But those who answer "Yes" will contrast "genuine" miracles, visions, or states of possession with illusory and/or self-deceiving ones. (Consider the role of the Devil's Advocate, who puts the counter-arguments when the Vatican assesses candidates for beatification. Or eavesdrop on the Fang people of Cameroon, when they argue about whether a supposed shaman really does have a hotline to the "ghosts" in the forest—Boyer 1994, ch. 6.)

(3) *Or perhaps religion satisfies an inner need for comfort and guidance?*

An especially complicated—and universalist—psychological story was told about that by Sigmund Freud (1913, 1927, 1930, 1932). It's difficult, today, to swallow it whole. Besides relying on the scientifically shaky Oedipus complex (Chapter 5.ii.a), he developed his own mythology of "the primal horde", to explain the historical origins of religion. But his insight that religion can offer various kinds of psychological security was sound. His account fitted monotheism best, but he did discuss totemism as well. Indeed, his work inspired Bronisław Malinowski's (1884–1942) pioneering studies of the Trobriand Islanders—who, said Malinowski, *didn't* develop an Oedipus complex, because in Melanesian culture the father's role wasn't as authoritarian as in Freud's Vienna (Malinowski 1915–18, 1922).

(4) *Possibly, our mental/spiritual health depend on it in some other way, linked perhaps to self-integration?*

This view was held by Carl Jung (1933), and by many Third Force psychologists (G. W. Allport 1951; Maslow 1962; see Chapter 5.ii.a). And since Freud saw religion as a protection against neurosis, he held a version of it too.

(5) *Perhaps religion aids social cohesion?*

A view favoured by many of those evolutionary psychologists who see religion as an *adaptation*, and by some sociologists and anthropologists. Thus Durkheim:

> [Religion is] a system of ideas with which the individuals represent to themselves the society of which they are members . . . The god of the clan, the totemic principle, [is] nothing else but the clan itself, personified and represented to the imagination under the visible form of the animal or vegetable which serves as totem. (1912/1915: 225–6)

(6) *Maybe there's some special faculty, or instinct, which leads us to religious belief?*

Darwin said not: he insisted that there's no "aboriginal endowment" for belief in "an Omnipotent God" or even "one or more gods" (1871: 143). (Some religious popularizers today, though not the evolutionary psychologists themselves, disagree: they even speak of "the God module".)

(7) *Or perhaps there are some more general mechanisms in human minds, evolved for other purposes but prone to generate religion?*

In other words, religion isn't an adaptation but a (possibly useful) side effect of non-religious adaptations.

Item (1), above, is a special case of this view. Recent cognitive science, however, has added further detail—as we'll soon see.

(8) *Finally, perhaps religion is learnt from the surrounding culture, just as table manners are?*

Despite its chicken-and-egg air, this is the answer that most anthropologists would give (see subsection f, below).

Each of these answers is consistent with at least one other. But three are mutually exclusive—namely (6), (7), and (8). The first two of these are nativist: they ascribe religious belief to inborn psychological mechanisms, either religion-specific or more general. The last is environmentalist—and universalist, too. That is, it respects the third and fourth 'Newtonian' tenets identified in Chapter 5.i. By implication, anything can be learnt—and whatever is learnt, is learnt in the same way.

It's these three answers which have most relevance for cognitive science. Some late twentieth-century cognitive anthropologists criticized their more traditional colleagues for their commitment to (8). They themselves were flying the flag for (7): the generation of the *extraordinary* out of the *ordinary*.

c. Symbolism

The sense in which religions are extraordinary was discussed by Sperber, in the mid-1970s. On his view, *the way in which we interpret* religious concepts is different from the way in which we interpret remarks about tables and chairs. He was the first anthropologist to explain religion in terms of the mind's underlying cognitive *processes*, and to take cognitive psychology seriously in so doing.

Abstract cognitive *structures*, to be sure, had been posited at mid-century by the then fashionable anthropologist Lévi-Strauss. He'd employed a binary semiotic "code", or symbol–meaning mapping, to analyse (for instance) different kinship systems—such as the "avunculate" pattern, in which the maternal uncle holds the family authority over a young boy. Similarly, myths and religions were supposed to be structured around basic semiotic oppositions and themes. Dichotomies such as *men/women*, *raw/cooked*, *village/forest*, *good/evil*, *elder/younger*, and others, were seen as fundamental to all cultures (Lévi-Strauss 1958/1963, 1964/1969).

Lévi-Strauss had been revolutionary in the early 1950s. Instead of focusing on cultural practices and/or artefacts, he claimed to be describing the human mind's classificatory rules, which structured those practices. That's why he was given prominence, thirty years later, in Gardner's Sloan-sponsored history (Section i.c, above). But he'd relied on abstract armchair analysis of ethnographic data, not on discoveries in cognitive psychology.

Sperber (1975), by contrast, argued that anthropologists should consider the processes by which people actually interpret symbols. In a word, this wasn't decoding, but inference. (That insight was later developed, in his co-authored book on *Relevance*: see 7.iii.d.)

As we've seen, Sperber called *God is everywhere* a "reflective" belief, accepted on the say-so of others: especially priests. But it's notoriously tricky. It's not clear just what it means, nor how we can know whether it's true *independently* of the words of the priests. (Nor is it clear how to recognize the priests in the first place, as we'll see.) Even Aquinas admitted that no particular observational belief follows from it, or conflicts with it. The same applies to the ritual sacrament of the Eucharist: the theologians tied themselves into knots over the bread and the wine.

Thomas Hobbes had little patience with them accordingly. He put the Ancient Greeks' mythical "Satyres, Fawnes, Nymphs, and the like" in the same class as his neighbours' "Fayries, Ghosts, and Goblins; and the power of Witches". The Church, he claimed, had encouraged or tolerated these beliefs "on purpose . . . to keep in credit the use of Exorcisme, of Crosses, of holy Water, and other such inventions of Ghostly men" (1651: 7). As for the dogmas pronounced by the theologians,

> [Such statements are among] those we call *Absurd*, *Insignificant*, and *Non-sense*. And therefore if a man should talk to me of a *round Quadrangle*; or *accidents of Bread in Cheese*; or *Immaterial substances*; or of *A free Subject*; *A free-Will*; or any *Free*, but free from being hindered by opposition, I should not say he were in an Errour; but that his words were without meaning; that is to say, Absurd. (1651: 20)

Three centuries later, the logical positivists agreed with him: religious statements are meaningless. As Antony Flew (1950/1955) famously put it, they suffer "death by a thousand qualifications".

If that's so, however, they take a long time a-dying. Most people might grant Hobbes the round quadrangle, but not the other examples. Religious concepts, they feel, do have some meaning. Atheists who reject *God is everywhere* normally say that it's false ("in an Errour"), not meaningless. They're happy to agree with Flew, that the meaning is highly elusive. But meaning *of some sort* there seems to be. How is that possible?

Sperber suggested an answer, by defining meaning in psychological—not logical—terms (Chapter 7.iii.d). In his sense, countless facts are potentially "relevant" to *God is everywhere*. For in the mind of a Christian believer, almost anything can be wheeled in to support, or illustrate, God's ubiquity, goodness . . . and so on (A. J. T. D. Wisdom 1944). Much the same is true, anthropologists tell us, in other cultures. The precise import of informants' remarks about their clan's totem, or the spirits in the forest, is as hard to pin down as anything Aquinas puzzled over.

For Sperber (1975), this was true of "symbolism" in general—religious concepts being a special case. The elusiveness—"inscrutability"—of symbolic meaning, he said, results from an asymmetry in the way it's interpreted. Whereas non-symbolic communication (including science) draws each claim from as many inferences as possible, symbolic language draws as many inferences as possible from each particular claim. It follows that a potentially unmanageable cloud of schema-based inferences—some symbolic, some not—attends every symbolic communication.

Think of how one reads certain types of poetry, for instance, or how one interprets certain types of visual art: ambiguity and unexpected associative richness are considered virtues, here. On Sperber's analysis, the slipperiness of religious statements, and the awe and mystery they arouse, results from this skewed interpretative process.

On Sperber's account, we don't have to be *told* to interpret the poem, picture, or prayer in this sort of way (though cultural training can lead us towards certain interpretive paths rather than others). If and when we find that we can't interpret a communication in the "rational" mode, we *automatically* switch to the "symbolic" mode. So by "rational", Sperber didn't mean consciously deliberated or argued, still less scientific. After all, science isn't/wasn't prominent in some cultures. But people everywhere make statements based on the evidence of their senses, from "The baked beans are on the top shelf" to "The totem pole is broken". Granted, culture-specific concepts inform such everyday perceptions (Chapters 6.ii and 16.iv.e). But Sperber's position was that non-symbolic interpretation kicks in first, as the (evolutionarily grounded) default procedure.

Just why we can't interpret religious statements rationally was considered at greater length by Sperber's follower Boyer. His answer relied on the contrast between the ordinary and the extraordinary.

d. The extraordinary out of the ordinary

Consider Darwin's dog. This creature, "a full-grown and very sensible animal", growled and barked fiercely when an unattended parasol left open on the lawn moved slightly, because of the breeze. That was unusual, said Darwin, since if anyone had been standing near the parasol the dog would have "wholly disregarded" it. In explanation, he attributed a primitive animism to his pet. But this animism was of type (7), not type (6):

> He must, I think, have reasoned to himself, in a rapid and unconscious manner, that movement without any apparent cause indicated the presence of some strange living agent, and no stranger had a right to be present on his territory. (Darwin 1871: 145)

In other words, the dog's ordinary reactions—the ascription of causes, the recognition of animate beings, and the assertion of the territorial imperative—were the root causes of his extraordinary ferocity.

Over a century later, the anthropologist Boyer (1959–) would offer a similar account of human religions. This didn't make him popular with his professional colleagues (Boyer 1994: 11). For most of them, as we've seen, psychology was irrelevant and human "universals" *tabu*.

Cognitive anthropologists, however, were less hostile. One of them, Scott Atran at the University of Michigan, even tried to take Boyer's theory further. He formulated "the Mickey Mouse problem", asking what distinguishes beliefs about the Disney rodent from beliefs about the gods (Atran 1998: 602). In a nutshell, his answer was: passionate personal commitment. So his evolutionary explanation drew on inherited mechanisms underlying motivation and social relations *as well as* the more strictly cognitive mechanisms stressed by Boyer (Atran 2002). Here, however, our focus is on Boyer—for whom Atran was a complement, not a rival.

By the mid-1990s, nativism had reappeared in psychology after its temporary eclipse, and had grown real teeth besides (Chapters 7.vi and 14.ix.c–d). So where Darwin could only hand-wave towards inborn mechanisms, Boyer (then at King's College, Cambridge) could call on developmental psychology, psycholinguistics, and neuroscience to locate them more closely. In addition, he could lean on Sperber's work on the cognitive mechanisms of symbolism and communication.

He'd already discussed culturally authorized "persuasion" by people regarded as truth-sayers (Boyer 1990). Now, he turned especially to religion, using many detailed examples from the African Fang people, with whom he'd lived for several years in the early 1980s (Boyer 1987, 1992, 1993, 1994).

His definition of religion (given in subsection b) was a psychological one. That's unusual: most anthropologists speak, rather, of religious *cultures*, *belief systems*, or *world-views*. Boyer regarded such terms as vague, mystical, and misleading, since they reify high-level abstractions instead of focusing on the underlying reality (1994, e.g. 51, 296). So although he often mentioned "culture", he did so as a convenient shorthand, not as a technical term. (For the record, he's now located in a Department of *Psychology*.)

He was similarly wary of theology. Religious representations, even religious experiences (naturalistically understood), are more real than religious "beliefs". Indeed, most people don't worry about the things that concern theologians. Boyer agreed with Meyer Fortes that even highly elaborate religious beliefs and practices "can be carried on perfectly well without a doctrine or lore of the nature and mode of existence of the 'beings' to whom they are ostensibly directed" (p. 94).

In short, it's a mistake to assume that people care greatly about the consistency of their religious beliefs. But that fact in itself is puzzling. Why do people seek consistency in respect of everyday trivia, but blithely ignore it in the seemingly important area of religion?

Boyer tried to give an answer. With respect to the *universal* aspects of religion, he suggested that the inferences that people link to religious statements aren't wholly unconstrained. (So when I said, above, that almost anything can be wheeled in to support religious claims, that "almost" was important.) The constraints he was talking about weren't further examples of symbolism, not even carefully argued theo-logical symbolism. Rather, they were cognitive schemas found in every human mind. These ordinary mechanisms are what give rise to the extraordinary claims of religion:

> Human evolution has resulted in the development of particular intuitive principles, geared to particular domains or aspects of the natural and social environment. Whatever cultural input can trigger some of these intuitive principles is likely to be more easily acquired and communicated, thereby giving rise to the recurrent features of cultural phenomena. Cultural recurrence (including the recurrence of religious representations) is therefore the outcome of a runaway process in the iterative application of epigenetic constraints. (Boyer 1994: 294)

The "intuitive principles" concerned cover a variety of ontological and relational schemas, in a number of different domains. They constitute our naive physics, naive biology, and naive psychology—several aspects of which had been discovered in pygmy children as well as in Westerners (e.g. Avis and Harris 1991). They've evolved for recognizing and making inferences about inanimate objects; causal connections; plants and animals; natural kinds such as water, or gold (conceptualized as having some hidden "essence"); human agency; and social status.

In making this list, Boyer was drawing not only on ethnoscientists' work on folk taxonomies (Section i.a–b, above), but also on recent developmental psychology (7.vi.i). Susan Carey (1978, 1985), for example, had noted that children overextend the words they're learning (so that "daddy" is applied to all men, and "doggie" to all four-legged animals), and suggested that animism results from this sort of overextension. Indeed, an interdisciplinary conference held at Ann Arbor in 1990 had focused on how universal cognitive mechanisms may give rise to various "cultural" phenomena (Hirschfeld and Gelman 1994).

Theory of Mind (7.vi.f), for instance, underlies anthropomorphic views about gods and spirits, from totems and witches to God our heavenly father. In using ToM (intentional) concepts to describe the supernatural, we help ourselves to the many default inferences associated with them. A father can wish, plan, love, protect, admonish, punish, and reward. And a witch, or a ghost, or a god can (by default) do all these things too.

Ghosts are especially interesting here, as is the awe/dread we often feel in the presence of a dead body—especially if we'd loved the dead person during their life. Regarding dead bodies in general, Theory of Mind naturally (*sic*) induces us to treat them as intentional systems—which, unfortunately, they no longer are. Boyer sees this mismatch as the source of the uncanniness experienced in the presence of the dead. And this in turn gives them their religious significance, and underlies the *interpersonal* dimensions of funeral rituals.

As for the religious significance of dead loved ones, that can be explained in comparable terms. Personal love is rooted in Theory of Mind, though it has weighty cultural aspects too. It's a highly complex set of cognitive, motivational, and emotional dispositions, all related to the purposes and attitudes of the loved one (Chapter 7.i.f). As a crucial computational structure within the lover's mental architecture, it can't simply be switched off at the loved one's death. Hence the inevitability of grief, and of mourning (again, see 7.i.f). (The same considerations imply that a committed believer in a personal God who loses their faith will suffer the tortures of hell in this world, if not in the next.)

And hence, too, the likelihood that some small comfort may be drawn from positing an *invisible* ghost, or soul, with whom some of the previously established personal relations can still be preserved. In other words, this isn't just superficial 'wishful thinking', but an attempt to maintain a central aspect of one's own mental structure.

Similarly, if priests or shamans or religious healers are a special *kind* of person, then they possess some hidden essence which gives them their priestly powers. (For the Fang people, this is an invisible magical organ, called an *evur*—Boyer 1994: 34–5, 45, 86–7.) However, since they look the same as everyone else, doubts can arise about their status—doubts that are *not* necessarily settled by their ancestry or gender, nor by any 'ordination' ritual they may have undergone (Boyer 1994, ch. 6, pp. 237–40, 252–3). It follows that doubts can arise also regarding the reflective beliefs about the supernatural which people are invited to accept on their say-so.

Religions, then, are natural phenomena: their key concepts are 'attractors' in our biologically rooted mental space. (In his later writing, Boyer related them to certain aspects of neuroscience: Boyer 2003.) But they're "un-natural" too (they're very *strange* attractors, a punster might say), for they *deny* some of the assumptions normally activated by these universal mechanisms. So an animal can be of only one species, but a totem may be a bear–snake. Nothing can pass through a solid wall—but Marley's ghost could, and so can the "ghosts" feared by the Fang people (Boyer 1994: 113–14). Every person is limited in power—but God isn't. Every physical event has a cause—but a creator–god doesn't. A block of wood or brass has no intentional states, nor any causal powers beyond gravity—but a graven idol does. And Everyman will die—but God won't; even animistic gods are ageless, or have an "age" that stays constant.

Communications using supernatural concepts are (up to a point) intelligible, contra Hobbes and Flew, because they automatically activate a host of familiar inferences in our minds. That's even true of 'weird' beliefs from other cultures—which is why Bartlett's subjects in Cambridge could make some sense of the alien story 'The War of the Ghosts' (Chapter 5.ii.b).

What makes such communications near-unintelligible, or slippery, is that one or more default assumptions is modified, or dropped. If witches fly on banana leaves (as claimed in the Fang religion), they'll have no difficulty in getting to wherever they want. But does it follow, or doesn't it, that they'd be 'grounded' if a forest fire destroyed the banana trees? If God is everywhere, and omniscient, then—unlike Ann's friend Sally (Chapter 7.vi.f)—He knows everyone's thoughts. But does it follow, or doesn't it, that (given that He's omnipotent too) He's part-responsible for the evil that humans do? And if He's wholly benevolent too, then what about other miseries? Darwin was one of many bothered by this:

I am bewildered . . . There seems to me too much misery in the world. I cannot persuade myself that a beneficent and omnipotent God would have designedly created the *Ichneumonidae* [a type of wasp] with the express intention of their feeding within the living bodies of caterpillars, or that a cat should play with mice. (letter to Asa Gray, 22 May 1860; in Darwin 1887)

And if God is omniscient, just how all-encompassing is that little prefix "omni"? Darwin, again:

[Do] you believe that when a swallow snaps up a gnat that God designed [or even foresaw] that that particular swallow should snap up that particular gnat at that particular instant? (letter to Asa Gray, July 1860; in Darwin 1887)

Such questions are inevitable, for they arise *naturally* from the conceptual/inferential schemas concerned. But they're also largely unanswerable, because those schemas have been fundamentally altered. (This is a psychological version of Immanuel Kant's "antinomies": metaphysical questions that we find ourselves compelled to ask, but which can never find an answer—Kant 1781.)

