a new "philosophy" (see 4.vi.c). His position was as much brain-as-machine as mind-as-machine, for he identified "the nature of thought" as the use of cerebral models whose *physical* properties paralleled those of external reality. Anticipating the inevitable anti-materialist objections, he declared:

> [People who scorn materialism] deserve criticism for blindly refusing to consider whether things are always what they seem—whether their own powers of introspection are able to tell them the secrets of their own mental processes and whether many of their own acts are not very similar to those of the machines, natural and man-made, which lie all round them and which they will not take the trouble to understand. (Craik 1943: 98)

> [There] is something wonderful in the idea that man's brain is the greatest machine of all, imitating within its tiny network events happening in the most distant stars, predicting their appearances with accuracy, and finding in this power of successful prediction and communication the ultimate feature of consciousness. (p. 99)

And he drew a robust epistemological moral:

> Further, I see no difficulty in understanding how anything so "different" from physical objects and concepts and reasoning can tell us something more about those physical objects; for I see no reason to suppose that the processes of reasoning *are* fundamentally different from the mechanism of physical nature. On our model theory neural or other mechanisms can imitate or parallel the behaviour and interaction of physical objects and so supply us with information on physical processes which are not directly observable to us [and which may even be imaginary]. Our thought, then, has objective validity because it is not fundamentally different from objective reality but is specially suited for imitating it . . . (p. 99)

It followed that the classic questions of philosophy were to be interpreted in a new way. One example (out of many):

> Our question . . . is not to ask what kind of thing a number is, but to think what kind of mechanism could represent so many physically possible or impossible, and yet self-consistent, processes as number does. (p. 55)

Despite claiming to have glimpsed "the secrets of [our] own mental processes", however, Craik didn't explicitly address the hot topics outlined above in Section i. Or rather, he made many remarks about the *topics*, but very few references to the contemporary philosophical *literature*. (By 1943, of course, only two of the four key contestants had appeared on stage: see Section i.b.)

It's not clear that many philosophers of the 1940s read his work, although the Cambridge-based and scientifically minded Braithwaite and Margaret Masterman occasionally mentioned him. If they had, they might have found it highly suggestive. But they might not have afforded it the status of "yet another philosophy" (Craik

1943, p. vii) because, by philosophers' standards, Craik's argument wasn't sufficiently rigorous.

A functionalist approach was implicit also in Turing's *Mind* paper of 1950. And, in his anticipation of various objections, he said a little about some questions in the philosophy of mind. Even so, he didn't engage with the philosophical literature, and he deliberately avoided discussion of the currently competing 'isms'. Philosophers did read his paper, of course—indeed, they flocked to it in droves. But as we've seen, they focused on the semi-joking behaviourism, not on the wholly serious functionalism.

As a result, these early functionalist ideas were initially picked up by psychologists and computer scientists, not philosophers. By 1960, the Logic Theorist had been proving the theorems of *Principia Mathematica* for a full four years (see Chapters 6.iii.c and 10.i.b). Moreover, its authors explicitly denied that they were making any claims about the structure of the brain:

> Discovering what neural mechanisms realize these information processing functions in the human brain is a task for another level of theory construction. *Our theory is a theory of the information processes involved in problem solving and not a theory of neural or electronic mechanisms for information processing.* (Newell *et al.* 1958*a*; italics added)

In the terminology soon to be introduced by another functionalist philosopher, this was a statement of *multiple realizability*. That is, a psychological (computational) theory can be expressed, and may be true, without making any commitment whatever as to the physical mechanisms that implement it. Put baldly: psychologists can ignore the brain. Put more precisely:

> whether the physical descriptions of the events subsumed by [psychological] generalizations have anything in common is, in an obvious sense, *entirely irrelevant* to the truth of the generalizations, or to their interestingness, or to their degree of confirmation, or, indeed, to any of their epistemologically important properties. (Fodor 1974: 14–15; italics added)

Machine-inspired "structural explanation" had already entered both experimental and Freudian psychology (J. A. Deutsch 1953, 1960; K. M. Colby 1955). Internal models, enabling one to "go beyond the information given", were posited by the 'New Look' cognitive psychologists (Chapter 6.ii). And the provocative *Plans and the Structure of Behavior* was coming off the press (Chapter 6.iv). These writings teemed with philosophically relevant remarks. Even so, hardly any philosophers at the time had their eye on the computational ball.

Masterman did (and Braithwaite, too). But she was thinking about conceptual structure and language, not mental processes as such (Chapter 9.x.d). Across the Atlantic, Putnam did too—and he *was* concerned with the metaphysics of mind.

Many years later, he said, "I may have been the first philosopher to advance the thesis that the computer is the right model for the mind" (Putnam 1988, p. xi). Given the views of McCulloch, Craik, and Turing, perhaps he should rather have said he was the first *card-carrying* philosopher to do so. However, as a card-carrier he could offer the rigorous argument, and the attention to philosophical 'isms', which Craik couldn't. It's not surprising, then, that Putnam's work, unlike Craik's, *was* seen as "yet another philosophy". Functionalism, at last, had appeared above the surface of the water.

b. The shackles loosened

Putnam's statement of functionalism in 1960 was hugely influential. His paper on 'Minds and Machines' didn't catch philosophers' attention through informing them of technical results. For AI—including Putnam's own recent work on automatic theorem proving (10.iii.b)—wasn't even mentioned, though Noam Chomsky was. Rather, it excited them because it promised an escape from the mid-century philosophical impasse described in Section i.

Indeed, it dismissed the previous philosophies as "empty"—and irrelevant to scientific psychology. This was Putnam's verdict even on Smart's identity theory, which he saw as the best of a bad bunch. And, as though to put icing on the cake, his paper picked up Turing's gauntlet at last—treating the challenge not as a threat but as an inspiration.

Putnam studied at Princeton, taught philosophy of science at MIT in the early 1960s, and crossed the Charles River to Harvard in 1965. He was especially interested in the philosophy of logic and mathematics, and in computational logic too. For instance, it was he who proved that Chomsky's transformational grammar was equivalent to a Turing machine (see Chapter 9.vi.d). Moreover, his (LT-inspired) paper on computational theorem proving was cited in Marvin Minsky's 'Steps Toward Artificial Intelligence' (10.i.g), and later helped lead to resolution theorem proving in AI (10.iii.b).

Situated in Princeton and MIT, the leading centre for automata theory and AI, Putnam was well aware that these disciplines might have implications for psychology. Initially, he shared the positivists' belief in the "unity of science" (see Chapter 9.v.a, and Oppenheim and Putnam 1958). But he soon recanted, for his functionalist writings depicted psychology as a science in its own right.

Putnam argued that there's nothing metaphysically special about mind. Every mind–body puzzle, including subjectivity, would also arise in an automaton that could inspect some of its own states and reason inductively about them. Even introspective infallibility would be paralleled, if the machine's Turing table led it to print *I am in state A* whenever it entered state A: since this would be automatic, there would be no room for "mistake". As for souls, he tartly remarked that if dualism proves that people have souls, it proves that Turing machines do too—and he was as loath to ascribe souls to computers as Descartes had been in respect of "worms, gnats, [and] caterpillars" (see Chapter 2.iii.e).

So far, so negative. But to establish these conclusions, Putnam made five substantive claims:

* First, that human beings and other organisms are finite automata, describable by Turing machine tables—including input–output rules specifying the action of sensory/motor organs.
* Second, that these descriptions focus on the machine's (abstract) "logical" states, not its (physical) "structural" states.
* Third, that a given logical state "may be physically realized in an almost infinite number of different ways".
* Fourth, that the logical and structural descriptions of an automaton are analogous to psychological and physiological descriptions of a person.
* And last, that "further exploration of this analogy may make it possible to further clarify the notion of a 'mental state'".

In sum:

> The *functional organization* (problem solving, thinking) of the human being or machine can be described in terms of the sequences of mental or logical states respectively (and the accompanying verbalizations), without reference to the "physical realization" of these states. (Putnam 1960, sect. 3; italics added)

The "further exploration" was provided a few years later (1967*a*,*b*). Abstract Turing machines, Putnam then declared, could in principle be implemented in Descartes's mental substance, if it existed. Actual mental states, however, are in fact implemented in brain states. These may vary. The physiology of pain (for instance) in a dog, or an octopus, differs from ours. But pain as such is defined psychologically, or functionally, not physiologically.

It follows, he said, that psychological predicates can't be understood as Rylean dispositions (see Section i.c). On the contrary, functionalist analyses explain such dispositions. As for the Turing Test, this is unreliable because two very different programs might generate exactly the same behaviour.

Putnam admitted that his appeal to Turing machines was vague—not least because he held that *everything* is a Turing machine, under *some* description. (Both he and Searle would later use this point to attack functionalism: see Sections v–vi.) Even so, Turing machines—or programs—are much easier to study than brains are:

> This hypothesis, in spite of its admitted vagueness, is far *less* vague than the 'physical–chemical state' hypothesis [i.e. identity theory] is today, and far more susceptible to investigation of both a mathematical and an empirical kind. Indeed, to investigate this hypothesis is just to attempt to produce "mechanical" models of organisms—and isn't this, in a sense, just what psychology is about? (Putnam 1967*b*: 435)

Moreover, computer models appeared to carry scant metaphysical baggage. The causal relations between hardware and software seemed to be clear, unlike those between "mind" and "body". (This happy assumption would eventually be questioned: see Section ix.c–f.)

The relevant computational models, said Putnam, should simulate not only perception and motor action but also reasoning, preferences, values, and beliefs. The implication was that a scientific psychology would broadly conserve the psychological relations implicit in everyday language.

These include specific conceptual links, such as those between *pity*, *help*, and *comfort* (see Section i.c), and the general architecture of rationality that's presupposed by the language of intention, accident, and excuse (cf. Austin 1957). But whereas the ordinary-language philosophers saw these relations as conceptual, Putnam saw them as explanatory. He even hoped to find some "normal form" for psychological theories, so that animals' hunger, aggression, and pain (though not their physiology) could be explained in much the same way as ours.

Functionalism, then, was not only a philosophy of mind but also an empirical theory—or rather, a 'schema' for generating empirical theories—about mental states and processes. Such a combination was highly suspect in certain circles, being seen as an example of scientism: the view that scientific facts are metaphysically fundamental, and that all important questions have some scientific answer (Stenmark 2001; cf. N. Maxwell 1984).

Putnam, following his teacher Quine (1908–2000), who favoured a "naturalized epistemology" (Quine 1952), saw philosophy as continuous with science. But Wittgensteinians didn't. He'd already crossed swords with them on the subject of dreaming, arguing—contra Malcolm—that novel scientific discoveries (in this case, REM sleep) may affect the meanings of everyday concepts (1962*a*).

Moreover, he'd already answered Turing's question (see Section ii) in much the same way. Although it's "false" or "improper" to say *baldly* that machines think, or use language, the strong analogy between digital computers and human behaviour makes it reasonable to extend the meanings of those words to cover both (Putnam 1960). Now, in his discussion of 'Psychological Predicates' (later retitled 'The Nature of Mental States'), Putnam was imbuing *all* psychological vocabulary with ideas drawn from computer science.

For philosophers not dismayed by charges of scientism, functionalism was a heady liberation. It promised to loosen the shackles imposed by the problems mentioned in Section i, and some remarked in Section ii.

Not all post-1960 versions of it were solely, or even partially, inspired by Putnam. Fodor's functionalism, for instance, owed much to Chomsky and Jerome Bruner as well as to Putnam (his tutor). Kenneth Sayre's maverick version leant on cybernetics more than on logic and AI (Sayre 1965, 1969, 1976). And my own followed Masterman and *Plans and the Structure of Behavior* (Boden 1965; 1970; 1972, esp. 52–9; and see Preface, ii).

But Putnam's functionalism, which focused on the metaphysical questions without referring to specific empirical data, was hugely important for many philosophers. It licensed talk about mind, while avoiding metaphysically mysterious events, processes, or substance. And it offered many other freedoms, too.

For instance:

* It underwrote the explanatory links between (and within) mind and body that we normally take for granted.
* Thanks to multiple realizability, it saved the main claim of identity theory (that each mental state is identical with some brain state), without stating—falsely—that all mental states of type *x* type are identical with brain states of type *y*.
* It was consistent with materialism but left space for an autonomous, non-reductionist, psychology—intentionality being grounded in causal–computational mechanisms.
* It ruled out psychological behaviourism,
* while saving the subtle conceptual analyses of logical behaviourism.
* But it reinterpreted these analyses as explanatory, identifying mental states in terms of their mutual causal relations.
* It valued what Dennett (1981*a*) would later call "folk" psychology, seeing our everyday talk as a proto-theory, a starting point for scientific study of both human and animal minds.

* Above all, it promised a novel research programme (for both philosophy and psychology) that was free to exploit the rigour, richness, precision, and testability of computational theories and models.

It's no wonder, then, that—for audiences leaning towards science—this new player swept its predecessors from the philosophical stage. Turing was posthumously promoted from spear-carrier to matinée idol, and functionalism soon became the orthodox position in the philosophy of cognitive science.

It wasn't universally applauded, to be sure. Quine, for example, held that psychology is *not* autonomous, because belief–desire vocabulary is in principle reducible to non-intentional terms (Quine 1953*b*, 1960). Others complained that functionalism can't allow for consciousness. Yet others were radically opposed to the entire 'scientistic' project. Some of these objections will be discussed in Sections v–viii.

First, let's look at some of the ways in which functionalism was expressed by its supporters.

16.iv. Three Variations on a Theme

Even orthodoxy allows reinterpretation. Functionalism is "the thesis that the essence of our psychological states resides in the abstract causal roles they play in a complex economy of internal states mediating environmental inputs and behavioral outputs" (P. M. Churchland and Churchland 1981: 121). But this general thesis developed into many mutually disputatious positions.

The most influential philosophers of functionalism, *post* Putnam, were Fodor, Dennett, Paul and Patricia Churchland, and Andy Clark (whose PDP-based philosophy was discussed in Chapter 12.x.e).

Other important accounts, functionalist in spirit if not in philosophical jargon, were offered by Chomsky (Chapter 9.ii–vii), Allen Newell and Herbert Simon (Section ix.b, below), and—later—Minsky (Chapters 7.i.g, 10.i.f, and 12.iii.d). Their scientific research influenced all the philosophers described in this section. (Sloman developed an interesting version in the 1970s too, but this was less influential than it deserved: see Section ix.c, below.)

The late 1960s saw extended statements of functionalism being provided by Fodor (1935–) and Dennett (1942–). Both men eventually became famous—even notorious. But their near-simultaneous books were very different. In part, the differences reflected the fact that Fodor was a cognitive scientist with a strong interest in philosophy, whereas Dennett was a philosopher with a nascent interest in cognitive science.

Fodor was an interdisciplinary animal. He had a joint appointment in psychology and philosophy at MIT, had attended both Chomsky's and Bruner's seminars in the late 1950s, and gave detailed tutorial seminars on Chomsky's *Syntactic Structures* at that time (Chapters 6.i.e and ii.b–c, and 9.viii.c). His first book, *Psychological Explanation* (1968), defended this new type of research. It supported Putnam's claims about multiple realizability and the autonomy of psychology, and spelt out the notion of "functional equivalence" in theoretical psychology. With respect to the philosophy of mind in general, it accused Ryle and Wittgenstein of conflating mentalism and dualism (see Section i.c).

His arguments against behaviourism were well received by sympathetic souls. But for those who'd already rejected it, there were no eye-openers here. Later, Fodor would offer surprises aplenty, with the publication of *The Language of Thought* (1975). Before then, the surprises came rather from Dennett.

a. Content and consciousness

When Dennett's book hit the scene in 1969, he himself was a surprise. Teaching in California since leaving Oxford in 1965, he was still unknown. His first three papers had appeared only a few months earlier, and were critiques of others—including Dreyfus (Dennett 1968)—rather than free-standing statements of his own position. Now, *Content and Consciousness* addressed the topics that would preoccupy him throughout his career: intentionality, consciousness, free will, evolution, and the comparison between human and animal minds.

Integrating challenging philosophical claims with wide-ranging scientific argument, many readers found it an exhilarating book. I remember writing to this total stranger across the seas, to say so—one of only four times I've ever done that. Anti-functionalists, it must be said, demurred. The *Times Literary Supplement* ran a damning review by a Wittgensteinian, who described it as "not a happy piece of work" and complained about the "many references to scientific findings and, it must be confessed, scientific speculations" ([Hamlyn] 1970). (This anonymous review was written by the philosopher of psychology David Hamlyn: Dennett, personal communication.) But many others were excited.

The central-state materialists welcomed this new version of centralism. So Smart, asked by Ryle to review it for *Mind*, decided to write a Critical Notice instead, and a fellow Australian did likewise (Smart 1970; R. L. Franklin 1970). In the USA, Thomas Nagel (1970) wrote a sympathetic, though unconvinced, review—and Gilbert Harman immediately ran a seminar on the book at Princeton. (Harman had already published on the psychological implications of Chomsky's work, and he later co-founded Princeton's Program/Laboratory for Cognitive Science with George Miller: Harman 1988.)

Dennett was soon invited to speak to Harman's group (his first public presentation) and elsewhere, so ending his "five anonymous years of apprenticeship" at Irvine. (He moved to Tufts University in the early 1970s, where he's remained ever since.) His 1969 book, and the paper he read at Princeton in December 1970, set much of the agenda in the philosophy of cognitive science for years ahead.

Dennett was nothing if not heretical. Despite being deeply influenced by Ryle (his ex-tutor) and Wittgenstein, he disagreed with them in important ways. He posited a "sub-personal" (functionalist) level of explanation as the key to understanding mental phenomena, and saw meaning as rooted not in public language and society but in mechanisms evolved in human and animal brains. He disagreed with Putnam, too. He leant heavily on Putnam's logicist account of minds as Turing machines, and often used AI examples in discussing sub-personal mechanisms (e.g. Dennett 1969: 101–13). However, the "functions" he was most interested in weren't purely logical, or even causal, but at base evolutionary (see below).

Moreover, he refused to identify thoughts with either functional states or brain states. To identify *x* with *y* is to say that both terms refer to the same thing—but Dennett argued that mentalistic terms don't refer to anything at all. *Thought*, *belief*, *intention*, *fear*, even *pain*: all these are non-referential (like the word *sake*, in "She did it for my sake"). Specifically, they are items in a mode of discourse we use to ascribe meaning, not to discover it. To be sure, "people *do* have beliefs, intentions, and so forth" (and machines don't: "a computer is no more *really* an information processor than a river *really* [desires to reach the sea]") (Dennett 1969: 89–90). But meaning, or content, isn't an extra item over and above bodily behaviour or brain states.

Here, Dennett was leaning on Quine (1908–2000) and on Wilfrid Sellars (1912–89). Sellars had distinguished the "manifest" and "scientific" images of man (1956). The former sees people as having beliefs, desires, and intentions, while the latter describes them in terms of physics and neurophysiology. These two images were seen by Sellars as distinct logical "spaces"—of reasons and of causes, or norms and facts. They provided different ways of talking about people—with no guarantee of a neat mapping between the two. And no guarantee, either, of reliability: Sellars specifically attacked "the myth of the Given", according to which experiential "data" are an unassailable foundation for knowledge (see Section viii.b).

As for Quine, he'd already argued that the language of belief and desire is an "essentially dramatic idiom" (Quine 1960: 219). Although Quine was Dennett's other philosophical mentor (besides Ryle) (Dennett 1994*b*), Dennett rejected his view that intentional language is in principle reducible to physics. If we stopped using this language, said Dennett, no existing thing need be ignored. But we could no longer interpret anything as meaningful.

Such interpretations assume rationality. When we say that someone carrying an umbrella wants to keep dry, we presuppose a rationally interrelated set of meanings which result in "appropriate" behaviour. This insight wasn't new: we saw in Chapter 5.iii.a that Thomas Dewey and Ralph Perry had said it long before. And (following Wittgenstein) Elizabeth Anscombe (1957) and Charles Taylor (1964*a*) had said it more recently.

But whereas Anscombe and Taylor had taken it for granted that meaning is intrinsic to people and/or language, Dennett asked what it is about human beings that makes it 'natural' to ascribe meaning to them. His highly unfashionable answer, in a nutshell, was: brain states and evolution.

The "crux" of any centralist theory of mind, he said, is "the ascription of content or meaning to particular central states of the brain" (Dennett 1969: 71). For Dennett, this couldn't be done (as both Putnam and Smart had tried to do) by assigning the content of mental states to the relevant brain states: the semantic traffic goes in the opposite direction.

The semantic content of neural states, for Dennett, is based in evolutionary function (pp. 48 ff.). And since evolution works on whole organisms, "one can only ascribe content to a neural event, state or structure when it is a link in a demonstrably appropriate chain between the afferent and the efferent" (p. 78). In calling a retinal cell a bug-detector, for example (see Chapter 14.iv.a), it's crucial that it's linked to a motor circuit that causes the frog's sticky tongue to shoot out appropriately (*sic*) or its leg muscles to make it jump to the right (*sic*) place.

Moreover, neural content is the basis of linguistic meaning:

> [Philosophers have asked] whether events and states of the nervous system could be assigned meanings or ascribed contents, and assigning meanings was seen as associating events or states

with verbal expressions. Verbal expressions, however, are not the ultimate vehicles of meaning, for they have meaning only in so far as they are the ploys of ultimately non-linguistic systems. (Dennett 1969: 88)

To posit meanings in the brain wasn't to posit languages in the brain. Dennett criticized scientists' talk of "brain-writing", and of neural "codes" and "languages", because it usually relied on unexplained mechanisms for understanding such languages (pp. 86–8). This, he said, is to postulate "little men" in the brain. (Bruner and Ulric Neisser had already argued that computational theories could avoid homunculism: see Chapters 6.ii.c and 7.i.b. But they hadn't focused on the problem of meaning, or intentionality, as such.)

As for comparing the brain to "a community of correspondents", this—said Dennett—was "the most far-fetched and least useful" of all the common analogies, since it appears "merely to replace the little man in the brain with a committee". (Ironically, he would later favour Minsky's "society of mind" in his mature theory of consciousness (Dennett 1991): see 12.iii.d.)

This Rylean disdain for homunculi extended also to philosophers' talk of *acts of will*, *volitions*, and the *self* (and to ego, id, and super-ego), when presented as "explanations" of mental life. In Dennett's words: "The solitary audience in the theatre of consciousness, the internal decision-maker and source of volitions or directives, the reasoner, if taken as *parts* of a person, serve only to postpone analysis" (p. 190).

However, to assign a neural basis to linguistic meaning wasn't to say that mental states could be neatly mapped onto neurophysiology: "[we cannot] find precisely worded *messages* for neural vehicles to carry . . . [but this] is merely an inability to map the fundamental onto the derived, and as such should not upset us" (p. 88). It will upset us, however, if we hope that neuroscience will eventually identify the neural vehicles of particular propositional attitudes.

Besides multiple realizability and the complexity of the brain, said Dennett, there's the difficulty that intentional vocabulary "has no real precision of its own". We talk about beliefs, for instance—but just what is it to believe a proposition? How many of its logical implications are involved? And just what does a child believe who announces "Daddy is a doctor"?

These questions, for Dennett, can have no clear answers. His account of belief resembled Wilhelm von Humboldt's of language (Chapter 9.iv.b). That is, what we call the "same" belief is probably different in every individual—and, even more important, can't be precisely pinned down in any particular case.

Despite insisting that ordinary-language terms like *belief* and *desire* are unavoidably imprecise, Dennett didn't deny their usefulness. His view on *conscious* and *aware* was very different:

[The philosopher who seeks to understand consciousness is] forced to do psychology rather than "pure" philosophy.

. . . Can a machine be conscious? This question cannot be answered until we arrive at a conclusion about what it is to be conscious, and ordinary language does not tell us . . . [We need] more than a solution to a conceptual problem via analysis of language, for language is deficient in this area. The way out is an analysis of phenomena at the sub-personal level, and although this leads one into areas many philosophers would prefer to avoid, the alternative is the perpetuation of traditional confusions. (p. 130)

The question *What is consciousness?* has no single answer, because this term is irredeemably confused, "an unhappy conglomerate of a number of separable concepts" (p. 114). Philosophers have assumed ever since Descartes that it's the most accessible concept of all. In fact, said Dennett, it's useless for philosophical or scientific purposes and should be replaced by new concepts that make the relevant distinctions clear.

Among the cases marked by the everyday term are those where someone can give an introspective report of their current thought, and those where they're evidently affected by some stimulus but can't report it (like the car-driver who negotiates a corner while engrossed in conversation). Dennett offered two new concepts, defined by sub-personal criteria, to distinguish such cases.

Following Putnam's example of the introspective automaton (see Section iii.b), he suggested that some functional systems—such as human brains—include a "speech centre". If a mental state is input to that centre, the immediate (Turing-tabled) output is a verbal expression whose content is the same as the content of the input state. This expression, when input to other subsystems, will cause further changes. Often, it leads to speech movements; but these may be inhibited, as in reading silently or simply keeping one's own counsel. For such a system, two senses of awareness can be defined:

(1) A is aware-1 that *p* at time *t* if and only if *p* is the content of the input state of A's "speech centre" at time *t*.
(2) A is aware-2 that *p* at time *t* if and only if *p* is the content of an internal event in A at time *t* that is effective in directing current behaviour. (pp. 118–19)

The sub-personal processes involved in awareness-2, said Dennett, may be very like those in AI models of perception, language, and problem solving (p. 151).

As for whether dogs and other dumb (*sic*) animals are conscious, we must distinguish the two senses. Understood as aware-2, animals are indeed conscious—sometimes, in highly discriminating ways. But understood as aware-1, they are not: in this sense of the term, only language-using creatures can be conscious.

So far, so good. Dennett's distinction was useful when applied to human beings, and even seemed to make retrospective sense of Descartes's views on animal consciousness (Chapter 2.ii.d–e). But there was a sting in the tail—or rather, two.

First, it followed that computers could be conscious. A computer can clearly be aware-2 of things. And it can also be aware-1, if it is set up so as to give verbal reports of some of its internal states. Dennett was unabashed:

> [This] may seem to be an intolerable situation, but only if one clings to the folklore that has accrued to the ordinary word "aware" . . . [There] is no important residue in the ordinary concept of awareness that is not subsumed under either awareness-1 or awareness-2. There is no room . . . for a concept of awareness-3, which would apply only to people and rule out all imaginable machines. (p. 121)

Second, it followed that there are no conscious epiphenomena, no experiential qualities, pure sensations, raw feels, or *qualia*. These denizens of the mind, about which there had been so much argument (see Section i), were mere metaphysical phantoms. This conclusion had been implicit in Putnam's functionalism, but Dennett (like Ryle before him) was resolutely explicit.

Even pain, he insisted, is a wholly functionalist phenomenon:

> Where discriminating is an analysable personal activity, like discriminating good apples from bad by checking for colour and crispness, we can distinguish the qualities from the discriminating of them. But in the case of distinguishing sensations as painful, the act of discrimination itself is the only clue to the localization (in space and time) of the presumed quality. Insisting that, above and beyond our ability to distinguish sensations as painful, there is the quality of painfulness, is thus insisting on an unintelligible extra something. (p. 92)

His comment here was reminiscent of Wittgenstein's, that "a nothing would serve just as well as a something about which nothing could be said" (see Section i.c). For Dennett, if there is no further function there is indeed nothing more to be said. But at the personal level, a verbal expression of pain is "a *bona fide report*", not—*pace* Wittgenstein—"an outcry of sorts" (p. 112 n.). (Some years later, Dennett would argue that the concept of pain is actually incoherent—and that *this* is the reason why one can't build a computer to feel pain: 1978*a*. See also Wall 1974, 1979.)

b. From heresy to scandal

Dennett's multiply heretical volume was strong meat—and a strong sauce would soon be added. Most early discussions of his position considered not just his book but also (sometimes, only) the paper first given at Princeton (Dennett 1971). The book had named two explanatory styles, or "stances" (e.g. p. 101): personal (intentional) and sub-personal (functional/physical). The paper named three: intentional, design, and physical.

The physical stance seeks explanations couched in physical, or purely neurophysiological, vocabulary. This is often infeasible in practice, even where artefacts are concerned, and is functionally uninformative in principle. Indeed, neurophysiologists were already using non-physical concepts, such as bug-detectors and orientation detectors (Chapter 14.iv).

The design stance, by contrast, "relies on the notion of *function*, which is purpose-relative or teleological" (Dennett 1971: 88). It's a form a reverse engineering, which assumes that the system is well, even optimally, designed to perform certain tasks. Artefacts, computers included, are typically understood in this way. The design stance can operate at various levels of abstraction, such as electronic circuitry, transistors and switches, multipliers and dividers, strategic units (like planners and line-finders), or programmed instructions. In other words, there may be many different levels of virtual machine (see Section ix.c).

But Dennett held that natural systems can be understood in this way too. Indeed, the design stance is "the proper direction for theory builders [in psychology and neuroscience] to take whenever possible" (1971: 96). Not only does it avoid unanalysed ascriptions of intelligence, but it can compensate for the *lack* of rationality that bedevils actual intentional systems.

The intentional stance was defined as before. But there were four reinforcements of points already made in *Content and Consciousness*.

First, Dennett declared that "Intentional theory is vacuous as psychology because it presupposes and does not explain rationality or intelligence", and wherever a theory uses intentional language, "there a little man is concealed" (Dennett 1971: 99, 96).

Second, he enlarged upon the fact that people's "rationality" is limited, which causes both principled and practical difficulties in assigning beliefs and desires to individuals. Third, he stressed the instrumental status of intentional discourse, as interpretation not discovery: "a particular thing is an intentional system *only in relation to the strategies of someone who is trying to explain and predict its behaviour*" (Dennett 1971: 87; italics added). And last, he pointed out that it was already impossible, even for the system's designer, to explain or predict the behaviour of the best chess-playing computers except by using intentional vocabulary.

To say of the computer that *It's trying to get its queen out early* is thus not an avoidable metaphor, but the only practicable way of understanding its performance. This description is (pragmatically) justified, even though there may be no specific programmed instruction, or program goal, to *get the queen out early*. The instructions and goals, whatever they are, were designed (*sic*) to have this overall effect. Nevertheless, even the programmer can't remember and/or run through the relevant rules so as to understand what's going on or predict what's likely to happen next.

Previously, Dennett would have said that no computer can *really* try to get its queen out early (see above). Now, he insisted:

> Lingering doubts about whether the chess-playing computer *really* has beliefs and desires are misplaced; for the definition of intentional systems I have given does not say that intentional systems *really* have beliefs and desires, but that one can explain and predict their behavior by *ascribing* beliefs and desires to them, and whether one calls what one ascribes to the computer beliefs or belief-analogues or information complexes or Intentional whatnots makes no difference to the nature of the calculation one makes on the basis of the ascription. (Dennett 1971: 91)

All very moderate, perhaps . . . until one realized that human beings were being classified as intentional systems *in just the same sense*. His ready admission that even the best computers were crude and narrow-minded, by human standards, didn't alter that.

Understandably, Dennett's provocative views sparked lively debate, both inside and outside the functionalist camp. His scandalous dismissal of *qualia*, in particular, aroused huge dissent (see Chapter 14.xi.b). Nagel, for instance, believed that no objective science could possibly explain the subjectivity of consciousness. Hence his unconvinced review of Dennett's first book (1970), and his memorable paper 'What Is It Like To Be a Bat?' (1974)—later answered by one of Dennett's students with 'What Is It Like To Be Boring and Myopic?' (Akins 1993).

Today, with respect to *qualia*, Dennett remains in the minority. But he's not alone. Sloman, for many years, has analysed consciousness in terms of a complex virtual machine—and *qualia* as computational phenomena within it (Sloman 1978, 1999; Sloman and Chrisley 2003).

At the end of the century, with most of his professional colleagues and lecture audiences still unpersuaded on *qualia*, Dennett would tell the (true) story of a card trick called 'The Tuned Deck'. This trick bemused even groups of expert magicians for many years. As an old man, its inventor revealed the secret: instead of creating *one exceptionally ingenious* card trick, he had craftily hopped about between *many familiar* ones. Once his expert audience had discounted trick A, because he'd fooled them into expecting it just before using trick B, he could use trick A at any time without their noticing it—and similarly for tricks B to Z.

'Pure' experience, for Dennett, is eternally elusive for much the same reason. Once we have detailed *all* the many functions—verbal naming and description, discriminatory behaviour, emotional responses, conceptual associations . . .—involved in seeing red, or smelling lilac, *nothing more remains* to be explained. By the same token, he now says, if you took a pill to get rid of only your toothache's *qualia* but not its causal effects—neural stimuli, wincing, rubbing your jaw, lack of concentration, bad temper . . .—then *you wouldn't even know*.

Dennett has become convinced, however, that disagreements on this issue are often rooted in a clash of intuitions quite impervious to argument (lecture at University of Sussex, May 2000). He's penned various imaginary conversations with a common-sense sceptic called Otto (one was given in Chapter 14.xi.b). But Otto is never persuaded, despite Dennett's responding to every one of his outraged objections.

Dennett put other issues on the agenda, too. His comments on the imprecision of belief led some functionalists to recommend that cognitive science abandon folk-psychological language entirely (P. M. Churchland 1979; Stich 1983). And his instrumentalism with respect to mental states—along with his "flagship" renunciation of it (in terms of "real patterns", and "*abstracta*" such as centres of gravity) (1981*b*; cf. 1987: 3)—caused gallons of ink to be spilled.

(Most of that ink was philosophical. But psychologists' pens were eventually wielded too. The intentional stance was applied in empirical studies of the "Theory of Mind" in young children, non-human primates, and other species: see Chapter 7.vi.f.)

Several of Dennett's later works received enormous attention (e.g. 1978*b*, 1987, 1988, 1991, 1996). This was especially true of his "multiple drafts" theory of consciousness, which pictured the mind as a virtual machine vastly more subtle (and more scientifically grounded) than his aware-1/aware-2 distinction had done (see 14.xi). A notorious aspect of his theory of consciousness was his attack on *qualia*; this had been a long time a-brewing, for it was first delivered late in 1978 and was widely circulated in draft before being published ten years later. Only his analysis of free will (1984*a*), in my opinion, received less regard than it deserved (see Chapter 7.i.g).