This, by the way, explains the phenomenon of heresy. If a powerful religious hierarchy has laid down a dogma, certain unorthodox answers may be officially denounced as "heresies". They're the ones which are likely to occur again and again, due to their close links with the intuitive schemas. Unorthodox answers that tempt only very few people aren't worth labelling as heresy.

It also helps explain the power of the priests, and the survival of religions once they've arisen. For the person who's socially sanctioned to interpret important life-relevant concepts which to the flock are unintelligible possesses a significant degree of social power. To that extent, natural religion (attained by method (1) defined above) *threatens* the status of the religious hierarchy. It's not surprising, then, that when Aquinas defined his Five Ways to the creator God, he pointed out that they said nothing about the personal God. For that, he said, we need not reason but revelation (guided, of course, by the Catholic Church). Claims to revelation, in turn, can be buttressed by religious experiences: item (2) on the list. Someone who's especially susceptible to—and/or especially skilled at inducing—florid states of possession, or strange visions, will very likely be revered as a religious authority (Chapter 7.i.i).

At this point, you may be thinking "What about quantum physics?" (thanks to Ron Chrisley for reminding me of this). Quantum physics, too, plays fast and loose with basic everyday concepts: cause, time, location, identity—not to mention Schrödinger's cat. (In that sense, quantum physics is a better candidate for Atran's Mickey Mouse problem than Mickey Mouse himself, or Karl Marx either—cf. Atran 2002: 13–15.)

The physicists themselves find this stuff weird (even "crazy": Chapter 17.i), and many others—myself included—simply can't begin to get their heads around it. If one's unable to cope with the mathematics, one can have recourse only to natural language—which is transgressed over and over again. So is quantum physics a religion?

Cynical remarks about power play and one-upmanship aside, no it isn't. Quantum physics does attract attention by (and even glory in) its inscrutability to common sense. (Sometimes, even non-physicists arrogantly trumpet the anti-commonsensical nature of science in general: L. Wolpert 1992.) But it grounds its counter-intuitive claims in as much empirical evidence as it can, justifying them by scientific experiments and by successful technologies. That is, it doesn't go in for Sperber's "symbolic" communication. Indeed, a key reason for the physicist Sokal's impatience with postmodernist interpretations of his field was that the postmodernists were doing just that (Section ii.b, above).

Moreover (recalling the other criteria in Boyer's definition), quantum physics doesn't buttress cultural rituals outside the laboratory, nor disseminate and validate sacred artefacts (with the possible exception, as I write this in mid-2004, of the *iPod*!). They don't claim the existence of strange forces that can influence specific events in the personal lives of those individuals who accept quantum physics. Similarly, they don't encourage prayer or propitiation as a way of avoiding unfortunate life events. Nor do they feel drawn to die, or kill, for physics. They're as envious as the rest of us of the status of the shamans, the power of the priests. So they may (they often do) 'play God' at cocktail parties, and even at scientific conferences involving non-physicists. But that's as far as it goes.

e. Anything goes?

Cognitive science has told us something about what sorts of bizarre ideas will arise—in James's terms, the production of religion. But are there any ideas *so* bizarre that they won't ever form the basis of a religious cult? To answer that question, we need to consider how religion spreads and how it's maintained.

(Boyer focuses on the cognitive aspects of *how* it's maintained, not the social/motivational reasons *why*. But he can allow, for example, that those cognitive aspects which buttress priestly power will be stressed by the priesthood in their own interests, and highlighted—largely thanks to them—in religious rituals. Similarly, items (3), (4), and (5) on the list of putative explanations above aren't inconsistent with Boyer's account, unless they're offered as the *only* explanation of the origin of religion. As for item (1), we've already seen that this is a special case of item (7)—which is Boyer's explanation.)

Religions spread and survive, according to Boyer, largely thanks to the flouting of the common-sense categories concerned. It's the counter-intuitive claims—about witches flying on banana leaves, or God being everywhere—which make religion so fascinating. (And, as just remarked, quantum physics too.) Like a 'face' with three eyes, they *naturally* attract even more attention than the unmodified schemas do. (They're further examples of behavioural novelty, which we've evolved to find attractive: see iv.b, above.)

That's why religious adherents themselves acknowledge, even revel in, the strangeness of their beliefs. A Fang adult takes it for granted that there are witches, never questioning this for a minute—but he does realize that witches are pretty strange. And the Church father Tertullian, converted by the courage of the Christians thrown to the lions in second-century Carthage, is famous for declaring *Credo quia absurdum est*: "I believe it because it's absurd." If his remark weren't so seductive, it wouldn't have survived for almost 2,000 years. (In fact, it hasn't survived unaltered. There's been a micro-evolutionary change, for his actual words were slightly different. Of the death of the son of God, he said *Credibile est, quia ineptum est*; and of the resurrection, *Certum est, quia impossibile*—Moffatt 1916: 170. However, saying "I believe it" is more personal—that's to say: more inference-arousing, more relevant—and so more memorable than saying "It's believable", or even "It's certain".)

It's no surprise, then, that religion is found everywhere. If it also happens to satisfy our needs for explanation, mental health, and/or social cohesion—items (1) and (3–5), above—its maintenance will be that much more likely. (Some psychological mechanisms making 'full-blown' religious belief possible are sketched in Boden 2002.) The recurrence of religion's universal core *isn't* due to cultural transmission.

But the recurrence of its superficial diversities *is*. Fang witches ride on banana leaves, Christian angels on clouds or wings. The survival of these representations from generation to generation is due to cultural transmission—or in a word, learning. For only by being a member of that culture, or an attentive visitor, can one acquire these concepts. To *that* extent, item (8) on our list, above, is vindicated.

It doesn't follow, however, that cultural learning is wholly unconstrained—a tacit assumption of item (8). Perhaps there are limits, even to religion? Are there some things which can't be believed, or can't even be thought?

Philosophers may approach this question in an 'absolutist' spirit. For instance, consider Colin McGinn's discussion of brain and consciousness (Chapter 14.x.d). He argued that we'll never find mind–body explanations. The problem (he said) isn't that the mind–body relation is *essentially* mysterious, or that minds are divorced from the material world: he assumed that consciousness arises from the brain. The problem is that our cognitive capacities aren't up to understanding it. Analogously, there's nothing mysterious about arithmetic, or the January sales—but dogs and goldfish will forever be oblivious to them. McGinn's claim, then, is that there are some truths that can never be known, or even entertained, by human minds. Some things, eminently worth thinking, simply can't be thought.

Possibly, that's so. For anyone who accepts a realist philosophy of science, this worry is inescapable. (For a non-realist, the problem can't arise.) It would be hubris to assume that we're potentially capable of understanding *every* aspect of the universe. But that's not what's at issue here.

For cognitive anthropologists, the question is different. It's this: are there some things that are thinkable in principle, but *not* capable of being widely accepted and/or reliably transmitted? Or can human cultures, differing greatly as we know they do, maintain just any idea?

Someone might cite multiply nested sentences here (Chapter 7.ii.b). For it's virtually impossible to understand them, especially without paper and pencil. We can easily get our heads around the linear version of *This is the house that Jack built*. But we couldn't cope with its hierarchically embedded equivalent. So a linguistic representation that's possible (grammatical) in principle is unintelligible in practice. However, its semantic content can be captured by a different representation, which can be understood even in the nursery. Indeed, Anglophone culture has already included Jack's house in its mythology—and the malt, the rat, the cat . . . right up to the farmer sowing his corn—by describing these things in the linear way.

A more telling example is Borges's joke taxonomy (Section i.b). In a weak sense, to be sure, he could understand it. He could describe it at his leisure, in written prose. But he couldn't have used it. He couldn't even have remembered it, except parrot-fashion—or perhaps with the help of a specially concocted mnemonic.

Some of the reasons were provided by Rosch, as we've seen. She showed that the structure of concepts, and the processes of conceptualization, simply don't fit the bizarre example imagined by Borges.

Even more to the point is Sperber's work on relevance. He and Wilson (1986) showed how inescapable constraints on information processing both bound and enable our rationality. Certain interpretations of what another person says won't arise, even though in principle they could. That's why, in Chapter 7.iii.d, I described relevance theory as addressing "the frame problem" for high-level thought. What goes for understanding goes for memory too. Something that's difficult to grasp in the first place will be difficult to retain—and to transmit. In other words, the mind's information processing influences not only James's "causes of production" of variation in ideas, but the "causes of maintenance" too.

Notoriously, beliefs can be shared in one culture which in others are literally incredible. Members of that culture can rely on this fact, in making sense (*sic*) of their fellows' communications. For instance:

> [Every] Freemason has access to a number of secret assumptions which include the assumption that all Freemasons have access to these same secret assumptions. In other words, all Freemasons share a cognitive environment which contains the assumption that all Freemasons share this environment. (Sperber and Wilson 1986: 41)

So what's irrelevant in one culture may be highly relevant in another. If a web of conceptual relations has already been learnt, a new communication may be effortlessly interpreted in a way that would never even occur to someone from a different cultural background. That's why one person can hold a belief which another can hardly understand, and certainly not credit: "How on earth can they believe *that*?"

But what of the 'Tertullian factor'? We've seen that the un-natural aspects of religious ideas help make them interesting, and therefore memorable. So perhaps the more bizarre the better?

Boyer thought not:

> [Certain] combinations of intuitive and counterintuitive claims constitute a cognitive optimum, in which a concept is both learnable and nonnatural (Boyer 1994: 121).
>
> Religious ontological assumptions generally comprise a culturally transmitted [i.e. explicit] part, which violates intuitive expectations, and a tacit, schematic part, which confirms them. Assumptions of this type *are likely to be more recurrent if they reach a cognitive optimum*, in which (1) the violation clearly marks off the putative entity or agency from ordinary objects and beings

and (2) the confirmation imposes maximal constraints on the range of inferences that can be drawn from cultural cues. (p. 287; italics added)

In short, the cognitive equilibrium between the familiar and unfamiliar must be maintained. If the balance is thrown too strongly towards the latter, the potential belief won't be accepted—or anyway, won't be widely communicated.

For instance, remember the flying saucers promised in the message from the Guardians on the planet Clarion (Chapter 7.i.c). They'd been expected in the first place only by the cult members. When they failed to arrive, the charismatic leader's second "message"—that the whole town had been saved from the flood at the last minute by the faith of the cult—was credited only by the few members still cooped up with her in her suburban house, offering each other mutual support. And when those few faithful finally tried to spread their "good news" over the media, nobody listened—except to laugh.

At first glance, rescue-by-flying-saucer seems no more bizarre than bodily ascensions or virgin birth, both of which are accepted by millions of people in "the same" culture. To be sure, the latter beliefs have two millennia of tradition behind them. But even that's not accidental. Boyer's analysis helps us understand why the idea of bodily ascension spread widely, and is still maintained by millions, whereas the vision of flying saucers didn't, and isn't. And even flying saucers and other-worldly Guardians are intelligible, having strong roots in our intuitive physics and theory of mind. Had Borges aspired to lead an 'animal' cult, he'd have found no followers: he'd have been on his own, tangled up in his artificial mnemonics. As Boyer put it, "the variability of cultural ideas is not unbounded" (1994: 5).

Most anthropologists, however, seem to assume that it is. The Borges example should give us pause. And Boyer suggested a simpler one: that *everyone* can be a medium, but only *every other day* (1994: 6). There are two things wrong with this. (In fact, they're two sides of the same coin.) On the one hand, a medium is supposed to be a special kind of person, whose essential properties (including access to the supernatural) can't be switched on and off. On the other hand, the natural (*sic*) assumption that "same causes have same effects" can't be—*can't be*, not just *isn't*—given up without strong justification. Conceivably, a medium might be able to commune with the dead only on the anniversary of the deceased's birthday, marriage, or death; or a Christian saint might be able to work miracles only at Christmas or Easter, or only on Sundays. But *every other day* . . . ? That's not merely bizarre. It's almost meaningless, since this imaginary limitation is utterly irrelevant to other 'spiritualist' representations. Even if *per impossibile* a tiny cult were to accept this every-other-day belief, it would never sweep the world.

Once an inferential constraint has been loosened, the way is left open for inferences that would otherwise be blocked. If angels are immaterial agents, they have no weight: so why shouldn't they fly around on golden wings? And once they're doing that, why shouldn't they stop to take a rest on a passing cloud? Clouds or rest, in turn, will trigger other mental schemas—some of which may be highly culture-specific. In short, this is epigenesis: the universal core can develop in many differently detailed ways (Chapters 7.vi.g and 14.ix.c). Hence the enormous cultural diversity that anthropology describes: given the creative imagination of *Homo sapiens*, weird stories about supernatural beings can blossom to our hearts' content.

However, our hearts—or rather, our minds—can't be contented by *just anything*. If too many default assumptions are flouted, the "relevant" inferences become so computationally unconstrained that they're not merely slippery but unmanageable—and unmemorable, too. In other words, they aren't really relevant at all. And since communication depends on the (mostly tacit) recognition of relevance, the problematic representation can't be transmitted either.

f. The impurity of induction

Anthropologists in general are highly suspicious of evolutionary approaches, as we've seen (Section ii.b). Chagnon, one of the two men slandered by *Darkness in El Dorado*, co-edited a large evolutionary volume soon after the sea change in anthropology had got under way (Chagnon and Irons 1979). Clearly, given the AAA's initial support for *Darkness* twenty years later, this did nothing to enhance his reputation in the eyes of the mainstream. And Boyer remarked defensively at several points in his 1994 book that universalist accounts still weren't considered *comme il faut* by most of his peers, because of "the occupational disease of relativism" (p. 111)—their chief weapon in the science wars (Chapter 1.iii.b).

Besides disliking evolutionary accounts (as scientistic), most anthropologists think they don't need them. For they generally assume that *cultural* transmission can work for all representations. This assumption depends on their faith in pure induction, item (8) on the list above. That is: any pattern, any similarity, in the input can be learnt if it's encountered often enough.

Some early cognitive scientists made the same assumption. (Not Warren McCulloch, however: see 4.iii.b and 14.ii.b.) Now, they don't. They believe, with Boyer, that

> The more people pick up available information from the environment, the more they are working on (and constrained by) implicit hypotheses about what is to be picked up. (Boyer 1994, p. x)
>
> The variety of situations that a subject experiences supports indefinitely many possible inferences, of which only a small subset are ever entertained by the subject. Unless we have a good description of the mechanisms that constrain the range of hypotheses, the empiricist account is insufficient. (p. 25)
>
> [There] is no such thing as a simple inductive device, and in fact there cannot be such a device. (p. 95)

One might say they've become more Kantian, for Kant argued that sensory experience must be informed by structuring "intuitions", or "categories" (Chapter 9.ii.c). But that doesn't mean they've all been reading Kant. (More likely, though also not necessarily true, they've been reading Noam Chomsky: 9.vii.c.) Their initial optimism was damped by difficulties, not to say failures, in *implementing* pure induction:

> This is, again, a very familiar point in cognitive modelling; unless one wants to accept indefinitely long searches, one must assume that knowledge structures [mental schemas] provide some information to constrain inferential processes. (Boyer 1994: 59)

In brief, inductive learning requires some initial guidance and/or restriction. Without that, the computational system would be overwhelmed by a host of similarities in the input, most of which are of no significance whatever. That's been shown independently by work in GOFAI, in connectionism, in linguistics, in developmental psychology, in adult cognitive psychology, in the philosophy of science, and in neuroscience.

The system may start out with relatively specific guidance—such as a module for face recognition, a "Language Acquisition Device" (not necessarily Chomskyan), or a scientific hypothesis (Chapters 7.vi.d–e, 9.vii.c–d, and 6.b–d, respectively). And/or initial processing restrictions may prevent it from being swamped by the input, being gradually relaxed thereafter (see 12.viii.c–d). Or it may benefit from a helpful input history (12.viii.e). There may even be different neural learning mechanisms for different domains: the domain-neutral associative bond may be what Randy Gallistel has called "the phlogiston of psychology" (14.ix.g).

But whatever the details turn out to be, the empiricist model of learning adopted by most anthropologists is vacuous:

> [Many] anthropological accounts of recurrence and transmission [have] a strong magical flavor . . . [Saying] that "cultural models are somehow transmitted through socialization" is not very different from saying that "performing the ritual somehow makes the rains fall". Or, to be less polemical, it is very much like saying that "turning the ignition key somehow makes the engine start", which certainly constitutes a reliable principle, but hardly a theory of thermal engines. (Boyer 1994: 265)

The theory of *mental/cultural* engines that we need is "a *rich* psychology", not an artificially simplified one (p. 288).

The banana leaves, and the angels' wings, are representations that can be easily transmitted (learnt) because they're inferentially linked to intuitive schemas about animate agents travelling through space. We don't bother to mention that if a witch/angel wants to speak to someone, they need to move to the place where that person is. Probably, we don't even explicitly think it: wings and banana leaves are much more interesting. In some languages, we might not even be able to make it explicit. But that doesn't mean we wouldn't be tacitly influenced by it: if a culture has no word translatable as *cause*, *belief*, or *intention*, it doesn't follow—contrary to some anthropologists' claims—that they don't possess those concepts tacitly (Lee 1949; Boyer 1991).

It's true that if we're challenged—or if the witch/angel is replaced by God, who we're told is *everywhere*—we're prepared to drop the commitment to location change. That's just one of Flew's death-dealing qualifications. They number "a thousand" because, where religion is concerned, no single inference is safe from dropping. Without any inferential guidance at all, however, we'd be lost. We couldn't acquire the concepts in the first place. (We couldn't even acquire religious *rituals* if they weren't rooted in intuitive intentional schemas, like those which underlay Robert Abelson's account of beliefs and actions: Chapter 7.i.c; cf. Boyer 1994: 202–5.)

Admittedly, highly abstract religions do exist: certain forms of Buddhism, for instance. However, they appeal only to highly literate specialists. The populace understands them in more concrete ways. Benedict Spinoza's (1632–77) austerely non-anthropomorphic vision of God has intoxicated many individuals, myself included. The Spinozahuis in The Hague where he died teems with his admirers, eager to sign the visitors' book as an act of homage. But his closely argued *Ethics* (1677), which rejects every familiar predicate in monotheism (even including "God is *one*"), will never become the basis of a culture-wide religion. It can be the topic of philosophy, or of psychology—but never of anthropology.

In sum, even religion has its limits. It's not the case that—in some culture, somewhere—anything goes. Cole Porter was wrong. But if Cole Porter was wrong, his contemporary Bartlett was right. In his book on memory and social psychology, Bartlett pointed out that anthropologists ignored the mechanisms that make culture possible:

> [Very little has been said about] social conduct in any genuinely observed sense, except by anthropologists *whose interests are apt to stop short at detailed description*. (Bartlett 1932: 239; italics added)

That's no longer true. Or anyway, it's no longer true of the entire profession. Thanks to the cognitive anthropologists, we now have computational accounts of a wide range of cultural phenomena. These are mostly schematic outlines, not nitty-gritty computer models. Nevertheless, the sixth point on the Sloan hexagon has been respected, polished, and sharpened.

9 TRANSFORMING LINGUISTICS

Theoretical linguistics has been enormously important in the history of cognitive science *as a whole*. But it might not have been. After all, why should psychologists, or philosophers, or anthropologists, or neurophysiologists, or computer scientists be interested in linguistics? If they happen to be concentrating on language, then perhaps it's relevant. If not, why should they bother with it?

As late as 1950, most of them didn't. And, in fact, most of them don't today. But in the late 1950s to 1970s all cognitive scientists had to pay some attention to it. This chapter explains why that was. (Why the interest then dwindled to near-zero is explained in Chapter 7.iii.a, and in Section ix.g below.)

The cyberneticists gave no thought to linguistics—and very little to language. The nearest they got was Warren McCulloch's 1920s search for a "logic" of verbs (4.iii.c), a pastime foreign to his cybernetic fellows. Even Gregory Bateson and Gordon Pask, who both championed language-based psychotherapy, weren't interested in the structure of language. When Alan Turing and others in the UK wrote the first computer programs involving language, they ignored linguistics (see x.a, below). And the (few) psychologists who focused on language paid scant attention to linguistic theory, and—crucially—didn't see their work as relevant for the study of mind *in general*. Nor was linguistics needed to spark off the cognitive revolution: that originated in psychology and AI, not linguistics (4.iii.e, 5.iii–iv, and 6.i–iii).

It turned out, however, that theoretical linguistics—specifically, the study of *syntax*—stoked the fire sparked off by other disciplines. (The contemporary work on phonetics was less relevant in this regard, and I shan't discuss it.) By the early 1960s no one involved in cognitive science, or in the philosophy of mind, could ignore it. The reason, in just two words: Noam Chomsky (1928–).

Linguistics turned computational with Chomsky. He tried to formulate a mathematical definition of language *as such*: a "computational" account, in the abstract sense later stressed by David Marr (7.iii.b). His work, including a pioneering paper on computer languages, encouraged others to persevere with, or to embark on, the computer modelling of language. But he himself didn't join them. He was highly sceptical about what's normally called computational linguistics, or natural language processing (NLP). He dipped his toes into the water only once (G. A. Miller and Chomsky 1963: 464–82)—by which time many others were already swimming in the shallows (see Section ix).

Chomsky's early publications—up to the mid-1960s—had a huge, and lasting, effect on cognitive science overall. This needn't have happened, even if his *linguistics* was, as one disciple later said, "*the* existence proof for the possibility of a cognitive science" (Fodor 1981*b*: 258). But Chomsky generalized his philosophical and methodological claims. He even defined linguistics as "part of psychology", focused on "one specific cognitive domain and one faculty of mind" (Chomsky 1980*b*: 1). Granted, he cared little about the psycholinguistic processing details—especially when they turned out to be less consilient with his theory than had at first appeared (Chapter 7.ii.a). But he saw his linguistics, in effect, as a theory of *mind*.

Specifically, he revived the then hugely unfashionable doctrine of *nativism*. This is the view that the mind/brain of the newborn baby is already equipped with knowledge of, or dispositions towards, language—and various other things, too. Modern proponents of nativism, such as his ex-pupil Steven Pinker (1954–), cite many biological data that were unknown to Chomsky (Pinker 1994, 2002). But he remains their key inspiration. Indeed, a very recent book by a leading anti-nativist has acknowledged that his "arguments [for linguistic nativism] are still widely read, *and carry as much weight today as any newly-produced publications*" (Sampson 2005: 7; italics added). In brief, he's still a major force.

Chomsky's influence on cognitive science was beneficial in many ways. In particular, he deepened the nascent questioning of behaviourism, and encouraged "mentalist" theories couched in terms of internal rules and/or representations (Chapter 6.i.e). He revivified research on nativism (7.vi), and indirectly encouraged the growth of evolutionary psychology (8.ii.d–e and iv–v). He offered a vision of theoretical rigour which inspired linguists and non-linguists alike. And, despite his own scepticism, his work encouraged others to attempt the computer modelling of mind. In short, for the field as a whole, he was a Good Thing.

Nevertheless, this chapter starts, unusually, with a health warning: *beware of the passions that swirl under any discussion of Chomsky* (Section i).

Next, Sections ii–v locate Chomsky in relation to the three centuries of language scholarship—including linguistically inspired philosophies of mind—that preceded him. The ancient writings are discussed in some detail here because he himself made a point of comparing his own work to them in a provocative way. I begin by distinguishing predecessors from precursors (in Section ii), and then consider the various writers named by Chomsky as his "rationalist" precursors (see Sections iii–iv). Section v sketches the state of theoretical linguistics during Chomsky's youth.

In Section vi, I describe how he first sought to change it. Section vii deals with his nativism, and the associated attack on behaviourism, while Section viii says a little about the subsequent changes in Chomskian theory. Various fundamental critiques of his account of language are outlined in Section ix, which also shows the need for the health warning.

Finally, the last two sections describe the early days, and the eventual maturation, of work in the computer modelling of language. These matters could have been discussed in Chapter 10, for NLP was central to GOFAI research. I decided to place them here instead, largely because the problems experienced in NLP recalled theoretical questions highlighted by the scholars featured in Sections iv–v, below.

A word on demarcation: this chapter deals with linguistics rather than psycholinguistics. The focus is on the nature of language *as such*. Psychological questions about how we understand, communicate, and remember linguistic meanings do crop up here, of course. But they're addressed more directly in many other parts of the book (e.g. Chapters 7.i.c, ii, iii.d, and iv.d–e; 8.i.a–b and vi; 10.iii.a and e; 12.x; and 16.i.c and iv.c–d). Indeed, Chomsky's influence led many linguists to ignore such questions: see Section ix.g, below.

9.i. Chomsky as Guru

Many people, including youngsters, take Chomsky as their political guru. Indeed, it's mostly because of his courageous and uncompromising political writings—which far outnumber his publications on linguistics—that he's the most-quoted living author (Barsky 1997: 3). I'll say a little about his politics in Section vii.a, below. But it's his role as a *scientific* guru that's relevant here.

I said, above, that Chomsky was a Good Thing for the development of cognitive science. So he was. But to acknowledge this isn't to accept the tenfold Chomsky myth.

a. The tenfold Chomsky myth

Those who uncritically take Chomsky as their scientific guru share ten beliefs:

* They think (1) that besides giving a *vision* of mathematical rigour, he always achieved it in his own work.
* They believe (2) that his linguistic theory was, or is now, indisputably correct in all essentials.
* They hold (3) that the (nativist) psychological implications he drew from it were convincingly argued at the time, and
* (4) that they are now empirically beyond doubt.
* On matters of history, they suggest (5) that his work of the 1950s was wholly original.
* And they suppose (6) that his writings of the 1960s were—as he himself claimed—the culmination of an august tradition of rationalism dating back 300 years.
* Some also assume (7) that without Chomsky's grammar there would have been no computer modelling of language.
* Many believe (8) that Chomsky was responsible for the demise of behaviourism.
* Most take for granted (9) that he reawakened and strengthened the discipline of linguistics.
* And many assume (10) that linguistics is as prominent in cognitive science today as it was, thanks to Chomsky, in the late 1950s to 1970s.

Each of these beliefs, strictly interpreted, is false. But all, suitably qualified, approach the truth. (The least defensible are nos. 9 and 10: in some ways, as we'll see, he *set back* the field of linguistics, and *undermined* its relevance for cognitive science in general.)

Moreover, many people in Chomsky's heyday accepted all of them (except no. 10, of course)—and a significant number still do, with no. 10 now added. That's why

Chomsky is not only a pivotal thinker in theoretical linguistics, but also a hugely important figure in the wider story of cognitive science.

However, "important" means *influential*, *provocative*, *fruitful* . . . perhaps even *largely beneficial*. It doesn't necessarily mean *right*.

b. A non-pacific ocean

The tenfold myth attracts passions of surprising depth. Surprising, that is, to anyone who believes the Legend: that science is a disinterested enterprise (see 1.iii.b).

While doing the research for this chapter, I was astonished to discover the lack of mutual respect between the two camps in linguistics, Chomskyan and non-Chomskyan. I'd known there were unpleasant tensions of course, but I hadn't realized their degree. They range from unscholarly ignorance of the very existence of important competing theories (as I discovered in a recent conversation with a young MIT linguist) to vitriolic hostility and public abuse.

As one illustration, a leading American linguist who (unusually) has an open mind on the issue of nativism has recently bemoaned "what is, I am afraid, an often disturbingly unserious, indeed irresponsible approach to the innateness position on the part of its major advocate" (Postal 2005, p. viii). Paul Postal (1936–) then quotes some "revealing", "outrageous", and "grotesquely untrue" remarks by Chomsky, the burden of which is that all the arguments against innateness are such confused nonsense that nobody ever bothers to answer them. And his verdict is that "These statements [by Chomsky] are not scientific comments but rather the analog of awful, partisan political discourse" (2005, p. ix).

As another illustration, a non-Chomskyan complained to me about Chomsky's theorizing about syntax:

> Anything that any human being actually says is at once defined by Chomsky out of the discipline, leaving him and his followers free to pursue their strange little version of navel-gazing, free from any contamination from the real world. *And I can't forgive Chomsky for perverting my discipline in this sick manner*. (Larry Trask, personal communication)

Larry Trask told me, a few months before his tragically early death in 2004, that he was happy for his remark to be quoted, since he'd said much the same in print. (And I'm confident that he'd have been happy with the italics, which are mine.)

Third, the computational linguist (and AI–vision researcher) Shimon Edelman (1957–) has recently referred to "the Bolshevik manner of [Chomsky's] takeover of linguistics", and the "Trotskyist ('permanent revolution') flavor of the subsequent development of [his] doctrine" (S. Edelman 2003). To be fair, he allows that there were cultural reasons for the "takeover" in early 1960s America (Koerner 1989). These were the widespread counter-cultural rejection of the views of the older generation (see 1.iii.c), and the post-Sputnik increase of research funding—especially at MIT (see 11.i). Thanks to that money, many new departments of linguistics were set up in the USA at that time, and it was "inevitable" that they'd be staffed by young lecturers trained at MIT (James McCawley, quoted in Koerner 1994). So Edelman isn't suggesting that Chomsky was an all-powerful tyrant, solely responsible for what happened. By the same token, the Chomskyan "revolution" wasn't caused by purely *intellectual* factors (S. Edelman 2003: 675).

And last, an anonymous linguist who reviewed this chapter accused me of pursuing "a personal vendetta" against Chomsky instead of "doing intellectual history". He, or possibly she, couldn't have been more wrong. I'm not a professional linguist, so have no axe to grind either way. (And like Postal, I have an open mind about linguistic nativism: see Chapter 7.vi.) Moreover, it's precisely because I'd done the intellectual history carefully that I'd realized just how questionable, and in certain respects just how damaging, some of Chomsky's claims were.

It's a telling sign that my account—which isn't written in a polemical spirit (though it does quote polemics, from both sides), and which gives chapter and verse for every criticism—should have been misinterpreted in that way. So be warned: these are turbulent waters. When it comes to Chomsky, few linguists, if any, are emotionally neutral.

(The same reviewer wanted me to change the chapter because "it will upset people". Well, I've no doubt that it will upset some people—though it will probably hearten others. But I haven't changed it: it's an honest account of what I found in the literature, and of what I was told in conversations with several leading linguists.)

Far from having mellowed with time, the passions have risen over the years. In Sections viii and ix, we'll see why this is so. But before then, we'll consider Chomsky's early work (up to the mid-1960s), its immediate reception, and—first of all—its intellectual background.

9.ii. Predecessors and Precursors

Let's start with some banalities:

A predecessor is a person who discussed the same topic as some later scholar.

A precursor is a predecessor who said similar things about it.

A precursor needn't have influenced the scholar concerned: intellectual anticipation isn't the same as intellectual ancestry.

Identifying precursors requires one to decide just what one means by "similar".

Similarity isn't merely a question of degree, but of nature. Two œuvres may have more or less of a certain feature, and/or they may have partly different features.

Finally, someone who interprets "similarity" too broadly not only obscures important differences, but casts all the scholars concerned in intellectual roles for which they aren't best suited. So reflected glory may be more distorting than illuminating.

a. Why Chomsky's 'history' matters

The points just listed, which relate to the caveats given in Chapter 1.iii.f, are pertinent in any discussion of the history of ideas. But they're especially relevant here. They concern not only Chomsky's intellectual pedigree, but also his rhetorical efforts to share in the glory associated with great names of the past.

Those efforts weren't mere self-seeking. Rather, they were a form of philosophical defensiveness. Chomsky had deliberately suppressed his (nativist) ideas on language-and-mind when writing his first book (1957), judging them to be "too audacious" for publication (see Section vi.e). When he did finally announce them, he defended them partly by locating them in the context of respected thinkers of the past (1965, 1966). In so doing, however, he misrepresented those thinkers in various ways.

"So what?" you may ask. "Why bother to rap Chomsky over his historical knuckles? He wasn't a historian, after all." Well, no. But historical accuracy is important here for two reasons.

He himself, in defending nativism, gave his Cartesian–rationalist labelling a high profile (and many Chomsky fans uncritically took him at his word). Today, his long-time champion Jerry Fodor (1998*c*) speaks of "the New Rationalists", of whom he counts himself one (7.vi.d). We need to know just how literally this tag should be taken.

Even more to the point, we must try to grasp the shifting subtleties of the long-standing debate about "innate ideas" if we're to understand nativism *in general*. In this context, we need to know what the philosophers he referred to actually said—which often differed, more or less, from what he implied that they said.

On the one hand, Chomsky himself repeatedly named as precursors people—dating back to the early seventeenth century—whose views differed significantly from his own, and implied that they were more similar to each other than is the case. (In so far as they are indeed his precursors, they're anticipatory rather than ancestral: he studied most of them only after developing his own ideas.)

On the other hand, the fact that linguists today situate themselves—in agreement or opposition—with respect to Chomsky might suggest that his work was a complete break with what went before. In other words, it suggests that his teachers were mere predecessors, not precursors.

In discussing these matters, we must distinguish his views on language-and-mind from his theory of language (primarily, of syntax) as such. The "one hand" (above) concerns the former. The "other hand" concerns the latter.

With regard to his grammatical theory, one might say that Chomsky had no precursors. More accurately, the sense in which others before him had "said similar things" was an attenuated one. He himself claimed that the transformational model of language was "not at all new", having been anticipated by the Port-Royal logicians of the seventeenth century (Chomsky 1964: 15–16). But that was true only in the most general sense. Even those of his immediate predecessors who developed formal theories of syntax did so in much less detailed ways. Chomsky's grammatical work, although clearly dependent on contemporary advances in formal linguistics and information theory, was largely novel (see Sections v–vi).

As for his views on the relation between language and mind, Chomsky was the first to say that he had many precursors (Chomsky 1964: 8–25). But most, he says, were long dead and largely forgotten:

> These early modern contributions were scarcely known, even to scholarship, until they were rediscovered during the second cognitive revolution, after somewhat similar ideas had been independently developed. (Chomsky 1996*a*: 7)

That remark apparently applies to Wilhelm von Humboldt (1767–1835), whose work one historian sees as having suffered "a pattern of recurrent, or successive, amnesia" in American linguistics (Hymes and Faught 1981: 98). And it applies also to the Port-Royal *Grammar* (see Section iii.c), which another historian of linguistics has described as "forgotten, [and] often misunderstood" by the end of the nineteenth century (Koerner and Asher 1995: 174). But it doesn't apply so clearly to the Port-Royal *Logic*, which was being translated into English for the fourth time just as Chomsky's first book appeared. And I know from my own experience that Herbert of Cherbury (on innate ideas) was routinely recommended to Cambridge philosophy undergraduates in the 1950s. Perhaps professional linguists weren't reading these people, but others certainly were.

These examples suggest that some of Chomsky's remarks about his precursors may need to be taken with a pinch of salt. Perhaps a sackful: a third specialist historian has gone so far as to say that Chomsky's version of the history of linguistics is "fundamentally false from beginning to end" (Aarsleff 1970: 583).

Even if that judgement is too harsh, there are systematic problems with regard to Chomsky's account. I noted, above, that talk of precursors depends on what one counts as similar. Chomsky interpreted the similarities so broadly that his descriptions of his forerunners were often misleading. In particular, his frequent uses of "rationalist" and "Cartesian" were inaccurate. And it's not at all clear that what his forebears had meant by the "inner form" of language, or by "creativity", was what he meant by these words.

The central doctrine of "Cartesian linguistics", said Chomsky, is that "the general features of grammatical structure are common to all languages and reflect certain fundamental properties of the human mind" (Chomsky 1966: 59). In other words, "Cartesian" linguistics holds that there is some inborn grammatical core of all natural languages.

Chomsky did attach a caveat to his inclusive term ("Cartesian"), pointing out that the rationalist/nativist writers he had in mind fell into more than one philosophical school. Nevertheless, he implied that they comprised a coherent tradition of humanist rationalism, one that had been forgotten but had now been revived by his own research (Chomsky 1966, 1968).