Today, the debate still rages: for an indication, see *Behavioral and Brain Sciences* (1988); Dahlbom (1993). But despite the elaboration of his views on consciousness, there's been no fundamental change in Dennett's position. On rereading *Content and Consciousness* after twenty years, he commented: "I am struck more by my doctrinal consistency than by my developments. Most of the changes seem to me to be extensions, extrapolations, and further arguments, not shifts" (1987, p. xi) (see also Dennett 1994*b*).

c. Must angels learn Latin?

In the 1970s, while Dennett's early writings were setting the philosophy of mind alight, Fodor was continuing his own attack on the Ryle–Wittgenstein approach (Fodor 1975: 2). His first book had appeared shortly before Dennett's, as we've seen. But his visibility soared in 1975, when his volume on *The Language of Thought* offered a form of functionalism very different from Dennett's.

It differed partly in its philosophical claims and concerns, for it was unambiguously realist about mental states and it ignored consciousness and freedom. But it differed also in its attitude to the practice of cognitive science.

Dennett had used chess programs and memory research as examples, but he wasn't especially concerned to help cognitive scientists do their job. Or rather, his help consisted in trying to dispel the conceptual confusions he felt they shared with many philosophers. Only much later would he collaborate closely with psychologists, ethologists, neuroscientists, and roboticists (see e.g. Dennett 1994*a*, 1996, and Chapter 15.vii.a). Fodor, by contrast, was committed to computational psychology and to Chomskyan linguistics, as such.

His early work referred to highly detailed research on perception, concept learning, decision making, problem solving, and—above all—psycholinguistics. He was a leading champion of Chomsky, and had already co-authored a textbook on the psychology of language (Fodor *et al*. 1974). He was also inspired by GOFAI, though more for its reliance on formal symbolism than for its modelling of specific mechanisms. And he adopted—and never relinquished—the implication of Putnam's 1960s papers, that "we have no reason to doubt that it is possible to have a scientific psychology that vindicates commonsense belief/desire explanation" (Fodor 1987*b*: 16).

In short, Fodor took the dual role of functionalism—as philosophy and theoretical psychology—especially to heart. That had been evident in his first book (1968), but it was even clearer in *The Language of Thought*. This aimed to provide clear theoretical underpinnings for the cognitive revolution already under way. It was a paradigm of 'classical', formalist, cognitive science. For it described intentional processes as syntactic operations defined on mental representations (see also Fodor 1978*b*).

This view was boldly presented as the only "even remotely plausible" candidate for a scientific psychology. There was no middle way, either then or later. At century's end, Fodor had developed serious doubts about whether all mental processes are computations. Nevertheless, he still held the same opinion about what a scientific psychology must be like: "[computational psychology] is far the best theory of cognition that we've got; indeed, the only one we've got that's worth the bother of a serious discussion" (Fodor 2000*b*: 1).

The book quickly became influential, even infamous. Like Newell and Simon before him (1972), Fodor insisted that the mind (or brain) is "literally" a computational system. Functionalist talk shouldn't be, though it often was, interpreted as a mere *façon de parler* (1975: 51, 76). And he drew two major implications, summarized as "no computation without representation" and "there's no point in angels learning Latin" (pp. 34, 86).

The first of these, if not the second, might prompt one to ask "Why the fuss?" After all, cognitive psychologists, Chomskyan linguists, and functionalist philosophers had been positing computation and internal representations for over fifteen years.—Yes, said Fodor, but they hadn't been clear about what these are. They hadn't realized that "Computation presupposes a medium of computation: a representational system," and that "The pressing question is what properties does the system of internal representations have." This wasn't a purely philosophical question: the answer must fit the facts, as any scientific theory must do (pp. 27, 33, 156).

Even this may seem fairly anodyne. But Fodor also said:

> [What] I am proposing to do is resurrect the traditional notion that there is a "language of thought" [later often referred to as LOT] and that characterizing that language is a good part of what a theory of the mind needs to do. (1975: 33)

That was guaranteed to raise many hackles. As we saw in Chapter 9.ii–iv, philosophers in past centuries had posited an internal language of thought to explain adult reasoning and/or to explain how children manage to learn their mother tongue. To adopt the first goal would upset the Wittgensteinians, who saw no room for any level of explanation between natural language and neurophysiology (which they assumed wouldn't employ any computational notions): see Section v.f, below. To adopt the second would outrage not only Wittgensteinians, with their commitment to public language, but also empiricists—who had already attacked Chomsky's nativism con brio (Chapter 9.vii.c). Never one to fear controversy, Fodor adopted both.

His central claim about mental representations was uncompromising, and very different from Dennett's:

> [Modern cognitive psychology assumes that] the computational states ascribable to organisms can be directly explicated as relations between the organism and *formulae*; i.e. formulae in the internal code . . . [And, even more importantly, it assumes that] for any propositional attitude of the organism (e.g. fearing, believing, wanting, intending, learning, perceiving, etc., that *P*) there will be a corresponding computational relation between the organism and some formula(e) of the internal code such that (*the organism has the propositional attitude if the organism is in that relation*) is nomologically necessary. (p. 75)

These formulae, said Fodor, are required not primarily for (public) communication, but for representing concepts, goals, and the like. Even animals, if they can represent such things, must have a language of thought. Internal representations are real structures, apt for discovery rather than mere interpretation. They are composed of atomic primitives, whose computational (semantic) properties determine the properties of the whole—as in the formulae of symbolic logic, or the sentences of natural language.

As for just what those primitives might be, they certainly included the basic concepts of the *innate* language of thought. And if his early 1960s work in generative semantics (Chapter 9.viii.c) had been correct, these would suffice (see below). However, worries about computational efficiency had now convinced him that natural-language words can't, in practice, be analysed into semantic atoms every time they're used. Rather, they're still present (as *functional* primitives) in the adult's internal code:

> [There] is no process for [analytic] definition *at all*; i.e., both the defined expression and its definition appear as items in the primitive vocabulary of the representational system. (1975: 133)

> Learning a definition principally involves learning a meaning postulate. It thus adds to the constraints (not on computing memory but) on long-term memory; it adds a rule of inference to the list that is stored there. That is why . . . abbreviatory definition and other recoding schemes make formulae easier to understand: Computing memory is expensive, but long-term memory is cheap. (p. 150)

In other words, an adult's language of thought includes all the words they know in their mother tongue. Hence Fodor's wry salute to his philosophical opponents: "There may, then, really be some point to the late Wittgensteinian insistence upon the surface richness of natural languages" (p. 156).

He also conceded that recent psychological research on the nature of concepts seemed to support the later, rather than the earlier, Wittgenstein (see Chapters 8.i.b and 9.x.d). That is, concepts appeared to be stored as stereotypes, exemplars, or even images rather than definitions. But he saw this as "terribly difficult", asking "How, for example, does one *access* an exemplar? If your concept of a dog is . . . a representation of a stereotypic dog, how do you go about determining what *falls under* the concept?" (p. 153). Ten years later, PDP connectionism seemed to many people to have answered his question (see 12.x). But Fodor was unconvinced, and later defended a strictly atomistic theory of concepts (Fodor 1998*a*).

Just what representations are actually involved in thinking was still unclear. Fodor allowed that they might include images (1975: 174–94). But although visual imagery could be a "vehicle of reference" it couldn't be a "vehicle of truth"—in other words, a thought. Thought, he said, is the ascription of properties to things, and is essentially propositional and rational: "The sequence of events that causally determines the mental state of an organism will be describable as a sequence of steps in a derivation if it is describable in the vocabulary of psychology at all" (p. 198).

This claim carried another surprise. Putnam had implied that all mental states, and a fortiori all propositional attitudes, are grist to the functionalist mill. But Fodor denied this. For him, psychology required computational causes. It included perception and concept learning, since these (or so it was thought at the time: see below) involved the generation and testing of hypotheses. And it might include some Freudian examples (p. 200), such as neurotic beliefs semantically generated by defence mechanisms (Chapter 7.i.a). But much of our most systematic and interesting mental life, he argued, was probably excluded.

Sensation, he said, isn't caused by computation. Creative thoughts might not be. Many associative processes probably aren't. And nor are emotional influences on perception and belief. Such matters might be explained by biology (neurophysiology), but not by psychology. In sum, functionalism's scope had been significantly reduced: "It may be that we are laboring in quite a small vineyard" (p. 202).

What about the notoriety? This arose because Fodor claimed that the innate language of thought was "as powerful as any language that one can ever learn" (p. 82).

He confessed that this claim was "scandalous", but insisted that no serious alternative had been proposed: "The only coherent [account of language learning] is one which presupposes a very extreme nativism" (p. 96). Human babies don't have adult concepts—such as *air-plane*—ready-formed. But they are born with the representational capacity (concepts and combinatorial operations) to express the meaning of any concept that can be learned later (p. 152). More accurately, they're either born with these concepts and operations or they mature, biologically, so as to attain them. What they do *not* do, is learn them.

Fodor's argument for this highly counter-intuitive position leant crucially on Bruner's research on learning and Chomsky's views on innate grammar (see Chapters 6.ii.b and 9.vii). Following Bruner, he saw concept learning as "essentially inductive extrapolation, [which] presupposes a format for representing the experiential data [and] a source of hypotheses for predicting future data" (p. 42). Since language learning involves learning not only what counts as a sentence but also the semantics of the vocabulary, it follows (he said) that "one cannot learn a first language unless one already has a system capable of representing the predicates in that language" (p. 64). Every word must be translatable into the innate language of thought, even though (as remarked above) it isn't normally translated into it.

The very possibility of an innate language, whatever its representational power, was highly controversial. Ryleans would scent an infinite regress of understanding (Dennett's "little man"), and Wittgensteinians would reject any pre-cultural private language. Fodor countered both objections by a brain–computer analogy:

> though the machine must have a compiler if it is to use the input/output language, it doesn't *also* need a compiler for the machine language. What avoids an infinite regression of compilers is the fact that the machine is *built* to use the machine language. Roughly, [the formulae of the machine language] correspond directly to computationally relevant physical states and operations of the machine . . . (p. 66)
>
> On this view, what happens when a person understands a sentence [in a language he has learned] must be a translation process basically analogous to what happens when a machine "understands" (viz., compiles) a sentence in its programming language. (p. 67)

He used this computer analogy also to explain why babies have to learn their mother tongue—even though, according to him, they already have the capacity to represent the meaning of every dictionary word. People need natural languages for much the same reasons that they need programming languages (see 10.v). We don't have world enough, or time, to express everything in terms of primitives—or to remember it, if we did.

And this brings us, finally, to the angels:

> If an angel is a device with infinite memory and omnipresent attention—a device for which the performance/competence distinction [see 7.iii.a] is vacuous—then, on my view, there's no point in angels learning Latin; the conceptual system available to them by virtue of having done so can be no more powerful than the one they started out with. (1975: 86)

Only a philosopher would have sailed so close to the wind as to risk this seeming absurdity. Like Dennett's denial of *qualia*, it exemplified the fourth cause of (non-philosophers') irritation identified in the preamble to this chapter. Fodor himself admitted blandly, even happily, that it looked like a *reductio ad absurdum* (p. 82).

Many critics noted that his argument was based in ignorance, for he assumed that no non-inductive theory of concept learning was conceivable. Philosophers also sought other flaws in his argument (e.g. Dennett 1977: 273; P. S. Churchland 1978; Sloman 1987*b*). As for the psychologists, most simply ignored this self-confessedly "scandalous" claim.

But both communities—and eventually, neuroscientists too—hotly debated many of his other claims (see, for example, Chapters 7.v.i, 12.x, 14.ix.e, and 15.vi–viii). That is, they questioned the existence, and the nature, of each of the following:

* an innate language of thought;
* real, individuated, representations;
* formal–computational (and compositional) internal states;
* mental states whose semantic relations depend on their syntactic structure;
* scientifically describable carriers of specific propositional attitudes;
* a psychological science approximated by common-sense belief–desire psychology;
* non-computational associative thought;
* and non-conceptual semantic content.

Angels aside, then, Fodor's influence was enormous. Even Dennett, who disagreed with him on many points, said: "Fodor challenges us to find a better theory, and I fully expect that challenge to be met, but when better theories emerge they will owe a good deal to Fodor's reconnaissance" (Dennett 1977: 280).

d. Fodorian frills

If Fodor's reconnaissance had led to surprises, so did his next scouting party. In 1980 he undertook "a meditation upon the consequences of assuming that mental processes are formal processes" (Fodor 1980*a*: 64).

He concluded that a "rational" psychology (Chomsky's term: see Chapter 9.ii–iv) must be "methodologically solipsist" (Putnam's term, but first used by Russell). And this implied that psychology will *never* do what it's normally intended to do—namely, explain how we gain knowledge of, or even beliefs about, the world.

Putnam's part in this philosophical drama was to have set the stage by distinguishing two general approaches to intentionality (Putnam 1975*a*). These differ over whether the meaning (and therefore the identity) of every mental state depends on the existence, and nature, of anything outside the subject whose state it is.

For proponents of "wide" meaning, such as the recently converted Putnam himself, it does. (As he put it, "'meanings' just ain't in the *head*!"—Putnam 1975*a*: 227.) For champions of "narrow" meaning, it doesn't. They are *methodologically* solipsist, said Putnam (p. 220): for them, the content of our mental states could be just the same even if nothing else existed. (Theories of wide and narrow meaning are often termed externalist and internalist, respectively.)

Fodor, *qua* computational psychologist, danced on the narrow side of the stage. Formal computation, being purely syntactic, excludes semantic concepts such as truth and reference, so can say nothing about the world. Terry Winograd's SHRDLU exemplified this, he said, being a simulated robot within a purely virtual reality (see Chapters 9.xi.b and 10.iv.a). The dire implication was that psychology can't ever tell us how we see tigers, smell lilacs, understand speech, or learn that politicians aren't to be trusted.

There seemed to be a chink of light, for Fodor granted that a "natural" (neurophysiological) psychology could discover the physical causes of sensation. However, to know the causes of *perception* is impossible in the general case. Science might tell us what a cat is, but not what a mat is—for the concept *mat*, like most concepts, doesn't name a natural kind. Someone's perception (belief, fear, desire . . .) that the cat is on the mat could be *naturally* explained only by explaining every causal detail involved. To do this for all objects of thought would require "the theory of *everything*" (Fodor 1980*a*: 70). As Fodor remarked, Leonard Bloomfield had used similar reasons in arguing that a naturalistic semantics is impossible (see Chapter 9.v.b). In short, despite its principled failure to engage with the real world, "computational psychology is the only one that we are going to get" (1980*a*: 66).

All was not lost, however: *philosophy* could come to the rescue. If we complemented a functionalist psychology by a theory of semantics then we could, after all, bring the lilacs and politicians into the picture. For we could then say how perception and belief are possible.

The rest of Fodor's career, with one important exception, was—and still is—devoted to defending his previous views (on intentional realism, "Rationalist" nativism, and the adult's rich language of thought) and to developing a philosophical semantics to fit (e.g. Fodor 1981*a*,*b*, 1987*b*, 1998*a*, 2000*a*).

The exception concerned the notion of mental modularity. When he wrote *The Language of Thought*, Fodor still followed the 'New Look' psychologists (6.ii) in seeing perception and learning as the formation and testing of hypotheses. "For all we know", he believed, "cognition may be saturated with rationality through and through" (1975: 173)—a view shared by Zenon Pylyshyn (1973), for whom even mental imagery reflected beliefs (7.v.a). By the early 1980s, however, the New Look was under fire from several directions.

For example:

* Chomsky had posited "mental organs", of which the language-acquisition device—underlying the language "faculty"—was only one (see Chapter 9.viii.b).
* GOFAI was increasingly relying on domain-specific knowledge (see 10.iv).
* David Marr, speaking of "the sensorium of sight" (Marr and Nishihara 1978), had detailed a variety of fast-acting, automatic, bottom-up processes in low-level vision (7.v.b–d).
* Developmental psychologists were discovering to their surprise that newborn babies have "knowledge" of—or, better, predispositions to attend to—various aspects of the world (including faces: see 14.ix.c). (To their surprise, because Jean Piaget, no less than the behaviourists, had denied this: Boden 1994*a*.)
* And Pylyshyn (1980) had defined the mind's "fixed functional architecture", whatever this turned out to be, as inescapable. It was "cognitively impenetrable", or uninfluenced by beliefs (see 7.v.a).

All these cognitive scientists agreed that the inborn propensities could generate actual ideas, or mental contents, *only* given the relevant environmental triggering. In sum, Immanuel Kant's views on the inherent structuring of the mind had seemingly been broadly vindicated (see Chapter 9.ii.c).

Fodor's response was *The Modularity of Mind* (1983). Like *The Language of Thought*, this book interested psychologists as well as philosophers. (It later received a detailed rebuttal from the developmental psychologist Annette Karmiloff-Smith: 1992.)

With his usual flair for scandal, Fodor picked up Chomsky's term and recommended "faculty psychology". He wasn't resurrecting the outmoded nineteenth-century faculty psychology, with its notions of Will, Perseverance, and Morality. Rather, by faculty psychology he meant "the view that many fundamentally different kinds of psychological mechanisms must be postulated in order to explain the facts of mental life" (1983: 1).

Following Pylyshyn, he defined mental modules as innate input systems whose computations were automatic, and couldn't be influenced top-down by concepts or beliefs. (One doesn't become immune to the Müller-Lyer illusion by learning that it is an illusion.) If rationality implies belief, then *perception*—despite being computationally complex at all levels—wasn't "saturated with rationality *through and through*" after all.

Cognition, however, was—and Fodor now saw this as a major problem (Chapter 7.iii.d). He argued that since any belief (hope, desire . . .) can be influenced by indefinitely many others, there can be no principled theory of problem solving or belief fixation. (Or, one might add, of 'New Look' perception, or of neurotic repression: see Chapters 6.ii.a and 7.i.a.) The best we can hope for is an informed natural history: a relatively unsystematic collection of problem-solving procedures and suggestive anecdotes. This would be an advance on common sense primarily in recognizing that propositional attitudes are (literally) GOFAI-computational.

But are they?—As we saw in Chapter 12, GOFAI would soon be challenged by PDP connectionism. (And Fodor would defend his position accordingly: Fodor and Pylyshyn 1988.)

e. Eliminative materialism

The earliest philosophers of PDP-based functionalism were the Churchlands. Their views on concepts, mental states, and consciousness were indicated in Chapters 12.x.b–c and 14.x.d.

As we saw there, they differed from Putnam, Dennett, and Fodor not only in rejecting GOFAI (abandoning logical deductions and intentional inferences for vector-to-vector transformations), but also in trying to avoid mentalistic language entirely. "Folk psychology" was to be discarded, not reduced. But their eliminative materialism was buttressed by PDP and computational neuroscience, not originated by them. To the contrary, it had long-standing philosophical roots.

Paul Churchland's earliest work pre-dated the resurgence of connectionism by several years. It had argued that advances in neurophysiology could conceivably lead us to think about minds in such a radically different way that beliefs, desires, fears, hopes . . . would be "eliminated", or "disappear" (P. M. Churchland 1979, 1981).

Even then, this idea wasn't new. The possibility had been implicit in Sellars's 1950s notion of the manifest image (see above), and had been made explicit in the early 1960s by Paul Feyerabend (1963*a*,*b*) and Richard Rorty (1965). Moreover, philosophers of science such as Russ Hanson (1958) and Thomas Kuhn (1962), and New Look psychologists such as Bruner and Richard Gregory (Chapter 6.ii), had already suggested that our empirical theories affect our perceptions.

The novelty in Churchland's approach was that he made a serious attempt to imagine how scientific knowledge could alter perception—including introspection—in a fundamental, all-encompassing, way.

Rorty too, in a book published in the very same year as Churchland's, considered the possibility of radically different types of perception. He imagined alien beings who never reported having *perceptions*, *ideas*, or other *mental representations*. Instead, they spoke in terms of neurophysiology. So, for instance, "When their infants veered toward hot stoves, mothers cried out, 'He'll stimulate his C-fibers' "; and a visual illusion might make them say "How odd! It makes neuronic bundle G-14 quiver, but when I look at it from the side I can see that it's not a red rectangle at all" (Rorty 1979: 71).

But Rorty wasn't arguing for scientific realism: far from it. Besides trying to banish the Cartesian concept of mind (partly by showing that intelligent creatures could do without it), he was denying that any form of knowledge, science included, is more fundamental than any other. According to Rorty, philosophy isn't an investigation but a "conversation", more like literary criticism than logic or science.

To Churchland, that was anathema. He insisted on the realist nature of science—he called his book *Scientific Realism and the Plasticity of Mind*—and used science (i.e. New Look psychology: Chapter 6.ii) to show that our perception actually is theory-laden.

Moreover, he tried hard to imagine *what it might be like* to have a radically different type of experience.

So, for instance, he described how he had trained himself to *see* the night sky so that certain astronomical facts, concerning the geometry of the solar system, were directly perceived, not inferred. These facts are usually regarded as counter-intuitive, precisely because they conflict with our normal perceptions. He explored other cases too, suggesting how children in an imaginary culture—whose 'ordinary' conception of reality was the one embodied in modern physics—might be taught to perceive the world in a very different, and more veridical, manner:

It is important for us to try to appreciate, if only dimly, the extent of the perceptual transformation here envisaged. These people do not sit on the beach and listen to the steady roar of the pounding surf. They sit on the beach and listen to the aperiodic atmospheric compression waves produced as the coherent energy of the ocean waves is audibly redistributed in the chaotic turbulence of the shallows . . . They do not warm themselves next the fire and gaze at the flickering flames. They absorb some EM energy in the 10^{-5} range emitted by the highly exothermic oxidation reaction, and observe the turbulences in the thermally incandescent river of molecules forced upwards by the denser atmosphere surrounding.

These observational descriptions, so arcane to us, are in no way arcane to the people under discussion. This is the only idiom they know. (P. M. Churchland 1979: 29–30)

As this passage suggests, a perceptual upheaval might involve not just seeing things differently, but seeing different things. In other words, our perception of physical reality might be informed by a different physical ontology. (And, *pace* Rorty, this alternative ontology might be *nearer the truth about reality*.) Instead of merely making us see/think of various "material objects" in a new way, science might lead us to discard such categories entirely:

The "facts", as currently conceived and observed by us, form the starting place for theoretical inquiry, but its successful pursuit may well reveal that we should vacate that starting place as hastily as possible. Large-scale intellectual progress will involve the wholesale rejection of old *explananda* as frequently as it involves the wholesale introduction of new *explanantia*. (P. M. Churchland 1979: 44)

And if the ontology of physical objects wasn't sacrosanct, neither was the ontology of mind.

It was even more difficult, however, to imagine how introspection might be systematically transformed, for the relevant neuroscientific theory wasn't yet available. (His "phase-space sandwiches" would come later: see Chapter 14.x.d.) Nevertheless, said Churchland, introspection is as theory-laden as any other form of perception. And the common-sense theory of mind—a "thoroughly thumb-worn theory whose cultural assimilation is complete" (p. 2)—didn't appear to map neatly onto what was already known about the brain.

Moreover, he predicted, this failure of mapping would probably deepen as neuroscience advanced:

[The] prospect we face is that a detailed neurophysiological conception of ourselves might simply displace our mentalistic [belief–desire] self-conception in much the same way that oxidation theory (and modern chemistry generally) simply displaced the older phlogiston theory of matter transformation. That we are long in the habit of making non-inferential introspective judgments in the terms of the theory to be displaced affects the matter not at all. (p. 5)

A halfway house, empty of physics and neurochemistry, would be a functionalist account. But this might be very different from what orthodox functionalists assumed:

Even as a functional characterization of ourselves, [folk psychology] may turn out to be taxonomically cockeyed, radically incomplete, and altogether too confused to merit continued use, when compared to the much superior functional characterizations that an adequate theory of the central nervous system can be expected to provide. (p. 113)

In short, folk psychology may be a *false* theory, rather than an approximate and/or incomplete one. (Incomplete, because—as Churchland pointed out—it works only for normal human agents, not for brain-damaged patients or animals.) To protest that we know it to be true through introspection (Cartesian "direct access") is futile. If our perception of physical things is theory-laden, and perhaps mistaken, so also is introspection.

These ideas hadn't yet quite gelled in Churchland's mind. Eliminative materialism was presented in his book merely as a coherent philosophical option, although his sympathies were clear. Two years later, however, he argued that it should definitely be adopted (P. M. Churchland 1981).

If there was no place for belief and desire in the philosophy of mind, there was no place for them in a scientific psychology either. But what was to replace them? What was the psychological equivalent of oxygen? Or, if we define ourselves (functionally) as "epistemic engines", how should we conceptualize the "epistemic states" through which we pass?

Churchland denied that these states can be helpfully seen as sentences, processed by some "ideal sentential automaton" (ISA). Orthodox functionalism, and logical positivism too, had adopted a "vision of rational intellectual activity as consisting essentially in a dance of propositional states, a dance whose form preserves certain propositional relations" (1979: 126). But he argued that the *normative* aspects of thought and knowledge ("epistemic virtue") can't be grounded in such an account. Since very young children don't use sentences, we can't explain the development of rationality in sentential terms—despite Fodor's "recent and noteworthy attempt to make a go of a linguistic interpretation of the infant's cognitive activities" (p. 131).

The fundamental constraints on what constitutes rational activity must therefore lie elsewhere: "we must try to penetrate to that deeper intellectual kinematics of which our manipulation of sentences is just the occasional and superficial reflection" (p. 141). Beyond assuming that they must contribute to evolutionary survival, he didn't pretend to know what these constraints are. But he used thermodynamic analogies in speculating about them.

He described animals as "informational sponges", absorbing information from the physical environment *and somehow using that information to get more information*. As for how that added value might be achieved, he imagined an intertidal creature, whose survival depends on its predicting the superficially chaotic variations in water level. This could be done, he said, by means of three internal oscillatory parameters, whose interactions "model" the relevant dimensions of the outside world—and he sketched the mathematics involved. (Compare Kenneth Craik's approach, described in Chapters 4.b–c and 14.viii.)

Churchland's closing words showed how far he already was from GOFAI functionalism. They also showed why he would later be so sympathetic to PDP connectionism, and to dynamical (vector transformation) approaches derived from neuroscience:

> And finally, it appears likely that the thermodynamics of "irreversible" processes will provide the underlying framework . . . for whatever genuine progress gets made here. For it is this theory that renders physically intelligible such things as the process of synthetic evolution in general, and the Sun-urged growth of a rose in particular. And what is human knowledge but a cortically embodied flower, fanned likewise into existence by the ambient flux of energy and information? (p. 151)

From the late 1980s on, accordingly, he and his wife treated those areas of cognitive science as sources of ideas about what cognition is, and how it works—two questions they saw as inseparable.

16.v. Counter-moves

So the functionalists reigned supreme, bickering among themselves about the rules of the club but encountering no serious opposition?—Not at all.

Outsiders protested that the functionalist enterprise was flawed in various ways. Indeed, one influential outsider was an ex-insider: Putnam resigned from the club some thirty years after founding it. As a result, the heady relief of the 1960s, on apparently escaping from the metaphysical impasse outlined in Section i, was gradually tempered.

'Friendly' objections, raised by people who spoke the same language as the functionalists, are discussed in this section. One influential critique was Block's (1978) 'Troubles With Functionalism'—but functionalism's troubles were many, and only a few can be mentioned here.

'Hostile' complaints grounded in a radically different perspective, a development of the neo-Kantianism sketched in Chapter 2.vi, are outlined in Sections vii–viii. Wittgensteinians were represented in both camps, as we'll see. So, too, was Putnam (Section vi).

a. Gödel to the rescue?

Disputes based in Gödel's theorem were voiced from the start. The general form of such objections is that computers are inherently limited in a way in which human minds are not.

Kurt Gödel had proved in 1931 that for any consistent logical system rich enough to contain elementary arithmetic, there is at least one meaningful sentence that cannot be proved in the system, but which humans can see to be true. And Turing himself had shown, independently of Gödel, that there are some well-defined questions that a given Turing machine can't answer (see 4.i.c).

For Turing, however, there was a crucial difference between a *given* Turing machine and *any* Turing machine. Accordingly, he rebutted "the mathematical objection" in *Mind*. He pointed out that "questions which cannot be answered by one machine may be satisfactorily answered by another". Moreover, no one had *proved* that we aren't subject to the same limitations. Certainly, we can sometimes see that a machine is giving the wrong answer (or failing to answer at all), which makes us feel superior. But we make mistakes too. And we can't triumph simultaneously over all machines: "There might be men cleverer than any given machine, but then again there might be other machines cleverer again, and so on" (A. M. Turing 1950).

Lucas (1929–) disagreed. A few years later, at a meeting of the Oxford Philosophical Society in 1959, he argued that "The Gödelian formula is the Achilles' heel of the cybernetical machine" (J. R. Lucas 1961: 116). This claim was the core of his seminal paper on 'Minds, Machines, and Gödel', published in *Philosophy* in 1961.

Gödel's proof, said Lucas, showed not that minds are "superior" to machines, but that they're different. However, describing the difference in positive terms was tricky:

> We are trying to produce a model of the mind which is mechanical—which is essentially "dead"—but the mind, being in fact "alive," can always go one better than any formal, ossified, dead system can. Thanks to Gödel's theorem, the mind always has the last word. (J. R. Lucas 1961: 116)

Despite the canny scare quotes, the terms *dead* and *alive* didn't really help.

Towards the end of his paper, however, Lucas expressed the difference by reference to the "unity" of consciousness. The crux of Gödel's theorem is self-reference, and it can be escaped only by moving up a level—at which point, an equivalent logical difficulty arises. But, said Lucas, in recognizing that when a conscious being knows something he also knows that he knows it, and knows that he knows that he knows . . . we aren't positing "an infinite sequence of selves and super-selves and super-super-selves". Rather, we're recognizing that a conscious mind, since it has no true parts, "can both consider itself and its performance and yet not be other than that which did the performance . . . [It] is already complete, and has no Achilles' heel" (p. 125). This argument took the place of the *proof* that Turing had asked for to show that humans aren't subject to the same limitations as machines.

Most readers saw Lucas's argument as a weapon in the battle against functionalism. But he hadn't originally intended it in that way: "[I was] innocent of functionalism rather than anti-functionalist. Like many other isms, it just passed me by" (personal communication). He'd been led to Gödel's theorem not by functionalism but by the problem of free will (see also J. R. Lucas 1970: 114–23).

That's why his paper ended in the claim that mechanism is false. He allowed that a super-computer might come to behave unpredictably, as if it had "a mind of its own". But in that case, "it would cease to be a machine, within the meaning of the act" (1961: 127). It followed, he said, that "no scientific inquiry can ever exhaust the infinite variety of the human mind" and that our concepts of freedom and morality are safe from the challenge of mechanism.

(Functionalists argued, to the contrary, that a computational approach can not only allow for what we call freedom but also explain how it's possible: Boden 1972, ch. 7 and pp. 330–4; 1978; Sloman 1974; Dennett 1984*a*.)

For every person who was convinced by Lucas's paper, someone else wasn't. It became hugely influential, and is still attracting readers in the new century (it's on his web site, and is viewed by around fifty people a week—see J. R. Lucas 2000: 5). At a meeting held at the University of Sussex in 1990 to mark the fortieth anniversary of Turing's

Mind paper, Lucas looked back on how the argument had progressed (J. R. Lucas 1996). Wryly recalling the many replies that had been "lacking in either courtesy or caution", he pointed out that a large number of different objections had been raised by his critics (including cognitive scientists Dennett, Clark Glymour, and Douglas Hofstadter). He didn't regard any as decisive, and ended as he'd done before: roundly proclaiming the demise of mechanism.

Lucas had written the paper at Princeton, where he went (in 1957–8) specifically to work on Gödel. One of the people he encountered there was Putnam, but he didn't manage to convince him: in his 1960 paper, Putnam dismissed the Gödelian objection as a fallacy. Thirty years later, however, he saw it as a problem—not a knock-down formal argument, but an epistemological reminder that our reason enables us to go beyond whatever it can formalize (Putnam 1988: 118; cf. Putnam 1997: 39).

Roger Penrose, too, used Gödel's theorem to attack strong AI and computational psychology (R. Penrose 1989: 102–8). As a Fields medallist (the mathematical equivalent of a Nobel prizewinner), his voice received a very wide hearing—not least, in the media worldwide. (It doubtless helped that his conclusion, the superiority of human minds over computers, was what the vast majority of people wanted to hear.) Nevertheless, like Lucas before him he was challenged repeatedly, and at length (e.g. Sloman 1992).—This show, as they say, will run and run.

b. Consciousness and zombies

A second objection to functionalism that was anticipated (teasingly) by Turing concerned consciousness. As various people would later point out, there's no such thing as *the* problem of consciousness (see Chapter 14.xi.a, and Section iv.a below). The most hotly disputed of the *several* problems of consciousness concerns qualitative experience, which was discussed in Chapter 14.x–xi. Here, we need add only two points.

The first is that the mid-century arguments about consciousness (Section i, above) acquired new versions in the context of functionalism. Often, they were couched in terms of "zombies": android robots behaving *exactly like us*, but lacking all sensation or feeling. The objection typically ran as follows: since such creatures are obviously logically possible, functionalism must be false.

Dennett (given his views outlined in Section iv.a–b, and in Chapter 14.xi.b too) didn't see this as obvious at all. On the contrary, he said, the concept of zombies is incoherent, and belief in their possibility "ridiculous" (Dennett 1991, ch. 10.4; 1995*b*). Sloman (1999) argued, similarly, that nothing could have the same computational architecture as us (necessary for it to behave exactly like us), yet lack sensation.

An early variant of the zombie argument was due to Ziff (1920–2003). He claimed that "no robot could sensibly be said to feel anything", because we could program it to act any way we liked (Ziff 1959). So, for instance, we could make it act "tired" when lifting a feather but not a ton, or blue things but not green things. Again, the functionalist would ask whether these apparent "possibilities" assume a virtual machine that is at base incoherent. (A robot might tap into reserves of energy when lifting green things, because of some general motivational attitude to green; the ton-weight case, ignoring 'emergencies', is more problematic.)