If we're to situate that research in its historical context, we need to understand how his nominated precursors differed—from him and from each other—as well as how they were alike. In this section, we'll consider their general philosophical background; specific examples are discussed in Sections iii and iv.

b. The rationalist background

In broad outline, the writers Chomsky named as his "rationalist" precursors agreed on two things. They believed that language is the origin of human thought, and that it's innate in every child.

Some—rationalists in the strict sense—interpreted "thought", here, to mean access to necessary truth. Some, but not all, remarked that the second (nativist) belief implies the existence not only of some specifically human propensity for language, but also of some common core of language as such. Some believed in, or hoped for, a past (or future) universal language, intelligible to everyone because it was (or would be) wholly or largely natural, not purely conventional. Some saw language as the essential core of humanity. And some stressed the role of language in creativity and culture.

As we'll see in Section vii.d, Chomsky wasn't a rationalist in the strong sense. He didn't posit innate access to necessary linguistic principles, still less to necessary truth. Nor was he interested in projects aimed at designing a universal language, or at locating the origins of language in prehistory. But he did believe that language is what makes us human, that language and thought are intimately connected, that language is essentially creative, that all languages share a common grammatical core, and that linguistic ability is innate in (only) the human species.

In Chomsky's own judgement, his most important precursor was René Descartes. As we saw in Chapter 2.iii.c, Descartes taught that language is uniquely human. We don't share it with any animal, nor could it be provided to a machine:

> If you teach a magpie to say good-day to its mistress, when it sees her approach, this can only be by making the utterance of the word the expression of one of its passions. For instance, it will be the expression of the hope of eating, if it has always been given a tidbit when it says the word. Similarly, all the things which dogs, horses and monkeys are taught to perform are only the expression of their fear, their hope or their joy [all of which are entirely mechanical: see Chapter 2.ii.d] . . . But the use of words, so defined, is peculiar to human beings. (Descartes 1646: 207)

No machine, according to Descartes, could "arrange words variously in response to the meaning of what is said in its presence, as even the dullest men can do". The human ability to arrange words variously was to be heavily stressed by Chomsky, who both sought to explain it and used it as a stick to beat behaviourism. However, what Chomsky meant by this ability wasn't what Descartes meant by it (see Section iv.f).

As for where language ability comes from, Descartes believed that it's provided to all human minds by God. His reason was that, because of its variability, it can't be explained in material terms. He pointed out that deaf-mutes—fellow human beings—spontaneously use gestures and make up signs that other people can learn to understand (1637, ch. 5).

It's not at all clear, however, that Descartes was a "Cartesian" according to Chomsky's definition (above). He didn't specifically say that language has a core structure, of which we have innate knowledge. Indeed, he described languages as unpredictably diverse, to be learnt from the environment much as other social customs are. And he attributed the variability of language to the innate power of reason (the ability to come up with new and appropriate thoughts), not to any property of language as such. He did believe, however, that some human abilities rest on innate knowledge.

c. The puzzle of innate ideas

In general, for Descartes, our knowledge depends heavily on innate ideas. These exist in the mind prior to any experience.

The idea of God must be innate, he said, since the concept of infinity could be neither derived nor—as Thomas Hobbes had argued (see 2.iii.b)—extrapolated from experience. The true proposition "God exists" is also innate (said Descartes), because it is self-contradictory to suppose its falsity. Similarly, he saw the necessary principles of logic and mathematics as present in the mind a priori.

For Descartes, no true *propositions* about the empirical world are innate: only experience can teach us that roses are red and violets blue. Here, he was less nativist than Chomsky, for whom knowledge of certain empirical facts about language—facts which might have been different—is inborn (see Section vii.c–d). But Descartes sometimes argued that the *sensory concepts* themselves must be innate, since no genuine causal relation between brain and mind is possible:

> [Besides the ideas of movements and figures] so much the more must the ideas of pain, colour, sound and the like be innate, that our mind may on occasion [*sic*] of certain corporeal movements, envisage these ideas, for they have no likenesses to the corporeal movements. (trans. Haldane and Ross 1911: i. 42)

Descartes wasn't the first to posit innate ideas, whether concepts or propositions (McRae 1972; Chomsky 1966: 59–72). They'd been spoken of for centuries. Plato's doctrine of *anamnesis*, introduced in *The Meno* to explain the slave boy's intuitive grasp of geometry, is a well-known example. Most rationalist writers followed Plato in attributing necessity to innate ideas. Descartes's occasional suggestion that even sensations are innate was unusual.

But familiarity didn't bring clarity. There was much controversy about just what this doctrine amounted to, in Descartes's writings as in other people's. This was so, irrespective of whether it concerned only concepts or also propositions.

Did it mean that we have *actual* ideas—of number, extension, God, or even colour—prior to any experience? Or did it mean that our *potential* to do arithmetic and geometry, to think about God, or to perceive red and blue, is a natural capacity, or disposition, possessed from birth by all human minds—as opposed to a learnt skill? And if the latter, *just what* is a "potential", "capacity", or "disposition" to have certain ideas? Are these expressions anything more than philosophically misleading ways of saying that we can, in fact, do so?

Many of Descartes's correspondents, including the arch-empiricist Hobbes, raised these questions. Comparing innate mental dispositions to a family's inborn propensity for a certain disease, Descartes replied:

> I never wrote or concluded that the mind required innate ideas which were in some sort different from its faculty of thinking; but when I observed the existence in me of certain thoughts which proceeded, not from extraneous objects nor from the determination of my will, but solely from the faculty of thinking which is within me, then . . . I termed them INNATE. (trans. Haldane and Ross 1911: i. 442)

But his reply didn't end the debate. On the contrary, it raged on long after he died.

John Locke (1690) interpreted the doctrine literally, and rejected it. Or rather: "he formulated every clear version he could think of and showed each to be either trivially true or obviously false" (Goodman 1969: 138). He likened the newborn mind to a blank wax tablet, or tabula rasa (which, trivially, has certain potentialities rather than others). Locke's view was very widely accepted at the time—not least, for its 'enlightened' political implications. Indeed, the entry on "Idea" in Ephraim Chambers's *Cyclopaedia* of 1728 stated that "our great Mr. Locke seems to have put this Matter out of dispute".

But Chambers was over-optimistic. Gottfried Leibniz (1690), specifically targeting Locke's discussion, interpreted the doctrine dispositionally, and defended it. He compared the mind to a veined block of marble, which both enables and constrains the figures that can be sculpted from it.

Empiricists accepted Locke's interpretation. They saw knowledge in general as built from passively received sensations, and language as the learnt ability to use certain words to stand for certain ideas.

In justification, they pointed out that languages are very different, and that children learn to speak as the people surrounding them do. They remarked that feral children, much discussed in the seventeenth and eighteenth centuries (Itard 1801), don't use language spontaneously, but will learn it if rescued while still young (for a modern discussion, see Curtiss 1977). They argued that dispositional accounts of innate ideas were merely pretentious ways of stating a commonplace: that people can learn language and mathematics. And they complained that positing innate ideas prevents one from asking more searching questions about the origins of knowledge. These empiricist arguments were still prominent in the twentieth century, and were marshalled by some of Chomsky's critics (see Section vii.c–d).

Those of a rationalist cast of mind favoured Leibniz's interpretation. But it was unclear just what cognitive dispositions might be involved and/or just how they contribute to knowledge. Rationalists claimed, for instance, that necessary truths are innate, but they couldn't explain why geometry and arithmetic seem to provide genuinely new knowledge.

That changed after the late eighteenth century, thanks to Immanuel Kant's *Critique of Pure Reason* (1781). The problem of innate ideas—at least as regards our knowledge of the physical world—seemed, to many, to have been solved by Kant's distinction (sketched in Chapter 2.vi.a) between empirical intuitions and categories on the one hand and sensory experience on the other. The former are (he said) innate, but are merely structuring principles. Only the latter can give actual content to our knowledge. In Kant's words: "Thoughts without content are empty, intuitions without concepts are blind" (Kant 1781: 61).

It was more difficult, however, to gloss language as innate in this sense. For there seem to be no universal structuring principles. Whereas we all acknowledge causality and Euclidean space, our languages appear chaotic. Not only do we use different words for the same thing (*children*, *enfants*, *tamariki* . . .), a fact linguists call "the arbitrariness of the sign", but we put the words together in very different ways. In short, languages differ not only in vocabulary, but also in grammar.

This seemingly incontrovertible truth, coupled with the growth of empiricism outlined in Chapter 2, led—in scientific circles—to the demise of the rationalist view of language. By the end of the 1940s, when Chomsky was a student, the predominant school of scientific linguistics favoured environmentalist accounts of language learning (see Section v.b).

That situation was partly due to the dominance of behaviourism in American psychology. But even anti-behaviourists fought shy of nativist theories of language. Thus the Gestalt psychologists, who developed neo-Kantian explanations of the perception of causation and identity, didn't do so for language. And Jean Piaget, who recognized universal features of language such as temporal order and hierarchy, saw them as based in the universals of logic. These in turn, he said, are constructed by the infant's sensori-motor activity in the physical world (Piaget 1952*b*; Piatelli-Palmarini 1980). In short, he saw language as neither unique nor innate.

In humanist circles, by contrast, the nativist viewpoint on language and mind survived. In the three centuries separating Descartes's birth from Chomsky's, it was elaborated in various ways. Literally Cartesian versions of innate ideas gave way to neo-Kantian and Romantic ones. And, in place of Descartes's mix of pure mentalism and mechanistic biology, there arose a holistic view of mind as grounded in self-organization, similar to the autonomous development of the embryo (see 2.vi). The diversity of languages wasn't denied: quite the contrary (see Section iv.b). But the basic humanist commitment to species-specific linguistic nativism remained.

9.iii. Not-Really-Cartesian Linguists

When is a door not a door? And when is a Cartesian not a Cartesian? The first question is more swiftly answered than the second.

The people named by Chomsky as Cartesians (and undeniably influenced by Descartes) differed between themselves about matters of interest to us—including some of the questions listed in Chapter 1.i.a. Many of those questions are still (largely) unanswered. So, quite apart from evaluating Chomsky's accuracy as a historian, there's good reason to consider just what they did say and just what they didn't say.

a. Descartes's disciple

Géraud de Cordemoy (*c*.1620–84), sometime Director of the Académie française, is the only person named as a precursor by Chomsky (e.g. 1996*a*: 3) who was an orthodox Cartesian. Born four years after Descartes, he was one of his leading disciples. Indeed, he was a member of the party who travelled to Stockholm in 1666 to bring Descartes's exhumed remains back to France—minus the writing forefinger, which the French ambassador was allowed to cut off, and the skull, which had been stolen. (After being sold several times, the skull ended up in the Musée de l'homme—Lindeboom 1979: 13–14.)

Descartes had died of pneumonia sixteen years earlier, having risen daily at four o'clock in the Swedish winter to teach Queen Christina (aka Greta Garbo) philosophy in her freezing castle. Cordemoy outlived his master by over thirty years. For much of that time, he was spreading, and elaborating on, Descartes's views.

In promulgating the Cartesian philosophy, Cordemoy devoted an entire essay to language, the *Discours physique sur la parole* (Cordemoy 1668: 196–256). As the title implies, he had much to say about the physical aspects of language (the lungs, speech organs, ears, and nerves), pointing out that the human bodily machine is naturally suited for producing and hearing it. He even discussed the bodily aspects of writing. Nevertheless, he argued that language is possible only for beings with souls (minds), which is to say, human beings. It can't be explained in purely physical terms, nor mimicked by artificial machines—and it isn't acquired by the learning methods used by animals.

Cordemoy marvelled at the child's acquisition of language, and remarked that it doesn't seem to depend on reinforcement:

> It's true that one usually tries to excite some emotion (such as joy) in infants, by exclaiming when one shows them something while speaking its name, so that they are more attentive and, being more affected by this method of teaching, retain the words better.
>
> But, no matter what trouble one takes to teach them certain things, one often finds that they know the names of thousands of other things, which one has not attempted to show them. And the most surprising thing about this is that, by the time they are two or three years old, and by the power of their attention alone, they are able to pick out the name of something from all of the constructions that one uses to talk about it.
>
> Next, and with the same concentration and discernment, they learn the words that signify the properties of the things whose names they know.
>
> Eventually, extending their knowledge further, they notice certain actions or movements of these things; and simultaneously observing people talking about them, they distinguish—by their ability to pay attention to the movements, and to hear people repeat certain words in combination with the names of the things or of their properties—those words which signify actions. (Cordemoy 1668: 213–14; my trans.)

Adverbs, he said, are acquired much later, because modifications of actions are less important to the infant than the actions themselves. And grammarians teaching adults a foreign language concentrate first on nouns, then adjectives, and then verbs—"in imitation of the precepts given by nature to children" (p. 215).

Words are partly physical, in so far as they are sounds produced by our vocal apparatus. In that, they resemble the cries of animals. But animal 'signs' are communications without meaning. Their communicative effect results from the harmony between beast and beast, and between animal and environment, established by God as a system of interlocking reflexes. Words, by contrast, have meaning as well as sound, for (as Descartes had taught) they are the voluntary expression of conscious thoughts guided by reason. This is evident from the unpredictability and aptness of the words produced by human beings.

Moreover, said Cordemoy, souls are universally the same. Differences in linguistic ability, and in intelligence in general, are due to imperfections in the brain, not the mind. Freed of the body, all human souls would be equal, because equally rational. (To deal with the philosophical mind–body problem lurking here, Cordemoy developed a neuropsychological version of occasionalism: Chapter 2.iii.b.)

Whether Cordemoy was a "Cartesian" as well as a Cartesian is questionable. (We've already seen that Descartes himself wasn't.) The quotations given above might be read as implying that some specifically grammatical capacity leads the infant to concentrate first on nouns, then on adjectives, and finally on verbs. And perhaps Cordemoy did believe that. However, his remarks about the modifications of actions being less important to the child than the actions themselves suggest that it is the child's general interests, not its specifically grammatical preparedness, that guide the order of language acquisition.

In sum, Cordemoy may not have believed that grammar as such is foreshadowed in the infant's mind. But he certainly believed that humans have a natural capacity for language, which has no parallel in either animals or automata.

b. Arnauld and the abbey

The belief in some universal basis of language was promoted also by Antoine Arnauld. He was a highly valued correspondent of Descartes (2.ii.g)—and of Leibniz, too (Arnauld 1662, p. xxxv).

Although he was influenced by Descartes's philosophy, Arnauld wasn't a Cartesian but a (highly controversial) Jansenist. He was known primarily for holding unorthodox views on grace and the Eucharist. More to the point, here, he rejected Descartes's claim that we have innate knowledge of God. He didn't think that God's existence can be proved by the light of reason, but taught that Christian theism is—literally—our best bet (Arnauld 1662: 357). That is, he accepted the famous "wager" argument of his friend Blaise Pascal—who spent his last years at Arnauld's home base, the Abbey of Port-Royal.

Port-Royal was a Cistercian abbey for women, allowed by papal decree to accept male seculars in retreat. Arnauld was associated with it from early childhood: one sister was appointed Abbess in 1602, and four more—as well as his widowed mother—were nuns. In maturity, he was a key member of the influential 'Port-Royal logicians', and the main author of their most famous publications: the *Grammaire générale et raisonnée* and its successor treatise on reasoning, *La Logique; ou, L'Art de penser* (Lancelot and Arnauld 1660; Arnauld 1662). These texts openly adopted some of Descartes's ideas. But, as many of their pietistic examples showed, they weren't promoting pure Cartesianism. In particular:

> Port-Royal, thanks to the excellent philosophical tools employed by Arnauld, in general grammar developed a branch of Cartesianism which Descartes himself hadn't emphasized: namely, the study and analysis of language in general, assumed to be founded in reason alone. This Cartesian branch, planted and nurtured at Port-Royal, to some extent advanced the ideas familiar in the seventeenth century, and anticipated the labours of the eighteenth century, in which it would be taken up directly by [among others] du Marsais [and] Condillac . . . (Sainte-Beuve (1867), quoted in Cornelius 1965: 121; my trans.).

The scholastic logic of the medieval period had leant strongly on grammar when it was first developed. Indeed, medieval treatises contain many statements broadly consonant with Arnauld's (and Chomsky's) views. Roger Bacon (1214–94), for example, taught that "Grammar is substantially the same in all languages, even though it may vary accidentally" (cited in Lyons 1991: 172).

But most medieval logicians—as opposed to grammarians—weren't much interested in the grammar of real sentences. Rather, they used natural language to construct a semi-formal language with its own grammar, in order to demonstrate certain formal inference patterns.

By the opening of the seventeenth century, then, the links between logic and language were primarily with rhetoric (I. Thomas 1967). The Port-Royalists changed that.

c. The Port-Royal *Grammar*

In their fresh approach to logic, Arnauld and his colleagues revived its relation to grammar—which characterizes human speech, they said, but not the mimicking of word sounds by parrots (Lancelot and Arnauld 1660: 21). They aimed to state a "rational grammar". By this they meant one that is universally shared, and based on necessary principles of reason rather than contingent (and diverse) facts of linguistic usage.

The Port-Royal group distinguished a sentence's underlying propositional structure from its final expression. In this, they were following the medieval and Renaissance logicians. They claimed that words have a "natural order", in the sense that they provide the natural expression of our thoughts. Or rather, words considered as parts of speech (Subject, Verb, Object, Copula) have a natural order, although words as constituents of phrases or idioms may not. The natural logic underlying the various parts of speech may differ from the common-sense view: all verbs, for instance, were analysed as the Copula and an attribute (so that *Peter lives* became *Peter is alive*). Language and mind (rationality) were thus seen as intimately connected.

Moreover, just as reason is universal, so are some grammatical features. These weren't formal syntactic rules, as they were for Chomsky. Rather, they were features which—because of their natural relation to thought—aid the function of language: communication. (Significantly, the two subtitles of the *Grammar* advertised 'The Fundamental Principles of the Art of Speaking' *before* 'The Reasons of the General Agreement, and the Particular Differences of Languages'.)

For instance (the group argued), all languages that distinguish singular and plural must *naturally* ensure that nouns and adjectives, and verbs and nouns/pronouns, agree in their number (Lancelot and Arnauld 1660: 148–9). For to do otherwise would be to confuse the hearer, who hopes to discover the speaker's thought.

The Port-Royalists were well aware that languages don't always behave 'naturally'. English, for instance, distinguishes singular and plural in nouns, but not in adjectives: both *man* and *men* can be *learned*. Greek is puzzling, too, since plural neuter nouns take singular verbs. Arnauld dealt with such counter-examples by saying that a "figure of discourse" or idiom (which may lend a superficial elegance to the language) will have "some word [implicitly] understood", and that the hearer copes "by considering the thoughts more than the words themselves" (Lancelot and Arnauld 1660: 149). The clear implication was that some natural languages might be more natural (closer to rational thought) than others. No prizes need be offered for guessing which one was favoured by the denizens of Port-Royal:

> [There] is scarce any language, which uses these [superficially unnatural] figures less than the French: because it particularly delights in perspicuity, and in expressing things as much as possible, in the most natural and least intricate order; tho' at the same time it yields to none in elegance and beauty. (p. 154)

Arnauld distinguished between agreement, which is universal (except in a figure of discourse), and government, which is "almost entirely arbitrary" (Lancelot and Arnauld 1660: 148). By government, he meant the fact that using one word can cause some alteration in the form of another. An example discussed at some length is the phenomenon of case: genitive, dative, accusative, and so on. The case, which is a logical relation in thought, may or may not be apparent in the form of the noun (compare the Latin *terra*/*terram* with the English *ground*/*ground*). There may or may not be a special particle for a certain case (such as the French *de*). And a verb may or may not always take the same case (consider *servir quelqu'un* and *servir à quelque chose*). Moreover, since "cases and prepositions were invented for the same use", many prepositions govern the noun they are used with—thus *ad terram*, but *ab terra* (chs. 6 and 11, and pp. 149–52).

The various languages differ greatly in whether, and if so how, they mark this or that case by changes in the form of words and/or by the insertion of extra words. Occasionally, different governments alter the sense of the governed word. So in Latin (Arnauld pointed out), *cavere alicui* and *cavere aliquem* mean *to watch over a person's safety* and *to beware of him*, respectively. Such meaning shifts are grounded not in logic, but in arbitrary linguistic convention (p. 152). (As these examples show, the Port-Royalists did consider several European languages. But their main focus was on French, and some of their universalist claims were inconsistent even with English or Greek.)

With respect to those grammatical constructions where they believed that logic is involved, the Port-Royalists gave many detailed examples of the natural order they had in mind. In discussing relative clauses, for instance, Arnauld related specific grammatical forms to their "subordinate propositions" in thought (Arnauld 1662: 118–21). He distinguished "explicative" and "restrictive" uses of words like *which* and *who*, and argued that a particular grammatical conversion (ellipsis) can produce the underlying thought in one case but not the other.

For example, the subordinate proposition expressed by the words "men, who were created to know and love God" can be attained by substituting the antecedent for the pronoun itself, thus: "men were created to know and to love God". The reason is that the relative clause here is (for Arnauld) explicative: according to his theology, the idea of "man" includes the idea of a being created to know and love God. By contrast, the restrictive clause in the sentence "men who are pious are charitable" doesn't express the subordinate proposition (arrived at by a similar pronominal substitution) that "man as man is pious". Rather, it states that men may be pious ("the idea of piety is not incompatible with the idea of man"), and that the idea "charitable" can be affirmed of the complex idea "pious man".

Chomsky described the Port-Royalists' work as an anticipation of his own contrast between "deep" and "surface" structure. Further, he endorsed some of their specific hypotheses about how these are correlated (Chomsky 1966: 33–51, 97).

He claimed, for instance, that they employed a type of phrase-structure grammar (see Section vi.c). They held that the deep structure, or thought, consists of one or more elementary (subject–predicate) propositions, whereas the surface structure may be syntactically very complex: recursively nested, for example. Moreover, expressing the thought as an actual sentence may require more than just expressing each elementary proposition in words. It may also involve rearranging, replacing, or deleting parts of the first-stage (unspoken) sentences—which is to say, transforming them (Chomsky 1966: 40).

Broad similarities certainly exist. But these concern aspects of Chomsky's thought that weren't especially original or controversial. Moreover, some of Chomsky's comparisons are questionable in detail.

For instance, he says that Arnauld's treatment of relative clauses anticipated various "modern" logical–semantic insights, including the distinction between meaning and reference "in pretty much their contemporary sense" (Chomsky 1996*a*: 7).

It's true that the explicative–restrictive contrast rests on a distinction between the meaning of the term concerned (in this case, "man") and those objects that are picked out by it (actual men—who may or may not be pious). However, some distinction between meaning and reference had already been made by medieval logicians. Moreover, the Port-Royal contrast between the "comprehension" and "extension" of a general term wasn't equivalent to any distinction made in modern logic. It muddled singular and general terms, and also gave a definition of meaning—according to which it's part of the meaning of "triangle" that the internal angles equal two right angles—which is now regarded as over-inclusive (Kneale and Kneale 1962: 318 ff.).

Indeed, modern logicians see Arnauld's definition of meaning as an example of psychologism (2.ix.b). They therefore criticize the Port-Royal group as "the source of a bad fashion of confusing logic with epistemology" (Kneale and Kneale 1962: 316). That's why, by the 1950s, the Port-Royalists were only a minority taste in philosophical logic.

Nonetheless, the Port-Royal *Logic* was a creative advance at the time, and dominated logic for the next 200 years. And their *Grammar* was regularly reprinted until 1846. Consequently, their view that grammar reflects thought was widespread throughout this period, and still respected in the late nineteenth century.

d. Deaf-mutes and Diderot

One of the thinkers who accepted this Port-Royalist view was Denis Diderot (1713–84). He was editor-in-chief of the *Encyclopédie*, the 'bible' of the French Enlightenment—a project that had started out as a scheme to translate Chambers's two-volume *Cyclopaedia* (see Chapter 2.ii.c), but which ended up as twenty-eight newly written volumes (Porter 2001: 8). And he, too, was someone named by Chomsky as a precursor.

Descartes, as we've seen, had referred briefly to deaf-mutes, in making a point about the universality of reason and communication. But Diderot wrote a 17,000 word essay about them, exploring the relations between gesture, language, and thought (Diderot 1751). Part of his aim was to discuss the origins of language, and to ask whether there is some "natural" universal language, intelligible to all human beings.

Both questions were prominent topics of debate in the eighteenth century. They featured in several novelists' tales of imaginary voyages—some of which described "universal" artificial languages and symbol systems (Cornelius 1965).

Some people argued that the spontaneous signing of deaf-mutes represented the universal gestural language from which conventional languages had originally developed, and which might now be deliberately extended to form a worldwide communication system (Knowlson 1975; Large 1985). This 'handmade' system would be naturally intelligible to all, because it would be logically transparent (much as the Russell–Whitehead logical notation was later intended to be: 4.iii.c). Others had suggested new sign languages and/or alphabets, designed for universal use (Large 1985: 19–63).

The most interesting of these projects was that of John Wilkins (1614–72), Bishop of Chester and a founder member—and first Secretary—of the Royal Society. More interested in phonetics than in grammar, he proposed a universal alphabet, systematically designed to encompass "all such kinds of simple sound, which can be framed by the mouths of men" (J. Wilkins 1668: 357–62).

His reference to "the mouths of men" was no mere rhetorical flourish. For his notation was comprised of iconic symbols depicting various positions of the speech organs: root/tip of tongue, one/two lips, top/root of teeth, back/front of palate, parts of mouth, and nose. It also marked whether or not the sound involved breathing. In addition, Wilkins designed a more easily usable alphabet. This had some highly stylized iconic features, and some coherence in using similar symbols to represent similar sounds.

The supposed intelligibility of this language wasn't grounded only in the universal ability to make speech sounds and mouth movements. For the systematic coherence spread into semantics, too. Wilkins gave every letter a significance, based on the forty classes into which, according to him, *everything* could be fitted. Each class was subdivided into differences, and these into species. To each class, he gave a two-letter syllable, and a consonant and a vowel were assigned to each difference and species, respectively. So flame was called *deba*: the *de* meant 'element', the *b* meant 'fire' (the first of the four elements), and the *a* meant a small part of the element: namely, a 'flame'. In short, semantic hierarchies were explicitly reflected in phonetics, and in spelling too.

Another aim of Diderot's essay, regarded by some as "one of the outstanding examples of literary criticism in the eighteenth century" (A. M. Wilson 1972: 123), was to distinguish various rhetorical genres. So he compared prose, poetry, drama, scientific writing, and so on.

Here, Descartes was lurking in the background. His clear prose, which reflected his views on the best "method" of thinking, had caused a revolution in scientific and philosophical writing. This is evident, for example, in the striking stylistic differences between the three versions of Joseph Glanville's *Vanity of Dogmatizing* (Glanville 1661–76). These arose because, between the first and second drafts, Glanville adopted the Royal Society's recommendation of Descartes's prose over the more florid writing of the early Renaissance. (One aspect of this was the rejection of interpretative accounts of Nature, considered as God's text, in favour of empirical ones: see Chapter 2.iii.b.)

Diderot went further, arguing that authors should choose not only the most appropriate genre for the type of thought they wished to express, but also the most fitting language. He had in mind not just choice of vocabulary (*le mot juste*), but selection among natural languages themselves. And here, Chomsky has remarked (1965: 7), he illustrated the lasting influence of Port-Royal. For he declared, as Arnauld had done before him, that French surpasses all other languages in the degree to which it matches the order of our thoughts. Everyone, in so far as they are rational, must think their thoughts in the same order. Because French matches this rational order best, he argued, it is the natural language for philosophy and science. Greek, Latin, Italian, and English are more appropriate for less reasoned enterprises, such as the theatre—and in general for persuasion, emotionalism, and deceit.

Only his French readers, no doubt, found that particular claim compelling. But Diderot's view that grammar has some principled basis in thought was widely shared.

9.iv. Humboldt's Humanism

Ten years after the final publication of the *Encyclopédie*, the Enlightenment criticisms of traditional institutions and beliefs were followed by Kant's radical critique of human knowledge itself. Accordingly, some late eighteenth-century philosophers, described as "Cartesians" by Chomsky, conceptualized language in neo-Kantian terms.

That is, they posited—however vaguely—some linguistic equivalent of the empirical intuitions and categories (2.vi.a). This was supposed to be a formative principle shared by all humankind, which moulds all conceivable languages much as the Kantian intuitions inform our ideas about physical reality.

Typically, this 'grammar' wasn't thought of as a static set of given principles—like the Port-Royal logic, or even Kant's space and time. Rather, it was a developing, self-organizing, inner form. As such, it was broadly comparable to the organic forms then being posited in *Naturphilosophie* and Johann von Goethe's biological morphology (see 2.vi.e).

One of these neo-Kantian writers was Johann Herder (1744–1803), who in a prizewinning essay on the origins of language argued that language wasn't given to us in its full form by God, but isn't wholly invented either (Herder 1772). It's part of our innermost nature, and very different from the narrowly focused and unvarying instincts of animals. Rather, it's the ground of mankind's freedom and self-development. Indeed, Herder compared the genesis of language to the mature embryo pressing to be born. He also described a nation's mother tongue as an aspect of the national "soul", or "spirit".

All these notions were to be taken up by the Romantics in general, and by Humboldt in particular. Humboldt, in turn, would have a strong influence on nineteenth-century Romanticism. (In the early 1800s, he spent four years in Paris at a time when William Wordsworth, for instance, was living there too.)

a. Language as humanity

Herder's essay was read, about ten years later, by the young Humboldt—in his teens at the time. Eventually, Humboldt became a renowned humanist scholar (and sometime Prussian ambassador to England). But he wasn't just a fine scholar: he added some enormously influential ideas of his own.

Humboldt's philosophy of language, like Kant's epistemology, has been described as a Copernican revolution (Hansen-Love 1972). For it presents the human mind as the creative origin of knowledge and culture, instead of being dependent on them for its ideas. Accordingly, his position (following the *verum factum* tradition of Giambattista Vico: see 1.i.b) promised a deep knowledge of language and culture—much deeper than scientific knowledge of material things could ever be.

Humboldt saw human beings as *set apart* from nature (including animals) by the mental faculty of language, through which the human mind or spirit is both developed and expressed. Like Herder, he thought of language in terms of organic development, describing it as a "living seed" and "an internally connected organism" (Humboldt 1836: 61, 21). He was thinking not only of the development of language in infancy but, even more, of the historical development of language from its earliest roots:

> *Language*, regarded in its real nature, is an enduring thing, and at every moment a *transitory* one . . . In itself it is no product (*Ergon*), but an activity (*Energeia*). Its true definition can therefore only be a genetic one. For it is the ever-repeated *mental labour* of making the *articulated* sound capable of expressing *thought* . . . To describe languages as a *work of the spirit* is a perfectly correct

and adequate terminology, if only because the existence of spirit as such can be thought of only in and as activity. (Humboldt 1836: 49).

Humanity as such was continually celebrated by Humboldt. He often did so in spiritual terms, as when he said that "thought at its most human is a yearning from darkness into light, from confinement into the infinite" (1836: 55). This causes a recurring difficulty when one tries to relate his work to modern linguistics and cognitive science (and when one translates his term *Geist* as "mind" rather than "spirit").

For instance, he pointed out, as Cordemoy had done before him, that human anatomy seems to be especially apt for the production of speech (a fact to be explored in fascinating detail over 100 years later: Lenneberg 1967). But he *didn't* explain these anatomical phenomena as due to the benevolent design of God. Instead, he saw them as aspects of the activity of the creative human spirit. He even linked bipedalism to—or explained it in terms of?—our language and humanity:

And suited, finally, to vocalization is the upright posture of man, denied to animals; man is thereby summoned, as it were, to his feet. For speech does not aim at hollow extinction in the ground, but demands to pour freely from the lips towards the person addressed, to be accompanied by facial expression and demeanour and by gestures of the hand, and thereby to surround itself at once with everything that proclaims man human. (1836: 56)

In short, although Humboldt's observations were often highly astute, many of his scientific questions were fundamentally different from those posed in the empiricist tradition. His work therefore sets one of the "traps" mentioned in Chapter 1.iii.a. To interpret Humboldt's questions and/or answers in terms of the explanatory categories of modern science—which Chomsky frequently did—is often to distort them.

It would be misleading, for instance, to praise Humboldt's naturalistic (i.e. non-theological) explanation of bipedalism as being about as close as a pre-Darwinian scientist could have got. For Humboldt was not only pre-Darwin: he was also pro-Goethe. In other words, his conception of "science" was very different from the empiricist's (see 2.vi).

Like Goethe (a close friend, and a neighbour), Humboldt favoured organic holism over analytic science:

The comprehension of *words* is a thing entirely different from the understanding of *unarticulated sounds* . . . [The word] is perceived as articulated, [which perception] presents the word directly through its form as part of an infinite whole, a language. (1836: 57–8)

It is thus self-evident that in the concept of linguistic form no detail may ever be accepted as an *isolated fact*, but only insofar as a method of language-making can be discovered therein. (p. 52)

Connected discourse . . . is all the more proof that language proper lies in the act of its real production. It alone must in general be thought of as the true and primary, in all investigations which are to penetrate into the living essentiality of language. The break-up into words and rules is only a dead makeshift of scientific analysis. (p. 49)

To be sure, language involves "a system of rules" (p. 62). But that system is an organic whole, which "grows, in the course of millennia, into an independent force", restricting how we can express (and think) our thoughts. Its generative principle is humanity itself ("the unity of human nature"):

> Language belongs to me, because I bring it forth as I do; and since the ground of this lies at once in the speaking and having-spoken of every generation of men, so far as speech-communication may have prevailed unbroken among them, it is language itself which restrains me when I speak. But that in it which limits and determines me has arrived there from a human nature intimately allied to my own, and its alien element is therefore alien only for my transitory individual nature, not for my original and true one. (p. 63)

The similarity between this passage and Chomsky's nativism is evident. But the differences are arguably even greater (see subsections e–g, below).

b. Languages and cultures

Drawing partly on Diderot's *Encyclopédie*, and in particular on the three volumes of its summary (the *Encyclopédie méthodique*) that were devoted to grammar and literature, Humboldt studied all the European languages, ancient and modern. But he didn't stop there.

He also described several native American languages, relying on novel data brought back by his younger brother Alexander—a noted scientist much admired by Charles Babbage (Hyman 1982: 72–4), who spent five years exploring the Americas. In addition, he was familiar with many oriental examples, including Chinese, Sanskrit, and Hebrew. And, thanks to the interest in non-Indo-European languages that was aroused by European colonialism in the eighteenth century, he also had knowledge of Melanesian and Polynesian—and the various dialects of Kawi, the ancient literary and sacred language of Java.

Kawi was especially interesting to him largely because it seemed to be a mixed language: although its vocabulary was Sanskrit, its grammar was Malayan. Moreover, its geographical position suggested (to him) that it might be linked to virtually all the known languages of the world. Given Humboldt's passion for intellectual synthesis, and his view that "language" is the fundamental unifying force within all humankind, Kawi seemed to offer the hope of integrating "old world" and "new world" languages—and cultures (Humboldt 1836, p. xii).

His three volumes on Kawi, prepared in the closing years of his life, included a 350-page introduction that gives the clearest statement of his views on *language in general* (Humboldt 1836). As well as considering syntax, morphology, and (especially) phonetics, Humboldt studied the various literatures and orally transmitted poetry and prose. When he thought of language, then, he had in mind both linguistics and literature.

These wide-ranging studies weren't mere scholarly stamp collecting: Humboldt was no Dr Casaubon. They were driven by Humboldt's novel ambition to distinguish language groups in terms of their grammatical (and phonetic) structure, rather than their historical origins. They were intended to show, too, that all languages are essentially alike:

> My aim is [not to gather the external details of individual languages, but] a study that treats the faculty of speech in its inward aspect, as a human faculty, and which uses its effects, languages, only as sources of knowledge and examples in developing the argument. I wish to show that what makes any particular language what it is, is its grammatical structure and to explain how the

grammatical structure in all its diversities still can only follow certain methods that will be listed one by one . . . (Humboldt 1836, p. xiv)

His studies also underpinned Humboldt's distinctive position on the relation between language and culture, and on the individuality of cultures.