Sometimes, it was claimed not that androids *needn't* be conscious, but that they *couldn't* be conscious. Scriven (1953), for instance, argued that no robot could be conscious, because it wouldn't be alive (see Section x.a). A few years later (Scriven 1960), however, he recanted: "I now believe that it is possible so to construct a supercomputer as to make it wholly unreasonable to deny that it had feelings."

The second point to be noted here is that the problem of *qualia* caused even some functionalists to admit defeat. If Dennett and the Churchlands—and Sloman (see Section ix.c)—thought they'd solved it, Chalmers and Fodor didn't.

Chalmers (1995, 1996*a*) called it the "hard" problem, which neither functionalism nor neuroscience could solve (see 14.x.d). But at least, he suggested, there was a glimmer of light. If we were to admit a "dual-aspect" notion of *information* as a fundamental feature of the natural world, then conscious experience could be accommodated in science. Sceptics complained that this wasn't explaining consciousness, but slipping it in through the cellar door—a millennial version of *élan vital* (see Chapter 2.vii.b).

As for Fodor, he had no hope of an answer. Saying that consciousness couldn't be a functional ("relational") phenomenon, he declared:

> Nor do we know, even to a first glimmer, how a brain (or anything else that is physical) could manage to be a locus of conscious experience. This last is, surely, among the ultimate metaphysical mysteries; don't bet on anybody ever solving it. (Fodor 1995*a*: 83)

This was about as pessimistic as Colin McGinn's (1989, 1991) claim that consciousness is as far beyond our cognitive capacity to understand as algebra is for dogs. Indeed, for "pessimistic" one might read "defeatist". (Whether neuroscience might one day enable us to understand *qualia* was discussed in Chapter 14.x–xi.)

c. That room in China

A third cluster of counter-moves concerned intentionality. These also were made from the inception of functionalism, and were mentioned (in passing) by Turing himself (1950).

One of these, emanating from Searle (1932–) at the University of California at Berkeley in 1980, soon became notorious. This was a sparkling intellectual hatchet job, featuring the Chinese room.

People unfamiliar with Searle's other writings often assume that he had no sympathy for cognitive science in general and AI in particular. That's not so. "Since the beginnings of the discipline", he has said, "I have been a practicing 'cognitive scientist' " (1992: 197). And he's described AI—and computer functionalism—as "one of the most exciting developments in the entire two-thousand-year history of materialism" (1992: 43).

Moreover, he welcomed the fact that NLP researchers studying conversation had used his own work on speech acts (see 9.xi.f), not least because it enabled him to improve the theory. As he put it:

> Now the beauty of AI, and this I really do admire, is that it forces you to pose those questions [about rules for understanding language] precisely and forces you to state your theory precisely. In fact the things I've written about—metaphors and indirect speech acts and so on—a great deal of it has been programmed by people working in various AI labs. So I think, in fact, that AI

is an immensely useful tool in the study of language and the study of the mind . . . (in Pagels *et al.* 1984: 356)

However, there's cognitive science and then there's cognitive science. In Searle's view, "most mainstream cognitive scientists simply repeated the worst mistakes of the behaviorists [by ignoring] the essential features of the mind" (1992, p. xii). Those features, he said, are intentionality (the focus of his 1980 paper) and consciousness (the focus of his 1992 book).

The central point of Searle's provocative paper—the semantic emptiness of AI programs, considered as uninterpreted symbols—wasn't new. As we've seen, Fodor had embraced this in his "meditation" on formalism published a few months before, and Mays had noted it as early as 1949 (Manchester Philosophy Seminar 1949; Mays 1951, 1952). What Searle originated was an elegant slogan ("all syntax and no semantics"), a terminological distinction ("weak" versus "strong" AI), and an extraordinarily seductive—and slippery—thought experiment.

The terminological distinction quickly entered the discourse of cognitive science. However, it wasn't usually understood in just the way that Searle defined it. Both "weak" and "strong", in this context, have been interpreted in different ways. Searle put it like this:

According to weak AI, the principal value of the computer in the study of the mind is that it gives us a very powerful tool. For example, it enables us to formulate and test hypotheses in a more rigorous and precise fashion. But according to strong AI, the computer is not merely a tool in the study of the mind; rather, the appropriately programmed computer really *is* a mind, in the sense that computers given the right programs can be literally said to *understand* and have other cognitive states. (Searle 1980: 417)

So defined, weak AI—as Searle was quick to point out—is on a par with using computers to test theories about rainstorms. It claims no more theoretical affinity with minds than with anything else.

"Weak AI" is usually understood, however, as the claim that some of the computational features—processes, structures, virtual machines, architectures—involved are substantive theoretical terms in psychological explanations. As explained in Chapter 1.ii.a, this is the core thesis of cognitive science. Searle implied that to go this far and no further (that is, to claim explanatory power while drawing the line at strong AI) was disreputable, an example of muddled—even pusillanimous—thinking based on some fuzzy "computer metaphor". For him, *programs are tools* and *programs are minds* were the only intellectually honourable positions—and he praised Newell and Simon for their "straightforwardness", accordingly (see Section ix.b).

As for "strong" AI, this too is ambiguous. There are at least eight readings of it: some true, some false, some requiring empirical investigation (Sloman 1992). So even if the thought experiment 'worked', anyone who said baldly that strong AI had been dismissed would be too quick.

Searle's thought experiment entered the discourse of cognitive science—and everyday discourse, too. It was featured on TV and radio around the globe, including the BBC's annual Reith Lectures (Searle 1984), and in many newspapers and popular science magazines.

This, it seems, was a surprise to Stevan Harnad, the editor of *BBS*—where (on the say-so of the associate editor, Pylyshyn) Searle's paper was first published, alongside twenty-seven peer commentaries. He hadn't been enthusiastic:

> I cannot say that I was especially impressed . . . [It] seemed to be yet another tedious "Granny Objection" about why/how we are not computers. . . . Across the ensuing years, further commentaries and responses continued to flow as, much to my surprise, Searle's paper became *BBS*'s most influential target article (and still is, to the present day) as well as something of a classic in cognitive science. (At [a Rochester Conference in 1982] Pat Hayes went so far as *to define cognitive science* as "the ongoing research program of showing Searle's Chinese Room Argument to be false"—"and silly", I believe he added at the time. (Harnad 2002: 294–5; italics added)

That last addendum was a dig at Searle, not Hayes. But one could be forgiven for thinking otherwise, having read Harnad's own writings on the topic:

> As the arguments and counter-arguments kept surging across the years I chafed at being the only one on the planet not entitled (*ex officio*, being the umpire) to have a go, even though I felt that I could settle Searle's wagon if I had a chance . . . [When I eventually joined the online discussion on "comp.ai"] I found comp.ai choked with such a litany of unspeakably bad anti-Searle arguments that I found I had to spend all my air-time defending Searle against these non-starters instead of burying him, as I had intended to do. (p. 296)

To Harnad's annoyance, even Searle believed him to be on his side, and urged him "to keep fighting the good fight". Now, however, Harnad himself admits that on the one "essential point" they'd actually agreed all along (p. 296). This historical vignette is just one illustration of the slipperiness of Searle's thought experiment.

Aspiring writers may take comfort in knowing that a paper disparaged by one editor was published nonetheless—and sped around the world immediately. But to match this phenomenon they'll need to think up an example that's equally seductive.

Just in case you can't already recite it in your sleep, here it is:

Situation: Searle in a windowless room; a slot through which paper slips with "squiggles" and "squoggles" on them are occasionally passed in; a box of slips carrying similar doodles, of various shapes; and a rule book, saying that if a squiggle is passed in then Searle should find a blingle-blungle and pass it out, or perhaps go through a long *sequence* of doodle pairings before passing some particular shape out.

Denouement: Unknown to Searle-in-the-room, the doodles are Chinese writing; the rule book is a Chinese NLP program, comparable to Wendy Lehnert's question-answerer (see Chapter 9.xi.d); and the Chinese people outside the room are happily using Searle to answer their questions about some topic or other.

Punchline: Searle entered the room unable to understand Chinese and, no matter how long he stays there, he still won't understand a word of it when he comes out.

Conclusion: Formal computation alone (which is what Searle-in-the-room is doing) can't generate intentionality. Therefore strong AI is impossible.

Arguably, Searle was here attacking a straw man. Newell and Simon, and Minsky and John McCarthy too, certainly believed that AI systems of a certain complexity would be *really* intelligent, and *really* have beliefs. But, as we'll see in Section ix.b, they didn't have abstract Turing-computation in mind.

Searle, however, did (1980: 417). He argued that programs are mere shufflers of meaningless shapes. Indeed, he said, any AI program could in principle be interpreted as (mapped onto) many different activities: tax laws, dance routines . . . whatever. As regards the program itself, the choice between "meanings" is arbitrary. Any meaning it appears to have is derived entirely from us. So although we can't help speaking of computers in intentional terms (as Dennett had said), they don't "intrinsically" merit such ascriptions—whereas people do. So strong AI is an illusion.

As for weak AI, Searle doubted that brains generally implement formal computations. If they don't, then (GOFAI-based) computational psychology—far from being, as Fodor had claimed, the only psychology on offer—can't even *begin* to explain our mental life. But even if they do, he said, the Chinese room argument showed that *something more* is needed for intentionality.

The Chinese room, like the Turing Test, spawned a minor philosophical industry. A goodly number of readers agreed that the Chinese room argument proved just what he said it proved, while just as many saw it as fundamentally wrong-headed. Critique and reply alternated in many different places, and in varied forms. For example, the Chinese *room* was transformed into the Chinese *gym*, to deal with connectionism (Searle 1982, 1984, 1990*a*,*b*, 1992). And, twenty years after the original publication, an entire volume of new critiques was specifically commissioned by a major university press (Preston and Bishop 2002).

The barrage of responses to Searle's paper mostly ignored the mysterious "something more"—with good reason, as we'll see below. Instead, they focused on his novel way of expressing the old empty-symbolism argument.

Many objections were versions of a position he'd anticipated—and rejected—as "the Robot reply". This said that Searle-in-the-room would acquire understanding of Chinese if sensori-motor mechanisms were added. In other words, symbols (or concepts) must be grounded in world-engaging activities in order to be meaningful, and to refer to individually discriminable things (e.g. Fodor 1980*b*; Dretske 1984, 1995; Harnad 1989, 1990).

Some philosophers of language in the 1980s held that causal processes aren't enough, that they have to be grounded in evolutionary history—in which case only *evolved* robots, at most, could possess intentionality (see Section x.d). And a number of critics argued that causation is intimately linked with *computation* as it is understood in practice, so that Searle's—and Turing's—abstract concept of computation is largely irrelevant (see Section ix).

d. Neuroprotein and intentionality

Searle, too, had stressed the importance of causation—but in a most unilluminating way. This concerned the "something more" needed for intentionality.

According to him, neuroprotein has "causal powers" capable of generating intentionality, whereas metal and silicon don't. As he put it some years later: "I think it is empirically absurd to suppose that we could duplicate the causal powers of neurons entirely in silicon" (1992: 66). The brain, he granted, is a digital computer—because *everything*, including your bedroom wallpaper, can be seen as a digital computer.

(We needn't discuss that point here: for rebuttals, see Chrisley 1995; Chalmers 1996*b*; Copeland 1996.) But its formal structure isn't the point:

> Whatever else intentionality is, it is a biological phenomenon, and it is as likely to be as causally dependent on the specific biochemistry of its origin as lactation, photosynthesis, or any other biological phenomena. No one would suppose that we could produce milk and sugar by running a computer simulation of the formal sequences in lactation and photosynthesis, but where the mind is concerned many people are willing to believe in such a miracle . . . (1980: 424)

We could even simulate brain functions (he said), by having the Chinese room contain a system of water pipes and adjustable valves corresponding to neurones and synapses. But still there'd be no understanding, because "[the brain's] causal properties, its ability to produce intentional states, wouldn't even have been simulated, never mind reproduced" (p. 421).

One might be tempted to describe this as a fairy story about the brain, except that fairy stories have some positive content. Even Penrose's shaky speculations about microtubules would offer more than this (Chapter 14.x.d).

Searle's move here, besides being empty, ignored the nature of explanation in neuroscience. Certainly, we have strong empirical evidence—as Descartes did too—that the brain is causally implicated in mental life. But at the level of *material stuff* (compare: lactose, chlorophyll), this is intuitively unintelligible.

In other words, we're in much the same philosophical position as the alien in the science-fiction story, if not *quite* so surprised by the brute facts:

> "They're made out of meat."
>
> "Meat?"
>
> "Meat. They're made out of meat."
>
> "Meat?"
>
> "There's no doubt about it . . . They're completely meat."
>
> "That's impossible. What about the radio signals? The messages to the stars."
>
> "They use the radio waves to talk, but the signals don't come from them. The signals come from machines."
>
> "So who made the machines? That's who we want to contact."
>
> "They made the machines. That's what I'm trying to tell you. Meat made the machines."
>
> "That's ridiculous. How can meat make a machine? You're asking me to believe in sentient meat."
>
> "I'm not asking you, I'm telling you . . . We probed them. They're meat all the way through."
>
> "No brain?"
>
> "Oh there is a brain all right. It's just that the brain is made out of meat."
>
> "So . . . what does the thinking?"
>
> "You're not understanding, are you? The brain does the thinking. The meat."
>
> "Thinking meat! You're asking me to believe in thinking meat!"
>
> "Yes, thinking meat! Conscious meat! Loving meat. Dreaming meat. The meat is the whole deal! Are you getting the picture?"
>
> "Omigod. You're serious then. They're made out of meat." (Bisson 1991)

Even neuroscientists can empathize with the alien's amazement. For in so far as we understand how neuroprotein (aka meat) grounds intentionality, we do so in terms of functional concepts. We speak of *messages*, *excitation*, *thresholds*, *codes*, *bug-detectors*, *orientation detectors*, and other types of *computation* (see Chapter 14). The neurotransmitters (meat juices) aren't interesting primarily for their biochemistry, but for the fact that they function to alter thresholds, for instance. Even the crucial sodium pump, whose material chemistry is thoroughly understood, is significant for its functional properties, in allowing an electrical impulse (message) to propagate along the axon. Similarly, we know a great deal about the chemistry of the synapse—but what's psychologically relevant is how this affects the neurone's message-passing functions (Chapter 14.ix.d and f).

Many of us may share Searle's unargued hunch about the inadequacy of metal and silicon. Neuroprotein may indeed be the only substance on earth that can support intentionality. But if so, why? Perhaps only neuroprotein allows the combination of chemical complexity, stability, and flexibility that's required for implementing the virtual machines that generate behaviour and thought? To say this, however, is—again—to make a functional point: what matters is what a particular metabolite enables the brain to *do* (see 14.ix.f).

Although this aspect of Searle's paper didn't engender much debate, it did encourage the fourth counter-move against functionalism: scepticism about multiple realizability.

e. How multiple is multiple?

Putnam's initial claim had been that all the functional properties of human and animal minds are in principle realizable in indefinitely many ways. But whether they were all multiply realizable in practice was another matter.

If philosophers were apparently licensed to ignore neuroscience, other cognitive scientists weren't. Indeed, even some philosophers felt that they would have to take notice of the brain after all, if it turned out that computations typical of brains could do things which other types of computation (in practice) could not.

This is why PDP connectionism, despite its many 'unnatural' features (such as back propagation), was often seen as relevant to *philosophical* theories of concepts and thinking (Chapter 12.x). It's why even connectionism was soon criticized for being insufficiently close to neurobiology, and urged to take facts about the brain on board (14.ii.d). It's why the Churchlands used ideas drawn from neuroscience, such as "phase-space sandwiches", to help justify their version of eliminative materialism (see 14.x.d). And, in the context of computer science, it's also why some AI scientists see Searle's argument as fundamentally irrelevant to their research (see Section ix).

Encouragement, however, isn't initiation: it didn't need Searle to make cognitive scientists consider neurophysiology. John von Neumann himself had surmised that the "logic" of the brain was very different from that of the von Neumann computer, and in 1947 McCulloch and Pitts had said much the same—offering hypotheses about what the alternative might be (see Chapter 12.i.c). Newell and Simon had long designed AI models that reflected specific properties of the brain, and Marr (among others) had asked what types of computation certain neural mechanisms could perform

(Chapters 7.iv.b and 14.v). In short, the functionalist dogma of multiple realizability was already being taken with a large pinch of salt.

Even so, the explanatory focus was more on *the types of computation* involved than on their biochemical embodiment. As the years passed, it became increasingly clear that neuroscience can provide crucial information about the functional organization of a cognitive system (the virtual machine), not just about how it happens to be materially implemented (Bechtel and Mundale 1999; Keeley 2000*a*). And at the turn of the twenty-first century, a connectionist textbook appeared which paid greater attention to neurobiology than the fledgling PDP had done (O'Reilly and Munakata 2000: see 14.ii.d).

f. Subconsciousness attacked

The fifth counter-move was more radical. The functionalists described brains as implementing computations, and even Searle was willing to entertain this as a hypothesis. But the more deeply committed Wittgensteinians saw it as absurd.

Their problem wasn't specifically with computation, although they thought that "supposing the brain to be a computer is mere fashion" (Anscombe 1974: 235). They were suspicious of *any* attempt to explain mental life in terms of sub-personal mechanisms that weren't consciously acknowledged by the subject. Even Freudian theory was suspect for this reason. Brain mechanisms there must be, of course—but those were the neurophysiologist's business.

This attitude was evident in the uncompromising rejection of New Look psychology by two of Wittgenstein's leading disciples, Anscombe (1919–2001) and Malcolm. At a meeting held in 1971 at the University of Kent at Canterbury, Gregory (1974*b*; cf. 1975) summarized his 'New Look' view of perceptions as hypotheses (see 6.ii.e). Anscombe would have none of it:

> Now an hypothesis is something answerable to evidence, to data. To what data could the perceptual hypotheses that Gregory speaks of be answerable, but to perceptions? *Are* these perceptions then in turn hypotheses, and so on *ad infinitum*? (Anscombe 1974: 213)
>
> *What* is framing the hypothesis? Is [it] the conception which Gregory suggests, that the framer is some mechanism that produces hypotheses that are answerable to input? For *we* who perceive don't know what the input is.
>
> Hypotheses are *that* things are the case . . . [It] looks as if Gregory's theory involved our perceiving apparatus itself as entertaining judgments. Hypotheses are predictive by way of inference. They also involve the logical constants, can be negative, universal, particular, conjunctive, and disjunctive. Perception can be all of these things except for being disjunctive . . . By perception's being alternative I would mean two perceptions presenting themselves as alternatives at the same time. (p. 218)
>
> When there being a tree here . . . is the description of what is plainly the case, plainly and visibly to the perceiver—it is absurd to call the perceptual belief an hypothesis. (p. 243)

Rather than speaking of hypotheses, she suggested, he should have spoken of "models", "patterns", or "schematic sketches of possibilities".

Gregory responded with some asperity:

> [How] much surprise are we allowed before a word becomes philosophically suspect? . . . I do not want a normal word, because I do not want to express a normal thought . . . The "framer" I

regard as brain mechanisms . . . Surely we do not *have* to say that total human beings alone have the prerogative to frame hypotheses? (Animals might do so—and are *they* conscious? Computers might do so—and surely *they* are not conscious?) Again, why should we be captured by the inertia of language? (Gregory 1974*b*: 232, 234)

Anscombe fought back: "I don't mind a bit if he uses the word 'hypothesis' in a novel way . . . I merely want to understand what he says and assess its value" (pp. 236–7). Gregory had found out some interesting things, she conceded, "but how are his enquiries logically facilitated by having the scientific hypothesis paradigm rather than by thinking of patterns and models?"

This defence would have rung more true if her initial paper had been more constructive in spirit. As Gregory put it, "[Do] these philosophers have rival theories of perception up their sleeves? If so, they must surely justify their linguistic preferences not from common usage but by reference to their theories" (Gregory 1974*b*: 234).

Malcolm (1971) went even further than Anscombe, rejecting the cognitive approach wholesale. Much as he'd earlier denied that scientific evidence could justify our saying that dreams occur at certain times during sleep (see Section iii.b), so he now dismissed cognitive structures and processes as "myth". He wasn't saying that *these* structures and processes (hypotheses, perhaps) are implausible whereas *those* (models, perhaps) are better founded. Rather, he was outlawing all theorizing about subconscious psychological mechanisms.

A powerful counter-attack, analogous to Putnam's (1962*a*) critique of Malcolm's views on dreaming, appeared immediately (M. Martin 1973). It argued that scientists typically extend linguistic usage, and that cognitive psychologists had good grounds for positing various types of unconscious process and structure. But Malcolm wasn't persuaded.—It's small wonder, then, that Fodor introduced his own approach in the mid-1970s by observing that "many philosophers [still believe] that Ryle and Wittgenstein killed this sort of psychology some time about 1945, and there is no point to speculating on the prospects of the deceased" (Fodor 1975: 2).

16.vi. Betrayal

Already under fire from these many directions, functionalism then had to face the unkindest cut of all. Putnam himself started to have doubts in the early 1970s, and explicitly disowned his brainchild some fifteen years later.

Ironically, GOFAI suffered a similar trauma at much the same time, being betrayed in 1986 by the erstwhile wunderkind Terry Winograd (Chapter 11.ii.g). But Putnam's disaffection with functionalism was the more shocking. For whereas Winograd had picked up someone else's ball before running with it, Putnam had sewn the ball together before throwing it onto the pitch.

In 1973, at a meeting on 'Computers and the Mind' at Berkeley, Putnam still defended the autonomy of psychology (Putnam 1975*b*). But he rejected his previous claims that the whole human being is a Turing machine, and that a mental state is a state of a Turing machine, saying he had been "too much in the grip of the reductionist outlook".

That was more a complaint about oversimplification than a rejection of the spirit of functionalism. By the late 1980s, however, rejection had won out:

> The desire that grips Fodor, then, as it once gripped me, is the desire to make belief–desire psychology "scientific" by simply identifying it outright with computational psychology . . . Mentalism is just the latest form taken by a more general tendency in the history of thought, the tendency to think of concepts as scientifically describable ("psychologically real") entities in the mind or brain. And it is this entire tendency that, I shall argue, is misguided. (Putnam 1988: 7)

> Functionalism, construed as the thesis that propositional attitudes are just computational states of the brain, cannot be correct. (p. 73)

One might compare this change of viewpoint with Bruner's contemporaneous flight from experimentation and computation to interpretation and narrative (Chapters 6.ii.c and 8.ii.a). Or one might see it as a Damascene conversion typical of the "counter-cultural" trend so prominent in the 1970s–1980s (see 1.iii.c–d). But it was much more carefully argued than most such examples (including Bruner's), and much longer drawn out than the episode on the road to Damascus.

The three pillars supporting Putnam's recantation were universal realizability, externalism, and meaning holism. Each one contradicted a central aspect of his 1960s position. And each one had arisen from *friendly* territory, in the sense that they developed while Putnam still had faith in functionalism.

In thinking further about the nature of language, he didn't improve functionalism but rejected it. Indeed, he ended up in what was traditionally seen as the enemy camp.

a. Friendly fire

Universal realizability was multiple realizability gone wild. The doctrine of mind–brain multiple realizability, said Putnam, "still seems to me to be as true and important as it ever did" (1988, p. xii). But now, he added a mind-computation version, which forbade the identification of mental states with specific computations.

Using an argument so highly technical that it was relegated to an Appendix, he claimed that *any* program is implemented in *any* object. So mental states supervene on computations much as they supervene on brain states: they can't be identified with each other.

This—if correct—put paid to computational psychology: if every pebble implements Newell and Simon's GPS, and every leaf Chomsky's grammar, why bother?

Searle later added this argument to his own arsenal (1992: 208–9). But others saw it as invalid, on the grounds that it ignored the causal aspects of computation. That, of course, was a heretical view—indeed, for most philosophers it qualified as *nonsense*. For their normal assumption was—and still is—that computation is a purely formal notion, not a causal one. This disagreement will be discussed at length in Section ix.

The second pillar of Putnam's self-critique was externalism. This is the type of philosophical semantics—whose popularity grew in the late 1970s and 1980s—which favours "wide" content (see Section iv.d).

Sometimes, wide content is understood in naturalistic terms, such as agent–environment relations (G. Evans 1982), natural kinds (Kripke 1980), or evolutionary history (Millikan 1984). And Putnam himself argued that the meaning of nouns like "water" is fixed by the physical constitution of the natural kind concerned—whether we know about it or not. (This was the import of his much-disputed "Twin Earth" example—1975*a*: 223–7.)

But he also saw interpretative norms as crucial. Indeed, he even argued that causal accounts are inherently non-naturalistic, because what we count as "the" cause (like "the" explanation) depends on our interests (Putnam 1982).

Wittgensteinians, of course, had long stressed the relevance of cultural practices and norms in assigning meaning to language. Now, Malcolm's milk bottles had come home to roost (see Section i.d). If we can't individuate concepts and beliefs without reference to the physical and cultural environment, then neither brain states nor computational states *as such* can carry the content that identity theorists and functionalists, respectively, had ascribed to them. As Putnam put it: " 'meanings' just ain't in the *head*!" (1975*a*: 227). (Compare Wittgenstein: "If God had looked into our minds he would not have been able to see there whom we were speaking of"—1953: 217.)

As for the third pillar, meaning holism, this was a neo-Quinean position which held that the meaning of an individual term (concept) isn't independent of the overall framework of beliefs in which it's involved.

It's not just that meanings are fuzzy, incapable of definition by necessary and sufficient conditions. Worse, they're essentially interconnected. No one can think *that there are churches in Vienna*, for example, unless they possess concepts like *city*, *building*, *religion* . . . and so on. The reason is that the meaning of the concept *church* involves the meanings of many other concepts.

Quine had developed this theory in his attempt to find an adequate philosophy of science—indeed, to ground philosophy *in* science. But it could also be seen as a modern version of the humanist Humboldt's view that language is inseparable from culture (Chapter 9.iv.b). You and I may use words we're happy to regard as 'equivalent', translating the Cook Island Maori *tamariki* as the English *children*, for example. But Western and Polynesian beliefs about children are subtly different, so (on this view) our concepts are different too. This scientific/humanist ambiguity explains why Putnam eventually crossed over to 'the other side' (see subsection b).

Dennett, you'll remember (I hope!), had argued that *beliefs* can't be pinned down, for this very reason. But it hadn't turned him away from a neo-functionalist view of cognitive science. However, it worried Putnam more than Dennett. It was puzzling over this fact, Putnam said later, which was "the beginning of the end of my attachment to functionalism" (1999: 118).

Eventually, it led Putnam to the conclusion that the very notion of a "functional state" is "not fully intelligible". (It also led him to conclude that the notion of an "internal phenomenal state" isn't fully intelligible either, another point on which he agreed with Dennett: Chapter 14.xi.c–d.)

Mental states (propositional attitudes), Putnam now argued, are similarly interconnected, and similarly impossible to pin down. No two people thinking "The cat sat on the mat" are thinking exactly the same thought, because their beliefs about cats and mats aren't identical. When we say that they *are*, we're relying on cultural norms that decide *what we are willing to count as* the "same" thought. (*Tamariki/children*, again.) It follows that no single computational account, howsoever complex, can fit every instance of "one and the same thought".

Whether Putnam, Quine, or anyone else (even Humboldt) ever took this doctrine literally is arguable. Putnam specifically allowed that two terms may have the same *denotation* (though not the same *sense*, or *meaning*): "rational animal" and "featherless biped", for example. But what's important here is that Fodor's functionalism, and GOFAI modelling in general, took a very different approach to meaning.

Even PDP models, which allowed for fuzziness and family resemblances in individual concepts (12.x.a–b), didn't reflect mutualities of meaning between beliefs. Indeed, Putnam's holism implied that *no* scientific theory could use meanings (concepts, mental states) as scientific objects, playing an explanatory role. (For Fodor's rebuttal, see Fodor 1987*b*, ch. 3.) That is, psychology—because it deals with meanings, or *content*—can't be naturalized:

> There is nothing in [my mature position on perception and conception] that is "antiscientific" in the sense of *standing in the way* of serious attempts to provide better models, *both neurological and computational*, of the brain processes upon which our perceptual and conceptual powers depend, processes concerning which we still know very little. Moreover, it is *a profound mistake* to equate serious science with Cartesianism cum materialism that has for three centuries tried to wrap itself in the mantle of science. (Putnam 1999: 48; first italics in the original, others added)

At the end of the century, Putnam remained unrepentant. Cognitive science, he said, had turned out to be more science fiction than science:

> There is no harm in speculating about scientific possibilities that we are not presently able to realize; but is the possibility of an "ideal psychological theory" of this sort [i.e. expressed in a "normal form": see Section iii.b] anything more than a "we know not what"? . . . Do we have any conception of what such a theory might look like? Even if we had a candidate . . . how would we go about verifying that it does implicitly define the unreduced psychological properties? One hears a lot of talk about "cognitive science" nowadays, but one needs to distinguish the putting forward of a scientific theory, or the flourishing of a scientific discipline with well-defined questions, from the proffering of promissory notes for possible theories that one does not know even in principle how to redeem. (Putnam 1997: 36)

One must take care, however, to note just what he meant by cognitive science. He *wasn't* saying that the research described in Chapters 6–15 is worthless. Nor was he complaining (like N. Stuart Sutherland: see Chapter 1.ii.c) that some self-styled cognitive scientists focus not on empirical work but on the philosophical disagreements within the field.

Rather, he was saying that those (like Fodor) who sought a computational theory that would map neatly onto individual propositional attitudes, and that would identify their content independently of our interpretative practices and the context of use, were doomed to failure. The "narrow" side of the semantic stage, for Putnam, can support no real action. And even wide content—*pace* Dretske, Dennett, or Ruth Millikan—can't be analysed in naturalistic, non-normative, terms.

b. Crossing the river

Putnam's 'friendly' three-pronged attack on functionalism, described above, was only part of his reason for abandoning it. By the late 1980s, he'd become committed also to a fundamentally hostile (neo-Kantian) critique. As we'll see in Section vii, various versions of this had been lurking in the background—specifically: across the English Channel—for well over a century. They reached Putnam via the later Wittgenstein, and eventually turned his ideas upside down.

Putnam described his apostasy as "a matter of being torn between opposing views of the nature of philosophy" (1988, p. xii). This opposition is evident, for instance, in the difference between the "early" and "late" Wittgenstein. One way of describing it is in terms of attitudes towards metaphysical realism.

The typical empiricist–scientific position is that a real world exists independently of us, with its own intrinsic properties and a determinate built-in structure. Our thoughts represent it, and are *true* in so far as they correspond to it. The business of science is to describe the world and our relation to it, and philosophy—including the philosophy of mind—must be constrained by the findings of science. As Bertrand Russell put it, in criticizing the later Wittgenstein:

> [Philosophers should resist] the desire to separate [philosophy] sharply from empirical science. I do not think such a separation can usefully be made. A philosophy which is to have any value should be built upon a wide and firm foundation of knowledge that is not specifically philosophical. (B. Russell 1956*b*: 329)

This form of realism, however, appears to put a metaphysical gulf between thought (i.e. representation) and world (reality). The typical neo-Kantian position, outlined in Chapter 2.vi, aims to avoid that difficulty.

It holds that things in the empirical world aren't mind-independent, but constituted by the concepts informing human minds. For Kant himself, there was also the noumenal world. Some of his followers dropped this unknowable thing-in-itself, and moved on to idealism: the view that *all* reality is constituted by human thought. Some implications for the philosophy of language and biology were noted in Chapters 9.iv and 15.viii.b, respectively. As for the philosophy of mind, the implication highlighted by the Continental phenomenologists in the first half of the twentieth century was that there is no metaphysically fundamental Subject–Object or mind–body (or even body–environment) distinction. The notion that there is, they argued, is a Cartesian illusion.

Illusion or not, this Cartesian view underlay most early cognitive science—some cyberneticians perhaps excepted (see Chapter 4.v–vii). In general, the mind was conceptualized without reference to the body, and Subject and Object were taken as given. There was no suggestion that the nature of mental states depends on the fact that we have bodies (as opposed to brains). Certainly, sensory transducers and motor effectors entered this functionalist story. But the prime theoretical focus lay inside the head. Mental life was seen as a sensori-motor sandwich (2.iii.a, 10.iv.b), a repeated cycle of *perception*, *thought*, *action*. And *thought* was where the interest lay.

This is why most early AI (as we saw in Chapters 9.x–xi and 10) confined itself to text-based examples, and discarded much of the real-world information even when sensori-motor aspects were included. In effect, seeing ('scene analysis') was treated as a species of reasoning. Even robotics, in GOFAI, concentrated on abstract representation and planning. The messy details of the real world, and of bodily movement in it, were excluded whenever possible. By contrast, many workers in situated robotics, such as

Barbara Webb for instance, would welcome these messy details as a way of testing their theories (see Chapter 15.vii.c).

Putnam had started out as an unabashed realist. Before formulating functionalism, he'd even believed that all sciences reduce to physics (see Section iii.b). But, like Wittgenstein before him, he changed his mind. By the early 1980s, he was convinced that there are no metaphysically intrinsic properties, no mind-independent facts, or "ready-made world" (Putnam 1982).

Properties (he now argued) are "essential" only *relative to a description*. If one crushes a statue, it is no longer a statue. But think of it as a piece of clay, and the crushing doesn't matter: shape isn't essential. In the final chapter of *Representation and Reality* (1988), Putnam developed this neo-Kantian theme. He avoided out-and-out idealism, allowing that minds are in the world, not the fundamental creators of it. But he avoided straightforward realism, too. He called his theory "*internal* realism":

> [My idea] is not the view that it's all *just* language. We can and should insist that some facts are there to be discovered and not legislated by us. But this is something to be said when one has adopted a way of speaking, a language, a "conceptual scheme". To talk of "facts" without specifying the language to be used is to talk of nothing; the word "fact" no more has its use fixed by the world itself than does the word "exist" or the word "object". (1988: 114)

He conceded that *within* any given conceptual scheme we need to distinguish between the natural world and our judgements about it. But it is we who determine the nature of our concepts, including *mind*, *body*, *self*, and *material object*. And it is we who construct normative and/or interest-relative notions such as *good*, *rational*, *justified*, and even *cause*. Since a fundamentally mind-independent (naturalistic) account of the world is impossible, mind and language are philosophically prior to science and can't be explained by it.

In short, Putnam had committed the ultimate betrayal: he'd crossed the metaphysical divide to join the neo-phenomenological camp. To be sure, he soon moved to the outskirts of the encampment: by the turn of the millennium, he had modified his "internal realism" of the 1980s to a less extreme (less idealistic) "common-sense realism", according to which we are *directly* aware of real, independently existing, things (Putnam 1999). But still, he had no truck with the notion of internal phenomenal states (*qualia*, sense data), nor with talk of "correlations" between mental and physical states (see 14.x.c–d).

Putnam wasn't alone in pitching his tent in the neo-Kantian compound. One philosopher of cognitive science was already there waiting, and others would soon arrive—as we'll now see.

16.vii. Neo-Phenomenology—From Critique to Construction

Some philosophers used neo-phenomenological ideas not to deny the possibility of a scientific psychology, but to suggest new ways of doing it. Susan Oyama (1985) was a case in point. As we saw in Chapter 14.ix.b, she conceptualized the mind not as a mysteriously pre-structured input–output machine, but as the outcome of a series of developmental shifts in a self-organizing system. However, her key interest was *the origin of form*, of which 'knowledge' is one example. Here, we'll focus on philosophers coming to neo-phenomenology from a concern with *the nature of representation*.

a. Where Dreyfus was coming from

If Putnam had done a philosophical volte-face, one important critic of cognitive science had been consistent in his neo-Kantianism since the early 1960s. Indeed, Dreyfus was already launching his polemic against AI and computational psychology while Putnam was still formulating functionalism (Dreyfus 1965, 1967), and his highly influential *What Computers Can't Do* appeared soon afterwards (1972).

Dreyfus's fourfold diagnosis of AI's failings was discussed in Chapter 11.ii.a–c. Here, our interest is in the philosophy underlying it. This was drawn primarily from the phenomenologists Heidegger (1889–1976) and Maurice Merleau-Ponty (1908–61), from the (closely related) Gestalt psychologists (5.ii.b), and from the later Wittgenstein. Another influence was Polanyi, whose philosophy of science had stressed the scientist's "tacit" knowledge and practical skills (Polanyi 1958; cf. H. L. Dreyfus and Dreyfus 1986; and see 13.ii.b)—and who'd countered Turing face to face in the 1940s by positing unformalizable knowledge (see Preface, ii).

All these thinkers inspired Dreyfus's rejection of AI's ontological assumption "that what there is, is a set of facts each logically independent of all the others" (H. L. Dreyfus 1972: 68). The early Wittgenstein, who had strongly influenced McCulloch (4.iii.c), had put it like this: "The world is the totality of facts . . . The world divides into facts . . . What is the case, the fact, is the existence of atomic facts" (1922: 31). But the later Wittgenstein had roundly rejected it, commenting for instance that "It makes no sense at all to speak absolutely of the 'simple parts of a chair' " (1953, para. 47). Dreyfus echoed this remark:

> Even a chair is not understandable in terms of any set of facts or "elements of knowledge". To recognize an object as a chair . . . involves a whole context of human activity of which the shape of our body, the institution of furniture, the inevitability of fatigue, constitute only a small part. And these factors are no more isolable than the chair. (Dreyfus 1972: 122)

The phenomenologists also inspired Dreyfus's claim that the objects we experience—and to which we have direct access: no representations required—are inherently meaningful, or significant. They exist within a field of human interests (what the Gestalt psychologists called a "life-world") that gives them *relevance*, and which informs and guides our thinking.

Heidegger, in particular, had highlighted the immediate "situation"—in which the phenomenological subject has its Being, and *creates* the "beings" in the world and its coping response to them. The person's situation isn't a part of some objective external environment, but a lived context for practical action. Similarly, Merleau-Ponty had said "Motility [is not] a handmaid of consciousness, transporting the body to that point in space of which we have formed a representation beforehand . . . [We must] avoid saying that our body is *in* space, or *in* time. It *inhabits* space and time" (1945/1962: 139).

It follows, Dreyfus insisted, that we don't need to posit a third level of discourse, between phenomenological experience and neurophysiology. He followed Merleau-Ponty's example in saying that "what the learner acquires in experience [of the world] is not *represented* in the mind at all but is *presented* to the learner as a more and more finely discriminated situation" (1998: 3). Indeed, he argued—like Malcolm: see Section v.f—that it's not even clear what expressions like "mental processing" or "mental operations" could possibly mean (1972: 91). He was especially critical of GOFAI, but he rejected *any* theory of internal representations. In short: "To avoid inventing problems and mysteries we must leave the physical world to the physicists and neurophysiologists, and return to our description of the human world which we immediately perceive" (1972: 183).

As for where the meanings come from, he said, they're grounded in the body. Here, he was following Merleau-Ponty, who had written extensively on the difference between one's own body and mere physical objects. The body, in the phenomenologist's sense, cannot be described in purely naturalistic terms since it is the *origin* of meaning, or value:

> My body is the fabric into which all objects are woven, and it is, at least in relation to the perceived world, the general instrument of my "comprehension."
>
> It is my body which gives significance not only to the natural object, but also to cultural objects like words. (Merleau-Ponty 1945/1962: 235)

Hence, said Dreyfus (1967), computers must have bodies in order to be intelligent. But this requires more than being a robot: "no one understands how to begin to program primitive robots, even those which move around, to *have a world*" (H. L. Dreyfus 1972: 211; italics added).

On this view, we cope with the world by exercising our "bodily skills", which range from pattern recognition, through language, to tool use. (Tool use was a favourite example not only of Heidegger, Merleau-Ponty, and Polanyi but also of George Miller in his cognitive science manifesto: Miller *et al.* 1960. It's instructive to compare what Heidegger and Miller said about what's involved in using a hammer: Chapter 6.iv.c.)

Skilled behaviour, for Dreyfus, isn't the result of computation or information processing, and nor is it the execution of a plan. We may (consciously) follow rules or make plans when we're learning the skill, but "there is a moment when we finally transfer control to the body" (H. L. Dreyfus 1972: 160). Then, we just do it.

For cognitive scientists reading Dreyfus's critique, there was no "just" about it. They wanted to know *how* behaviour, skilled or unskilled, happens. (Later, they would also want to know how bodily skills *develop*: 12.viii.c–e and 14.ix.a–d.) The intellectual chasm between them and Dreyfus was huge:

> The alternative [i.e. phenomenological] view has many hurdles to overcome. The greatest of these is that it cannot be presented as an alternative scientific explanation . . . [We] shall have to propose a different *sort* of explanation, a different sort of answer to the question "How does man produce intelligent behavior" or even a different sort of question, for the notion of "producing" behavior instead of simply exhibiting it is already colored by the [Cartesian/scientific] tradition. For a product must be produced in some way; and if it isn't produced in some definite way, the only alternative seems to be that it is produced magically. (H. L. Dreyfus 1972: 144)

[The alternative answer] takes the form of a phenomenological description of the behavior involved. It, too, can give us understanding if it is able to find the general characteristics of such behavior . . . Such an account can even be called an explanation if it goes further and tries to find the fundamental features of human activity which serve as the necessary and sufficient conditions for all forms of human behavior. (p. 145)

Compare Merleau-Ponty:

[Phenomenology] is a matter of describing, not of explaining or analysing . . . The whole universe of science is built upon the world as directly experienced, and if we want to subject science itself to rigorous scrutiny and arrive at a precise assessment of its meaning and scope, we must begin by reawakening the basic experience of the world of which science is the second-order expression. (1945/1962, p. viii)

Cognitive scientists could happily allow that phenomenologists often provide subtle descriptions of experience. One excellent example, published a few years later (with the book motto drawn from Heidegger), concerned the changes in consciousness and bodily skills that happen when one learns to improvise jazz on the piano (Sudnow 1978/2001). But they wanted to know, in scientific terms, *how* the body enables this to happen.

Dreyfus's insistence that it's simply a matter of physical energies affecting the brain, while true at one level of discourse, didn't help. As Sutherland (1974) soon pointed out, "leaving it to the neurophysiologists" might itself involve the use of what Dreyfus had called third-level concepts. Indeed, Marr had already developed a computational theory of the cerebellum—specifically aimed to show how bodily skills can be learnt, smoothed, and controlled (Chapter 14.iv.c). To be fair, this was a connectionist account, not a GOFAI one. Nevertheless, it was a computational theory (see Section ix, below).

Given this intellectual chasm, Dreyfus-versus-X—where X is virtually any pre-1990s cognitive scientist—was less a meeting of minds than the simultaneous snarling of different species of beast. Dreyfus's book caused some bewilderment even among philosophers, for the relation between Anglo-American and Continental philosophers in the early 1970s was more like ships passing in a foggy night than opponents engaging in the arena.

In other words, most Anglo-Americans (with notable exceptions, such as Mays and Taylor) paid scant attention to anything said by the Continentals. When they did, they weren't impressed.

The realist Russell had expressed this intellectual chasm in uncompromising terms. Dismissing the later Wittgenstein as "completely unintelligible", he complained, "I have not found in Wittgenstein's *Philosophical Investigations* anything that seemed to me interesting and I do not understand why a whole school finds important wisdom in its pages" (B. Russell 1956*b*: 319). In his obituary of Wittgenstein a few years before, he'd been more tactful. The later philosophy was mentioned only indirectly: "Getting to know Wittgenstein was one of the most exciting intellectual adventures of my life. In later years there was a lack of sympathy between us . . . " and—as the closing words—"Of the development of his opinions after 1919 I cannot speak" (B. Russell 1951: 297, 298). Despite this conventional observance of *de mortuis nil nisi bonum*, the message was clear. In Russell's eyes, Wittgenstein had betrayed everything he (with Russell) had previously stood for.

On the other side, Heidegger and Merleau-Ponty were no less hostile to realism. And Heidegger was hostile to clarity too. He notoriously declared that "Making itself intelligible is suicide for philosophy" (Blackburn 2000).

Russell wasn't the only one to bridle at such a sentiment. By the 1940s, Heidegger was "a figure of fun, too absurd to be taken seriously as a threat" by analytic philosophers (Dummett 1975: 437), and accused by Anthony Quinton (personal communication) of "ponderous and rubbishy woolgathering". The one-time editor of *Mind* Simon Blackburn (2000) has provided a hilarious critique of Heidegger, and speaks of "the purgatory of trying to read [him]" (2005: 78). Similarly, Paul Edwards delivers some savage sarcasm in his attempt "to stem this [current] tide of unreason" (2004: 9). Noting that Heidegger's work has appeared in about twenty languages, he remarks that there's no Hebrew translation: "This is perhaps just as well—the Jews have surely suffered enough already" (p. 11).

Given such entrenched hostility within the Anglo-American camp, it's doubly strange that this German philosopher should now be so fashionable in some areas of cognitive science. For besides eschewing "intelligibility", he scorned the cyberneticists' view of man-as-machine as the ultimate metaphysical illusion. (He was also a savage critic of technology in general.) One might say that he foresaw what Donna Haraway (1986/1991) would call the "cyborg" culture, and fought against it with all the contempt he could muster.

Ryle had been unusual among analytic philosophers, having read fairly widely in phenomenology and being at least partly sympathetic to it (Ryle 1929, 1962). And Taylor (1971) had recently followed his critique of behaviourism (see Chapter 5.iii.b) by drawing on Heidegger, and on hermeneutics, to argue that science—because it's constructed by human subjectivity—can't hope to explain meaning.

But most Anglo-American philosophers at that time—and as noted above, many even now—judged Heidegger to be "a prolix charlatan and poisoner of good sense", whose prose style was "an abomination", mere "bombastic, indecipherable jargon" (Steiner 1978: 13, 16). When analytic philosophers such as Putnam strayed into the enemy territory of anti-realism, they were more likely to start from paths laid down by Wittgenstein (or even Quine) than Heidegger. So, for instance, they would follow Wittgenstein (and Ryle) in seeing "folk psychology" not as a psychological theory, adequate or otherwise, but as a network of conceptual necessities, constitutive of the very concept of mind.

The prime exception, and the person who was most responsible for bringing Heidegger's work back into Anglophone philosophy, was Rorty (although Dreyfus would come a close second). Rorty's first attempt at resurrecting Heidegger was in a conference paper read in 1974, and published soon afterwards (Rorty 1976). But the most influential was his book *Philosophy and the Mirror of Nature* (1979). His accusation there that Descartes had "invented" the mind (cf. 2.iii.a) was largely due to Heidegger. So, too, was his focus on *practice* as opposed to *cognition*.

b. Hands-on Heideggerians

Rorty's efforts were by no means universally welcomed. But nor were they in vain. By the end of the century, more people were willing to take anti-Cartesian, even Heideggerian, ideas seriously—and to use them *constructively* in generating new approaches in cognitive science. (Whether they were faithful to the originals in so doing is another matter: see below.) Even Dreyfus was now recommending a ‘‘reconciliation’’ between phenomenology and AI (H. L. Dreyfus and Dreyfus 1990).

Some of these anti-Cartesians were scientists doing hands-on research in computer science, AI, A-Life, psychology, or neuroscience. They included a number of people mentioned elsewhere in this book (including in Section x, below): Winograd, Michael Arbib, Brian Smith, Philip Agre, Rodney Brooks, Inman Harvey, Randall Beer, Howard Pattee, Esther Thelen—and Maturana and Varela, whose assault on Cartesian realism dated back to the 1960s.

None of these people was originally inspired by Dreyfus, though some cited him in support after developing their own position. Indeed, with the part-exception of Pattee they weren't initially inspired by the philosophical literature at all. Their unorthodox views arose, rather, from reflecting on their own scientific research.

Winograd, for instance, had been frustrated by the limitations on his GOFAI wizardry in NLP (Chapter 9.xi.b). Later, he was influenced partly by Dreyfus (a Stanford colleague from the mid-1970s) and Heidegger, and also by the Frankfurt School, Maturana and Varela, and Fernando Flores (11.ii.g). Indeed, he and Flores co-authored a book in which they explicitly rejected classical realism (Winograd and Flores 1986: 30–1). So did Varela, who had recently applied autopoietic theory to cognitive psychology (Varela *et al.* 1991).

The psychologist Thelen saw the mind/brain as a dynamical system closely coupled with the environment, making this seemingly obvious brain–environment distinction problematic (Thelen 1985; Thelen and Smith 1994) (see Chapter 14.ix.b). Harvey, too, had questioned Cartesian realism, in connection with his work in evolutionary robotics (Husbands *et al.* 1995; Harvey 2000, 2005). And Smith's research—a heady mix of hard-headed computer science and highly speculative metaphysics—had surpassed all but Maturana and Varela in its commitment to criticizing realism.

Others such as Brooks (1987) had rejected representation (and reason too: 1991*b*), if not realism. (That's not to say that Brooks *argued for* realism: he simply assumed it, not being concerned with metaphysics.)

The situated robots described by Brooks, Harvey, Beer, and Arbib were all featured in previous chapters (13.iii.b, 14.vi.c, and 15.vi.c and vii.c). Here, we need add only that our discussion (above) suggests that situated robots are ill-named. To be sure, they respond relatively directly to specific environmental cues, in virtue of their physical constitution. That's why they were sometimes described in terms of phenomenological ideas about the body and the lived situation (e.g. Haugeland 1995). But they aren't situated in the full sense, because they aren't genuinely *embodied*.

As Merleau-Ponty would have been quick to point out, being an autonomous mobile robot isn't the same as having a body. This follows, too, from the philosophical biology of Maturana and Varela (Chapter 15.vii.b, and Section x.c, below). As for Agre and Smith, they're considered in Sections ix.c and ix.e, below.

c. Flights from the computer

Other late-century anti-Cartesians were philosophers of cognitive science—such as John Haugeland, Timothy van Gelder, and Clark. In general, they were sympathetic to the 'insider' attacks just mentioned. Like these scientists, they identified with cognitive science as an explanatory enterprise. If it was faulty, they wanted to fix it—not abandon it.

Today, Haugeland (at the University of Pittsburgh) is a leader of the neo-phenomenological movement in the philosophy of cognitive science. He took Dreyfus's work seriously from the start, and wrote a paper with him for the Kent meeting where Malcolm and Anscombe had also spoken (see Section v.f) (H. L. Dreyfus and Haugeland 1974). But his phenomenological sympathies were then largely implicit. They became fully explicit only in the 1990s.

Whereas Dreyfus's attacks on AI were unremittingly hostile, in both substance and tone, Haugeland's critique was more measured, and more constructive. In his first monograph, he complained:

> Debunkers want to shoot AI down before it takes off, regardless of any actual research, as if the very idea were somehow crazy or incoherent. But the prospects for cheap victories strike me as slender. (1985: 249)

So, for example, he doubted whether computational psychology, or "cognitivism" (1978), could conceptualize moods, and ego involvement (see Chapter 7.i.d). But instead of dismissing cognitivism outright, he said that such phenomena "deserve a lot more study, even in AI" (1985: 238). Similarly, while suggesting that GOFAI couldn't model imagery, he allowed that some non-GOFAI computers could (p. 228).

In the 1980s, Haugeland saw cognitive science as "a great intellectual revolution", based on "a profound and distinctive empirical hypothesis" (pp. 2, 249). Its "paradigm", namely GOFAI—defined so as to include the claim that thought *is* symbol manipulation (pp. 112–13)—was "the most powerful and successful approach to psychology ever known" (p. 250). It had already made some important discoveries, and might—or, as the sceptics claimed, might not—make many more:

> By disciplining theory, the computational model also liberates it: issues can be formulated and accounts developed that were hitherto essentially inconceivable. Certainly these early explorations have encountered unanticipated complexities and difficulties, but even they constitute a wealth of unprecedented empirical knowledge. (p. 211)

> We hate to withhold judgment: scepticism is intellectual anemia. How much more fun, more vigorous, more apparently forthright to take sides! Yet, sometimes, the results are just not in. I am not really convinced that GOFAI is impossible; on the other hand, I'm certainly far from persuaded that it's inevitable. I am dubious: near as I can see, after thirty years, the hard questions remain open. (p. 254)

In short: "no 'disproofs' of AI are proposed, but at most some issues to ponder" (p. 213).

One of the issues to ponder was intentionality. In questioning whether one can "make sense" of AI programs, Haugeland wasn't merely saying (like Searle in 1980) that AI meanings are derivative, but (like Dreyfus) that meaning originates in the lived context and is expressed by embodied, situated, action.

In the 1980s, he put this in Dennettian—not phenomenological—terms. To ascribe meaning, he said, we must "ascribe beliefs, goals, and faculties [to mice as well as to men] so as to maximize a system's overall manifest competence . . . [namely] the ability to achieve goals by making rational decisions in the light of knowledge and perception" (1985: 214–15, 264). Even then, however, phenomenology was in his mind (and his endnotes). He wasn't sorry, he said, to have neglected phenomenology in his text—but he regretted not having more space to discuss "the 'background' of everyday practice" (1985, p. ix). This concept was prominent in Continental philosophy. It had also been stressed by Searle, who defined it as "a set of nonrepresentational mental capacities ['know-how'] that enable all representing to take place" (1983*b*: 143).

Ten years later, Haugeland's phenomenological sympathies were more explicit—and more committed. Previously, he'd felt no qualms in ascribing intelligence to mice (1985: 214). Now, in a glowing review of Dreyfus's unrepentant update, *What Computers Still Can't Do* (H. L. Dreyfus 1992), he declared: "There's only *one* world, *this* one—and it's ours . . . In my own view (and I suspect also in Dreyfus'), there is no such thing as animal or divine intelligence" (Haugeland 1996: 127). Even if there were, he said, that would only extend the scope of who "we" are—for "the *world* just is the realm of the meaningful; in other words, it is where intelligence abides" (p. 127). And he explicitly rebutted the realist's challenge:

> But what about the physical universe: countless stars and galaxies, vast mindless forces, fifteen billion years of atoms and the void? Isn't that the *real* world, a fleeting speck of which we happen to throw an interpretation over, and regard as meaningful? No, that's backwards. The physical universe is *a part of* our world . . . it is *not* primary. Accordingly, cognitive science would be trying to build from the roof down if it began its investigation of intelligence with our understanding of physics. The foundations of intelligence lie not in the abstruse but in the mundane. (p. 127)

Card-carrying functionalists couldn't be expected to agree. They preferred his earlier dismissal of "zany idealism" (1985: 39).

As for Haugeland's opinion of functionalists, he now accused them of presupposing "tendentious and substantive metaphysics" (1996: 120). In other words: Descartes's metaphysics, minus his substance dualism.

Haugeland's metaphysics was phenomenological. It started out from the subject's lived presence in the immediate situation, and was unremittingly externalist with regard to meaning. It followed, he argued, that the scope and boundaries of intelligent systems are not what is usually assumed—by functionalists, as by common sense. Study of "the brain alone" is insufficient for understanding intelligence, and even "an entire individual organism may not be, by itself, encompassing enough" (1996: 121).

Compare Dreyfus:

> But what about *my* experience, one may ask; my private set of facts, surely that is in my mind? This seems plausible only because one is still confusing this human world with some sort of physical universe. My personal plans and my memories are inscribed in the things around me just as are the public goals of men in general. My memories are stored in the familiar look of a chair or the threatening air of a street corner where I was once hurt . . . After all, personal threats and attractions are no more subjective than general human purposes. (H. L. Dreyfus 1972: 178)

Through the 1990s, Haugeland's philosophy grew increasingly Heideggerian (dare one say "zany"?). It eventually included claims such as "The general form of free human commitment—of care or faith—is love'' (Haugeland 1998: 2). Smith might have sympathized, as we'll see (cf. Section ix.e). But most cognitive scientists wouldn't.

Van Gelder (1962–), then based at the Australian National University and Indiana University (now, in Melbourne), exhorted the philosophers of the 1990s to consider not the computer, but the Watt governor (1992/1995, 1998; van Gelder and Port 1995). The old opposition between AI and cybernetics had recently been reawakened by wide-ranging work in dynamical systems (see 4.v–vii, 14.viii–ix, and 15.viii.c, ix, and xi). Van Gelder took this work as his model.

In arguing (as Dreyfus had done) that the brain is an analogue system of constantly varying energy levels, he tried to be constructive. Unlike most dynamical theorists, he allowed for internal representations. But he described them in a novel way. Challenging Fodor's claim that formalist psychology was ''the only one that we are going to get'' (see Section iv.d), he asked, 'What Might Cognition Be, If Not Computation?'—and answered: state transitions in dynamical systems (1992/1995). He described this hypothesis as a vindication of David Hume's dream of a scientific psychology based on mathematical laws like those of physics (see Chapter 2.x.a).

Unfortunately, to try to be constructive isn't necessarily to succeed. Several philosophers protested that van Gelder was saying little of any substance.

For instance, he insisted that he wasn't ''vainly attempting to do *without* complex internal structures [but was] dramatically reconceiving how they might be instantiated'' (1998: 626). As remarked in Chapter 15.vii.c however, it's doubtful whether the dynamical approach can distinguish specific propositional content. Even Clark, who credited the dynamical approach with significant explanatory power, complained that the system's internal functional organization (and the adaptive roles of its components) is obscured by the highly abstract vocabulary of dynamical theory (A. J. Clark 1997: 118–28).

Likewise, Sloman argued that dynamical theory can't represent any interestingly complex mental state (1993, sects. 7–8). If one construes a mind/brain (or a computer) as having a single ''atomic'' state—a point in a high-dimensional, numerically defined, vector space—with a trajectory in the phase space of possible global states, one loses all the important structure in the system. One can't identify the many coexisting, more or less independent, subsystems (and sub-subsystems . . .), or their various, and largely asynchronous, interactions.

Of course, said Sloman, one can try to characterize these in detail—perhaps by constantly varying the number of dimensions, adjusting the numerical parameters, and/or defining attractors on different levels. But once one starts doing this, the distinction between a dynamical systems view and a more conventional AI view begins to disappear. It's no accident, then, that computer scientists speak of computational substructures and sub-processes, not trajectories of global patterns of bits or electric pulses. We need the concept of the virtual machine (see Section ix.c). In short, whereas Hume can be forgiven for taking physics as the model for psychology, today's philosophers cannot.

Yet others objected that the notion of a ''dynamical system'' is so wide that it includes whirlpools and windmills—and digital computers, too (Giunti 1997). Unless one can say just which types of dynamical system are specifically cognitive, one isn't saying much (Chrisley 1998).

Moreover, current computer models of dynamical systems aren't actually continuous, even if—like CTRNs (15.ix.b)—they're called continuous. Rather, they involve discrete state transitions (they're implemented in von Neumann machines). So, contra van Gelder, they *cannot* do things which classical computation can't do.

Finally, van Gelder defined "computation" in terms of Turing machines, arguing (correctly) that this abstract notion can't support various aspects of real information-processing systems, such as temporality. But, as both Sloman (1993) and Ronald Chrisley (1999) pointed out, there are good reasons for adopting a very different definition of computation, immune to van Gelder's criticisms (see Section ix.c and f).

To dismiss highly general philosophical claims for a certain theoretical approach isn't to say that it's never useful (especially if enriched by others: cf. Sloman's remarks, above). A meeting on 'Dynamic Representations in Cognition', co-organized by van Gelder at Indiana University in 1991, considered situated robotics, neuroscience, and psychology (Port and van Gelder 1995). The approach seemed helpful, for instance, in explaining the sudden shifts, or "phase transitions", between different gaits (walk, trot, canter, gallop), or the development of skills such as reaching, grasping, and coordinated kicking (Thelen 1995; see 14.ix.b).

One paper even applied dynamics to Simon's old stamping ground: decision making (Townsend and Busemeyer 1995; cf. Busemeyer and Townsend 1993). It defined a "decision field theory", to reflect the fact that decision making is temporal (unlike logic or probability theory). Continually shifting considerations—preferences, values, expectations, inferences, potential conclusions—"push" and "pull" against each other as the mind moves through the decisional state space; and the trajectory varies with the time available. (Similarly physics-based language was used by William James, in a startlingly apposite passage comparing the phenomenology of choice with the elasticity of a material object—quoted in Townsend and Busemeyer 1995: 102.)

Prima facie, this example seems to contradict the criticisms (above) about dynamics being unable to deal with propositional content and cognitive structure. But to show that the appearance and interaction of "atomic" states X, Y, and Z can be dynamically described isn't to use those states' specific internal structure to explain *why* they arise or *why* they influence each other in the ways they do. The decisional (semantic) trajectories defined by Townsend and Busemeyer were suggested by their prior understanding of rationality, not by the 'physics' of their field theory. That is, the various possible options, and the reasons for and against, weren't actively generated but were taken as given. What was being studied was how the mind then vacillated between them.

Analogously, Haugeland (1978, sect. 6) suggested long ago that a holographic system could act as an associator of visual patterns, and thus underlie (human) chess playing. The first member of a pair of chess positions would be "an important common substructure" in chess, and the other a move (or two alternative moves) that's generally powerful in response to such structures. That's plausible, perhaps, as a description of what goes on in the practised player's mind. But it's not clear that it can explain why response X or response Y was tried out in the first place. That, too, would have to be explained as a series of pattern associations (see 12.x.g).

d. A computational philosophy of embodiment

Clark, like van Gelder, was impressed by the late-century research in dynamical systems—and also by work in animate vision and A-Life (14.vii and 15.v). By the early 1990s, he was already well known as a philosopher of connectionism (Chapter 12.x.e). Then, he 'intermitted' from Sussex for seven years to work at the University of Washington, St Louis—a world-leading base for neuroscience. (Now, he's back in the UK, at the University of Edinburgh.) The intellectual environment in Washington helped him to shine a biological searchlight onto connectionism, and to relate the philosophical question of what counts as a "representation" to various types of neural mechanism (see Chapter 14.viii.d).

The diversity of biological representations, and their difference from the static entities posited by Fodor and GOFAI, was one theme of his book *Being There* (1997). This punning title linked Heidegger with both Woody Allen and Peter Sellers (not easy!). But it was the provocative subtitle, *Putting Brain, Body, and World Together Again*, which announced the main theme.

Clark aimed to counter the disembodied, individualistic picture inherited from Descartes. He did more than insist that "'meanings' just ain't in the head". He described his position as "active externalism", because it focused on the active role of the environment in driving cognitive processes (what he later called "cognitive technology": A. J. Clark 2001, ch. 8)—see Chapter 12.x.e. Indeed, he went further: he saw the (natural and cultural) environment as *constituting* minds and mental capacities.

The empirical roots of this position were deep and long-standing (Chapter 5.ii.b–c). Gibsonian "ecological" psychologists had long stressed the role of the agent's actions (and interests) in exploring its environment, and the specific bodily adaptations involved. Jean Piaget had applied similar insights in the context of "epigenetic" development. Even GOFAI workers had often remarked, though also often forgotten, that the external world provides a rich source of information, lessening the need for detailed on-board memory.

All these ideas had recently been revivified by an upsurge of research on enactive cognition, cognitive and developmental neuroscience, situated and evolutionary robotics, and dynamical systems (see Chapters 8.iii, 14.vi–vii and ix.d, and 15.vi–viii). The picture of the mind/brain as a *self-organizing* system had been reinforced by connectionism on the one hand and developmental neuroscience on the other. Moreover, dynamical approaches had stressed the difficulty, even arbitrariness, of locating the boundary between closely coupled systems.

Clark was the leading philosopher of cognitive science to draw on these later studies in detail. Others included Horst Hendriks-Jansen (1996) and Michael Wheeler (1996, 2005), both also from the Sussex stable. Clark distinguished a range of explanations found in this literature, and defined criteria for deciding when one is appropriate rather than another. But as well as offering such methodological morals, he painted a picture of "active, embodied, cognition"—and of "the *extended* mind".

The latter idea had already been bruited by neo-Kantians such as Dreyfus and Haugeland (see above), and by phenomenologists in general (Rowlands 2003). It had been argued also by postmodernist and/or feminist philosophers such as Donna Haraway (1986/1991). It had even been supported by 'pure' functionalists. Newell and Simon, for instance, had spoken of the environment as providing an "external memory" (see 7.iv.a). Indeed, the notion that individual minds, or selves, are constituted—constituted, not merely influenced—by their social–cultural relations with other selves was a commonplace of much social psychology and social–political philosophy (Hollis 1977—and see Chapter 13.iii.e).

But this view of the mind hadn't been prominent in the functionalist camp. In his first book, Clark had quoted the PDP group's comment that "the external environment [is] a key extension to our mind", and described it as "highly revealing" (A. J. Clark 1989: 133). There, he had related it to the mind's creation of a multiplicity of *virtual* machines. Later, he developed it at length, drawing insightfully on the new empirical evidence mentioned above. And he gave a *computational* justification for it.

So he described language and culture as "natural" artefacts. Like ants' pheromone trails and termites' nests, they are part of the natural history (cf. "forms of life") of the creatures who made them. Their function, said Clark, is to restructure the computational tasks we face into a form better suited to the human brain—a basically connectionist, pattern-recognizing, system.

He'd already argued this (in terms of "representational trajectories") in relation to PDP research in general, as we saw in Chapter 12.viii.d. Now, he focused on the specifically human examples. We naturally construct a system, or "scaffold", of cultural situations. That system makes our situated (i.e. largely automatic) actions more efficient, given the computational resources we possess. (This is why chairs are imbued with human, and even personal, meanings: see above.)

These social and physical artefacts, Clark argued, are so closely coupled with our intelligence that they are in effect integral to it. They inform, and are informed by, our thoughts, memories, decisions, emotions, and desires. In a very real sense, then, a human mind, or self, isn't encapsulated within one individual's skull, or even (skin-delimited) body, but is dynamically extended across the human environment:

> [The] boundary between the intelligent systems and the world [is] more plastic than [has] previously been supposed—in many cases, selected extra-bodily resources constitute important parts of extended computational and cognitive processes. Taken to extremes, this seepage of the mind into the world threatens to reconfigure our fundamental self-image by broadening our view of persons to include, at times, aspects of the local environment. (A. J. Clark 1997: 213–14)

Clark's "externalism" was very similar to Clifford Geertz's 'non-psychological' anthropology (Chapter 8.ii.a). But it was even more shocking, for whereas Geertz had spoken of the "mind" being located outside the head, Clark said this also about the "self"—even closer to the bone, as one might say. Minus the scientific trimmings, his view soon reached a much wider philosophical audience, in a prizewinning paper co-authored with his Washington colleague Chalmers (Clark and Chalmers 1998). The prize was awarded by *The Philosopher's Annual* for one of "the year's ten best papers in philosophy"—*any* area of philosophy. Not everyone was convinced, however: for a critique, see (Butler 1998, ch. 6).

The implication for cognitive science was that we must think of, and therefore study, mental capacities or skills in a new way. The skill of *ship navigation*, for instance, emerges from (is situated within) a complex coupling of individual personalities, social roles and conventions, maps and instruments, mariners' knowledge, problem solving (often spread across several crew members), and a variety of bodily skills (for details, see Chapter 8.iii).

Similarly, said Clark, "much of what we commonly identify as our mental capacities may . . . turn out to be properties of the wider, environmentally extended systems of which human brains are just one (important) part" (1997: 214). Those systems, of course, include computers. Clark's friend van Gelder (2005) has explicitly linked current PC functionality to changes in the "self-constitution" of the rationality of the people who use them—changes which he regards as largely welcome (see Chapter 10.i.h).

A few years later, Clark would have mentioned the intriguing performance artist Stelarc, who came as Visiting Artist to Sussex's Centre for Computational Neuroscience and Robotics. Stelarc was the first person to explore the possibilities and implications of a wide range of man–machine interconnections (M. Smith 2005). One project initiated with CCNR, for instance, was to use electrical signals from his muscles to control a specially built robot many miles away. Indeed, he'd already done this in simple ways (and we saw in Chapter 14.x.b that comparable results have been achieved by linking monkeys' brains to far-distant robots).