If thoughts can be expressed only in language, difference in language implies difference in culture. Humboldt argued that each natural language is unique. *Perfect* translation is impossible, since apparently equivalent words will have different associations in the minds of speakers of the two languages (and even in individual speakers of "one" language). Nevertheless, *good* translation—on which he had many interesting things to say (Novak 1972)—can expand the language and mentality of the reader.

Although he held that everything can in principle be expressed in every language, he pointed out that in practice languages (cultures) differ in what they choose to express. Translations of literary masterpieces can thus awaken latent potential in the receiving nations. (Scientific thought, he said, varies less across languages.)

Each culture, for Humboldt, has its own *Weltansicht*, its unique manner of regarding the world. Human individuals are deeply informed by their culture, as well as by their unique life experience. And their cultural identity must be thought of holistically. For a language, like an organism, is a self-organizing whole, not a collection of independently definable parts.

c. Humboldt lives!

Humboldt's stress on the diversity, and the holism, of cultures informed some early twentieth-century work on topics relevant to cognitive science. So, too, did his views on the near-identity of language and thought.

The holistic view of language was to be taken up, for example, by the linguists Ferdinand de Saussure (1857–1913) and Roman Jakobson (1896–1982). Although his birth-date locates Saussure firmly in the nineteenth century, his general intellectual presence dates from well into the twentieth. For his influence blossomed only after his death, with the posthumous publication of his lecture notes on "general" linguistics (Saussure 1916).

After a lifetime of detailed research in historical philology, Saussure had finally considered language as such. (It was he who coined the phrase "the arbitrariness of the sign"—see ii.c, above.) He described language as a holistic system, in which the meaning of one word, or sign, can be defined only in relation to others. To include a word, such as *cat*, in a language is not to provide an inert pointer referring to some pre-existing class, but to identify some class by distinguishing it from others picked out by different words (*kitten*, *dog* . . .).

Jakobson was a neo-Humboldtian whom Chomsky has acknowledged as a major influence in the origination (not just the *post hoc* justification) of his own thinking. Based at Harvard while Chomsky was a Junior Fellow there, Jakobson concentrated on phonology, not meaning, and combined holism with nativism (compare Humboldt's "inner form", discussed below). He claimed—as it turned out, wrongly (Sampson 1974)—that the seemingly chaotic speech sounds heard around the world can be defined in terms of twelve oppositional "distinctive features" (Jakobson 1942/3; Jakobson *et al.*

1952). These, he said, comprise a hierarchical system of phonological capacities shared by all human beings. Each language selects only some of the possibilities available.

As for linguistic diversity, Humboldt's ideas were echoed by the anthropological linguist Franz Boas (1858–1942), who set in hand the systematic description of the fast-disappearing native American tongues (Boas 1911). (It was he who'd translated the story used in Frederic Bartlett's experiments on memory: see Chapter 5.ii.b.)

Whereas previous accounts of these languages had focused largely on vocabulary, Boas focused on grammar. He argued that each natural language has a distinct grammatical structure. Moreover, he said, the structural differences can't always be expressed by using shared grammatical categories, as when one says that adjectives are usually put after the noun in French but before it in English. Rather, they may need grammatical categories specifically designed to describe the particular syntax concerned.

Edward Sapir (1884–1939) and Benjamin Whorf (1897–1941) went further, claiming that virtually none of the concepts of one language can be understood (thought) by people brought up to speak another. Whorf even held that each language conceals a specific metaphysics, or ontology, unintelligible to people with different mother tongues (Carroll 1956). On this view, there is no 'true' ontology: languages differ arbitrarily from each other, and views of reality differ likewise (cf. 1.iii.b).

This claim—that a person's thought can't escape their language—was hotly disputed through the 1960s and beyond (Hoijer 1954; R. Brown 1958; Hymes 1964: 149–53; Rosch 1977; Lucy 1992). Empiricist philosophers complained that the Sapir–Whorf 'hypothesis' is slippery and vague, and if clarified becomes either obviously true or obviously false (M. Black 1959). But many social scientists, doubting the obviousness, garnered evidence to test it.

Some of these people, influenced by Chomsky's nativism (see Section vii.c–d), claimed that apparently arbitrary differences in colour vocabulary are in fact underlain by universally shared colour categories (O. B. Berlin and Kay 1969; Rosch/Heider 1972; Rosch 1973; see Chapter 8.iia–b). This early work had glaring methodological faults (Sampson 1980: 95–102). But Chomskyans still reject the Sapir–Whorf hypothesis, saying "there is no scientific evidence" for it and attributing it to "a collective suspension of disbelief" (Pinker 1994: 58).

Others followed Sapir and Whorf, suggesting that cognitive differences may be associated with, or even grounded in, syntactic variations as well as vocabulary. For instance, the Navaho language uses a different form of the verbs for handling things (such as *throw*), depending on the shape of the object handled. This grammatical distinction isn't found in Indo-European languages, and suggests that speakers of Navaho may have a relatively keen awareness of shape (Carroll and Casagrande 1966: 26–31; Lucy 1992: 198–208). Only "suggests": independent tests need to be done to confirm any specific instance of the Whorfian hypothesis.

d. A fivefold list

There's a puzzle here, however.

To concentrate on the syntactic differences between languages seems decidedly un-Chomskyan, given that Chomsky posited a universal grammar. Indeed, Humboldt's aim of describing the grammatical structure of as many languages as possible was defined as the major goal of linguistics by the very people against whom Chomsky reacted in the 1950s (see Section v.b, below). And Chomskyans, as remarked above, reject neo-Humboldtian views on the boundless diversity of languages and concepts.

Yet Humboldt was repeatedly named by Chomsky as an important precursor, who had essentially similar aims. In his first act of homage to the "Cartesian" linguists, Chomsky devoted more space to Humboldt than to anyone else (Chomsky 1964: 17–25; 1966: 19–28).—Why is this?

The answer is fivefold:

* First, Humboldt insisted on the universality of language in the human species.
* Second, he saw it as an innate mental faculty, or force, distinct from other psychological abilities and from the instincts of animals.
* Third, he saw language as inexplicable in terms of its ultimate origins (although he explained many features of specific languages by reference to earlier ones).
* Fourth, he contrasted the finite number of objects in the physical world, including the fixed number of speech sounds, with the infinite creativity of language, which can always come up with some new thought. Language, therefore, implies freedom.
* And fifth, he saw language as having an organic "inner form" that unites humanity, irrespective of culture, in a fundamental way.

Stated briefly, as I've just done, the similarities between Humboldt and Chomsky seem to be clear—indeed, overwhelming. In truth, however, they're neither.

We needn't waste time cavilling over the first two items. These (nativist) beliefs are evident in Humboldt's reply to the familiar empiricist argument that children will learn quite different languages, depending on who brings them up:

> Man is everywhere one with man, and development of the ability to use language can therefore go on with the aid of every given individual [i.e. caretaker]. It occurs no less, on that account, from within one's own self; only because it always needs an outer stimulus as well, must it prove analogous to what it actually experiences, and can do so in virtue of the congruence of all human tongues. (Humboldt 1836: 59)

He also argued (like Chomsky) that the infant's linguistic capacity must be shared with everyone else—otherwise, how could they learn so quickly (pp. 58–9)?

So far, so similar. But the last three items need fuller discussion.

e. Origins

The third item is included in the list because Chomsky claimed that there could be no evolutionary explanation of language—or at least, that we could never find one. Language, he argued, is a holistic system with an all-pervasive structure, not a collection of independently acquired habits or tricks. Humboldt had said much the same thing. But Humboldt, born almost 100 years before *On the Origin of Species*, couldn't consider the possibility of a Darwinist evolutionary account. Chomsky could, and did.

Chomsky was no less pessimistic than Humboldt about our ever understanding the origin of language as such:

> There seems to be no substance to the view that human language is simply a more complex instance of something to be found elsewhere in the animal world. This poses a problem for the

biologist, since, if true, it is an example of true "emergence"—the appearance of a qualitatively different phenomenon at a specific stage of complexity of organization. (Chomsky 1986: 62)

In fact, the processes by which the human mind achieved its present stage of complexity and its particular form of innate organization are a total mystery .... It is perfectly safe to attribute this development to "natural selection", so long as we realize that there is no substance to this assertion, that it amounts to nothing more than a belief that there is some naturalistic explanation for these phenomena. (p. 83)

Admittedly, "evolution" was listed as one of only five keywords for Chomsky's official précis of one of his books (1980*b*: 1). However, this was due not to the author but to the editor, on the grounds that talk of universal grammar predictably raises questions about origins (A. N. Chomsky, S. Harnad, personal communications).

Chomsky's pessimistic remarks of the 1980s, cited above, implied that "emergence" is inexplicable. They implied, also, that the naturalistic explanation of language would refer to some single genetic mutation, or possibly some small set of mutations, that occurred early in our species' history, whose effect on the "emergent" phenotype is opaque. If that were so, then we couldn't hope to find it/them, nor to understand its/their significance if we did.

Similar anti-evolutionary scepticism has often been associated with the complex structure of the eye. Darwin himself admitted that to explain the eye in terms of natural selection "seems, I freely confess, absurd in the highest degree" (quoted in Cronly-Dillon 1991: 15). Nevertheless, he rebutted this scepticism in general terms, and evolutionary biology can now do so in detail. It turns out that the eye is neither a miracle nor even a singularity: eyes have evolved independently a number of times. (Or perhaps not: evidence that all types of eye have evolved from the same root is given in Gehring and Ikeo 1999.) Possibly, then, we shall one day understand the evolution of language much as we now understand the evolution of the eye.

Some Chomskyans, indeed, have speculated at length about the evolution of "the language instinct" (Pinker 1994). As for Chomsky himself, he now allows that we're beginning to understand how a qualitatively different phenomenon can arise spontaneously from a simpler base (see Chapters 14.x.a–b and 15). By the new millennium, he had even suggested that language might be based in spontaneous physical self-organization:

There is little doubt that the human language faculty is a core element of specific human nature ....

Recent work suggests more far-reaching possibilities. The minimal conditions on usability of language are that languages provide the means to express the thoughts we have with the available sensorimotor apparatus. *One far-reaching possibility* is that, in non-trivial respects, the language faculty approaches an optimal solution to these minimum design specifications (with "optimality" characterised in natural computational terms). If true, that would suggest interesting directions for the study of neural realization, and perhaps for the further investigation of the critical role of physical law and mathematical properties of complex systems in constraining the "channel" within which natural selection proceeds.

What the work on optimal design of language seems to suggest is that language *might* be more like the appearance of familiar mathematical structures in nature such as shells of viruses or snowflakes than like prey/predator becoming faster to escape/catch one another [see Chapter 15, below]. When the brain reached a certain state, some small change *might* have led to a reorganisation of structure that included a (reasonably well-designed) language faculty. *Maybe.* (Chomsky 1999: 31; italics added)

However, if natural selection must somehow underlie language, as it underlies every other biological phenomenon, that's not to say that Chomsky expects a detailed evolutionary explanation. On being charged (on the evidence of the passage just quoted) with changing his views on the role of natural selection, he replied:

[I presuppose] that natural selection is operative in this case (as in others). [And I have raised some tentative] questions about the role of "the 'channel' within which natural selection proceeds." That natural selection proceeds within such a "channel" is too obvious to have been questioned by anyone. Only the most extreme dogmatist would produce a priori declarations about its role in any particular case, whether it is virus shells, slime molds, bones of the middle ear, infrared vision, or whatever.

As before, I take no particular stand on the matter, for the simple and sufficient reason that virtually nothing significant is known—even about vastly simpler questions, such as the evolutionary origins of the waggle dance of honeybees. (Chomsky, email to "evolutionary psychology" list, 19 Oct. 1999; italics added)

Chomsky's agnosticism, here, is well judged. It's not clear that one can go much further than speculation on this topic. Languages don't fossilize. Nor do soft structures such as vocal cords (although oral bones and skulls do). Moreover, animal communication systems seem to be very unlike ours, having only finite productive power—as both Humboldt and Chomsky were keen to point out.

On the other hand, mammalian movements are highly variable—and recent work suggests that gestural language is grounded in neuroscientific mechanisms (such as mirror neurones; Arbib 2005) originally evolved for controlling other bodily actions (14.vii.c). Even the logic of *subject–predicate* has been attributed to specific neural circuits in the brain, embodying mechanisms necessary for many tasks performed by non-human primates (Hurford 2003).

In sum, if scepticism about the very possibility of linguistic evolution is out of place, pessimism about our ever being able to detail it may not be (Maynard Smith and Szathmáry 1995, ch. 17; 1999, ch. 13).

f. Creativity of language

The fourth item is included on the list (in subsection d, above) because Chomsky sees Humboldt as anticipating his own notion of the creativity of language. He first argued for this in 1962, at the International Congress of Linguists in Cambridge, Massachusetts; his paper was revised and expanded before publication (Chomsky 1964: 17–22).

Certainly, Humboldt constantly described language—alias the human spirit—as creative, indeed as self-creative. And he spoke of language making infinite use of finite means:

But just as the matter of thinking, and the infinity of its combinations, can never be exhausted, so it is equally impossible to do this with the mass of what calls for designation and connection in language. In addition to its already formed elements, language also consists, before all else, of methods for carrying forward the work of the mind, to which it prescribes the path and the form.

> The elements, once firmly fashioned, constitute, indeed, a relatively dead mass, but one which bears within itself the living seed of a never-ending determinability. (Humboldt 1836: 61)

Whether Chomsky is right to see Humboldt, and the other "Cartesians", as a precursor in this respect is another matter.

Chomsky's definition of the creativity of language referred to syntax, not thought (see Section vi.b). Admittedly, when (in the early 1960s) he included semantics within his grammar, novel meaning would automatically accompany novel form. But even then, he still prioritized syntax (see Section viii.c).

Descartes, by contrast, had focused on the power of (language-informed) reason or imagination to generate new thoughts, expressible in language. And Humboldt, too, had spoken of the power of language to define new thoughts. Chomsky stressed the purely formal fact that his grammar can generate infinitely many new sentences and deep structures, saying that "this 'creative' aspect of language is its essential characteristic" (Chomsky 1964: 8), and that "recursive rules . . . provide the basis for the creative aspect of language use" (Chomsky 1967: 7). His later complaint that "A number of professional linguists have repeatedly confused what I refer to here as 'the creative aspect of language use' with the recursive property of generative grammars, a very different matter" was thus misdirected (Chomsky 1972*a*, p. viii). In short, his notion of linguistic creativity was not that of his august predecessors.

Moreover, Chomsky's concept of creativity fails to capture all the cases ordinarily covered by the term, including those which Humboldt seems to have in mind here:

> At every single point and period, therefore, language, like nature itself, appears to man—in contrast to all else that he has already known and thought of—as an inexhaustible storehouse, in which the mind can always discover something new to it, and feeling perceive what it has not yet felt in this way. (Humboldt 1836: 61)

What Chomsky calls creativity is the exploration of an unchanging conceptual space, or thinking style (namely, generative grammar). Some human creativity is like this: run-of-the-mill jazz improvisation, for instance, or mundane examples of what Thomas Kuhn (1962) called normal science. But the most interesting cases are not.

These cases involve either unfamiliar combinations of familiar ideas, or the transformation of an existing conceptual space by altering one or more of its defining dimensions (Boden 1990*a*/2004, 1994*b*; cf. 13.iv). Such transformations make it possible to generate structures that were previously impossible (Humboldt's "things not felt this way before"?). Successive transformations over days, years, or even centuries (Humboldt, again?) can evolve the thinking style in complex and unpredictable ways: the development of post-Renaissance tonal music, for example (C. Rosen 1976; Boden 1990*a*: 59–62).

Both these types of creativity go beyond what Chomsky means by the term. And both, arguably, were what the Romantics were interested in. The poet Samuel Taylor Coleridge (1772–1834), who popularized neo-Kantianism in England, highlighted the mind's propensity for combinational creativity (Livingston Lowes 1930; Boden 1990*a*, ch. 6; see also the preamble to Chapter 12, below). And transformational creativity is perhaps comparable to the more structured, developmental, creativity posited by Humboldt.

I say "arguably" and "perhaps", here, because this point depends on how we understand the fifth item on our list. Just what did Humboldt mean by the "inner form" of language?

g. The inner form

In his Kawi-introduction, Humboldt described this inner form as a creative human force that is unfurled and developed in life, a vital linguistic instinct whose expression can be shaped, favoured, and hindered by external circumstances (Humboldt 1836, esp. 48–53). The environment doesn't impose itself on a passive tabula rasa, but elicits an active response from a mind inherently suited to make linguistically relevant distinctions—between speech sounds and other sounds, for example. And, he said, even (indeed, especially) the languages of "so-called savages" show a typically human diversity of expression.

The broad similarity to Chomsky's approach is, again, evident. And Chomsky declared that Humboldt's notion of form as generative process was "his most original and fruitful contribution to linguistic theory" (Chomsky 1964: 17). But the similarity between the two linguists becomes more fuzzy on closer inspection.