The distinction/link between 'real' and 'virtual' worlds (Chapter 13.vi) is a prime interest not only of Stelarc (1986, 1994, 2002*a*, *b*), but also of Clark. He recently returned to it in his popular book describing human beings as "natural-born cyborgs"—in which he did, indeed, mention Stelarc (A. J. Clark 2003*a*: 115–38; cf. Haraway 1986/1991). Mainly, however, he showed how various novel types of computing technology—wearable computers, environmental computers, extrasensory prosthetics, virtual reality, augmented reality . . . —were destined to change people's thinking, experience, and self-image as much as language, writing, and printing already have done.

For all his sympathy with the new methodologies, however, Clark refused to share their all-encompassing scorn for the old orthodoxy:

> The true lesson . . . is not that we somehow succeed *without* representing (or, worse, without computing). Rather, it is that the *kinds* of internal representation and computation we employ are selected so as to complement the complex social and ecological settings in which we must act. (A. J. Clark 1997: 221)

In one important respect—and despite his occasional references to Heidegger, Merleau-Ponty, and Dreyfus—Clark doesn't 'fit' into this section. Putnam, Dreyfus, and Haugeland had all rejected realism. Even Putnam's "internal realism" held that our concepts of mind, body, and self are prior to science, not grounded in it.

By contrast, Clark's theory of "the extended mind" rested as much on scientific research as on philosophical argument. (Russell would have approved.) Like the vast majority of cognitive scientists, he presupposed realism. Indeed, he specifically declined to engage in the realism/anti-realism debate:

> Heidegger was opposed to the idea that knowledge involves a relation between minds and an independent world . . . —a somewhat metaphysical question on which I take no stand. (A. J. Clark 1997: 171)
>
> Varela *et al.* use their reflections as evidence against realist and objectivist views of the world. I deliberately avoid this extension, which runs the risk of obscuring the scientific value of an embodied, embedded approach by linking it to the problematic idea that objects are not independent of the mind. My claim, in contrast, is simply that the aspects of real-world structure

which biological brains represent will often be tightly geared to specific needs and sensori-motor capacities. The target of [my] critique is thus *not* the idea that brains represent aspects of a real independent world, but rather the idea of those representations as *action-neutral* and hence as requiring extensive additional computational effort to drive intelligent responses. (p. 173)

Other *fin de siècle* analytic philosophers were less wary of these metaphysical issues. By the end of the century, anti-realist voices were increasingly heard in the general philosophy of mind—as we'll now see.

16.viii. Mind and "Nature"

By the dawn of the twenty-first century, the "opposing views of the nature of philosophy" still caused radical dissent—even mutual contempt. And the contempt wasn't new.

Realists and anti-realists exemplify what William James (1907) called "tough" and "tender-minded" philosophers, respectively—and little love is lost between them. As James put it, "The tough think of the tender as sentimentalists and soft-heads. The tender feel the tough to be unrefined, callous, or brutal" (p. 13). James's diagnosis was confirmed by Russell's tone of exasperation, when criticizing the later Wittgenstein (see Section vii.a, above).

Later still, it was illustrated by the "science wars" (see 1.iii.b), and by arguments about postmodernism in general (Gross and Levitt 1994/1998; Gross *et al*. 1996; Sokal and Bricmont 1998). Some examples in social psychology and anthropology were mentioned in Chapters 6.i.d and 8.ii.b–c, respectively.

Not least, this mutual mistrust has imbued discussions of mind-as-machine. For example, Guy Robinson (1972) ridiculed functionalism and strong AI by borrowing Thomas Hobbes's contemptuous rhetoric: "When men write whole volumes of such stuff, are they not mad, or intend to make others so?" Since Hobbes himself was a committed mechanist (see 2.iii.b), Robinson was being more than a little mischievous. But he was also being sincere.

By the millennium, many philosophers—in private, if not in print—either shared Robinson's reaction or rejected it with equal passion. Nevertheless, the two approaches had recently become more closely intertwined in some people's work than anyone would have imagined, thirty years earlier.

The new recruits to neo-Kantianism included some hard-headed—but not tough-minded—philosophers raised (like Putnam himself) in the analytic tradition. They respected science but not scientism, and regarded functionalism, and most of cognitive science, as passing illicitly from the former to the latter. Indeed, they shared Rorty's hope for "the disappearance of psychology as a discipline distinct from neurology" (1979: 121). They saw mind (the realm of rationality) as distinct from nature (the realm of the physical and life sciences), and scientific data as philosophically irrelevant. Russell didn't live to see this: presumably, he was turning in his grave.

a. No representations in the brain

One example of this new approach appeared as a volume in a popular series of student-oriented textbooks on 'Problems of Philosophy'. Gregory McCulloch (1952–2002) described the mind as inseparable both from the body and from its surroundings (McCulloch 1995).

Gregory (unlike Warren!) McCulloch leaned heavily on Wittgenstein and Jean-Paul Sartre, and to a lesser extent on Heidegger and Dreyfus. He rejected "mentalism"—by which he meant functionalism, and in particular the language-of-thought hypothesis. Fodor's position, he said, was probably not even the only available scientific psychology—and, for sure, it gave "no account at all of the folk psychological [everyday] mind" (McCulloch 1995: 155). (Clark's 2001 textbook on the philosophy of cognitive science was similar in some ways, but lacked the anti-realism.)

Michael Morris (1955–), a colleague of Clark's (and mine) at Sussex, sympathized with this position. He, too, insisted on the inseparability of the world and our conceptions of it. He avoided idealism, he said, because his theory was *externalist* about meaning. (He later changed his mind about that: see below.) And he had no time for functionalist defences of folk psychology. The notion of folk psychology, on his view, is a scientistic "myth"—one that is "wrong in every particular" (Morris 1992: 111). To say that the death penalty acts as a deterrent is to make a psychological claim (one that's often made by the folk). To regard people as having beliefs and desires, he insisted, is not.

To treat beliefs and desires as theoretical entities, said Morris, is to adopt a fundamentally mistaken (Cartesian) conception of the mind. When we say "She did it because she thought it would help", we are not—*pace* Fodor and his functionalist friends—identifying a causal relationship, but a rational one (pp. 108–9).

As for brain processes, these can cause other bodily happenings, but not behaviour. Or at least, brain processes can't cause the kind of behaviour for which *persons* are *responsible* (namely, *actions*):

> But what *does* cause the behaviour? Nothing. The relevant kind of behaviour [i.e. behaviour which someone is responsible for] is not caused; it is just done. This does not violate such principles as that every event has a cause. People's deeds are not events . . . Events happen; they occur; they are caused. Deeds are just done . . . [This] does not cut deeds adrift from the order of event causation. There is no problem, for example, with thinking that that bit of neuron activity's causing *my hand to rise* is partially constitutive of my action when *I raise my hand*. (p. 136; italics added)

In short, propositional attitudes aren't causes, as they were said to be by functionalist-Putnam. Rather, they are aspects of a system (a human mind) imbued with values. An orthodox Wittgensteinian might put this by saying that they're semantic pieces in the game of rationality, whose rules aren't causal laws but epistemic norms of coherence, evidence, and warrant. Morris prefers to say that there are only two fundamental norms, or "values": namely, moral goodness and truth—intelligible only in combination and contrast with each other. (Hence the title of his book: *The Good and the True*.) The precondition for both of them, he argues, is our personal responsibility.

It follows from this that beliefs and desires can't be explained by *any* naturalistic account. Neuroscience, computational psychology, evolutionary semantics (see Section x.d) . . . none of these can account for rationality. Our evaluation of truth (and our respect for whatever is properly termed *knowledge*) is a philosophical precondition for science, not something that can be explained by it.

This anti-naturalistic position was rooted in the mid-century (pre-functionalist) Wittgensteinian arguments that *intentions*, since they are characterized in terms of the action intended, can't be causes (Melden 1961; cf. Boden 1972). But, writing some thirty years later (and with Clark and myself as colleagues), Morris felt that he had to say something about cognitive science.

This made him unusual, since most neo-Kantian philosophers—including the much more well-known John McDowell (1942–), discussed below—simply ignored its detailed claims. By the same token, it made him interesting for our purposes here. For surely, there should be rather more detailed intellectual contact between philosophy of mind and neuroscience than all-encompassing references to "the brain". Granted that science can't answer philosophical questions, philosophers (of mind) should attempt to situate those scientific theories (of the brain) which at least *appear* to be relevant.

Morris argued that mental representations *as understood in functionalist cognitive science* don't exist—not in Fodor's realist sense, nor in Dennett's instrumentalist sense either (Morris 1991). In other words, there are no *non-semantically individuated objects or states which have meaning, or content*, because no naturalistically identified event can be inherently meaningful. Whereas Dreyfus had implied that cognitive science is a waste of time, Morris didn't. But he argued that cognitive science—*qua* science, not metaphysics of mind—can manage perfectly well without positing representations in the sense defined above (1991: 28–30).

For example, he said, it can investigate certain abstract properties of cognitive capacities, such as the differences between connectionism and other AI architectures. This needn't have any direct bearing on the human mind, but it may—perhaps in respect of the nature of concepts, for instance. (Here, Morris was tacitly agreeing with Churchland's claim that neuroscience may be relevant even to a normative epistemology: Chapter 12.x.c.)

Again, it can study the capacities of actual cognitive systems, using computational concepts of various kinds to discover *functional* relations between *semantically* individuated states.

And third, it can offer partial explanations of psychological capacities, if it can find non-semantically identified types of event that correspond with semantically identified ones—whose meanings are then *stipulatively* assigned to the relevant scientifically identified events. That is: given that we already understand what it is for the cat to sit on the mat, we can decide (*sic*) to assign this meaning to certain neural or computational states. Accordingly, Morris would have no quarrel, for instance, with Clark's claim that neuroscience has discovered various types of representation. (He did suggest, however, that representations would actually be found only for low-level cognitive capacities.)

(For the record, Morris now thinks that he *was* idealist then, even though he believed that he wasn't: personal communication. His view today, in a nutshell that I shan't attempt to crack open, is this: "(1) That the world as it is in itself is entirely independent of our conceptions of it. (2) That there is no correspondence between our conceptions of the world and the world as it is in itself. (3) That most so-called realists—i.e. the ones who believe in correspondence—are in fact committed to idealism (because only an idealist can think that the world as it is in itself has to correspond to our conceptions of it). And (4) that we can perfectly well describe the world as it is in itself—though not by means of any correspondence, of course." What's interesting here, given that Morris is broadly of the anti-Russellian camp, is his continued effort to repudiate idealism. That, clearly, he sees as a step too far.)

b. Mind as second nature

Similar evaluations of science and scientism, and so of the "proper" scope of cognitive science (though without the attention to theoretical details) informed McDowell's highly influential John Locke Lectures.

These were given in Oxford in 1991, and published a few years later (McDowell 1994*a*). McDowell, then at the University of Pittsburgh but originally from the Oxford stable, shared Rorty's view that Descartes had "invented" the mind, not described it (cf. Chapter 2.iii.a).

He was strongly influenced by Sellars's dualism of logical spaces, as Dennett had been too (see Section iv.a). But he rejected Dennett's functionalist analysis of consciousness (see also McDowell 1994*b*). For McDowell, conscious experience is an irreducibly *rational* category—like belief, intentional action, and all other mental phenomena. Accordingly, he rejected any suggestion that the laws of natural science could explain human psychology.

He also refused to follow Nagel—or Everyman—in ascribing subjective consciousness to bats. Subjectivity (he argued) requires meaning, or content, which requires concepts. Without concepts, there can be no particular view of the world, nor any understanding of its general properties. So, despite what most cognitive scientists assume, there can be no such thing as non-conceptual content (12.x.f). And, for McDowell, there can be no such thing as animal experience. He allowed—contra Descartes (Chapter 2.ii.d–e)—that it would be "outrageous" to deny that animals have feelings (such as pain) or "perceptual sensitivity to their environment". But these aren't rational phenomena, so aren't experiences. (Whether they can be anything over and above the patterns of animal behaviour to which Descartes himself drew attention is unclear.)

McDowell wasn't alone in drawing a sharp distinction between humans and animals: most neo-phenomenologists did so. Haugeland, for instance, changed his mind about intelligence in mice as his position became more Heideggerian. And Wittgensteinians in general argued that animals have no concepts, or thoughts. At the Kent meeting, for instance, Peter Geach (1916–) announced to a crowded lecture hall that "You can't really say that dogs are intelligent." This elicited fierce growls from a blind philosopher's normally silent guide dog—and hoots of laughter from the rest of the audience (and Peter, too).

(Wheeler was an exception, here. Although his view of cognitive science was strongly influenced by Heidegger, who had specifically denied *Dasein* to animals, Wheeler argued that they, too, construct their own "worlds": 1996, 2005. Clark, similarly, rejected Heidegger's "thoroughly social", language-based, view of embodied action—A. J. Clark 1997: 171.)

To claim, as McDowell did, that there is no non-conceptual content is to say there are no mind-independent data (no "Given") to act as the foundation of our knowledge of the world. In other words, no purely causal processes could justify, or even provide rational grounds for, our empirical beliefs. Although causal mechanisms (of perception, for example) are necessary for our having beliefs, no scientific psychology—on this view—can explain how these beliefs emerge.

When cognitive scientists study low-level vision, for instance, they typically describe causal (neurophysiological) processes in computational–intentional terms (see Chapter 7.v.b–d). They say that DOG detectors and the like provide information (cf. 'content') about light-intensity gradients, edges, and depth. For McDowell, such talk may be scientifically defensible: "It would be dangerous to deny, from a philosophical armchair, that cognitive psychology is an intellectually respectable discipline, *at least so long as it stays within its proper bounds*" (1994*a*: 55; italics added). But, he insisted, it's also "a recipe for trouble", since it implicitly encourages the myth of the Given. Perceptual mechanisms as such can provide no meaning, no semantic content, whatsoever.

Moreover, the brain can't generate—still less, justify—beliefs, hunches, inferences, or knowledge. All these are matters of normative rationality (the "demands of reason" imply that we "ought" to believe the truth, and to reflect on our own ideas). They therefore lie forever outside science. In that sense, McDowell declared, cognitive science is impossible.

Like Putnam and Morris, McDowell wanted to avoid idealism—including Rorty's version of it (see Section iv.e). He tried to do this not by resurrecting Kant's noumenal world, but by positing a direct (non-representational), and *natural*, relation between mind and the empirical world.

What he meant by "natural", however, was highly unusual. Certainly, his form of naturalism—like the usual forms, which he termed "bald" naturalism—implied *not supernatural*. (On this point, he aligned himself with Aristotle, who had seen rationality as part of human nature: see Chapter 2.ii.a.) But he distinguished between "nature" and "disenchanted nature".

The latter (modernist) notion is the world as described by the laws of science, conceptualized as existing independently of us. The former (as he defined it) includes also "second nature": the habits of rational thought and action into which human infants are initiated by adults as they mature, and which involve the emergence of "resonance" or "responsiveness" to meaning.

Babies, he said, are the only animals (*sic*) to possess the natural, inborn, capacity to acquire concepts, epistemic norms, and other cultural practices—including the interpretation of behaviour in terms of rational relations between beliefs and desires. This "natural capacity" can't be explained by science, because the logical space of causal laws (as opposed to rational norms) has no room for meaning. If neuroscientists discovered innate brain mechanisms underlying some Chomskyan language acquisition device, they wouldn't have explained our capacity for language. And evolutionary biology couldn't do this either:

> It would be one thing to give an evolutionary account of the fact that normal human maturation includes the acquisition of a second nature, which involves responsiveness to meaning; it would be quite another thing to give a constitutive account of what responsiveness to meaning is. (pp. 123–4)

So far, so familiar: neo-Kantians in general drive a wedge between reason and cause. But McDowell, using the concept of second nature, claimed to be able to reconcile them. Philosophy, he said, must be sharply distinguished from science. Nevertheless, philosophers inclined—mistakenly, but understandably—to a *bald* (scientistic) naturalism could rest easy:

> This should defuse the fear of supernaturalism [including various forms of Platonism]. Second nature could not float free of potentialities that belong to a normal human organism. This gives human reason enough of a foothold in the realm of law to satisfy any proper respect for modern natural science. (p. 84)

Whether Russell, for example, would have seen this as satisfying a "proper respect for science" is highly doubtful. For sure, Fodor didn't. He praised McDowell's book for raising "a number of our deepest perplexities"—but defiantly added, "Which, however, is not to say that I believe a word of it" (Fodor 1995*b*: 3).

Nor was it to say that he could actually disprove it, on pain of contradiction. (This was a paradigm case of the "profoundly irritating" nature of first-rate philosophy: see preamble, above.) Claiming that the two logical spaces hadn't been reconciled, Fodor identified several aspects of McDowell's position that he felt were mistaken, unjustified, or merely metaphorical. What is it, for instance, to "resonate" to meaning? And he stated his own, alternative (but not strictly provable), claims.

McDowell, he said, was "as good a contemporary representative of this [anti-naturalistic] philosophical sensibility as you could hope to find". But, he insisted, "it's all wrong-headed. Science isn't an enemy, it's just us" (Fodor 1995*b*: 8).

c. Mind and VR-as-nature

In the preamble to this chapter, I said that a new twist on the realism/anti-realism debate is related to developments in VR (13.vi). This "twist" combines debate about the existence/non-existence of a real world outside us with debate about just what Fodor's word "us" (in the quotation above) really means. The latter question isn't asking what a particular individual's self is "really" like (a problem raised with respect to the different types of VR avatar in Chapter 13.vi.e). Rather, it's asking what it is to be a human being, and to have (or if you prefer, to be the origin of) genuinely human experience.

These deep philosophical questions have been triggered by the fictional exploration of VR in the hugely popular film of 1999, *The Matrix*. (And I really do mean *hugely* popular: a Google search on 10 January 2006 elicited 104 million items.) The human beings in this story are supposed to be experiencing a purely virtual world, while their living but inert bodies are farmed for energy by the machines in charge. The machines are clever enough to fool the people (the brains?) into thinking that they are walking, talking, and eating in a world much like our own.

Among the leading philosophers of mind who've written about the implications of *The Matrix* are Clark, Chalmers, McGinn, and Dreyfus—with his son Stephen (H. L. Dreyfus and Dreyfus 2002; cf. Dreyfus 2000, 2003). Led by Dreyfus (who remarked that, for the first time, the students were now assigning significant homework to their professors), they all contributed online papers to the Warner Brothers *Matrix* web site. Searle and Dennett gave interviews on the web site, too.

Besides these big guns, the cinematic version of Descartes's worry about the *malin génie* (see 2.iii.b) has prompted many other philosophical discussions, some specifically placed in the context of "popular culture" (Irwin 2002). A clear-headed account that's especially helpful for non-philosophers has been written by Matt Lawrence (2005). But the most relevant in the context of this book are the initiating paper by Dreyfus and son and the later essay by Clark.

Dreyfus uses the distinction between telepresence and VR in arguing that the experience of the *Matrix* inhabitants isn't authentic, and—even more "worrying"—isn't fully human either. In telepresence, such as the distance surgery outlined in Chapter 13.vi.b, radio signals from the real world reach the human participant. The person may have the experience of looking at a TV screen, and of hearing sounds through earphones. So far, so VR. But this virtual reality is closely based on, indeed causally linked with, a genuine reality. Moreover, as Dreyfus points out, that reality can fight back—as reality does, all too often. For instance, the surgeon may receive signals that are not only uncontrollable but highly unwelcome, if the tele-operated robotic tool (located many miles away) encounters unexpected flesh or bone in the real patient's body.

In purely fictional VR, however, as depicted in *The Matrix*, any apparent fighting back on the part of the virtual reality is pre-programmed by the designer. It follows, says Dreyfus, that certain sorts of creativity, which are characteristic of real humans in real environments, are blocked off. Radical changes in the person's mode of interaction with the VR world simply aren't possible, because the possibilities have been strictly limited by the VR program. In that sense, the experience of the *Matrix* inhabitants isn't fully human, even though it may be indistinguishable from genuine experience almost all of the time.

Clark's (2003*b*) paper is more closely linked to cognitive science as such. He sets out the filmgoer's three interpretative options: *The Matrix* as "dream, simulation, or hybrid". Citing various experimental findings (some of which were mentioned in earlier chapters), he defends the cognitive science view of human experience as shifting, constructed, and embodied—and dependent on specific brain mechanisms, including the neurophysiology of wakefulness and dreaming. And he draws specific comparisons, including some important contrasts, between our experiences when awake or dreaming and our experiences when involved with VR. The cinematic humans do indeed have experiences "much like our own", as remarked above. But they aren't entirely like our own, and nor are they compatible with what's known about the neurophysiology involved. (The film is science fiction, to be sure: but human physiology was supposed to be unchanged.)

On the issue that's central to this section, Clark finally opts for a version of realism. That is, he argues that *if* it were the case (which it isn't, not quite) that the humans depicted in *The Matrix* had *exactly* the same experiences of perceptual and bodily engagement with a real, and often resistant, world as we do when we're fully awake, *then* they'd be "embodied intelligences through and through", each having/being "a real body, realized in the non-standard medium of bits of information". In other words, having the experience of engaging with a resistant world, by way of one's senses and motor actions, is (so Clark claims) *what it is* for the mind to be "embodied".

However, it's by no means evident that Clark's arguments (or those of another would-be-realist interpreter of *The Matrix*: Chalmers 2003) would satisfy a more down-to-earth realist. In short, the realism/anti-realism dispute hasn't been settled yet. Maybe it never will be—a possibility that makes the "scientists and engineers" mentioned in the preamble distinctly uncomfortable.

16.ix. Computation as a Moving Target

For all his passionate dissent from McDowell's anti-realist position, Fodor didn't pretend to have a knock-down argument. This isn't surprising: as we've seen, we're dealing here with "opposing views of the nature of philosophy".

It's little wonder, then, that shock and excitement—not to mention scepticism—greeted the claim that one can dissolve this long-standing metaphysical impasse by reflecting on the nature of *computation* (see subsection e, below).

It's almost as wonder-worthy, you might think, that anyone bothered to reflect on the nature of computation in the first place. Hadn't Turing settled that question, once and for all? Wasn't he the one (or he and Alonzo Church the two) who'd claimed that the intuitive notion of "computation" could be formally defined (see Chapter 4.i.c)? Unless someone was going to find *extra* meanings hidden in mathematicians' intuitive use of the term (as, in a sense, Penrose tried to do: 1989; cf. Sloman 1992), what more was there to say?

Well, quite a lot—as we'll now see. And much of that has relevance for what we're prepared to count as "cognitive science", because (by definition) one of the two intellectual footpaths followed by cognitive science is computation (see Chapter 1.ii.a).

a. Three senses of computation

The seminal definition, in this context, was Turing's (see Chapter 4.i.c). He saw computation as the step-by-step symbol manipulation carried out by a Turing machine, conceptualized in abstract mathematical terms. Although he held that these operations could in principle be implemented in physical mechanisms, his concept of computation was a purely formal one.

His definition remains fundamental to theoretical computer science, and no cognitive scientist would dispute its importance. Indeed, it's still the only *rigorous* account of what computation is.

However, as the practices of AI and computer science became increasingly varied, two additional senses arose. (A recent paper distinguishes about a dozen different senses, but for our purposes here that's over-egging the pudding: B. C. Smith 2002.) Neither of these is well defined, as we'll see. But to ignore them is to miss much of the intellectual excitement that's driven the field over the past thirty years or more.

Turing (1936) defined computation in formal terms, as an exercise in pure mathematics. His definition was a formative influence on cognitive science, in the sense that McCulloch and Pitts (1943) used it in proving the logical equivalence of their abstractly defined neural networks and Turing machines (Chapter 4.iii.e). But when (a few years later) digital computers appeared on the scene, enabling logical computations to be implemented in electronic machinery, the notion of computation became less clear.

The notion of proof itself—and GOFAI's stress on theorem-provers (Chapter 10.iii.b)—was questioned (even by lawyers) when mechanized 'proofs' of more than a million inferences came on the scene (MacKenzie 1991*b*, 1993). These programs, it was argued, could be informally checked but not formally verified. Yet (so one eminent software expert declared) their conclusions should be accepted as *proofs* nonetheless:

> We must beware of having the term "proof" restricted to one, extremely formal, approach to verification. If proof can only mean axiomatic verification with theorem provers, most of mathematics is unproven and unprovable. The "social" processes of proof are good enough for engineers in other disciplines, good enough for mathematicians, and good enough for me. (cited in MacKenzie 1993: 177)

For our purposes, what's important is that the notion of computation absorbed some of the features of the machines in which it was implemented. Certainly, a program could still be thought of as a series of well-formed formulae of some logical calculus, or programming language—in other words, as a set of uninterpreted mathematical expressions. But it could also be considered in a very different way, as essentially connected with causal processes in computers (see subsections b–c, below).

With the rise of functionalism in the 1960s, Turing's mathematical definition, already featured in the pages of *Mind* in 1950, became more familiar to philosophers. Indeed, it was for many years the only concept of computation they considered. Several philosophers discussed it at length, and used it as a defining criterion of cognitive science and/or AI (e.g. Haugeland 1985; Fodor 1980*a*; Pylyshyn 1980; Copeland 1993). We've already seen that it's the notion relied on by the authors of various key papers:

* by Mays (1952) in rejecting the Turing Test;
* by Putnam (1960) in defining functionalism;
* by Fodor (1975, 1980*a*) in defining cognitive psychology, and in arguing for methodological solipsism;
* by Searle (1980) in saying that AI programs are "all syntax and no semantics";
* and by van Gelder (1992/1995) in criticizing computationalism and recommending dynamical models instead.

The relevance of Turing's definition wasn't argued by these philosophers, so much as assumed by them. Putnam, for instance, took it for granted in his discussion of multiple realizability. And Searle treated it as an unassailable premiss in his attack on strong AI. He even took it to be a premiss shared by his philosophical arch enemies Newell and Simon, the high priests of strong AI. He had good reason for this. Nevertheless, we'll see (in subsection b) that one might read Newell and Simon's work in a different way.

By the 1990s, however, some philosophers and logicians were puzzling over the definition of "computation", and asking *just which* actual and notional machines were equivalent to Turing machines, and which were not (Bringsjord 1994; Calude *et al.* 1998; Copeland and Sylvan 1999).

AI practitioners were moving beyond Turing-computation too. For instance, certain types of neural network (in which the weights could be represented as irrational numbers) were said to be capable of analogue computation (Siegelmann 1995, 1999). Indeed, even *without* such maverick methods, AI scientists weren't interpreting computation as rigidly as outsiders assumed. Sloman—a skilled AI programmer, as well as a philosopher—has said:

> No programmer or computer engineer has, to my knowledge, ever thought of programs in [Searle's] way, and as a programmer myself I have never thought of programs that way. (This criticism of Searle was made by many computer scientists and AI people around 1980.) (Sloman, personal communication)

Sloman goes even further, for he sees Turing machines as largely "irrelevant" for the history of computers and AI (Sloman 2002). Both of these, he argues, are natural developments of two types of artefact: machines for controlling machines (including mechanical looms, musical boxes, and Hollerith machines), and machines for operating on abstract entities (numbers, logical terms, or other symbols). These existed long before Turing was even a gleam in his mother's eye (see Chapters 2.iv and ix, 3, and 4). They blossomed—in power, sophistication, and range of application—in the 1940s–1950s because of electronic technology, not because of Turing's mathematics. Much as Babbage didn't need Turing machines to design a close equivalent of a von Neumann computer (Chapter 3.iii.b), so the modern pioneers of computing and AI didn't strictly *need* them either. The people for whom Turing machines were crucial were those doing *theoretical* computer science.

That's all true. (And Turing himself, before learning about electronics, thought that physical computers were infeasible because they'd have to be as big as the Albert Hall: Chapter 4.i.d.)

One must add, however, that Turing used his theoretical ideas when designing the ACE, and that the designers of MADM—the first stored-program general-purpose electronic digital computer—did so too (3.v.b–c). One must add, also, that AI and computational psychology—and the von Neumann computer itself—were recognized as exciting possibilities in the mid-1940s partly because of a marriage between Turing machines and Russell's logic (4.iii–iv). Furthermore, Turing's paper in *Mind*, which was deeply influenced by his earlier work, was intended as a manifesto for AI and was hugely influential in the young AI community (see Section ii, above). In short, although computers and AI would have happened even without Turing machines, the way in which they did happen was deeply influenced by them.

What's especially relevant in this context is that *philosophers* focused on Turing's formal definition of computation. This said nothing about implementation, whether the physical or the virtual machine. But he'd made provocative claims in the philosophers' trade journal about (future) AI's ability to model the mind, and was (wrongly) believed by them to have offered a behaviouristic Test for successful AI. Putnam, when defining functionalism, used the abstract concept of Turing machines and didn't even mention AI.

Moreover, philosophers in general could cope with mathematical logic, but knew little about computers and even less about the experience of using them. For these reasons, they assumed (and most still do) that Turing-computation was *essential* to the inception and practice of symbolic AI. Having this (first) sense of computation in mind, then, they usually see "computation" as typified by GOFAI and often regard "cognitive science" as essentially symbolic.

The second sense of computation is less restrictive, for it amounts to *Whatever methods are actually used in computer modelling*. Because the list of practicable methods has lengthened with the advance of AI/A-Life, just what this second sense picks out has changed over the years—and will continue to do so.

GOFAI still qualifies, of course. But so do the several kinds of connectionism (Chapter 12); the coordinate transformations of tensor network theory (14.viii.b–c); the various styles of evolutionary programming (15.vi); and the many types of cellular automata (15.v and viii). Situated robotics and dynamical models inspired by physics are covered too (15.vii–viii and xi).

Indeed, new and notional forms of computation are now being discussed. Some of these involve "quantum computers" (D. Deutsch 1985), which—in case they are practically feasible—could do Turing-computation much faster than conventional computers do. (In November 2001, scientists at MIT reported having used a "quantum computer" to find the factors of 15; some of the large banks, dependent as they are on prime-number cryptography, were sufficiently worried to employ consultants to look into these issues immediately: C. T. Ross, personal communication.)

Others involve what Jack Copeland and Diane Proudfoot have called hypercomputers (Copeland 1998*b*; Copeland and Proudfoot 1999; Copeland 2000). These, like Turing's imaginary O-machines mentioned in Chapter 4.i.c, would compute the uncomputable (the key terms being interpreted in the intuitive and Church–Turing senses, respectively). The philosopher Selmer Bringsjord, for instance, has argued that hypercomputation is already being performed by human minds, and that it might one day be performed by computers too (Bringsjord 1992; Bringsjord and van Heuveln 2003: 64–7; Bringsjord and Zenzen 2003). Although he criticizes Penrose's statement of the argument from Gödel, he provides a "modal" version of it which also rejects current AI as the core of a science of mind (Bringsjord and Arkoudas 2004).

At present, ideas about hypercomputers are more speculative than practical (Bringsjord 2001; Copeland 2002*a*; M. Scheutz 2002). But if they're implemented in some future technology, they too will be included under this second, catch-all, sense of "computation".

The more inclusive notion of "computational" concepts has become increasingly prominent since the mid-1980s, in discussions of mind as machine. But it was there right from the start. When cognitive science first emerged, most of the people involved were active both in logical-computational theorizing and in dynamical cybernetics—which they saw as part of the same general enterprise. It wasn't until some years later that these two types of computer modelling were restricted to different research communities (see 4.v–viii).

McCulloch and Pitts, for instance, saw their seminal connectionist paper of 1947 as a new way of developing the ideas they'd put forward in 1943 (Chapter 12.i.c). So did their contemporaries. The sociological separation of GOFAI and connectionist AI happened later. Defining their collective project in a way that excluded the non-GOFAI activities (as Fodor, for instance, did) would have struck them as bizarre.

But perhaps it's better to be bizarre than to be boring? This undiscriminating definition of computation may seem to have no bite, for it doesn't imply any particular philosophical position. Indeed, some philosophers prefer to define cognitive science in terms of formal representations and Turing-computation largely *because* they then know just what it is that they're talking about. If all non-symbolic enterprises fall by the referential wayside, too bad.

What's more, the second definition may even seem perverse. For the proponents of some of the methodologies just listed made a point of distancing themselves from classical AI, as we've seen. They insisted that their models involved a "new form of computation, one clearly based upon principles that have heretofore not had any counterpart in computers" (Norman 1986*b*: 534); and they spoke of "*sub-symbolic* processing" (Smolensky 1988), of "intelligence *without* representation" (R. A. Brooks 1991*a*), and of "cognition *not* computation" (van Gelder 1992/1995). Why, then, did a growing number of people come to think of computation—and therefore cognitive science—in such an all-inclusive way?

The answer is that these modelling approaches—like different programming languages (see 10.v)—involve significantly different virtual machines, with different capabilities.

* A PDP system, for example, has strengths and weaknesses largely complementary to those of a GOFAI program.
* Localist connectionist networks are different again.
* Cellular automata differ from classic sequential programs, and their performance varies according to the types of rule they embody.
* One evolutionary model may be significantly different from another, and all can do things which non-evolutionary programs in practice can't.
* Dynamical systems, such as CTRNs, are unlike classical AI, and can traverse their state space in diverse ways.

Moreover, one virtual machine can be implemented in a different virtual machine . . . and so on. We saw in Chapter 12.viii–ix, for example, that a *sequential* virtual machine can be emulated by a *parallel* virtual machine implemented in a *serial* computer (which in turn may involve several 'layers' of programming languages, ultimately implemented in the machine code).

A host of interesting questions have already arisen about the types of virtual machine that could model human minds—or, more provocatively, what type(s) of virtual machine(s) the mind might actually *be*. Others haven't yet been asked, because they (will) concern types of computer model still to be developed. As remarked above, these may involve highly unconventional machines, including hypercomputers (Calude *et al*. 1998).

To restrict "computation" or "cognitive science" only to Turing computation and GOFAI is as unreasonable as restricting "physics" to the mathematics available to Galileo. When Galileo said (in 1623) that the Book of Nature is "written in the language of mathematics", he didn't mean that the concepts used in *his* mathematics could solve all the problems of physics, but that physicists need to travel along mathematical pathways. And indeed, modern physics isn't definable in terms of only one type of theory (van Fraassen 1980; Cartwright 1983).

Analogously, cognitive science employs a variety of concepts and models, which are "computational" in a general sense. (Even dynamicists speak of the "computations" performed by their models.)

The third sense of computation is philosophically the most controversial. It's also the most unclear. Indeed, it's not so much one sense as a group of rather different senses, all informed by the same general aim.

This aim is to present computation as intentional, and meaning as computational—in part, by focusing on the causal relations involved. The third-style approach conflates *what computers do* with *what minds do*, by way of an account of intentionality that supposedly applies to both. In the rest of this section, we'll consider four—or, more accurately, three and a bit—examples of this third sense of the term.

b. Physical symbol systems

The earliest, and most influential, third-style example was due to Newell and Simon (Newell and Simon 1961, 1976; Newell 1980).

Their AI programs specified formal computational systems of the type defined by Turing. As psychologists, however, they were interested in computations that are grounded in the world and capable of directing behaviour in it. Accordingly, they outlined a semantic theory designed to avoid what Putnam and Fodor called methodological solipsism, and to support what Searle would term the Robot reply.

Their central claim was that intentionality is achieved, in both minds and computers, by implementing certain types of formal computation. Such implementations, or Physical Symbol Systems (PSSs), were seen as "the necessary and sufficient means for general intelligent action". In other words, the mind *is* a PSS. Moreover, said Simon (towards the end of the century):

> [Some programs can] demonstrably understand the meanings (at least some of the meanings) of their symbols, and [they] have goals . . . In contrast [to a simulation of digestion], a computer simulation of thinking thinks . . . We need not talk about computers thinking in the future tense; they have been thinking (in smaller or bigger ways) for forty years. They have been thinking "logically" and they have been thinking "intuitively"—even "creatively". (Simon 1995*a*)

In arguing their case, Newell and Simon defined computation in causal terms. A *symbol*, they said, is a physical pattern with causal effects. The meaning of a symbol is the set of changes it enables the information-processing system to effect, either *to* or *in response to* some object or process (outside or inside the system itself). Analogously, concepts such as *representation, interpretation, designation, reference, naming, standing for*, and *aboutness* were causally defined. For example:

> Two notions are central to this structure of expressions, symbols, and objects: designation and interpretation.
>
>> *Designation*. An expression designates an object if, given the expression, the system can either affect the object itself or behave in ways depending on the object.
>
> In either case, access to the object via the expression has been obtained, which is the essence of designation.
>
>> *Interpretation*. The system can interpret an expression if the expression designates a process and if, given the expression, the system can carry out the process.
>
> Interpretation implies a special form of dependent action: given an expression, the system can perform the implicated process, which is to say, it can evoke and execute its own processes from expressions that designate them. (Newell and Simon 1976: 116)

Whereas the meaning of an atomic symbol depends on its causal history and effects, that of a complex symbolic expression depends on the meaning of its components *and the relations between them*. It was the complex expressions which interested them, for they saw these as the inner core of mentality. But how were these relations depicted? Within any implemented symbol structure, they said, the component symbols are "related in some physical way (such as one token being next to another)".

However, implementation details can vary (multiple realizability, again). So computational psychologists may choose to concentrate on symbol types, rather than symbol tokens. In practice, then, Newell and Simon usually focused on the formal properties of their psychological theories, not on their physical implementation. ("Usually", because they did sometimes take account of neuroscientific evidence: see Chapter 7.iv.b.)

This is why they're typically seen—by Searle (1980), for instance—as proponents of the first sense of computation, not the third. On that view, PSS theory holds that causation grounds the interpretation of computations once implemented, not that it's involved in defining computation *as such*.

c. From computation to architecture

In emphasizing the causal basis of meaning in computational systems, Newell and Simon weren't alone: Sloman did so too.

He dismissed causal theories of meaning (like theirs) that assume some physical relation between a symbol and its referent, because we can refer to non-existing things (e.g. 1986*a*). But he did stress the *virtual* causal processes required for understanding. Moreover, whereas Newell and Simon had taken the concept of cause for granted, Sloman argued that we don't yet understand computation largely because we don't yet understand causation.

Sloman initiated his third-style approach in the 1970s, and is still developing it (Sloman 1978, 1992, 1996*a*,*b*,*c*, 1999, 2002). Throughout this period, he was seeking a new way of thinking about computation, even a new concept of computation—but not a new *definition* of it. In his view, we shouldn't expect to find any precise definition of computation that could function as *the* core notion of cognitive science.

Nor should we expect to find a precise definition of mind (or any other category of folk psychology—such as intelligence, for instance). Philosophers who propose candidates for this illusory honour prompt endless disputes about whether this or that system *is* a mind, *really*. Sloman, by contrast, always stressed the complexity, variety, and many degrees of overlap between different actual or conceivable systems.

He now recommends that we "abandon the notion that the concept of computation is the only or even the central foundation for the study of mind" (1996*a*: 215). He expects the concept to be eventually "replaced by a new taxonomy of designs, covering a more general class of architectures and mechanisms" (1996*a*: 216). This taxonomy will include both minds and mindlike systems, with no clear boundary between them. Computational mechanisms—including many types of virtual machine—are of course involved. But so are physical mechanisms, including neurochemical influences (14.ix.f).

In short, Sloman is a philosopher who takes the design stance seriously. He offers "not a philosophical argument about 'correct' concepts to use, but an engineering argument about the appropriateness of different (animal or artificial) designs for different tasks" (1996*a*: 216).

As remarked in Chapter 2.i.a, the word *engineering* can be a powerful turn-off. Sloman is well aware of this. But he was already arguing in the 1970s, in his book *The Computer Revolution in Philosophy*, that philosophers need to understand computation if they are to solve a raft of philosophical problems (1978, esp. ch. 6). These concern every area of philosophy, but especially the philosophy of mind, science, and language (Sloman 1978, chs. 2–3 and 10; 1986*a*).

He defiantly predicted: "[Within] a few years philosophers, psychologists, educationalists, psychiatrists, and others will be professionally incompetent if they are not well-informed about these [AI's] developments" (1978, p. xiii). At that time, the content of his claim was considered as provocative as its tone. Now, even with "engineering" added, it would be taken rather more seriously.

Many philosophers, however, would still discount it. For they think they already know what computation is—because Turing told us. Sloman allows that Turing's definition is the only precise one, and the only one associated with a clear and solid body of theory. It suffices for dealing with abstract mathematical matters (such as decidability, incompleteness, and complexity), where neither time nor causality is involved.

He allows, too, that Turing's definition has acted as a powerful "catalyst" to cognitive science. But—as Newell and Simon implied in defining PSSs—that notion of computation isn't really what we're interested in, when we ask whether minds are computational machines.

Partly in response to Searle's attempt to divorce computation from intentionality, Sloman argued in the 1980s that computers of appropriate complexity could understand. As for what "appropriate" meant, or "understanding" either, this required further research. But the computers of that time already embodied simple examples of some of the processes needed, such as building and comparing structured representations. The important question, he said, isn't "When does a machine understand something?"—which misleadingly implies some clear cut-off point at which understanding ceases. Rather, it is "What [many] things does a machine—whether biological or not—need to be able to do, in order to be able to understand?" (Sloman 1986*b*).

Although Sloman shared Newell and Simon's impulse to think about computation in terms of causal relations, he differed from them on two crucial points. First, he criticized them for ignoring causal processes within the virtual, as opposed to the physical, machine. For the philosophy of mind, as for psychology, it's the virtual machine which counts (see Section iv). Sloman's later writings explored the increasingly diverse computational processes and ontologies that are instantiated in AI and other forms of computer science. Even hands-on professionals, he said, don't fully understand what their machines are doing.

Second, he didn't take the concept of cause as a philosophical given. On his view, no current analysis captures all our intuitions about causality. It's closely linked with notions of possibility and conditionals, which is why Humean analyses fail. But "possible worlds" accounts, he believed, aren't satisfactory either (Sloman 1996*c*). Nor are the (closely related) attempts in recent theoretical computer science to understand concurrent interacting processes, such as are found on the Internet or in control systems for complex machinery (Sloman, personal communication). But such interactions need to be understood, if we are to achieve a satisfactory notion of causation *as such*.

Besides considering everyday examples, Sloman discussed the causal relations within a wide variety of virtual machines, and between the virtual and the physical machine (Sloman 1992, 1996*b*,*c*). One of his conclusions was that a virtual process can properly be said to cause a physical one, so that *qualia*—which he analyses in computational terms (Chapter 14.xi)—aren't epiphenomenal, but really do cause changes in the brain. But while he has suggested various desiderata for a comprehensive theory of causation, he's under no illusion that he has found one. Nor has he achieved the comprehensive taxonomy of designs necessary, he believes, for understanding both minds and computers. His third-style work is a promissory note rather than a definitive theory.

For many years, Sloman's publications were few and far between, and rarely in mainstream journals. His ideas were highly valued, nevertheless, by a small but discriminating international audience. As we saw in Chapter 10.iv.b, his work on computer vision involved several ideas that were ahead of their time, being rediscovered later by others. He was personally acquainted with most of the AI pioneers, and played an important role in the institutional development of cognitive science in England (where he worked at the University of Sussex for almost thirty years).

In the 1990s, various aspects of his research suddenly became more visible. His long-standing work on motivation and emotion (7.i.f) attracted increasing international attention, as did his approach to consciousness—which, like Dennett's, explicated it in terms of a complex virtual machine. And his ideas on computation, though not yet gathered into the long-awaited book, became more readily accessible through increased publication in print, and on the Web. In short, his influence grew. Many philosophers, however, were still wary of his (principled) refusal to offer crisp definitions, and bemused by his semi-technical discussions of computer architectures and virtual machines.

Sloman, then, is one of those—few, but growing in number—who regard computation (even within GOFAI) as a deep philosophical puzzle. And, as the other side of the coin, he's convinced that even computer scientists don't properly understand what computers are already doing—never mind what they might do in future.

d. The bit in "three and a bit"

This doubly problematic position—that computation is a puzzle, and that even hands-on users don't understand it—is held also by the AI scientist Agre (1997). His 1980s critique of GOFAI planning (see 13.iii.b) was the seed of his later ideas on computation. These are far from what one might expect from a hands-on AI professional.

Like Sloman (and, or so I've argued above, Newell and Simon too), Agre sees computation and intentionality as essentially connected. But he reaches this conclusion in a very different way, being a member of the neo-phenomenological camp discussed in Section vii.

Drawing on postmodernist authors such as Jacques Derrida as well as on Heidegger and Wittgenstein, Agre developed an "interactionist" approach to computation that is radically opposed to classical functionalism. He applied his interactionist vocabulary—or metaphors: his account was far from clear—not only to the computer as the human observer experiences it, but even to the electronic circuitry involved (e.g. Agre 1997: 92–102). And he insisted that computation can't be understood without considering the technical specifics of real examples:

> Computational principles, on my view, relate the analysis of a form of interaction to the design of machinery. These principles are irreducibly intuitive, taking precise form only in the context of particular technical proposals. (Agre 1997: 20)

> The tokens of mechanized logic are not exactly meaningless, since they are useless without the meanings that they are routinely treated as carrying. (p. 96)

Must combinational logic be understood within the mentalistic framework of abstraction and implementation? The happy answer of no can be sustained only by cultivating an awareness of the choices that lie implicit within day-to-day technical practice . . . In order to formulate an alternative, let us start by speaking about digital circuitry in a different way, rescuing it from the discourse of abstraction and implementation and reappropriating it within the alternative discourse of intentionality and embodiment. (pp. 103–4)

[One] should not confuse the articulated conceptions that inform technical practice with the reality of that practice. As [Brian Cantwell] Smith (1987) has pointed out, any device that engages in any sort of interaction with its environment will exhibit some kind of indexicality . . . AI-research needs an account of intentionality that affords clear thinking about the ways in which artifacts can be involved in concrete activities in the world. (pp. 241–2)

Despite his potentially off-putting references to Derrida (hardly an iconic hero of cognitive science: 8.ii.b), Agre—like Sloman—was later invited to contribute to a volume seeking to go beyond Turing-computation (Agre 2002). Nevertheless, I've chosen to describe him, unflatteringly, as "the bit in 'three and a bit' ". Why? The reason is not just his almost perverse unclarity, but the fact that his writing is heavily dependent on another AI researcher, who surpasses him in thoroughness—and, it must be said, in perversity too.

e. A philosophy of presence

As the last quotation indicates, one of the 'technical' authors who strongly influenced Agre was the Canadian computer scientist and philosopher Brian Cantwell Smith (1950–).

Originally trained at MIT, Smith's work was mostly done at Xerox PARC and Stanford (in the Philosophy Department), where he helped found Stanford's CSLI (Center for the Study of Language and Information). Later, he moved to the cognitive science programme at Bloomington, Indiana, and thence to Duke University, North Carolina. Now, he's Dean of Information Science at the University of Toronto.

His interests were always wide, combining intellectual interdisciplinarity with sociopolitical commitments. For example, he was co-founder—with Winograd—of Computer Professionals for Social Responsibility, and CPSR's first President (see Chapter 11.i.c). But no one could have foreseen that this MIT graduate would attempt to turn the notion of computation upside down—or, if you prefer, to enrich it immeasurably. I offer you that choice, because Smith's work is still hugely controversial.

Smith's research, developed over the past quarter-century, is the most far-reaching attempt to address philosophical puzzlement about the nature of computation. One might say that there's nothing it doesn't *attempt* to reach. (Some would add that there's nothing it *does* reach.) It is rich fare, though still a minority taste. Among the gourmets attracted to it, however, are some respected philosophers of cognitive science—and the computer scientist Matthias Scheutz, editor of the *Computationalism*: New Directions volume mentioned above (see B. C. Smith 2002).

This puzzlement grew out of Smith's hands-on experience as a computer professional, where knowledge of the material implementation often didn't enable him to understand what was going on. As he put it:

> [With] respect to computer systems *we already know the answers to all the physiological questions* (we have the source code and wiring diagram), without that necessarily leading to any serious understanding, at the right explanatory level, of "what the program is doing". (B. C. Smith 1996: 148)

He drew the obvious moral: "we should be cautious about any hope that by understanding the brain we will thereby automatically understand the mind" (p. 148).

As for the notion that *Of course we know what it is that computers are doing, because Turing told us*, Smith dismisses that as far too quick. For him, what Silicon Valley treats as computation *is* computation. And the denizens of Silicon Valley, he says, construe "computation" in at least six distinct ways—each of which allows for further distinctions within it. These different meanings are: formal (uninterpreted) symbol manipulation; effective computability; execution of algorithms; digital state machines; information processing; and physically embodied symbol systems. Certainly, one may be tempted to chide the Valley residents for their unclarity—and he does. But for Smith it is what their computers actually do which is important. Turing-computability (the first item on his sixfold list) doesn't capture that.

Smith's mature position—which he dubs "a philosophy of presence"—is another example of interactionist, neo-phenomenological AI. But it's more philosophically sophisticated than most, and much more provocative. Indeed, many professional philosophers (though by no means all, as we'll see) would regard "provocative" as an overly polite description.

Deeply influenced by his technical experience of Silicon Valley's various artefacts, Smith stresses the causal relations between program states (as Sloman had done too), the controllability of various devices, their basis in physics, and their being inescapably situated in the real (and the virtual) world. He sees computation as "inherently participatory", and computers as having "intentional capacities ultimately grounded in *practice*"—analogous to the human practices stressed by Heidegger and Dreyfus (B. C. Smith 1996: 305, 149).

His first publications, in the early 1980s, were on the semantics of programming languages. There, he distinguished Turing-computability from (implemented) computation as such, which *makes things happen* in computers. In other words, computation is a causal concept. He was thinking primarily not of the program's electronic implementation, but of causation in the *virtual* machine.

On that view, the expressions of any given programming language aren't mere empty syntax. They refer (*sic*) to virtual objects and causal processes such as variables (whose values may or may not differ at different times), numbers, procedures, strings, and larger structures containing these. Computer scientists, said Smith, should define their basic terms (such as "variable") accordingly (B. C. Smith 1982). He even designed a novel programming language, and a new semantics for LISP, on this principle.

This early work was seen by some readers as pure computer science—and it was included in an influential collection on knowledge representation in AI (B. C. Smith 1985). But Smith already had two philosophical aims: to put intentional flesh onto dry logicist bones, and to show how self-reflective knowledge is possible. His unorthodox approach whetted some philosophers' appetites, and his promised book was eagerly awaited.

Meanwhile, his ideas were developing in discussion with colleagues at Xerox PARC and Stanford who were working on situational semantics for AI and linguistics (for instance, Stanley Rosenschein, Jon Barwise, and John Perry), and with philosophers such as Haugeland, Adrian Cussins, and Bruno Latour.

His work began to influence the philosophy of cognitive science. It was cited, for instance, in an attempt to escape from the Chinese room (Boden 1988: 247–51); in an argument that non-conceptual content registers the world without articulating it as objects and properties (Cussins 1990); and in a rebuttal of Putnam's claim that computational states are universally realizable (Chrisley 1995). In 1991 Smith indicated his current position in a radical critique of Douglas Lenat's encyclopedia project (see 13.i.c and ii.a):

> [Lenat views] representation as explicit—as a matter of just writing things down. I take it as an inexorably tacit, contextual, embodied faculty, that enables a participatory system to stand in relation to what is distal, in a way that it must constantly coordinate with its underlying physical actions. (B. C. Smith 1991: 285)

But this was a mere taster. Five more years were to pass before the promised book appeared (a brief "introduction" appeared six years after that: B. C. Smith 2002).

Significantly, the title had changed—twice. Originally heralded in 1982 as *Is Computation Formal?*, it was flagged in 1991 as *A View from Somewhere: An Essay on the Foundations of Computation and Intentionality*. It was eventually published (in 1996), however, as *On the Origin of Objects*. In short, the enquiry into computation had become an enquiry into metaphysics.

Smith described the book as an overview, a philosophical "story stripped of its computational heritage" (1996, p. x). What he meant by that was that (like Chomsky in the 1950s: Chapter 9.vi.a) he was holding back most of the technical research that led to his ideas. However, four foundational volumes on *The Origins of Computation and Intentionality* were announced as "in preparation", and (again, like Chomsky) drafts were already informally available.

Now convinced that one must understand metaphysics to understand computation (and vice versa), Smith had developed a novel approach to the nature of objects, individuation, particularity, subjectivity, and meaning. All these matters, he argued, are inescapable if one wants to say *what computers actually do*.

On his view, neither physical objects nor intentional subjects are metaphysically given (as they were for Descartes). They all arise from the "participatory engagement" of distinguishable regions of the metaphysically basic dynamic flux. This flux, described as "riotous fomenting fields" (1996: 281), is the subject matter of field-theoretic physics, and—having no objects—involves neither individuality nor particularity. Objects emerge, or are constructed, as a result of dynamic participatory relations. Smith used the analogy of an English garden, whose order-in-wildness has to be both constructed and continuously maintained (p. ix).

So where others were broadening *Dasein* from humans to animals (see Section viii.b), Smith broadened constructive dynamical interaction from animals to rocks, and even to atoms. All these, he argued, are regions of the flux which achieve particularity and identity through participatory activity. But only some involve *minds*.

Intentionality is at base a form of registration (alias representation: cf. Bennett 1976) that requires a relatively high degree of disconnectedness, or autonomy, as well as connectedness. (The neural emulators and other types of representation discussed in Chapter 14.viii exemplify various combinations of connectedness/disconnectedness.) This type of engagement gives rise to subjectivity and objectivity alike. And its participatory aspect can't be escaped:

> [One] of the most important facts about the inherently participatory picture of registration being painted here is that the form of objectivity available to it cannot be achieved by mistakenly trying more and more to completely disconnect from the world, in a vain attempt to achieve the infamous view from nowhere [Nagel 1986]. On the contrary, the ability to register—*the ability to make the world present, and to be present in the world*, which is after all what this is a theory of—requires that one inhabit one's particular place in the deictic flux, and participate appropriately in the enmeshing web of practices, so as to sustain the kinds of coordination that make the world come into focus with at least a degree of stability and clarity. (pp. 305–6)

In other words, 100 per cent disconnection—pure objective contemplation—is neither possible nor useful: Smith spoke of "the utter futility [that results] when one pulls word and world too far apart" (p. 306).

Smith's third-style position on computation was even more evident now than it had been in the early 1980s. He explicitly denied any fundamental metaphysical distinction between intentionality in human beings and computers:

> The constitutive patterns of partial connection and partial disconnection, of interwoven separation and engagement, while in detail so infinitely various as to defy description, nevertheless reveal regularities across a wide range of cases—from high-level political struggles for autonomy to simple error-correction regimens in low-level computer circuitry. (pp. 347–8)

One's mind can't fail to boggle on reading Smith's book. Quite apart from specific claims such as those quoted above, his overall philosophical agenda—to reconcile the "opposing views of the nature of philosophy" outlined in Section vi.b, above—couldn't be more ambitious. In a recent paper intended as an "introduction" to his book, Smith says as much himself:

> For sheer ambition, physics does not hold a candle to computer or cognitive . . . science. Hawking and Weinberg are wrong. It is we, not the physicists, who must develop a theory of everything. (B. C. Smith 2002: 53)

And "everything", here, really does mean everything. In his book, Smith claims to have retained the major insights of both Continental and empirical–analytic traditions, without any of their problematic ontological assumptions. He also claims that his metaphysics gives us norms as well as facts, and that his account of objectivity can be "ultimately construed as a way of *living right*, rather than merely as a way of speaking truthfully" (1996: 108). (Compare Morris on the good and the true: Section viii.a, above.)

As one might expect, Smith's readers were mostly bemused. And even those who appreciated his effort were often highly ambivalent. For instance, the Washington University computer scientist Ronald Loui, who reviewed the book in *Artificial Intelligence*, described it thus:

> [It is] an important book, even a beautiful book. It reasserts its author as one of the deepest and [most] erudite thinkers of computing. It is also, to this reviewer, an intellectually uninteresting book and thoroughly frustrating to read. (Loui 1998: 353)

After listing some of the "frustrations", which included Smith's decision to spend so much time on metaphysics ("I would have demanded an apology rather than an admission": Loui 1998: 353), he continued:

> Along the way, gems are dropped that reflect an incredibly rich understanding of computing. I consider these gems to be more valuable than the details of the main line of Smith's investigation. . . . *If Brian Smith were not paralysed by metaphysical problems*, he could deliver the seminal work on the philosophy of computing just by collecting and displaying these gems of his insight. (Loui 1998: 354; italics added)

Nevertheless, *On the Origin of Objects* was published carrying high praise from philosophers and computer scientists alike. Haugeland, for instance, saw not paralysis but fundamental, all-engrossing, metaphysical insight. He was quoted on the dust jacket as saying: "Smith recreates our understanding of objects essentially from scratch—and changes, I think, everything."

As remarked at the outset of this chapter, however, philosophical problems don't get solved in a hurry. One shouldn't expect that Smith's highly unorthodox metaphysics would—or will—convince everyone. Some may disdain its 'engineering' origins in his practical experience of computing (see Chapter 2.i.a). Even setting such snobbery aside, however, agreement won't come easily.

Phenomenologists won't readily endorse his use of field-theoretic physics to arrive at conclusions largely similar to theirs. For as we've seen, they believe that a naturalistic philosophy of mind is impossible. Similarly, Searle attacks Smith's ascriptions of intentionality to computation, arguing that syntax (pattern) isn't really "in the physics" but is "observer-relative"—so that Smith's work provides no escape from the Chinese room (Searle 1990*a*; 1992: 209).

Even those who—like Smith himself—reject formalism while favouring a mind-as-machine credo may disagree with him in various ways. My own view, for instance, is that he helped himself to the "dynamic flux"—his version of Kant's noumenal world—without proper licence. He claims that he's pulled this concept up by its own bootstraps (in the final sixty pages), to form a "constructivist" metaphysics of objects and intentionality (cf. also pp. 188–9). But it seems to me that he begs this fundamental philosophical question instead of answering it.

In addition, many readers will be bemused—perhaps even repelled—by the extraordinary mix of dry argumentation and intoxicating (or embarrassing) rhetoric. The rhetoric is evident in his promise to do the metaphysical bootstrapping just mentioned:

> I have been assuming an underlying space of physical feature fields—fields that were never paid for, and which anyway are about to be discarded . . . The fields will go. But the patterns will remain: restless patterns of stabilization and coordination, of invention and description and activity and design, of struggle and submission and conquest and peace, sometimes collaborative, sometimes singular. All these participatory activities arise out of ineffable connection and subside back into it, at a different place or different time or under different circumstances, often benefitting from the perspective of abstraction and registration, but never escaping from the located, the directed, and the exquisitely particular. (1996: 312–13)

The crucial point, however, is that it's not only Smith's *rhetorical style* that's surprising. (Surprising, that is, to analytic philosophers and computer scientists. Devotees of Heideggerian metaphysics would be less bemused, for he too constantly appealed to freedom, commitment, poetry, and love.) In short, Smith's *account of computation* is very different indeed from what most philosophers expect.

Different or not, Smith is adamant that understanding computation is crucial for cognitive science:

> It is sobering, in retrospect, to realize that *our preoccupation with the fact that computers are computational* has been the major theoretical block in the way of understanding how important computers are. They are computational, of course; that much is tautological. But only when we *let go of the conceit that that fact is theoretically important* . . . will we finally be able to see, without distraction, and thereby, perhaps, at least partially to understand, how a structured lump of clay can sit up and think. (B. C. Smith 2002: 52–3)

f. The moral of the story

The general moral, here, is that the rise of third-style discussions (such as those of Sloman, Agre, and Smith) strongly suggests that we don't yet know what computation—understood intuitively as what computers do—*is*. In particular, we can't assume without question that it's utterly distinct from intentionality. It follows—if the mind is a computational machine—that we don't yet know what the mind is, either.

The core thesis of cognitive science—that mental processes are computational—should therefore be interpreted transparently, not opaquely (Chrisley 1999). In other words, the claim isn't that mind can be explained by our current ideas about computation, but that it's explicable by *whatever theory turns out to be the best account of what computers do*.

"Computers", as suggested above, may turn out to include hypercomputers, computing functions that aren't Turing-computable. So Copeland (2000, 2002*b*) has argued for much the same position as Chrisley, in opposing "wide" to "narrow" mechanism. Narrow mechanism sees the mind as some sort of Turing machine, whereas wide mechanism allows for types of computation that aren't Turing-computational—but which are executed in *machines* nonetheless. If wide mechanism is true, then classical functionalism bites the dust. But mind-as-machine doesn't.

There's a clear analogy, here, with physicalism in metaphysics. Physicalists don't normally tie themselves down to today's physics, but have in mind *whatever turns out to be the best account of the physical world*. The best physics may turn out to be surprising (yet again). And, as Chrisley points out, the best theory of computation may turn out to be surprising too.

It's clear from the rise of the second (inclusive) and third (causal/intentional) senses discussed above that the concept of computation has been a moving target since its introduction in the 1930s. Turing's definition is still the clearest, to be sure, and is understandably still cited by philosophers. But even Searle now allows (largely because of Smith) that the mathematics and electronics haven't been clearly connected, and that "there is little theoretical agreement among the practitioners on such absolutely fundamental questions as . . . What exactly is a computational process?" (1992: 205).

In sum: the still widespread notion that philosophers can give—or just assume—a quick definition of computation, and then get on to the *really* interesting philosophical issues, takes far too much for granted.

16.x. What's Life Got To Do With It?

All the minds we know about are found in living things. But why?

* Couldn't there be mind and meaning without life?
* And what is life?
* Given that it involves self-organization, just what sort of self-organization is it?
* Must it involve evolution, for instance?
* Is embodiment essential? And what's that? Is mere physicality enough for embodiment?
* Or is metabolism needed too—and, again, what's that?
* What's the link, if any, between metabolism and mind?
* Could life be generated artificially, and if not why not?
* Is strong (i.e. virtual) A-Life impossible in principle?
* If so, does it follow that strong AI is an illusion too?

These questions took a long time to surface in cognitive science. Or perhaps one should rather say to *resurface*. For in the very early days, life and mind were both discussed—and were treated largely on a par.

The cyberneticians of the 1940s applied their theories of self-controlling machines to both living organization and purpose (see 4.v–vii). Life wasn't regarded as necessary for teleology, for self-guided missiles were said to exemplify goal seeking (Rosenblueth *et al.* 1943). However, since life and mind were supposed to consist in fundamentally similar principles of control, it didn't seem surprising that all the minds we know about are grounded in living things.

McCulloch had been a member of this life-and-mind movement since its inception in the 1930s. But he'd been deeply interested in logical analyses of language even before then (see 4.iii.c). In the event, his paper of 1943 turned attention away from life in favour of mind.

Control by feedback gave way to logic-based computation. The NewFAI computer-modelling community saw mind and meaning as matters for propositional logic, their origin in adaptive behaviour and living embodiment being downplayed. Even unreconstructed cyberneticians now sometimes spoke of mind without mentioning life: when William Ross Ashby wrote a paper on cybernetics for *Mind*, he concentrated on defending materialism against mind–body dualism, not on exploring the philosophy of self-organization (Ashby 1947).

In short, by mid-century the link between life and mind—though still widely accepted, even taken for granted—wasn't explicitly considered. The people on the NewFAI side of the emerging cybernetics/symbolic schism (4.ix) ignored life and spoke only of mind. The people on the other side said very little about mental phenomena beyond perception and goal seeking: self-reflection and reasoning were mostly ignored.

That life/mind split within cognitive science lasted for several decades. Much the same was true in philosophy, especially the analytic variety. It's still the case, in 2006, that the link between life and mind is ignored (beyond mere lip-service) by the mainstream. However, these issues are now arousing interest—largely as a result of the rise of A-Life.

a. Life in the background

Even in the early 1960s, there were a few exceptions to what I've just said. Most important, with respect to their historical role in cognitive science, were the people impressed by cybernetics who were developing holistic philosophies—and computer models—of life and/or mind (15.vi–vii).

The most influential of these (all discussed later in this section) were to be the Chilean neuroscientist Maturana (with Varela and Milan Zelený), whose similarity to Dreyfus was mentioned in Section vii.b above, and the philosopher Howard Pattee, with his students Robert Rosen and Peter Cariani. Both Maturana and Pattee were working on the concept of life from the 1960s. Although they had some early disciples, their ideas didn't become widely known until the 1990s. By the new millennium, however, Maturana and Varela's ideas had been published in semi-popular form, and an entire issue of the journal *BioSystems* was devoted to Pattee's work and influence (Rocha 2001).

All of the above were either scientists (like Maturana) or philosophers very close to science, so close that they sometimes got involved in scientific work (Pattee, for instance). None were "pure" philosophers.

In general, the mid-century philosophers who were interested in the puzzle of life-and-mind came from the Continental, not the analytic, side of the fence. As a result, they were largely ignored by the scientific community. Moreover, they were exceptions even within their own, neo-Kantian, tradition. To be sure, phenomenologists in general took the human being's embodied living-in-the-world as philosophically basic. And Wittgenstein saw language as part of our "natural history", declaring: "What has to be accepted, the given, is—so one could say—*forms of life*" (1953: 226). Most of them had scant interest, however, in what biologists mean by life—which includes oak trees and barnacles, as well as human beings.

One exception to this was the existentialist theologian Hans Jonas (1903–93), who developed a new philosophy of biology in the 1950s. Unlike Maturana and Varela, he wasn't interested in biology for its own sake, but as an aspect of what he saw as the disastrous cultural denouement of Descartes's materialism (Jonas 1966: 58–63).

An ex-pupil of Heidegger, Jonas fled Germany for England when the German Association for the Blind expelled its Jewish members (Jonas 1966, p. xii). From the mid-1950s to the mid-1970s he worked at the New School of Social Research, in New York. Despite still regarding Heidegger as "the most profound and . . . important [proponent] of existential philosophy" (p. 229), he rejected his philosophical dichotomy between humans and other living things—and his pro-Nazi sympathies, too. He explained the latter in terms of "the absolute formalism of [Heidegger's] philosophy of decision", in which "not *for* what or *against* what one resolves oneself, but *that* one resolves oneself becomes the signature of authentic Dasein" (Jonas 1990: 200). And that, in turn, he saw as a result of the stripping-away of value from nature, its "spiritual denudation" by Descartes and modern science (Jonas 1966: 232).

It was in response to this disenchantment of nature that Jonas published various essays on life in the post-war years, and collected them as *The Phenomenon of Life* in 1966. They outlined a framework for a biology that would admit value as an intrinsic feature of life in general. ("Outlined" and "framework" are important here: he discussed almost no specific examples.)

Embodiment, and in particular metabolism, was seen by Jonas as philosophically crucial (1966: 64–91). Not only was life essential for the emergence of mind (pp. 99–107), but *all* self-organized matter was, in a sense, ensouled—though where Maturana and Varela spoke of life as involving *cognition*, Jonas spoke of life as involving *self-concern*. (He lauded Heidegger for having "shattered the entire quasi-optical model of a primarily *cognitive* consciousness, focusing instead on the wilful, striving, feeble, and mortal ego"—1996: 44.) As he put it:

> One way of interpreting [the ascending scale of life] is in terms of scope and distinctness of experience, of rising degrees of world perception. . . . Another way, concurrent with the grades of perception, is in terms of progressive freedom of action. . . . [One] aspect of the ascending scale is that in its stages the "mirroring" of the world becomes ever more distinct and self-rewarding, beginning with the most obscure sensation somewhere on the lowest rungs of animality, even with the most elementary stimulation of organic irritability as such, in which somehow already otherness, world, and object are germinally "experienced," that is, made subjective, and responded to.
>
> [We spoke, above, of freedom.] One expects to encounter the term in the area of mind and will, and not before: but if mind is prefigured in the organic from the beginning, then freedom is. And indeed our contention is that *even metabolism, the basic level of all organic existence, exhibits it: that it is itself the first form of freedom*. (Jonas 1966: 2–3; italics added)

Even in "the blind automatism of the chemistry carried on in the depths of our bodies", there is "a principle of freedom . . . foreign to suns, planets, and atoms". For living organisms have a special type of identity and continuity: a stable dynamic form made of an ever-changing material substrate. In short, "mind is prefigured in organic existence as such" (p. 5). Plants, too, have "metabolic needs", although they stand in an "immediate" relationship to their environment. And metabolism is the necessary base of all forms of mediation: perception, motility (action), emotion, and—ultimately—conscious imagination and self-reflection. (These phenomena emerge as a result of evolution: Darwin, *despite* his materialist assumptions, had enabled us to understand this: pp. 38–58.) Life and mind are ontologically inseparable: "the organic even in its lowest forms prefigures mind, and . . . mind even on its highest reaches remains part of the organic" (p. 1).