Humboldt's definitions of the inner form of language were both various and vague:

> The constant and uniform element in this mental labour of elevating articulated sound to an expression of thought, when viewed in its fullest possible comprehension and systematically presented, constitutes the *form* of language. (1836: 50)

So far, so (apparently) Chomskyan. However, Humboldt immediately added a gloss that doesn't sound Chomskyan at all:

> In this definition, form appears as an *abstraction* fashioned by science. But it would be quite wrong to see it also in itself as a mere non-existent thought-entity of this kind. In actuality, rather, it is the quite individual *urge* whereby a nation gives validity to thought and feeling in language. (p. 50)

Two pages later, having remarked that "the characteristic form of languages depends on every *single* one of their smallest *elements*", and that "language, in whatever shape we may receive it, is always the spiritual exhalation of a nationally individual life", he passed from nation states to the ultimate nature of language:

> From the foregoing remarks it is already self-evident that by the form of language we are by no means alluding merely to the so-called *grammatical form* ... The concept of form in languages extends far beyond the rules of *word order* and even beyond those of *word formation*, insofar as we mean by these the application of certain general logical categories, of active and passive, substance, attribute, etc. to the roots and basic words. It is quite peculiarly applicable to the formation of the *basic words* themselves, and must in fact be applied to them as much as possible, if the nature of the language is to be truly recognizable. (p. 51)

In that quotation, Humboldt seemed to have historical philology in mind. The crucial questions would then concern (for instance) how the Indo-European languages developed, and how they differ from the Malayan group, rather than (for example) the relations between active and passive, or the hidden depths of *John is easy/eager to please*. But Chomsky interprets inner form as embracing "the rules of syntax and word formation as well as the sound system and the rules that determine the system of concepts that constitute the lexicon" (Chomsky 1966: 26–7). And Chomsky's interpretation finds support in the following remark of Humboldt:

> [We must engage in] a laborious examining of fundamentals, which often extends to minutiae; but there are also details, plainly quite paltry in themselves, on which the total effect of languages is dependent, and nothing is so inconsistent with their study as to seek out in them only what is great, inspired, and pre-eminent. Exact investigation of every grammatical subtlety, every division of words into their elements, is necessary throughout, if we are not to be exposed to errors in all our judgments about them. It is thus self-evident that in the concept of linguistic form no detail may ever be accepted as an *isolated fact*, but only insofar as a method of language-making can be discovered therein. (Humboldt 1836: 52)

Because Humboldt defined "inner form" in so many different (and imprecise) ways, it's not clear whether he really is Chomsky's precursor in this fifth sense. Indeed, one might say that he never *defined* it at all: "what it means is never revealed either by way of explanation or example, let alone definition which is a device he seems to have spurned" (Aarsleff, in Humboldt 1836, p. xvi). It's hardly surprising, then, that "for a hundred years all discussion has failed to converge on any accepted meaning" (p. xvi). ("*All* discussion" includes scholars who can read Humboldt in the original German, as I myself cannot; so I don't think the translation can be to blame, here.)

When Humboldt was more specific about just what these formal relations might be, he was often less plausible. Thus he remarked that certain stories have developed independently in different cultures, explaining this not as the result of shared human experiences but as the unfolding of innate ideas (Novak 1972: 128). He even claimed that similar sounds are used by numerous languages to express similar ideas—where he wasn't thinking of onomatopoeia, as in *buzz*, *miaow*, or perhaps *crack* (Jespersen 1922: 57).

In short, Humboldt's "inner form" of language was specified only a little more clearly than Leibniz's veins of marble. Even his friends criticized him for his irremediable vagueness (Humboldt 1836, p. xv). And one of his twentieth-century admirers, the Danish linguist Otto Jespersen (1860–1943), put it in a nutshell: "Humboldt, as it were, lifts us to a higher plane, where the air may be purer, but where it is also thinner and not seldom cloudier as well" (Jespersen 1922: 57). If such a remark could be made even by an admirer, less sympathetic critics would clearly need some persuading.

A twentieth-century linguist wishing to revive the unfashionable humanist/nativist ("Cartesian") approach would face several challenges:

* They'd have to clarify the relation between linguistic structure and meaning.
* They'd have to explain just how linguistic variability is possible, and how it differs from the changes (learning) found in other types of behaviour.
* They'd have to specify what the universal innate ideas of language might be, and reconcile them with the diversity of actual tongues.
* And they'd have to show that nativist theories of language aren't mere optional alternatives to empiricist accounts, but inescapably more appropriate.

In Sections vi–viii, we'll see how Chomsky tried to do all those things. And in Section ix we'll see that by the 1980s, despite his enormous influence over the preceding quarter-century, some of his fundamental arguments were being rejected.

First, however, we must understand why it was that "Cartesian" linguistics became unfashionable in the first place.

9.v. The *Status Quo Ante*

Chomsky's immediate predecessors had no interest in the tasks just listed. The professional linguists he encountered as a student dismissed questions about inner forms of grammar, although some did engage with Jakobson's inner forms of phonology. They assumed that languages are arbitrarily diverse systems, wholly learnt from the environment.

If Humboldt's influence was still strong (whether acknowledged or not), it was in his wish to describe the many distinct grammars exemplified by natural languages, and to avoid historical bias in doing so. These two aims suffused the tradition in which Chomsky was trained: American "descriptive", or "structuralist", linguistics.

Following Boas's lead (see Section iv.c), the structuralists produced detailed descriptions, or taxonomies, of the grammatical categories of many little-known languages. They saw linguistics as an autonomous enterprise based firmly in the present, an example of what Saussure (1916) had called "synchronic" linguistics. That is, they aimed to describe speech, morphology, and grammars by a scientific method not tainted by history—nor, as we'll see, by introspection.

Like any intellectual movement, this one included a variety of positions. With respect to structuralism as a whole, it's been said that Chomsky's linguistics "continued some fundamental traits of its predecessor, recovered others, and unwittingly rediscovered still others" (Hymes and Faught 1981: 1). What's most relevant for our purposes is that the dominant school in the late 1930s–1940s—Bloomfieldian linguistics—adopted a broadly behaviourist methodology, and that it included theorists who tried to analyse linguistic structure in formal terms. Chomsky's work would undermine the former and emphasize the latter.

a. Two anti-rationalist 'isms'

The Bloomfieldians' rejection of introspection, and their striving for formalism, were inherited from two closely related movements in early twentieth-century thought. These were behaviourism in psychology and positivism in the philosophy of science.

Introspection was ousted from (American) psychology long before being banished from linguistics. Boas's follower Leonard Bloomfield (1887–1949) started out as an admirer of Wilhelm Wundt, whose mentalistic folk psychology informed his first book (Bloomfield 1914). As a professor of German, he could read Wundt in the original: the first five (of ten) volumes of the *Volkpsychologie*, had been published by the time Bloomfield wrote his text. (A brief summary appeared in English two years later: Wundt 1916.) His book also paid homage to Humboldt, as the founder of general linguistics (1914, ch. 10).

With hindsight, it's intriguing that Bloomfield recounted Wundt's theory of "inner forms". A meaning, or inner form, may be expressed in various grammatical sequences, as in *Mary ate the apple* and *The apple was eaten by Mary*—plus, of course, equivalent sentences in other languages. Wundt had argued that linguistics should focus on *sentences*, where a 'sentence' can't be defined in terms of words or phrases, but is recognized intuitively by native speakers. He'd also held that processes of transformation (*Umwandlung*) produce grammatical sequences from inner forms.

But Bloomfield didn't follow up these ideas. In the very year in which he praised Wundt's mentalistic work in a leading psychological journal (Bloomfield 1913), another such journal published John Watson's seminal paper on 'Psychology as the Behaviorist Views It' (J. B. Watson 1913). That paper swept the board in psychology: Watson was elected President of the American Psychological Association only two years later. Eventually, Watson would defeat Wundt in linguistics too.

Bloomfield soon abandoned Wundt, and his pre-Watsonian talk of inner forms and hidden transformations. Indeed, thanks to a "shocking" book very different from his first one, he became the leader of "scientific" structuralist linguistics, which downplayed meanings and had no place for inner forms (see below). But this didn't happen overnight. Two decades would pass before the behaviourist approach conquered in linguistics.

Watson's iconoclasm had been fuelled by frustration with the experimental impasse in psychology, *not* by independent philosophical argument. But the later behaviourists justified their approach by appeal to logical positivism, which swept the philosophy of science in the 1920s and 1930s.

Several leading positivists emigrated from Europe to America shortly before the Second World War. They included Hans Reichenbach (1891–1953) and Rudolf Carnap—one of whose protégés was Walter Pitts (see 4.iii–iv).

Besides stressing observational evidence and operational definition, these philosophers tried to axiomatize physics (an aim which intrigued the young Herbert Simon: Chapter 6.iii.a). In this, they were still following Descartes's formalist dream, which had inspired modernism—in science, art, and politics—since its origin in the seventeenth century (Toulmin 1999: 152–60). Believing that other sciences could then be defined in terms of physics, they hoped to "unify" science within a single deductive system.

Some behaviourists tried to do much the same thing, expressing their theories in terms of psychological definitions and quasi-axioms. The most detailed examples were developed by Clark Hull in the late 1930s and early 1940s (C. L. Hull 1943) (see 5.iii.b). But perhaps the most ambitious appeared much earlier, when logical positivism was relatively new: Albert Weiss's 'One Set of Postulates for a Behavioristic Psychology' (1925).

Weiss listed ten "postulates", or axioms, of psychology, outlining its potential unification with physics. These ranged from the motions of electrons and protons, through behaviour (including language, as "the characteristic factor in human behavior"), to civilization. And, strange as it may seem, civilization was defined by Weiss partly by reference to "electron–proton movements" (Postulate 9). The underlying thread supposedly linking electrons to civilization was Weiss's assumption that "human behavior and social achievement are ... forms of motion", as opposed to "psychical or mental phenomena".

As for language, this was defined as a system of "sensorimotor and contractile effects" linking stimulus and response with environmental changes.

If that were so, then sentences about propositional attitudes, using (intentional) verbs such as *know*, *believe*, *want*, and *hope*, could be analysed in purely truth-conditional (extensional) terms. But it's not clear that this is possible. The truth of *Mary believed that the bracelet had been lost*, for instance, is independent of the truth of the embedded sentence about the bracelet.

Philosophers were aware of this difficulty. So much so, that many saw intentionality as an insuperable logical–metaphysical boundary between psychology and natural science (Chisholm 1967; cf. Boden 1970). (What's more, many still do: see Chapter 16.) But the behaviourists ignored it. They either avoided psychological terms entirely or assumed—with Weiss—that they could be interpreted as forms of motion (stimulus and response).

Not all behaviourists went so far as trying to axiomatize psychology, but they did accept the positivists' general viewpoint. Indeed, they shamelessly took it for granted. Psychology textbooks before the 1970s typically opened with a chapter first exulting that psychology had at last 'escaped' from philosophy, and then uncritically offering a positivist account of science.

b. The shock of structuralism

Bloomfield was influenced by both behaviourism and positivism. He was converted to the former by Weiss (Bloomfield 1931), and invited by the philosopher Otto Neurath to contribute one of the first essays in a positivist encyclopedia of "unified science" (Bloomfield 1939). (Not that one can put too much weight on that: Thomas Kuhn's (1962) devastating attack on positivism—and Popperianism—would later appear as an annexe to the same encyclopedic review.)

At one stage, Bloomfield followed Weiss's example by formulating a set of fifty postulates for scientific linguistics and, for comparison, twenty-seven postulates for historical linguistics (Bloomfield 1926). More to the point, he referred repeatedly to "stimulus" and "reaction" in his most influential book, *Language* (Bloomfield 1933, e.g. 29–30).

This was the volume which tipped the linguistic profession—at least, in America—into the behaviourist mould. To be sure, the neo-Humboldtians Boas, Sapir, and Whorf weren't converted. They continued to study language (and meaning) in much the same way as before. But the mainstream shifted.

Bloomfield's new account was seen on its publication as "a shocking book: so far in advance of current theory and practice that many readers, even among the well-disposed, were outraged by what they thought a needless flouting of tradition" (B. Bloch 1949: 92). Nevertheless, it soon became "almost orthodoxy" (p. 92).

Part of this new orthodoxy was the *rejection* of speculation on the relation between language and mind:

> [Many linguists accompany their] statements about language with a paraphrase in terms of mental processes which the speakers are supposed to have undergone. The only evidence for these mental processes is the linguistic process; they add nothing to the discussion, but only obscure it. (Bloomfield 1933: 17)

Another part was the rejection of *meaning* as a theme for linguistics. Meaning, Bloomfield argued, can't be studied scientifically. Meanings are in practice defined (even by mentalists) "in terms of the speaker's situation and, whenever this seems to add anything, of the hearer's response" (p. 144). Rigorously defining the speaker's situation is impossible, however, for we don't know what associations the speaker has learnt (a point with which Humboldt would have agreed).

Accordingly, the Bloomfieldians focused on phonology and syntax, not semantics. They identified their theoretical categories without reference to meaning, by attending to physical measurements and statistical distribution patterns. They all tried to define their terms clearly. But many wished to replace verbal definitions by formal–symbolic ones. If that could be done, they thought, they might even identify scientific (meaning-free) methods by which phonological, morphological, and grammatical categories could be reliably—perhaps automatically—discovered.

In this journey towards formalism, they were running in parallel with empiricist philosophy of language—though with less delicate tread. During most of Bloomfield's life, the dominant movements were logical atomism and logical positivism, both of which drew heavily on Bertrand Russell's logic (Urmson 1956).

Some philosophers focused on meaning. For instance, they tried to define class concepts by lists of necessary and sufficient conditions; and they discussed the semantics of definite descriptions (noun phrases starting with *the*), and of the English words *and*, *if–then*, and *some*. (There's more to the English *and* than meets the logician's eye: according to logic, *London is the capital of England and fish have gills* is unproblematically true, but these two conjuncts would never be linked by *and* in normal conversation.)

It was this general approach which led the young McCulloch to try to formulate a logic of verbs: distinguishing past, present, and future while ignoring grammatical questions, such as where to place the past participle (4.iii.c). But it didn't affect mainstream linguistics, which had outlawed studies of *meaning*. The philosophy of language that was potentially relevant for structuralism was concerned rather with *grammar*.

Some positivists discussed logical/linguistic syntax at length (Carnap 1934; Reichenbach 1947, ch. 7). Indeed, Carnap explicitly argued that the best way to understand natural grammar is to compare it with the syntax of an artificially constructed language. But this positivist work attracted only the bravest structuralist souls. It was highly abstract (Carnap's formal notation was notoriously obscure, as remarked in Chapter 4.iii.f), and said very little about the specifics of natural languages. Not until the late 1940s was there a structuralist grammar that could compare in sophistication with logical studies of syntax.

Bloomfield himself, in his "shocking" book, offered a very simple formalism to explain the appearance of new word forms. His "proportional formulae" represented the selection of new forms by analogy with previously experienced ones: see Figure 9.1. (Bloomfield 1933: 406).

Bloomfield used these formulae to explain both correct uses of regular forms, such as the plural *cows*, and overgeneralizations of irregulars, such as the past-tense *dreamed* instead of *dreamt* (cf. Chapters 7.vi.a and 12.vi.e). He applied proportional formulae also to syntactic innovations in the history of a given language: for instance, the change in sixteenth-century English when people started to introduce subordinate clauses by the word *like* (as in *to do like Judith did*) (Bloomfield 1933: 407).

sow : *sows* = *cow* : *x*

scream : *screams* : *screaming* : *screamer* : *screamed*
= *dream* : *dreams* : *dreaming* : : *x*

Fig. 9.1. Proportional formulae for creating new word forms. Reprinted with permission from Bloomfield (1933: 406)

However, to call these expressions "formulae" was to claim too much. One can't reasonably complain that they had to be interpreted intuitively, for in the early 1930s the notion of automatic computation had yet to be defined (see 4.i.c), still less implemented. Even so, they were highly informal. Apart from the proportionality sign borrowed from mathematics, there was no symbolization here, nor even an explicit separation of the words into constituent morphemes (such as *scream* and *-ed*). This wasn't a new notation, nor a grammatical calculus, merely a mnemonic for summarizing certain morphemic patterns.

Bloomfield's gloss on Figure 9.1 showed that it wasn't a description of conscious (verbally reportable) processes, either:

> Psychologists sometimes object to this formula, on the ground that the speaker is not capable of the reasoning which the proportional pattern implies. If this objection held good, linguists would be debarred from making almost any grammatical statement . . . Our proportional formula of analogy and analogic change, like all other statements in linguistics, describes the action of the speaker and does not imply that the speaker himself could give a similar description. (Bloomfield 1933: 406)

Unconscious (physiological) mechanisms were doubtless responsible for the speaker's behaviour: Bloomfield didn't believe in magic. But the linguist's job was to describe the abstract structure of the linguistic behaviour, not to speculate on the processes by which it was achieved.

c. The formalist Dane

A more ambitious linguistic formalism was published a few years later by Jespersen. Situated as he was in Europe, Jespersen wasn't a card-carrying structuralist. Indeed, Chomsky (1996*a*) names him as a "Cartesian" precursor. But his early attempts at formalism attracted praise from Bloomfield (1933: 86), and were cited by Reichenbach in his positivist analysis of "conversational" language (Reichenbach 1947, ch. 7).

Initially, Jespersen used his notation to describe only phonemes, which he analysed in considerable detail. His "analphabetic" phonetic symbolism, a twentieth-century version of Wilkins's project of the 1660s, represented many distinct states of the vocal organs. In his *Analytic Syntax* (1937), Jespersen extended his notation to cover grammatical structure too. His work was not only ambitious, but original:

> So far as I know, this is the first complete attempt at a systematic symbolization of the chief elements of sentence-structure, though we meet here and there with partial symbolizations . . . (Jespersen 1937: 97)

He compared his notation with the formulae of chemistry and logic (p. 13). And (without digressing to explain the individual symbols) we can see that it was an analytic tool far in advance of Bloomfield's proportionalities. The phrases *burning hot soup* and *wide open windows* were both rendered as "2/321", and *curious little living creatures* was "21(21(21))"—(see p. 19). The sentence *I saw the soldiers, some of them very young indeed* was represented as "S V O [1^qp1 323]"—(see p. 47), and *I've found the key that you spoke of* as "S V O (12($3^c/1^{c}$*S_2 V p*))"—(see p. 76). And the two superficially similar sentences *The story is too long to be read at one sitting* and *The story is too long to read at one sitting* were represented respectively as "S V P (32p1(I^b3))" and "S* V P(32p1(IO^o*3))"—(see p. 64). As for more complicated examples, the sentence *Brother Juniper, forgetting everything except the brother's wishes, hastened to the kitchen, where he seized a knife, and thence directed his steps straightway to the wood where he knew the pigs to be feeding* became this: "S(1 1 2(Y O p1($1^2$1)) Vp1 2(3^c S V O & 3 V O($S^2$1) 3p1 2(3^c S V O(S_2 I)"—(see p. 93). As Jespersen laid it out, it was as follows:

> Brother Juniper, forgetting everything except the brother's wishes,
> S(1 1 2(Y O p1(1^2 1))
> hastened to the kitchen, where he seized a knife, and thence directed
> V p 1 2(3^c S V O & 3 V
> his steps straightway to the wood where he knew the pigs to be
> O(S^2 1) 3 p 1 2(3^c S V O(S_2 I)
> feeding. [NB Opening/closing brackets are unequal in number.]