In other words, Jonas was offering an answer to the question of *why* all the minds we know about are found in living things. At the same time, he was offering an answer to the question of *what life is*.

He explicitly refused to speculate about the origins of life (p. 4), even though this was already being discussed by biochemists (Chapter 15.x.b). His interests were ontological, not scientific: metabolism was "the break-through of being" from mere physicality to "the indefinite range of possibilities which hence stretches to the farthest reach of subjective life" (p. 3). (Accordingly, he retained a Heideggerian hostility to technological theories/analogies of life or mind: pp. 108–26.)

The book was reissued (by several different publishers) in 1979, 1982, and 2001, and translated into German in 1994. So one can't say that it was wholly ignored. Indeed, because of his stress on the intrinsic value of life and humankind's responsibility towards it, Jonas's work—especially his volume on ethics (Jonas 1984)—has recently become better known thanks to the environmentalist movement.

In the 1950s and 1960s, however, his philosophy of biology was ignored by analytical philosophers and mainstream biologists alike. (And by cyberneticists too, whose analysis of living purpose and rocket teleology *in the very same terms* he'd rejected as "spurious and mainly verbal"—1966: 111.) The same was true of Maturana and Varela's early work, but they have now earned a clear, if still marginal, place in the history of cognitive science. Jonas has not (but see Di Paolo forthcoming). He's relevant here not as a protagonist in that historical drama, but as a mid-century philosopher who tried to argue the case that mind requires life, rather than taking it for granted.

Another philosopher who'd done this was Henri Bergson (Chapter 2.vii.c). By the end of the twentieth century, Bergson's views on "creative evolution" were being revived in some philosophical circles—especially in "process" philosophy/theology (Sibley and Gunter 1978; Papanicolaou and Gunter 1987). This emulated Bergson alongside the even greater hero Alfred North Whitehead (4.iii.b). But some unorthodox scientists were taking an interest too. The physicist–philosopher Henri Bortoft (1996) put Bergson second only to Goethe as a precursor of current dynamical theories in science and philosophy (see 2.vii.c). And a few neo-Bergsonian philosophers even tried to relate his ideas to cognitive science and/or A-Life.

For example, Gilles Deleuze (1925–) revived certain aspects of Bergson's philosophy by stating them in terms of ideas about dynamical systems (Deleuze 1966/1988). I'm saying that at second hand, I must confess, for Deleuze himself is nigh unreadable by anyone more accustomed to analytical philosophy. Much as Richard Montague's work couldn't spread among linguists until a clear account of it had been provided by Barbara Partee (see 9.ix.c), so Deleuze's has been made accessible to cognitive scientists by his expositor Manuel DeLanda (2002).

Although he rejected Bergson's dualist interpretation of *élan vital*, Deleuze offered a "re-enchantment" of matter, nevertheless. He even (confusingly) used the term "spirituality" in talking about matter and life. But this wasn't intended as transcendent spirituality: rather, it referred to the abstract principles of self-organization, and the structured spaces of possibilities, that are inherent in matter/energy.

He saw matter not as inert stuff subject to external influences, but as the source of formative material *processes*. A soap-bubble, for instance, actively minimizes the surface tension at every point (it dynamically "computes" its own shape). The dynamical structures generated by matter were said to be constrained, in part, by abstract topological principles describing connectivities and attractors of various kinds (compare Stuart Kauffman's work on NK networks, and Randall Beer's on CTRNs: 15.ix.b and xi.b).

On this view, life was a special case of matter, and mind a special case of life. It followed that there's no *special* difficulty about giving a naturalistic, even a materialistic, account of mind or intentionality, even though spelling one out in detail may be highly challenging.

However, these intriguing analogies weren't helpful in furthering scientific understanding. (Or anyway, they haven't been helpful yet: DeLanda's relatively accessible version of Deleuze appeared only two years ago, and it remains to be seen whether many scientists will take it up.) Admittedly, the ever-maverick neuroscientist Karl Pribram (1987)—accused in the early 1960s of actually *believing* the MGP manifesto (6.iv.c)—described the cerebral basis of some cognitive processes in Bergsonian terms. But that's not to say that he *used* Bergson's ideas to make discoveries which otherwise would not have been made. Rather, he pointed out an analogy between Bergson's views on memory and his own (long-standing) holographic/holonomic theory (cf. 12.v.c).

Cognitive scientists who weren't already sympathetic to dynamical systems and/or Kauffman's approach to A-Life weren't likely to be interested in Bergson's work at all, even if they encountered it. And that was unlikely: as remarked in Chapter 2.vii.c, it had been more or less forgotten since mid-century—especially by philosophers of an analytic cast of mind.

For over thirty years, then, the concept of life was usually ignored in discussions of mind as machine. To be sure, the psychologist Miller raised the topic—but he immediately dropped it like a hot potato. He was, he said, "unclear" whether epistemic (cognitive) systems should be defined as animate or inanimate. The advantage of defining them as animate was that "we cut artificial intelligence free to develop in its own way, independent of the solutions that organic evolution happens to have produced" (G. A. Miller 1978: 9). (This remark pre-dated the concept of strong A-Life by a decade: clearly, Miller thought it obvious that computers and life are incompatible.) But whether it made "any real difference" in conceptualizing the study of *mental* processes was "unclear".

Most analytic philosophers tacitly assumed some life–mind linkage—which would imply that if computers aren't alive then they aren't psychological systems. They evidently thought this point so obvious that, even when they bothered to state it explicitly, they didn't offer any arguments for it.

Scriven, for instance, confidently declared—without giving reasons—that "Life is itself a necessary condition of consciousness" and that "Robots . . . are composed only of mechanical and electrical parts, and cannot be alive" (Scriven 1953: 233). Lucas hinted at a similar position in his own reply to Turing's 1950 paper (see Section v.a). Geach insisted that AI systems can't have beliefs and intentions because they're "certainly not alive" (Geach 1980: 81). And some, such as Searle (1980, 1992) and Ruth Millikan (1984), explicitly linked intentionality with biology (neurochemistry and evolution, respectively). But even they didn't discuss the nature of life as such.

Two exceptions that proved (i.e. tested) the rule were Putnam's (1964) paper on 'Robots: Machines or Artificially Created Life?' and Geoffrey Simons's (1983) book *Are Computers Alive?*

Despite its title, Putnam's paper focused mainly not on life, but on consciousness. At one point, Putnam endorsed Ziff's claim that it's an "undoubted fact" that if a robot isn't alive then it can't be conscious. But he was relying on "the semantical rules of our language", not on any quasi-explanatory relationship between life and mind.

He also said (this time, disagreeing with Ziff) that something which is clearly a mechanism might be alive. Again, however, this was linguistic philosophy in action. Sometimes, Putnam heretically recommended *changes in meaning* due to new scientific data, as he did when countering Malcolm's account of dreaming (Putnam 1962*a*). But in the paper on robots and life, he was talking only about what *current usage* allowed one to say (or imagine) without contradiction. The nearest he got to discussing a substantive claim about life was to scorn the suggestion that the primary difference between a robot and a living organism is the "softness" or "hardness" of the body parts (1964: 691).

Much later, Putnam's paper was discussed at length, and accused of incoherently combining Aristotelian and Cartesian views (Matthews 1977). At the time, however, it didn't prompt philosophical interest in the concept of life.

Simons, writing twenty years after Putnam, used concepts drawn from GOFAI and cybernetics to claim that computers can be *really* alive, and *really* intelligent. He specifically denied that the genesis of the system is relevant to whether it's alive: "A mechanically *assembled* [i.e. not evolved or self-constructed: see below] system may reasonably be regarded as living . . . " (1983: 23). However, his argument was neither deep nor convincing, and (deservedly) attracted little attention.

b. Functionalist approaches to life

With the rise of A-Life in the late 1980s, the nature of life became an inevitable topic for computational research. Inevitable, but in practice not central: most A-Life workers focused on other questions, maintaining a diplomatic silence on this one. Some of their colleagues, however, were more bold.

The relevant discussions were guided by two radically opposed philosophies. (Sounds familiar?—see Section vi.b.) These were functionalism and metabolic holism, a special case of dynamical systems theory.

Functionalism, in this context, is the view that the characteristics of life (see Chapter 15.ii.b) can be described by informational concepts. So self-organization involves the appearance of new levels of order, abstractly defined. Autonomy, emergence, development, adaptation, responsiveness, and evolution concern various types of structure, process, and control. Even reproduction (on this view) can be defined informationally, as self-copying.

The one exception is the concept of metabolism, which concerns not information but energy. Thoroughgoing A-Life functionalists weren't worried by this, as we'll see. But their opponents argued that they should be.

It's often assumed (wrongly) that all A-Life workers are thoroughgoing functionalists. This is largely because Christopher Langton, following John von Neumann's lead, wrote this position into his definition of the field in 1986 (Chapter 15.ii.b and ix).

Moreover, he drew the obvious implication: a licence for strong A-Life. If living self-organization is definable in logical terms, then a virtual "creature" implemented in computer memory that satisfied these abstract criteria—whatever they are—would be genuinely alive. ("Whatever they are", because definitions differed. For instance, Langton suggested including the lambda parameter, Andrew Wuensche the Z-parameter: Chapter 15.viii.a.)

Some A-Life colleagues were quick to join Langton in this claim. Thomas Ray, for instance, declared:

> The intent of [my] work is to synthesize rather than simulate life . . . To state such a goal leads to semantic problems, because life must be defined in a way that does not restrict it to carbon-based forms. It is unlikely that there could be general agreement on such a definition . . . Therefore, I shall simply state my conception of life in its most general sense. I would consider a system to

be living if it is self-replicating, and capable of open-ended evolution [generating] structures and processes that were not designed-in or preconceived by the creator. (Ray 1992: 372)

As we saw in Chapter 15.vi.b, Ray's Tierra system did indeed generate phenomena not designed-in by Ray. These included co-evolving parasites, hyper-parasites, cheaters, and symbionts. Ray's response was a curious combination of modesty and hubris:

[The] results presented here are based on evolution of the first creature that I designed, written in the first instruction set that I designed. Comparison with the [virtual] creatures that have evolved shows that the one I designed is not a particularly clever one . . . It would appear then that it is rather easy to create life. (p. 393)

As for the problematic concept of metabolism, Ray said two things. On the one hand, the computer consumes physical energy too. On the other, the equivalent of metabolism can be functionally defined:

In studying the natural history of synthetic organisms, it is important to recognize that they have a distinct biology due to their non-organic nature. In order to fully appreciate their biology, one must understand the stuff of which they are made. To study the biology of creatures of the RNA world would require an understanding of organic chemistry and the properties of macro-molecules. To understand the biology of digital organisms requires a knowledge of the properties of machine instructions and machine language algorithms. (p. 397)

I will discuss the inoculation of evolution by natural selection into the medium of the digital computer. This is not a physical/chemical medium; it is a logical/informational medium . . . Evolution is then allowed to find the natural forms of living organisms in the artificial medium. These are not models of life, but independent instances of life. (Ray 1994: 179)

For some broadly functionalist A-Life scientists, this was a step too far—and *much* too far for most philosophers (e.g. Harnad 1994; Olson 1997). Those A-Life colleagues were content to interpret most of the characteristics of life in informational terms—but not metabolism, which is irredeemably physical. However, since they defined metabolism as mere energy dependency, their rejection of Ray's position was intuitive rather than strongly argued (see below).

Many A-Life colleagues simply avoided the question, by way of the "diplomatic silence" mentioned above. They were interested in studying specific aspects of life, such as evolution or flocking, not in discussing its general nature. They were even less interested in considering the "strong A-Life" scenarios sketched by Langton and Ray—and later by Steve Grand (1958–).

Grand's first claim to fame was that he designed the hugely popular computer game Creatures. This swept the world in the early 1990s (see Chapter 13.vi.d), and was still being widely celebrated—for broadly counter-cultural reasons—in the new century (Kember 2003: 91–105).

Creatures enabled the user to evolve unusually sophisticated computer creatures (Grand and Cliff 1998). Their neural-network brains supported simple learning, and included 'neuromodulators' as well as several types of 'neurone'. The creatures also had a simulated biochemistry, with the potential to model a large number of metabolic and hormonal functions, from digestion to ovulation. As a piece of lifelike software engineering, it was way beyond the general state of the art when it appeared, and is still impressive. Indeed, it could conceivably be used as a powerful test bed for AI models of motivation and emotion such as those discussed in Chapter 7.i.e–f (Boden 2000*b*).

Grand's current technical aim is to build an "imaginative" robot called Lucy, whose intelligence will emerge "naturally"—and holistically—from its 100,000-neurone hardware (Whitby and Grand 2001). As he points out, this attempt to build Dennett's (1978*c*) "whole iguana" is very different from MIT's Cog project, with which Dennett himself was involved (see 15.vii.a).

The Cog robot was carefully designed module by module, bits of its "intelligence" being successively bolted on. Grand, by contrast, wants an already integrated intelligence to emerge from a relatively unorganized base. Rather than providing Lucy's brain with spatial maps or orientation columns, for instance, he hopes that these would emerge spontaneously (much as ocular dominance columns arose in the work of Christoph von der Malsburg and Ralph Linsker: see Chapter 14.vi.b and ix.a). And the robot would learn to perform "voluntary" actions by associating the image (representation, model) of the desired action with the muscle movements required to achieve it (compare Marr's theory of the cerebellum: 14.v.c).

The Lucy project is startlingly ambitious—I'm tempted to say, utterly impracticable. But the A-Life expert David Cliff (personal communication) believed Creatures to be utterly impracticable too, when first consulted by the games company to whom Grand had offered it. Given what Grand had told them it could do, it must—so Cliff thought—be either hype and/or a superficial con trick, carefully tailored to present a convincing 'demonstration'. (Even the impressive SHRDLU, you'll remember, could handle only the one conversation without tripping over its toes: 9.xi.b.) And the fact that it had been two-finger-typed on Grand's bedroom computer wasn't promising. Not until he got down into the machine code was Cliff convinced—at which point he suggested how it could be improved still further, using some of the ideas discussed in Chapters 7.i.f and 15.vi–ix.

Grand didn't know about those ideas already, because he's an autodidact. As such, he's undeterred by received academic opinion. And he's a highly creative computer engineer, who's already designed one apparently impossible system that does just what it was intended to do. He's thus in an entirely different class from the self-publicizing roboticists Kevin Warwick and Hugo de Garis, on whose 'research'—technical no less than philosophical—I forbear to comment, for fear of scorching the page.

I wouldn't bet a large sum of money on Lucy. And I don't agree with those cultural commentators who claim that Grand is "one of the 18 scientists most likely to revolutionise our lives in the coming century" (ICA 2000). Nevertheless, as Richard Dawkins has remarked, "If anybody can pull off a spectacular breakthrough, it'll probably be him" (Whitby and Grand 2001: 13). (For the most recent status report on Grand's progress, see his web site at <http://cyberlife-research.com>.)

At the turn of the century, Grand (2000, 2003) made a number of highly provocative claims about the philosophical significance of his own past and future work. He sees his virtual creatures as more than merely *lifelike*: they are "sort of alive", or even "a sort of life". When challenged on this point, he insists (personal communication). Grand is an autodidact in philosophy too, but here there's no good reason to give him the benefit of the doubt. Whereas Creatures (considered as technology) clearly does what he said it would do, his philosophical arguments are challengeable—and, in my view, as mistaken as Ray's. Strong A-Life is no more plausible in Creatures than in Tierra—and even Grand's predicted robot Lucy wouldn't count as genuinely *alive* (see the discussion of metabolism, below).

Where the general public were concerned, Lucy made something of a splash. Although it must be said—and often is said, by other roboticists—that if Grand hadn't fitted a furry gorilla-face onto the head, and if he'd called it Robot 37 instead of Lucy, people wouldn't have been quite so interested. (Similarly, the young Minsky's robot arm aroused no attention until he put a shirtsleeve on it: see 1.iii.h.) Quite apart from the overexcitement of the journalists (the same old story!), a number of commentators have picked up on it as an expression of wider cultural concerns.

The anthropologist Lucy (*sic*!) Suchman, for example, who cast doubt on GOFAI planning some twenty years ago and focused on *human–machine communication* soon after that (13.iii.b), described her robotic namesake as one among the disturbing category of the "almost human" (Castañeda and Suchman forthcoming; cf. Suchman 2004).

Besides the familiar anthropologists' fare of totems and other things "doing duty as persons", these include children, non-human primates, and AI/A-Life machines. The cultural status of children has been a focus of commentary at least since Jean-Jacques Rousseau (1712–78), and twentieth-century developmental psychology has helped fuel this fire. As for primates, advances in field ethology have led to the culturally problematic Great Ape programme (7.vi.f). The eighteenth-century automata (2.i.b) challenged contemporary notions of the person (Riskin 2003). Now, as Suchman pointed out, various actual and imaginary AI projects are exciting comment not only in the philosophy of mind but in our wider culture too.

Lucy (which Suchman discusses at length) is only one example of the "almost human" produced by AI/A-Life. Cog, and especially its successor Kismet (see 13.vi.d), are others. The feminist philosopher Evelyn Fox Keller (forthcoming), for instance, sees some "serious anxieties" with respect to providing Kismet and the like with facial expressions that reliably elicit emotional reactions in human viewers. (She's particularly worried by the plan to use robots like Brian Scasselatti's Nico to *test* theories in human developmental psychology.) Still other almost-humans—all media darlings in their day—include ELIZA, expert systems, AI agents ("softbots"), VR avatars, Turing's computer conversationalist, Stanley Kubrick's HAL, and Steven Spielberg's David.

The behaviour—and man–machine interactions—of many of these systems is far more human-like than Lucy's is. But because Grand, besides providing the superficial furry face, speaks of *life* as well as *mind*, his work aroused more outside comment than most. In addition, his A-Life system is not virtual/intellectual (as softbots are) but *embodied*—or at least, *material*. It's therefore of interest to those commentators, including phenomenologists and many feminist philosophers, for whom the downplaying of embodiment in the analytic–scientific tradition has been a fundamental mistake (Haraway 1997: 186, 302–3, and *passim*; Kember 2003: 105–15, 198 ff., and *passim*).

Suchman (like Haraway, and also Clark: vii.d, above) takes personhood, in whatever culture, to be constituted not by an individual person-in-the-mind but by the nexus of social relations and interactions available. On that view, the cultural status of robots, and other AI/A-Life systems, is determined less by their seeming intelligence than by the pattern of interactions we choose to engage in with them. But the influence is reciprocal: in so far as we do engage with them, we modify our own self-image in various subtle ways (cf. 13.vi.d).

c. The philosophy of autopoiesis

Some A-Life researchers dismissed all these science-fictional scenarios *because they were fundamentally opposed to functionalism in the first place*. Among these were the proponents of Maturana's theory of "autopoiesis".

This was perhaps the best-developed philosophy of metabolic holism. (The competing candidate is the work of Pattee's group: see below.) It even inspired several computer models of biochemical autopoiesis (Zelený 1977; Zelený *et al*. 1989), and a wide range of work in A-Life (McMullin 2004). This included work in "wet" A-Life, in which biochemical autopoiesis *as such* was studied too (see Chapter 15.x.b; Bachman *et al*. 1990; Walde *et al*. 1994).

Originated in the 1960s, Maturana's theory was strongly influenced by Heinz von Foerster's cybernetics. Despite the fact that an English translation was published over a quarter-century ago in the highly respected Boston Studies in the Philosophy of Science (Maturana and Varela 1972/1980), it has remained a minority taste. It's clear from my personal acquaintance that many philosophers have never even heard of it.

One reason, no doubt, is its rebarbative vocabulary and unrelenting abstraction. Also, it has some highly counter-intuitive implications, as we'll see. Nevertheless, it offers a principled way of grounding mind in life. Rather than arguing (like Searle) that neuroprotein happens to cause intentionality, as chlorophyll happens to cause photosynthesis, this view grounds intentional categories in an essentially autopoietic biology.

For Maturana and Varela (1972/1980), life is "autopoiesis in the physical space". Autopoiesis in general is defined as the continuous self-production of an autonomous entity. As they put it (you're advised to take a deep breath here):

> An autopoietic machine is a machine organized (defined as a unity) as a network of processes of production (transformation and destruction) of components that produces the components which: (i) through their interactions and transformations continuously regenerate the network of processes (relations) that produced them; and (ii) constitute it (the machine) as a concrete unity in the space in which they (the components) exist by specifying the topological domain of its realization as such a network. (Maturana and Varela 1972/1980: 79)

Or more colloquially, an autopoietic system "pulls itself up by its own bootstraps and becomes distinct from its environment through its own dynamics, in such a way that both things are inseparable". This type of self-organization can occur in the world of human communication, in which case we have some kind of social institution (cf. Teubner 1987, 1993). But when it happens in the physical world, we have a living organism.

The autopoiesis concerned here is a special case of homeostasis (see Chapter 4.v.c), where what's preserved isn't one feature, such as blood temperature, but the organization of the system as a unitary whole. This requires the self-creation of a unitary physical system, by the spontaneous formation of a boundary—at base, the cell membrane—and the continuous generation and maintenance of the body's own components.

For Maturana and Varela, *body* and *embodiment* are autopoietic categories. So too are *cognition*, *communication*, *meaning*, and *language*, all of which they defined in terms of the interactions of living things. In the more accessible version of their theory that appeared around 1990 (Maturana and Varela 1987, 1992), and in Varela's book co-authored with cognitive psychologists (Varela *et al.* 1991), they focused on human language, understanding, society, and consciousness—all described as necessarily rooted in our biology.

In fact, they were overly liberal with their ascriptions of intentionality (Boden 2001), for they declared that "Living systems are cognitive systems, and living as a process is a process of cognition" (1972/1980: 13). Taken seriously, this extends knowledge even to algae and oak trees. One can—and should—express the idea that algae and acorns are pre-adapted to their environment without using the concept of *knowledge*. Such over-liberality was an occupational hazard for cyberneticians: as we saw in Chapter 4.v.e, Gregory Bateson had similarly attributed *knowledge* to redwood forests, and *mind* to whirlpools and oscillating electrical circuits.

From the autopoietic viewpoint, both strong A-Life and strong AI are absurdities. For computers aren't autopoietic systems. Even self-assembling robots, if assembled from manufactured parts as opposed to being self-organized by some alien biochemistry, wouldn't be alive. (Nor would they have bodies.) Consequently, robotic intelligence is impossible too.

Autopoietic theory is a special case of the general (anti-functionalist) position that metabolism is essential for life. Believers in strong A-Life (such as Ray, quoted above), when confronted with this view, typically pointed out that computers consume energy too. They sometimes added that the "physics and chemistry" of their virtual creatures is constituted by the computer's memory and operating system.

A number of philosophers, some of whom weren't committed to autopoietic theory, replied that metabolism is more than mere energy dependency. Rather, it's the self-production and self-maintenance of the physical body by energy budgeting, involving self-equilibrating energy exchanges of some *necessary* complexity (Pattee 1989; Cariani 1992; Sober 1992; Boden 1999). They argued that strong A-Life is possible only if virtual systems can metabolize *in the sense just given*, or if metabolism is inessential for life. But neither alternative is tenable.

Living 'tin-can' robots are also excluded by this approach. Only robots powered by complex biochemical cycles of synthesis and breakdown would be truly alive, and truly embodied. This is the basis of the intuition scorned by Putnam, that "softness" and "hardness" matter (see above).

Elliott Sober (1948–) cited other biological properties, besides metabolism, in arguing against strong A-Life (Sober 1992). Digestion and predation (for example) each relate an organism to something outside itself, where that "something" is essentially physical. Both can be realized in multiple ways (defined by biochemistry and behaviour), but in every instance some physical organism has to interact with—hunt, eat, transform—another. Like metabolism itself, these features can be usefully simulated by A-life models. But they can't be replicated, so strong A-Life is impossible.

Sober's argument would be endorsed by autopoietic theorists. But to see metabolism as essential for life isn't necessarily to accept autopoietic philosophy. For this has some surprising implications, which many people reject. One was noted above, namely, the conflation of life and cognition. Another was remarked in Chapter 15.viii.b: the embargo on terms such as *input*, *output*, *function*, *feature-detector*, and *representation*. Two more concern features often listed in definitions of life: reproduction and evolution.

Maturana and Varela's claim that the formation of the cell membrane is *the* fundamental phenomenon of biology, and that life involves the "total subordination of [all the processes of change within] the system to the maintenance of its unity" (1972/1980: 97), implied that reproduction isn't essential for life. For them, this process is not (as functionalists claim) informational self-copying, but the formation of new autopoietic unities from previous ones. It follows that life is prior to reproduction (pp. 105–7). This wasn't a merely conceptual point, but a substantive biological hypothesis: that the earliest living organisms needn't have been able to reproduce (Boden 2000*b*).

Evolution, also, was seen by them as inessential, because it requires reproduction. (Inessential for life, but not for what's normally regarded as knowledge: they admitted that only evolution can generate the complex organisms typically credited with cognition.)

This conclusion, though unusual, is less controversial. For, *pace* Ray, and many theoretical biologists too (e.g. Maynard-Smith 1996), there are three independent arguments against defining life in terms of evolution. First, populations, not individual organisms, would be paradigm cases of life. Second, creationism would be conceptually incoherent, not just false. And third, a population in evolutionary equilibrium wouldn't count as alive.

d. Evolution, life, and mind

Some philosophers of A-Life, nevertheless, took evolution (together with metabolism) to be the sort of self-organization which characterizes life. Pattee was an early example, followed by his students Rosen (1985, 1991) and Cariani (1992, 1997). He'd modelled co-evolution in the 1960s (see Chapter 15.vi.a). Subsequently, he focused on the emergence of new phenotypic structures and functions.

A crucial example, for Pattee (1985), was novel types of "measurement", or classification. These were understood as ranging from enzyme activity to sensory perception—as in the evolution of new sensory organs (see Chapters 4.v.e and 15.vi.d). Pattee's concept of measurement was intriguingly similar to Smith's "participatory registration"—but, unlike Smith, he retained the first definition of computation distinguished in Section ix.a. So he specifically dismissed strong A-Life, arguing that measurement requires physical interaction, which can't be realized by formal computational systems. A fortiori, no novel biological functions can emerge in formal evolutionary systems (15.vi.d). He did allow, however, that "weak" A-Life modelling (simulation) could help clarify central biological and psychological concepts.

In the 1990s, another philosopher of A-Life argued that evolution is an essential criterion. Mark Bedau (1954–) explicitly accepted the three counter-intuitive implications mentioned above, because of the explanatory power gained by defining life in evolutionary terms (Bedau 1996). And this explanatory potential, he said, was augmented by A-Life. In presenting his account of "supple adaptation" (alias evolution), he argued that A-Life modelling can deepen our understanding of life as such, because it helps us to study evolution in dynamic and quantitative terms. Moreover, he extended his evolutionary argument from life to mind (Bedau 1999, in preparation).

A-Life philosophers weren't the only ones to link life and mind. Others, too, had grounded knowledge and meaning in biological evolution. Dennett had sketched an evolutionary account of meaning in *Content and Consciousness*, although philosophers then were more interested in other aspects of his work (see Section iv.a). By the mid-1980s, however, two influential examples of teleological or evolutionary semantics had appeared.

The philosopher of science David Papineau (1947–) argued that the content of beliefs depends on how they guide actions to satisfy desires, whose content is basically determined by natural selection (Papineau 1984, 1987). Similarly, Millikan (1933–) grounded intentionality in evolutionary history (Millikan 1984). Her book title was deliberately provocative: *Language, Thought, and Other Biological [sic] Categories*. This was guaranteed to raise philosophical hackles in devotees of the later Wittgenstein, and neo-Kantians in general (see Sections vi–viii, above).

Millikan upset many science-inclined naturalists too, by giving more philosophical weight to evolution than to neuroscience. Thus she argued that a perfect simulacrum of a human being, magically constituted in the middle of a swamp by a sudden combination of the relevant molecules, would have *no* beliefs, desires, or other intentional properties (1984: 93, 337–8; 1996; cf. Boorse 1976). It would, of course, utter the very same words as a human being would, if engaged in 'conversation'. For all the language-relevant events in the swamp-man's brain (and ears, and lips . . .) are, by hypothesis, identical with those of a person. But it wouldn't be a genuine conversation—for, on the swamp-man's side, no meanings or intentions would be being expressed. (In her defence, one could point out that we accept thermodynamics *even though* it allows the theoretical possibility of a snowball in hell: is swamp-man any more implausible?)

This imaginary example highlighted her central—and controversial—claim, that current meanings depend in part on events that happened millions of years ago. Millikan was saying, in effect, that Searle had been wrong about the "something more" that's needed *in principle* for intentionality. According to her, it's not neurochemistry as such that grounds meaning—nor even neurochemistry in interaction with the body and environment. Only evolutionary history can fix the system's semantics.

If Millikan's (or Papineau's) version of biological semantics is correct, then no 'ready-made' AI system, nor even a self-organizing—but non-evolutionary—A-Life system, could enjoy mind, intelligence, or meaning.

However, evolutionary semantics was later related to research in evolutionary robotics (Boden 2001). We saw in Chapter 15.vi.c that a robot's neural-network 'brain' may evolve 'feature-detectors' analogous to those found in mammalian visual cortex. So a mini-network may evolve that's sensitive to a light–dark gradient at an orientation matching one side of a white cardboard triangle, and that's used by the robots as a navigation aid (Harvey *et al.* 1994; Husbands *et al.* 1995). Such examples challenge Searle's (1980) view that the "meaning" of a computer model must always be derivative, and arbitrary to boot (see Section v.c).

One could debate whether the feature-detector means "light–dark gradient sloping up and to the right" as opposed to "left side of the white triangle". But similar difficulties attend the ascription of non-conceptual content to animals. (Are bug-detectors really *bug*-detectors, whether for the frog or for the frog's brain?—see Chapter 12.x.f and Cussins 1990: 416–17.)

The important point is that the various meanings one might want to ascribe to the robot aren't arbitrary. Nor are they derivative, based only in the human purposes involved in their design. They aren't based purely on causal regularities, either. They spring to mind as candidate meanings because the mini-networks concerned have evolved, within that task environment, to discriminate certain visual features and guide the robot's movements accordingly. That is, they're environmentally, enactively, and evolutionarily grounded.

However, to say these A-Life "meanings" aren't arbitrary isn't to say they're genuine. There's no consensus among A-Life researchers on whether evolutionary robotics could produce real intentionality. For the pure A-Life functionalist, it could: the triangle-detector is a primitive case, and more advanced (animal-like) examples would embody richer meanings. For Maturana, it couldn't: evolution and intentionality can occur only in biological organisms—so quasi-evolved robots can quasi-embody only quasi-meanings.

Nor is there a consensus among philosophers unconnected with A-Life, for the nature of life, mind, and the life–mind relation remain controversial.

Not everyone accepts an evolutionary semantics, for example. A causal semantics can't support the common-sense intuition that mind can arise *only* from life, unless the relevant causal relations can be shown to arise *only* in living things. And a model-theoretic semantics can't support it at all.

The competing A-Life methodologies of the early 1990s were systematically compared, and related to earlier philosophies of life, by Peter Godfrey-Smith (1994). He distinguished three dimensions of variation: internalism and externalism; asymmetrical and symmetrical externalism; and weak and strong versions of the continuity of life and mind.

Internalist approaches see life as autonomous self-organization, wherein internal constraints govern the history and interactions of the constituent units of the system. Examples include autopoietic theory and Stuart Kauffman's autocatalytic networks (15.viii.b). Externalist approaches explain the system's internal structure primarily as a result of its adaptive interactions with the environment. Work on evolutionary robotics is one example.

The asymmetric externalist emphasizes the organism's adaptive responses to its environment. By contrast, the symmetric externalist pays attention also to the active role of the adaptive organism in shaping that environment. Examples are situated robotics, and Ray's or Pattee's models of co-evolution, respectively.

Finally, the weak continuity theorist sees mind as emerging only from life, but as significantly different from it, whereas the strong continuity theorist regards mind and life as ontologically similar, sharing basic organizational principles. Descartes wasn't a continuity theorist at all, for he saw mind and living bodies as utterly distinct (see Chapter 2.iii and Matthews 1977). Examples of strong continuity theorists include the Naturphilosophen (Chapter 2.vi), the cybernetics movement (Chapter 4.v–vii), and autopoietic theorists. Arguably, they also include philosophers of non-conceptual content (Chapter 12.x.f) and participatory computation (see Section ix.e, above). And someone who argues that not all living things are cognitive systems (see above) is supporting weak continuity in that respect.

However, "mind" covers a number of abilities, and some of these may be strongly continuous with life whereas others aren't. Language has often been seen as a cut-off point. For instance, we saw in Chapter 2.ii.a, g, that Aristotle was a strong continuity theorist for perception and autonomous movement, but perhaps not for human reason (cf. Matthews 1992). Heideggerians who confine *Dasein* to human beings, or Wittgensteinians who ascribe intentionality only to linguistic concepts, count thus far as weak continuity theorists. But some neo-phenomenologists (such as Clark and Wheeler) ascribe intentionality to non-human animals, too.

Analogously, many AI connectionists allow that GOFAI insights will be needed to model the 'logical' aspects of human thinking (see Chapter 12.viii–ix), whereas some dynamical theorists deny this (Section vii.c, above). And nouvelle AI (a label recalling the minimalism of nouvelle cuisine) insists that AI must be grounded in 'lower' abilities, like those of our evolutionary precursors, whether or not it has to add GOFAI methods on top.

In sum, the relation between life and mind is still highly problematic. That applies to work in AI/A-Life, and to philosophy too. The common-sense view is that the one (*life*) is a precondition of the other (*mind*). But there's no generally accepted way of proving that to be so.

17

WHAT NEXT?

This chapter might have joined chapter XI of *Through the Looking Glass* as one of the shortest in the English language. For in response to "What next?", what is there to say but "Who knows!"? Fundamental advances, in particular, are unforeseeable. As Captain Cook's biographer put it, "Genius, of whatever sort, takes us unawares: is not, even in retrospect, deducible" (Beaglehole 1974: 3).

One doesn't have to adopt a Romanticist view of creativity, nor a literal interpretation of "genius", to agree with that. Creative ideas are unpredictable for a number of very different reasons, not all of which will be mentioned here (but see Boden 1990*a*, ch. 9). And some are more unpredictable than others. Even a carefully designed technological artefact will have some unpredictable features, as we saw in Chapter 8.v.b (Ziman 2000*b*). A relatively speculative creative idea can be more surprising still. (And its social impact is even less predictable: Tim Berners-Lee himself couldn't have foreseen that in a mere three years, from 1993 to 1996, the Web would grow from 130 sites to over 600,000—Battelle 2005: 40.)

More precisely, *historically* creative ideas, never generated by anyone before, are unforeseeable. Creative ideas that are new only for the person concerned can sometimes be foreseen, and even deliberately brought about, by other people—think of Socratic dialogue, for example. In what follows, I'll use "creative" to mean historically creative.

17.i. What's Unpredictable?

One source of unpredictability is serendipity: the finding of something valuable without its being specifically sought. Since this is unexpected by definition, prediction simply isn't on the cards when it's involved. The classic case in science is Alexander Fleming's noticing the dirty dish of agar-jelly, which led eventually to the discovery of penicillin. In cognitive science, the part-accidental discovery of several visual-feature-detectors is another illustration (Chapter 14.iv.a–b). In both cases, of course, a good deal of careful and systematic work had to follow the initial observation, before anything worth calling a "discovery" could be achieved.

Another source of unpredictability is change in the wider cultural context. The generation—and still more, the acceptance—of new scientific ideas can be discouraged, encouraged, and even part-guided by social–political factors (see 1.iii.b–d and 2.ii.b–c).

The positive reception of heterarchy (10.iv.a) and distributed cognition (13.iii.d–e), for instance, was influenced by political ideology, and of expert systems by nationalism and economics (11.v). Even if cultural changes could be predicted (which they can't), their effects on contemporary scientific thinking could not.

This applies also to shifts in the power relations between the various groups/disciplines within cognitive science, and so to *what will be seen as cognitive science* in the future:

> Some 25 years after its various beginnings there still is no such thing as a core cognitive science. Depending on where one looks, which departments one queries, who one's friends are, the core of cognitive science will be asserted to be neurophysiology, psychology, artificial intelligence, linguistics, or some more vague concept like human/machine interaction or symbolic or connectionist modeling. The result may not have been cognitive science, but it has been exciting and scientifically fruitful. It has created a community of interests and increased interdisciplinary communication. But as of now there are still viable independent cognitive sciences such as neurophysiology, linguistics, and psychology that flourish with or without the cognitive science label or affiliation. *It is difficult to say at this point where this will lead*. (G. Mandler 1996: 23; italics added)

A specially important type of cultural change concerns new technology. Sometimes, the new instruments are needed in order to do things that obviously needed doing—for instance, developing micro-electrodes to record from the cell body of a single neurone—or anyway, a very small number thereof (2.viii.e). Such cases are relatively predictable: it was clear that people would try, and probable that someone would eventually succeed. Other technological tools may come as more of a surprise, at least to people in other areas of science: a few biophysicists may have been able to predict brain-scanning techniques, but psychologists couldn't.

Technology can be used to prompt new concepts, as well as to find new data. Indeed, technical ideas have been transmuted into psychological theories on many occasions (Gigerenzer 1991*b*, 1994). Moreover, machines have been used as analogies for the brain for hundreds of years (Fryer 1978)—jukeboxes included (2.viii.f). The latest, of course, is the computer itself. So sceptics often say that it's just the latest in a long line of such analogies, to be displaced eventually by some unforeseen invention coming who knows when.

Well, yes and no. In cognitive science, the computer isn't merely a superficial analogy, a metaphor fished out of the memory—perhaps for purposes of popularization—after the real scientific work has been done. On the contrary, it provides substantive concepts in psychological and neuroscientific theories.

The computational concepts concerned were diverse even at the outset (4.ix), and have multiplied over the years (16.ix). Besides symbolic, connectionist, and evolutionary AI, they include dynamical systems described by differential equations (14.vi, 15.viii–ix and xi). The future may well hold unpredictable new machines, even less imaginable today than quantum computers are. But cognitive scientists believe that only *some sort of computational machine* will be relevant. For their key claim is that mind can be explained (not by today's ideas about computation, but) by *whatever theory turns out to be the best account of what computers do* (Chrisley 1999; see 16.ix.f). In that sense, they would endorse Philip Johnson-Laird's remark that "The computer is the last metaphor; it need never be supplanted" (1983: 10).

Other psychological reasons for unpredictability apply to all instances of creativity. They include the rich idiosyncrasy of human minds and the relative—though only *relative*—freedom of creative thinking (13.iv; cf. 7.i.g). Introspectively, it may seem as though almost anything can happen—at least, according to the molecular biologist François Jacob:

> Day science employs reasoning that meshes like gears . . . One admires its majestic arrangement as that of a da Vinci painting or a Bach fugue. One walks about it as in a French formal garden . . . Night science, on the other hand, wanders blindly. It hesitates, stumbles, falls back, sweats, wakes with a start. Doubting everything . . . It is a workshop of the possible . . . where thought proceeds along sensuous paths, tortuous streets, most often blind alleys. (Jacob 1988: 296)

If the creative scientist himself "wanders blindly" much of the time, so much less can his thoughts be foreseen by other individuals—who don't even know his *present* thinking in much detail.

Moreover, some new ideas strike us as paradoxical, not to say crazy, even *after* they've occurred. That often happens in instances of "transformational" creativity, in which one or more dimensions of the previously accepted style of thinking is/are radically altered or dropped (Boden 1990*a*, chs. 3–4). The more basic the dimension, the more fundamental the conceptual change will be. In such cases, it's hard for the new idea to be understood, and even harder than usual for it to gain acceptance. A fortiori it's harder to predict.

In particle physics, that's par for the course. Freeman Dyson reported an encounter between Niels Bohr and Wolfgang Pauli, who'd given a lecture on his new theory:

> Bohr rose to speak. "We are all agreed", he said to Pauli, "that your theory is crazy. The question which divides us is whether it is crazy enough. My own feeling is that it is not crazy enough." (Dyson 1958: 74)

And Dyson commented:

> The objection that they are not crazy enough applies to all the attempts which have so far been launched at a radically new theory of elementary particles. It applies equally to crackpots. Most of the crackpot papers which are submitted to *The Physical Review* are rejected, not because it is impossible to understand them, but because it is possible. Those which are impossible to understand are usually published. When the great innovation appears, it will almost certainly be in a muddled, incomplete and confusing form. To the discoverer himself it will only be half-understood; for everybody else it will be a mystery. *For any speculation that does not at first glance look crazy, there is no hope.* (italics added)

Cognitive science as a whole is less rococo, less conceptually bizarre, than particle physics. But several seemingly crazy ideas have found a respected place within it, after being fiercely resisted as "absurd"—perceptual defence, for example (Chapters 6.ii and 16.v.f), and object-oriented programming (10.v.d and 13.v.d). And remember the punchline of the quip about *Plans and the Structure of Behavior*: ". . . and Pribram believed it!" (6.iv.c). When people said that, they weren't dismissing those new ideas as worthless. They were allowing that they were weird-but-interesting, so worth thinking about. (Karl Pribram was made the fall guy because he'd recently defended a holographic theory of memory—hardly the usual bread-and-butter fare: 12.v.c. Nor is Bergsonian philosophy, but Pribram later dallied with that as well: 16.x.a. His reputation as a maverick was deserved. However, even those who called him "crazy Karl Pribram" later admitted that his strange ideas had "caught on", and that "his neurophysiological speculations are decades beyond other physiological work"—Walter Weimer, interview in Baars 1986: 309–10.)

Many future contributions, too, will seem weird initially—though just how weird they'll need to be remains to be seen. The "particle physics" of the field is conscious experience. This has already prompted many highly counter-intuitive theories, including some crackpot publications. I argued in Chapter 14.xi.e that a currently undreamt-of (i.e. crazy) approach will be needed to explain it.

Close runners-up in order of difficulty, and so in licensed craziness, are intentionality and computation. We saw in Chapter 16.ix.e how an extraordinary (crazy?) theory of those-two-together has come from an AI scientist–philosopher who thinks that "For sheer ambition, physics does not hold a candle to computer or cognitive . . . science" (B. C. Smith 2002: 53).

Sometimes, experts declare future progress to be not so much unpredictable as impossible. This view was implicit in Thomas Watson's notorious remark in 1943, as IBM chairman, that "I think there is a world market for maybe five computers." (He died in 1956, so never knew just how wrong he was. But he wasn't alone: Howard Aiken, of all people, said, "there will never be enough problems, enough work, for more than one or two of these computers"—Edwards 1996: 66.) And it was explicit in the advice given to Konrad Zuse in 1937 by Kurt Pannke, a manufacturer of specialized calculators:

> "Someone informed me", Dr. Pannke began, "that you have invented a computing machine. Now, I don't want to discourage you from continuing to work as an inventor and from developing new ideas, but I must go ahead and tell you one thing: in the field of computing machines, practically everything has been researched and perfected to the last detail. There's hardly anything left to invent . . ." (Zuse 1993: 42)

(To be fair to Pannke, he later changed his mind. He provided money to fund Zuse's home-based research, and recommended his machine to the German military—fortunately, with no effect: see 11.i.a.)

17.ii. What's Predictable?

I can't imagine anyone suggesting that there's "hardly anything left" to be discovered in cognitive science. But I've just allowed that creative ideas can't be predicted, only awaited. So perhaps I should now present you with an empty page, and leave it at that? After all, that's a respected rhetorical device. Laurence Sterne did it 250 years ago, when he declined to describe a beautiful woman in *The Life and Opinions of Tristram Shandy*, leaving it to the reader's imagination instead.

I don't have the courage to follow Sterne's example. But it wouldn't be appropriate in any case. For there is something that can be said.

All scientific research, in whatever domain, is located within some identifiable conceptual space where further creative exploration (and transformation) is clearly possible, and where some dimensions seem especially rich in potential with respect to current unsolved problems (Boden 1990*a*, 2004). Peer review, especially of proposals for future research, depends on that fact. We can't predict the detailed outcome of such explorations and transformations, much as David Livingstone couldn't foresee his discovery of the Victoria Falls. But we can reasonably expect that if we follow *these* dimensions of the space (compare: the Zambesi River, the mountains glimpsed ahead . . .), we'll find something of interest. That is, we can have intellectually defensible, if not infallible, hunches about where future discoveries are likely to occur.

In so far as such predictions are possible, I've indicated mine already. The previous chapters have told "the story so far"—but always with an eye to possible future episodes. So the relatively small volume of *recent* work that I've mentioned was chosen not just because it's recent, nor even because it's intriguing. It was selected because I think it's promising, capable of development in ways that seem likely to be fruitful.

One way of justifying our hunches about where interesting new ideas are likely to arise is to rely on sub-hunches about *how* those ideas might be generated. In other words, some specific exploratory pathways are recognizable as familiar ones, because they've often been found to be fruitful.

* For instance, once a simple deterministic space has been defined, it's very likely that people will eventually try to complexify it in certain ways. So when John von Neumann defined the basic cellular automaton, he knew very well that probabilistic and even evolutionary CAs would be explored later (Chapter 15.v–vi).

* Again, once problem solving had been seen as a simple hierarchy (6.iii), it was inevitable that more complex and/or 'open-execution' plan hierarchies would be explored (10.iii.c). It was even a good bet that theories of problem solving would eventually be transformed by hierarchy's being made less pure (10.iv.a), or perhaps deliberately dropped (13.iii.b, 15.viii.a).

* Third, when Alan Turing wrote his morphology paper, he knew that increasingly complex systems of reaction–diffusion equations would be explored, once computer power allowed (15.iv).

(Similar remarks apply to creativity in artistic contexts. So, for example, it was nigh inevitable that post-Renaissance composers would progressively complexify tonal harmony. And it was always on the cards that someone—it happened to be Arnold Schoenberg—would eventually transform the space of tonal music by dropping the home-key constraint altogether: C. Rosen 1976; Boden 1990*a*, ch. 4.)

In short, the common notion that creative thought is unpredictable because it's chaotic (in the everyday sense) is mistaken. There's significant method in creative madness. It's our tacit recognition of this fact which enables us to identify certain work as promising, even though we can't spell out the promises.

17.iii. What's Promising?

The recent empirical research that I see as promising in these terms includes the following (listed here in no particular order):

* hybrid systems I: symbolic/connectionist (Chapters 12.iii.d and ix.b, 15.viii.a)
* hybrid systems II: situated/deliberative (7.iv.b and 13.iii.c)
* hierarchical networks (12.viii.b and ix.b)
* connectionist work on the role of imagery of words (12.ix.e)
* statistical approaches to NLP (9.x, preamble, and 9.x.f)
* integration of connectionist learning with detailed neurophysiological data (14.ii.d)
* modular and/or time-based neural networks (12.ix.a, 14.ix.g)
* programmed/evolutionary neuromodulation (14.ix.f)
* AI-evolved organic–silicon computing networks (14.ix.f)
* computational neuro-ethology (14.vii, 15.vii)
* insect navigation strategies (15.viii.a)
* types of cerebral representation, especially emulators (14.viii)
* the epigenesis of thought and language in normal and brain-damaged children (7.vi.g–i)
* models of clinical apraxia and aphasia (12.ix.b, 14.x.b)
* theories of control in hypnosis (7.i.h)
* brain-scanning, *provided that* it's related to specific psychological theories (14.x.b)
* developmental trajectories (12.viii.c–e and x.e)
* fast/simple heuristics (7.iv.f–g)
* the origin of specific bounds on human rationality (7.iv.h)
* cognitive technology, including virtual reality (10.i.h, 13.vi, 16.vii.d)
* computational theories of creativity (9.iv.f, 13.iv)
* evolutionary modelling (14.ix.d and f, 15.vi)
* achieving open-ended evolution and/or creativity (13.iv.c, 15.vi.d)
* mathematical analyses of dynamical systems (14.vi and ix.b, 15.ix.b and xi.b)
* homeostasis in CTRNs (15.xi.a)
* distributed cognition and agents (8.iii, 12.ii–vi and x, 13.iii.c, 15.viii–ix)
* computational architectures integrating knowledge, motivation, and emotion (7.i.e–g and 7.iv.b–c).

If forced to choose only one of these items, I'd pick the last: work on integrated mental architectures. Indeed, I did that on the fiftieth anniversary of the 1953 discovery of the double helix, when the British Association invited several people to write 200 words for their magazine *Science and Public Affairs* on "what discovery/advance/development in their field they think we'll be celebrating in 50 years' time". This choice reflected my own long-standing interests in personality and psychopathology (Preface, ii). But it wasn't idiosyncratic: two years later, the UK's computing community voted for "The Architecture of Brain and Mind" as one of the seven "Grand Challenges" for the future (<http://www.ukcrc.org.uk/grand_challenges/index.cfm>). One member of the five-man committee carrying this project forward is Aaron Sloman, who's been thinking about architectural issues since the 1970s (7.i.f, 10.iv.b, and 16.ix.c). If progress is to be made on this front, my hunch is that his team will be in a good position to make it.

The Grand Challenges grew out of the UK government's 'Foresight' Programme (instituted in 2003 for a ten-to-twenty-year planning horizon), and in particular out of its Cognitive Systems Project. Naturally, government ministers aren't falling over themselves to help solve the problems of cognitive science for their own sake. For them, applications are all—whether in health, education, business, transport, arts and entertainment, or (of course) the military. But as the Project's official Report (DTI 2004) makes clear, scientific and technological motives are often very closely related (and can be satisfied only by interdisciplinary thinking). It should be no surprise, then, that architectures to support "emotional" robots and "social" human–computer interactions are now being investigated at the behest of Whitehall—and, naturally, of the Pentagon too.

The strength and range of the list of "promises" given above show that cognitive science is still a fruitful "scientific research programme" (Lakatos 1970). *Mind-as-machine*, in both its incarnations (1.ii.a), has generated many suggestive theories. These have been amended—and sometimes dropped—on the basis of further advances in our understanding, but in many cases the central insights remain. Marr's work on vision is one obvious example (7.v.b–f), but others have been described in previous chapters.

The field's potential won't be unlocked without new psychological–computational *theories*. Greater computer power may well be necessary, but it won't be sufficient. Even quantum computers and hypercomputers won't suffice to fill the bill (16.ix.a). Fundamental scientific advance will need more Ideas, not just more Bytes. Likewise, more and/or fancier PET/fMRI brain scanning won't suffice either, even though it will often be useful (14.ii.d and ix.c).

On a higher plane of abstraction, I've discussed some recent philosophical research concerning

* the nature of computation (16.ix)
* the variety of virtual machines (16.ix.a)
* conscious experience (14.x–xi)
* the nature of intentionality (16.x.d)
* the origin of conceptual content (12.ix.e and x.f)
* the nature/existence of non-conceptual content (12.x.f and 16.viii.b)
* mind and/as embodiment (16.vii)
* the boundary between self and world (16.vii.d)
* the nature of life, and its relation to mind (15.i and 16.x)
* the resolution/reintegration of neo-Kantian and analytic philosophical viewpoints (16.vii.b–d, ix.d–f, and x.a).

All of these matters will be key foci of effort and controversy in the foreseeable future. Indeed, they're so difficult, and so deep, that I expect them to remain key foci well over 100 years from now. For as remarked at the outset of Chapter 16, philosophical problems don't get solved in a hurry.

Nor, in these cases, will they get solved in disciplinary isolation. They'll require fundamental *and reciprocal* advances in up to five fields: philosophy, psychology, anthropology, neuroscience, and AI/A-Life. (Theoretical linguistics, as opposed to the philosophy of language, is less relevant here—unless we include *cognitive* linguistics: see 7.ii, preamble, 9.ix.g.)

17.iv. What About Those Manifesto Promises?

In Chapter 6.iv.c I said that a good way of judging how far cognitive science has succeeded is to compare it with the hopes/promises expressed in *Plans and the Structure of Behavior* (Miller *et al.* 1960). By the turn of the millennium, virtually all of MGP's promises had been at least partially met. The "satellite images", and the Newell Test, outlined in Chapter 7.vii surveyed many different examples.

To mention just two:

* hypnosis has been demystified (along with multiple personality and religious experience): (7.i.h–i, 8.vi.b, and 14.x.c), and
* MGP's distinction between Plans as animal instincts and as human purposes is now far better understood (7.i and iv, 14,vi.c, and 15.vii).

Although discussions of these matters have been hugely complicated since they wrote their manifesto, today's answers are broadly consistent with theirs. For TOTE units were—deliberately—defined so abstractly that they covered *both* the inbuilt sensori-motor skills of crickets and hoverflies *and* the deliberative (and hypnotic) planning of human beings.

Neither "demystified" nor "far better understood" implies that all the relevant questions have been answered. Far from it. But we're much clearer now about just how MGP's questions can be profitably put.

Consider, for example, their nature–nurture distinction mentioned above. This simplistic duality has given way—within cognitive science, if not yet in the minds of the general public—to an epigenetic view of development. This view was already waiting in the wings before cognitive science got started (5.ii.c). Now, it's prominent in disciplines as varied as psychology, neuroscience, philosophy, A-Life, and robotics (7.vi, 14.vii and ix.c, and 15.viii.a).

There's no reason why this process should cease now. And it doesn't require every psychological question to be answerable by a simulation. For MGP's futuristic remarks concerned a general approach to the mind: computational theorizing, not necessarily computer simulation as such. We'll surely see many new computer models (some of which will reflect new findings in neuroscience). We'll probably see radically new *types* of model (16.ix). Functioning computer models can test a theory's implications and coherence more rigorously than any other method (7.iii.c). But the novel theoretical concepts are what's important, in understanding what sort of system, or virtual/physical machine, the mind/brain is.

One thing is beyond dispute: that the rich subtlety of human minds is even more awe-inspiring than the arch-humanist Wilhelm von Humboldt (9.iv) believed it to be. Indeed, I've already identified this realization as the major result of computational psychology as a whole (7.vii.a). It follows that it will never be possible to capture every psychological detail, whether in a theory or a simulation. Predicting, explaining, or interpreting the specific thoughts/actions of individual people will always be largely "idiographic" (7.iii, preamble), a matter for the unargued intuitions of psychologists *qua* human beings, not for their deliberate conclusions *qua* scientists.

However, that doesn't spell disappointment for MGP. For on the one hand, idiographic insights can often be enriched, and sharpened, by considering general mechanisms. Remember, for instance, the varied ways of expressing different types of anxiety in speech (7.ii.c). On the other hand, the prediction/explanation of highly particular personal matters wasn't what MGP were aiming for. (Nor is this the aim of scientific psychology in general: 7.iii.d.) Rather, they hoped to understand how such phenomena are *possible*.

It's not only MGP's questions which can now be posed more fruitfully. The familiar puzzles that opened this story (1.i.a), many of them centuries old, have all been illuminated—and some even solved—by the successors of the visionary manifesto.

More answers will doubtless be found: the future of cognitive science will be as exciting as its past. But to say *what they'll be* would be like an eighteenth-century Admiralty Board foreseeing James Cook's extraordinary achievements in navigation and map-making: impossible.

—— (1993), *The Computer—My Life*, trans. from German P. McKenna and J. A. Ross (London: Springer); first pub. as *Computer, mein Lebenswerk*, autobiography (Munich: Verlag Moderne Industrie, 1970; rev. 1984).
Zwaan, R. A. (1999), 'Embodied Cognition, Perceptual Symbols, and Situation Models', *Discourse Processes*, 28: 81–8.
Zytkow, J. (ed.) (1997), *Machine Discovery* (London: Kluwer Academic); also available as a special issue of *Foundations of Science*, 1/2 (1995–6).

LIST OF ABBREVIATIONS

AAA	American Anthropological Association
AAAI	American Association for Artificial Intelligence
ABC	Agent-Based Computing
ABSET	Aberdeen set-theory programming language
ABSYS	Aberdeen compiler system
ACE	Automatic Computing Engine
ACT	adaptive control of thought
ACTF	a version of ACT, in a series named by successive letters of the alphabet
Adaline	Adaptive Linear Element
ADIOS	Automatic Distillation of Structure
AI	artificial intelligence
AISB	Society for the Study of Artificial Intelligence and Simulation of Behaviour (UK/Europe-based)
ALICE	Algorithmically Integrated Composing Environment
ALPAC	Automatic Language Processing Advisory Committee (of the US government)
AM	Automated Mathematician
AMG	Architecture Machine Group (the MIT group that preceded the Media Lab)
AN	auditory neurone
APA	American Psychological Association
APU	Applied Psychology Unit (University of Cambridge)
ARPA	Advanced Research Programs Agency (of the DOD)
ASL	American Sign Language
ATF	axon transfer factor
ATN	augmented transition network
BBC	British Broadcasting Corporation
BBN	Bolt, Beranek & Newman, now called BBC Technologies
BBS	*Behavioral and Brain Sciences*
BGA	Bruner, Goodnow, and Austin (1956)
BNA	British Nationality Act
BPS	British Psychological Society
BR	belief representation
BVSR	Blind Variation and Selective Retention
C3	command, control, and communications
CA	cellular automaton
CAD/CAM	computer-aided design/manufacture
CAS	Center for Adaptive Systems (Boston University)
CASTE	Course Assembly System and Tutorial Environment
CBC	Computer Based Consultant
CD	conceptual dependency
CDU	cathode-display unit
CF	context-free
CFPS	context-free phrase-structure
CFPSG	context-free phrase-structure grammar
CHIP	Center for Human Information Processing (UCSD; now renamed Center for Brain Cognition)
CIA	Central Intelligence Agency (USA)
CLRU	Cambridge Language Research Unit
CLS	Concept Learning System
CMAC	Cerebellar Model Arithmetic Computer

CMU	Carnegie Mellon University
CNE	computational neuro-ethology
CNM	Connectionist Navigational Map
CNS	central nervous system
COGS	Cognitive Studies Programme/School of Cognitive and Computing Studies (University of Sussex)
CORA	Conditioned Reflex Analogue
CPSR	Computer Professionals for Social Responsibility
CQG	complete quantum gravity
CREA	Centre de recherche en épistémologie appliquée (Paris)
CRT	cathode-ray tube
CS	context-sensitive
CSLI	Center for the Study of Language and Information (Stanford, Calif.)
CSPSG	context-sensitive phrase-structure grammar
CTR(N)N	continuous-time recurrent (neural) network
CUNY	City University of New York
DARPA	Defense Advanced Research Programs Agency (USA) (formerly ARPA)
DCB	Direct-Conflict-Brother
DEC	Digital Equipment Corporation
det (*or* Det)	determiner
DNA	deoxyribonucleic acid
DOD	(US) Department of Defense
DOG	Difference of Gaussians
DPA	Darwinian psychological anthropology
DTF	dendrite transfer factor
EAM	Elementary Adaptive Mechanism
EDSAC	Electronic Delay Storage Automatic Calculator
EDVAC	Electronic Discrete Variable Automatic Computer
EE	evolutionary epistemology
EEG	electroencephalograph
ELMER	Electro-Mechanical Robot
ELSIE	Electro-Mechanical Robot, Light-Sensitive with Internal and External Stability
EM	external memory
EMCSR	European Meeting on Cybernetics and Systems Research
EMI	Experiments in Musical Intelligence (now Emmy)
ENIAC	Electronic Numerical Integrator and Computer
EPAM	Elementary Perceiver and Memorizer
EPSRC	Engineering and Physical Sciences Research Council (UK)
ESRI	elementary self-replicating instructions
FAHQT	fully automatic high-quality translation
FANs	folding architecture networks
FAP	fixed action pattern
FAQ	frequently asked question
FARG	Fluid Analogies Research Group
FFA	fixed functional architecture
fMRI	functional magnetic resonance imaging
FORTRAN	Formula Translation programming language
FRAME	Fund for the Replacement of Animals in Medical Experiments
FREDDY (FREDERICK)	Friendly Robot for Education, Discussion and Entertainment, the Retrieval of Information, and the Collation of Knowledge
FRS	Fellow of the Royal Society
FSG	finite-state grammar
GA	genetic algorithm
GB	government-binding
GEB	Hofstadter, *Gödel, Escher, Bach: An Eternal Golden Braid* (1979)
GNP	gross national product

GOFAI	good old-fashioned AI
GOFAIR	good old-fashioned AI and robotics
GPS	General Problem Solver
GSIA	Graduate School of Industrial Administration (Carnegie Mellon University)
GSOH	good sense of humour
GSPG	generalized phrase-structure grammar
HAM	human associative memory
H&H	Hunt and Hovland
HCI	human–computer interaction
HOT	higher-order thought
HPSG	head-driven phrase-structure grammar
HRR	holographic reduced representations
IAAI	'Innovative Applications of AI'
IAS	Institute of Advanced Study (Princeton)
IBE	inference to the best explanation
ICA	Institute of Contemporary Arts (London)
IEEE	Institute of Electronics and Electrical Engineers (international)
IFIP	International Federation for Information Processing
IFIPS	International Federation of Information Processing Societies
IJCAI	International Joint Conference on Artificial Intelligence
IJCNN	International Joint Conference on Neural Networks
IKBS	Intelligent Knowledge-Based Systems
IMHO	in my humble opinion
INNS	International Neural Network Society
IPL	Information Processing Language
IR	information retrieval
IRCAM	Institut de recherche et coordination acoustique/musique
IRE	Institute of Radio Engineers
IRM	Innate Releasing Mechanism
IRMA	Innate Releasing Mechanism Analogue
ISA	ideal sentential automaton
IT	information technology
JASSS	*Journal of Artificial Societies and Social Simulation*
K&T	Kahneman and Tversky
KIPS	knowledge information processing systems
KMB	Kilmer, McCulloch, and Blum
KR	knowledge representation
LAC	Lattice Artificial Chemistry
LBP	loopy belief propagation
Leabra	Local, Error-driven and Associative, Biologically Realistic Algorithm
LFG	lexical-functional grammar
LGN	lateral geniculate nucleus
LISP	list-processing language
LMS	least mean square
LOT	language of thought
LRAAM	labelling recursive auto-associative memories
LRB	*London Review of Books*
LT	Logic Theory Machine, or Logic Theorist
LTM	long-term memory
MAC	Multi-Access Computing (time sharing); Man and Computers; Machine-Aided Cognition
MACT	*Mathematical Anthropology and Culture Theory*
Madaline	a group of Many Adalines
MADM	Manchester Automatic Digital Machine
M&V	Maturana and Varela
MARIAL	Center for Myth and Ritual in American Life

MCC	Microelectronics and Computer Technology Corporation
MENACE	Matchbox Educable Noughts And Crosses Engine
MGP	Miller, Galanter, and Pribram (1960)
MIT	Massachusetts Institute of Technology
MITECS	*MIT Encyclopedia of the Cognitive Sciences*
MM	massive modularity
MMM	moderately massive modularity
MMORPG	Massively Multi-Player Online Role-Playing Game
MMPI	Minnesota Multiphasic Personality Inventory
MN	motor neurone
MOMA	Museum of Modern Art (New York)
MOP	memory organization packet
MRC	Medical Research Council (UK)
MT	machine translation
MTCLA	Machine That Can Learn Anything
MUD	Multi-User Dungeon
NASA	National Aeronautics and Space Administration (USA)
NCST	National Centre for Software Technology (Bombay)
NE	neuro-ethology
NEA	National Endowment for the Arts (USA)
NEH	National Endowment for the Humanities (USA)
NERISSA	Nerve Excitation, Inhibition, and Synaptic Analogue
NewFAI	newfangled AI
NIH	National Institutes of Health (USA)
NIPS	Neural Information Processing Systems
NK	network with N units, each with K inputs
NLP	natural language processing
NLS	online system
NOAH	Nets of Action Hierarchies
NOMAD	Neurally Organized Multiply/Mobile Adaptive Device
NORAD	North Atlantic Defence
NP	noun phrase
NPL	National Physical Laboratory (London)
NSF	National Science Foundation (USA)
NSL	Neural Simulation Language
NYU	New York University
OED	*Oxford English Dictionary*
ONR	Office of Naval Research (USA)
OPEC	Organization of Petroleum Exporting Countries
OPS	Official Production-System language
P&W	Premack and Woodruff
PARC	Palo Alto Research Center
PC	personal computer
PCB	Prerequisite-Conflict-Brothers
PCBG	Prerequisite-Clobbers-Brother-Goal
PDP	parallel distributed processing
PET	positron emission tomography
PM	Prerequisite-Missing
PNA	polyamide-linked nucleic acid
PROLOG	Programming in Logic
PS	production systems
PSG	control structure for production systems: see Newell (1973*a*) (The "G" is alphabetical: the 7th, and last, in the series)
PSS	Physical Symbol System
PURR-PUSS	Purposeful Unprimed Real-world Robot with Predictors Using Short Segments
RAAM	recursive auto-associative memory

RAF	Royal Air Force
RAND	Research And Defence Corporation (USA)
REM	rapid eye movement
RLE	Research Lab of Electronics (MIT)
RN	residual normality
RNA	ribonucleic acid
RR	representational redescription
RRE	Royal Radar Establishment
RT	run and twiddle
RTF	reticular formation
SAGA	Species Adaptation GA
SAGE	Semi-Automatic Ground Environment
SAIL	Stanford AI Laboratory
SAM	Sound Activated Mobile
SARA	Simple Analytic Recombinant Algorithm
SASci	Society for Anthropological Sciences
SCB	Strategy-Clobbers-Brother
SCI	Strategic Computing Initiative
SDI	Strategic Defense Initiative
SERC	Science and Engineering Research Council (UK)
SETI	Search for Extra-Terrestrial Intelligence
SFI	Santa Fe Institute
SFN	Society for Neuroscience
SIGART	Special Interest Group on Artificial Intelligence (of the ACM)
SIP	semantic information processing
SNARC	Stochastic Neural-Analog Reinforcement Calculator
SOAR	Success Oriented Achievement Realized
SPA	Society for Psychological Anthropology
S–R	stimulus–response
SRC	Science Research Council (UK)
SRI	Stanford Research Institute
STeLLA	Standard Telecommunications Laboratories Learning Automaton
STEVE	SOAR Training Expert for Virtual Environments
STM	short-term memory
STRIPS	Stanford Research Institute Problem Solver
SUNY	State University of New York
SYCO	*Syritta computatrix* (simulated hoverfly)
SYNICS	Syntax and Semantics programming language
TAU	thematic abstraction unit
TG	transformational grammar
THES	*Times Higher Education Supplement*
TINLAP	Theoretical Issues in Natural Language Processing
ToM	Theory of Mind
TOP	thematic organization point
TOTE	Test–Operate–Test–Exit
TPE	temporal propositional expression
TREAC	Telecommunications Research Establishment Automatic Computer (UK)
TT	Turing Test
TtB	Take the Best (Ignore the Rest)
TTT	Total Turing Test
TTTT	Total Total Turing Test
UC	University of California
*UCI	unit of cultural instruction
UCLA	University of California at Los Angeles
UCSD	University of California at San Diego
Umass Amherst	University of Massachusetts, Amherst

US	United States
UWE	University of the West of England
VDU	visual-display unit
VLSI	Very Large-Scale Integration
VP	verb phrase
VR	virtual reality
WHO	World Health Organization
XOR	exclusive or (i.e. *p* or *q*, but not both)