Jespersen stated his general policy as "to follow the sentence or word combination that is to be analyzed word for word". (Even without the detailed explanations, one can see this strategy at work in the examples given above.) However, he allowed many exceptions to this rule. Specifically, "such combinations as *the man*, *a man*, *has taken*, *will take*, i*s taking*, etc. (generally also *to take*), even *can take*, are reckoned as one unit" (Jespersen 1937: 15).

Some of Jespersen's remarks about language recall Humboldt, whom (as remarked in Section iv.g) he admired greatly—and, with hindsight, Chomsky too. For example:

> What is certain is that no race of mankind is without a language which in everything essential is identical in character with our own . . . (Jespersen 1922: 413)

> The complexity of human language and thought is clearly brought before one when one tries to get behind the more or less accidental linguistic forms in order to penetrate to their notional kernel. Much that we are apt to take for granted in everyday speech and consider as simple or unavoidable discloses itself on being translated into symbols as a rather involved logical process, a fact that is shown, for instance, by the number of parentheses necessary in some of the examples. (Jespersen 1937: 15)

The reference to the "notional kernel" betrays Jespersen's belief, previously argued in his *Philosophy of Grammar* (1924), that behind the syntactic categories which describe the partly "accidental" form of an actual language there are deeper categories that are independent of existing languages. He saw the linguist's task as to investigate the relations between notional and syntactic categories, and to discover in what way all natural languages are "essentially identical".

Despite these Chomskyan overtones, Jespersen's work was significantly different from Chomsky's. Most importantly, his grammatical formalism wasn't generative. It described the syntactic structure of a sentence as given, not how it could in principle be built. (The term "generative" is here intended in its timeless mathematical sense, indicating the class of structures defined by some set of derivational rules.) As a corollary, Jespersen didn't explicitly ask what makes word strings grammatical or ungrammatical, since his theory was applied only to sentences actually present in the corpus.

(A "corpus" is a representative sample of sentences, or phrases, gleaned from some natural source: books, conversations, interviews ... In Jesperson's time it might have held only a few score items. Today, it may hold hundreds of thousands. The CHILDES corpus, for instance, is a database containing over 150 megabytes of speech-exchanges between parents and children of various ages, some using a second language and some the mother tongue; sub-corpora can be extracted which hold only utterances of parents/carers, or only utterances of 4-year-olds ... and so on.)

Jespersen failed to consider sentence generation partly because this typically requires syntactic procedures to be performed recursively. For instance, one noun phrase can be nested inside another, and that in another ... and so on. But the mathematics of recursion wasn't yet understood.

Even fifteen years later, when functioning machines using recursion were available, the scientific potential of recursion wasn't obvious. The philosopher Carl Hempel (1905–97) observed in 1952 that "recursive definitions which play an important role in logic and mathematics ... are not used in empirical science" (Hempel 1952: 11 n. 11). As Chomsky put it in the 1960s:

> The fundamental reason for the inadequacy of traditional grammars is a ... technical one. Although it was well understood [by traditional grammarians] that linguistic processes are in some sense "creative", the technical devices for expressing a system of recursive processes were simply not available until much more recently. In fact, a real understanding of how a language can (in Humboldt's words) "make infinite use of finite means" has developed only within the last thirty years, in the course of studies on the foundations of mathematics. (Chomsky 1965: 8)

d. Tutor to Chomsky

The first linguist to take recursion seriously was Zellig Harris (1909–92) at the University of Pennsylvania—where the ENIAC was built in the mid-1940s (3.v.b). Harris taught Chomsky as an undergraduate and as a graduate student, and they kept in close contact after the younger man moved to Massachusetts.

Chomsky later acknowledged Harris as his main inspiration, and a frequent discussant of his own work (Chomsky 1975: 4). Harris was no more interested than Bloomfield in the humanist/nativist ('language-and-mind') questions listed at the close of Section iv.g. But if anyone was a precursor of Chomskyan grammatical analysis, it was he.

In 1951 Harris published a book widely received as the most important contribution to descriptive linguistics since Bloomfield's *Language*. His *Methods in Structural Linguistics* was shown to Chomsky in proof, on joining Harris's seminar in 1947. It contained a detailed discussion of how to use distribution patterns to identify phonemes, morphemes, morpheme sequences (phrases), and other linguistic classes. In addition, it offered a formalism for representing such classes. This formalism—which Chomsky adopted and modified—was used by Harris to state a finite set of grammatical rules that could describe an infinite set of sentences.

When electronic computers appeared on the horizon, Harris hoped also to define a formal method which, if expressed as a computer program, would automatically identify the grammatical classes and patterns within a set of sentences drawn from an unknown language with an alien grammar (Z. S. Harris 1951, 1968). In this, a computer-age version of a long-standing structuralist goal, he didn't succeed.

That should have been no surprise, for the task is in principle impossible. It assumes that scientific categories and hypotheses can be derived from the data by theory-free induction—a view that was already being questioned by Popperian philosophers (K. R. Popper 1935; Goodman 1951). One can't even identify phonemes and morphemes without some guiding grammatical theory (Chomsky 1962: 125). However, Harris's system was "the most ambitious and the most rigorous attempt that has yet been made to establish what Chomsky was later to describe as a set of 'discovery procedures' for grammatical description" (Lyons 1991: 34).

It turned out, many years later, that the discovery procedures needed may be less specifically linguistic than some Popperians might expect. Recent work in the machine learning of language shows that relatively "light" theoretical assumptions can go a long way, if combined with powerful statistical techniques (see Section xi.a, below). These assumptions aren't language-specific in the sense that interested Chomsky, for they aren't grammatical.

Nevertheless, the general Popperian point still stands. In the 'pure' statistical analysis of the linguistic data, words are given for free by the spaces between the input letter strings. Moreover, phonetic categories—in the form of the alphabet—are taken for granted. From the point of view of psycholinguistics, the latter is entirely defensible. Although nativism with respect to syntax is highly questionable (see Section vii.c–d), nativism with respect to phonetics isn't: there's a finite set of human speech sounds, and newborn babies pay more attention to them than they do to sounds in general. Refutation of the Popperian claim would require successful induction over purely acoustic features—and even then, the acoustically structured anatomy of the cochlea could be seen as providing an implicit theory. (Although whether, and if so in what sense, acoustic feature detectors are really "innate" is debatable: cf. Chapter 14.vi.b and x.a–b.)

Harris introduced Chomsky not only to the project of rigorous formalism, but also to the notion of transformations (Z. S. Harris 1952, 1957, 1968). This idea wasn't mentioned in *Methods*, but was already prominent in Harris's mind. Indeed, by 1947 (when the book was completed) he was discussing it in his seminars, and in conversations with other linguists (Bar-Hillel 1970: 292; Z. S. Harris 1952: 18–25). The young Chomsky was a research assistant for some of the necessary analyses (Z. S. Harris 1952, n. 1). By the time of his own first publications, Harris's work on transformations was well known.

"Discourse analysis" was, in effect, a scientific study of the phenomenon of literary genre that had so fascinated Diderot. It showed how to give a structuralist description of entire connected texts, including spoken conversation. Its first public presentation (in 1949) was to an audience of anthropologists, for Harris's motivation in defining transformations was to apply linguistics to culture and personality. One might almost say that Humboldt's assimilation of culture and linguistics was being revived—but from a very different philosophical base, and with a very different methodology.

Instead of asking a priori what type of language should be used for a certain type of task, as Diderot had done, Harris asked what sentence structures actually occur within discourses devoted to that task. He answered this question in terms of inter-sentence distribution patterns, defined in terms of grammatical "transformations" specifying relations between entire sentences or morpheme sequences. Two syntactically complex sentences might be transforms of one, simpler, kernel sentence. And he found that "often it is possible to show consistent differences of structure between the discourses of different persons or in different styles or about different subject matters" (Z. S. Harris 1952: 1).

Rhetoricians and literary critics, Diderot included, had known for centuries that some such differences exist. And they had identified various genres and authorial signatures accordingly. But discourse analysis could describe these structural differences more precisely, as well as discovering many that hadn't been noticed before.

Harris's Presidential Address to the Linguistic Society of America in 1955 summarized his approach. Two sentence structures, related (for instance) as *active/passive*, or even as *question/answer*, were classed as transforms of each other on the basis of their observed distribution patterns. Specifically, they must share the same set of individual co-occurrences of morphemes. For example, *The kids broke the window* and *The window was broken by the kids* share the same verb and two nouns, although in reverse order. (The sentence *The young people destroyed the pane of glass* wouldn't count as a transform: Harris approached meaning only indirectly, through word distributions.) Problems arise with the morpheme pair -*ed/will*, since the first co-occurs with *yesterday* whereas the second does not (*The cliff crumbled yesterday*, *The cliff will crumble tomorrow*). Accordingly, just what is to count as the relevant "sentence environment" is not a straightforward matter. Harris (1957) gave a detailed discussion of how this problem can be addressed. (I can't resist remarking that the cliff actually crumbled on 11 January 1999, a few weeks after this passage was written, when Beachy Head—a famous landmark, and suicide point, near my home—sent tens of thousands of tons of chalk crashing into the English Channel.)

e. Not quite there yet . . .

If Harris's work was a crucial inspiration for Chomsky, it was nonetheless different from his in two—maybe three—important ways.

First, Harris defined his transformations by reference to distributional (statistical), and purely surface, features of sentences, as we've seen. Chomsky, by contrast, defined transformational grammar in terms of deep and surface structures. Or rather, he did so in his publications in the 1950s and 1960s, which are the crucial ones for our purposes. (More recently, he has dropped the deep/surface distinction: see Section viii.b.)

Another often remarked difference is that Chomsky's theory was generative whereas Harris's wasn't. Chomsky certainly saw his grammar as being original in this way, and Harris apparently agreed: "Noam Chomsky has combined transformational analysis [which features also in my own system] with a generative theory of sentence structure [which does not]" (Harris 1968: 4).

This is puzzling, however. It's true that Harris's aim was to describe sentences, not to show how they could be generated. But, as noted above, his formal theory potentially covered an infinite set of sentences. In that sense, it was a generative system—even though Harris didn't describe his rules as "derivational", nor use them to discuss sentence generation (cf. Hymes and Faught 1981: 166).

The third difference is uncontestable, and the most significant of all. As Harris put it: "Chomsky [unlike myself] has produced a mathematical specification of context-free languagelike systems within a spectrum of languagelike systems" (Z. S. Harris 1968: 4). In other words, Harris didn't locate his formalism within *the class of all grammars*.

That idea was developed by Chomsky. In so doing, he brought theoretical linguistics into the ambit of information theory, computer science, AI, and computational psychology.

9.vi. Major Transformations

The major transformation in twentieth-century linguistics dates back to 1957, with the publication of Chomsky's *Syntactic Structures*. It wasn't a high-profile event. On the contrary, the volume appeared in an obscure specialist series, from a small publishing house in Holland. Chomsky himself said later that they accepted it only because it was recommended by Jakobson, and that it wouldn't have been noticed but for a long, and near-simultaneous, review in a leading linguistics journal by his student Robert Lees (1957).

Lees didn't merely recommend the book, he championed it. Chomsky's "first established convert", he "went around to linguistics conventions and got the ball rolling" (Weimer 1986: 300). As Howard Gardner put it, he was "playing Huxley to Chomsky's Darwin" (H. Gardner 1985: 189). This was to become an all-too-common role for Chomsky's students, as we'll see (Section viii.a).

Nevertheless, Lees and Jakobson weren't the only ones to be impressed. This little book, of only 118 pages (and by an author only 29 years old), revolutionized the subject.

a. Chomsky's first words

If linguists had had their eyes open, the revolution might have happened a few years earlier. For Chomsky's first book wasn't his first publication. A handful of technical papers had already appeared, most in journals not read by linguists, such as the *Journal of Symbolic Logic*.

One of these was Chomsky's paper on 'Three Models for the Description of Language' (1956). This was a hierarchical classification of grammars, defined in purely abstract (non-linguistic) terms. With hindsight, it's clear that this paper, not *Syntactic Structures*, was Chomsky's most original and most well-founded contribution—even if many of Chomsky's fans have never read it (cf. also Chomsky and Miller 1958; Chomsky 1959*a*).

'Three Models' did what Harris admitted he'd never thought of doing: it located the grammar of natural language within the class of all possible grammars. At the top of Chomsky's formal hierarchy were the "recursively enumerable" languages: namely, all languages having some finite definition. A subset of those were the "context-sensitive" grammars, which in turn contained the "context-free" grammars (see below). At the lowest level were the "regular" grammars, definable in very simple terms. (Twenty years later, other linguists would insert "indexed grammars" between the context-sensitive and context-free levels: see Section ix.d.)

Computer scientists were interested immediately. Similar research was already being done by some of them, but Chomsky's was a highly valued contribution.

His distinction between context-free and regular grammars (Chomsky 1956) helped them to codify, respectively, the lexical structure of artificial languages and the high-level structure of programs. Moreover, he proved in 1962 that different types of computational device—again, abstractly defined—would be needed to deal with the various classes of grammar. A universal Turing machine (see Chapter 4.i.c) can compute *any* definable language. Push-down stacks (see Chapter 10.v.b) can compute context-free languages (an insight that helped establish the theoretical basis of modern parsers, and of compiler design). And, since regular grammars are lower down in the hierarchy, they can compute those too. But push-down stacks aren't necessary for dealing with regular grammars. Such grammars can be computed by finite-state machines (described below).

The linguists, by contrast, didn't notice these early papers. For they weren't published in 'their' journals. (Chomsky's initial connection with MIT was the Research Laboratory of Electronics, from which the Linguistics Department later emerged: see 10.ii.a.) In other words, the scientific cooperation dreamt of by Descartes (2.ii.b–c) was—temporarily—prevented by disciplinary specialism.

Nor did they read the mimeograph/microfilm versions of the typescript of Chomsky's voluminous background research, which had been available to the cognoscenti since 1955. Even the cognoscenti had found it hard going, and very few (perhaps none?) devoured it from first page to last. This wasn't mere laziness on their part: the typescript was neither easily legible nor readily intelligible. Many long passages consisted of sequences of definitions expressed in algebraic symbolism. Indeed, in 1956 MIT Press had refused to publish it in its original form. (It was eventually published twenty years later: Section ix.d.)

In short, most professional linguists, if they'd encountered this work at all, weren't interested. They saw Chomsky's line of enquiry as "unpromising and exotic" (Chomsky 1975: 2). They weren't unaccustomed to formalism, as we saw in Section v.c–e. But whereas Harris (and Jespersen) had employed formalism in the service of meticulous empirical description, Chomsky's early research focused on formalism *as such*.

Most psychologists weren't interested either. Some mathematical psychologists realized the crucial implication of the 'Three Models' theme: namely, that human minds must have a level of computational power capable of dealing with whatever class of grammar is appropriate to natural languages. But, working within the information-theoretic paradigm, they assumed that regular grammars would suffice.

It was *Syntactic Structures*, described by Chomsky as a "sketchy and informal outline" of this background material, which set the linguistic world afire. Its impact for linguistics was immediately likened—in the review that Chomsky mentioned (above)—to the transition from alchemy to chemistry (Lees 1957: 375–6). And as we'll see, it had a revolutionary effect outside linguistics too.

b. The need for a generative grammar

The research summarized in *Syntactic Structures* was inspired by Harris's discourse analysis. It also reflected Chomsky's interdisciplinary education: at Harris's suggestion, he'd studied mathematics and philosophy as well as linguistics. Formalism had flourished in the philosophy of science for some years, as we've seen. But Chomsky went beyond mere formalism. His approach was fundamentally mathematical in a sense in which Harris's wasn't.

Chomsky asked two new questions about natural-language syntax. On the one hand, he sought to state a generative grammar—as opposed to a merely descriptive one—for a given language (such as English). On the other hand, he aimed to compare the computational power of various types of grammar.

Readers of *Syntactic Structures* weren't burdened with the bristling technicalities of his 1956 paper, but those ideas underlay the argument. Although he didn't locate his new grammar at a particular point within the grammar hierarchy, Chomsky's focus on differences in computational power largely explains the book's wide influence: across linguistics, computer science, psychology, and the philosophy of language.

The brief text of *Syntactic Structures* took a fresh, not to say shocking, approach. It denied two fundamental structuralist (Bloomfieldian) assumptions: that the goal of linguistics is to define a discovery procedure for grammars, and that language can be explained in probabilistic, behaviourist, terms. Moreover, it started out not from a rich description of actual usage but from dry definitions mentioning not a word of English, Sanskrit, or Kawi.

In the opening pages, Chomsky defined language, and the goal of linguistics, in abstract terms:

> I will consider a *language* to be a set (finite or infinite) of sentences, each finite in length and constructed out of a finite set of elements. All natural languages are languages in this sense . . . Similarly, the set of "sentences" of some formalized system of mathematics can be considered a language. The fundamental aim in the linguistic analysis of a language L is to separate the *grammatical* sequences which are sentences of L from the *ungrammatical* sequences which are not sentences of L and to study the structure of the grammatical sequences. The grammar of L will thus be a device that generates all of the grammatical sequences of L and none of the ungrammatical ones. (Chomsky 1957: 13)

A generative grammar is a set of (timeless) derivational rules. It doesn't tell us just how to build or parse a specific utterance. In other words, it isn't a computer program. However, it is a computational notion. The "device" mentioned here—and the "machine" mentioned elsewhere (e.g. p. 52)—was a purely mathematical one, as is a Turing machine (see 4.i.c–d).

But if Chomsky wasn't talking about computers he was, indirectly, talking about people:

> Any grammar of a language will *project* the finite and somewhat accidental corpus of observed utterances to a set (presumably infinite) of grammatical utterances. In this respect, a grammar mirrors the behavior of a speaker who, on the basis of a finite and accidental experience with language, can produce or understand an indefinite number of new sentences. Indeed, any explication of the notion "grammatical in L" . . . [offers] an explanation for this fundamental aspect of linguistic behavior. (p. 15)

Even so, his grammar wasn't a set of instructions for psychological processing. Rather, it represented the underlying grammatical competence of the speaker (see Chapter 7.iii.a).

In offering his new vision of what a theoretical linguistics should be like, Chomsky asked four interrelated questions:

* How can we discover a grammar for a given set of sentences?
* How can we know that a grammar generates all and only these sentences?
* How can we evaluate alternative grammars?
* And how can we express the differences between grammars, of either artificial or natural languages?

His answer to the first question wasn't what structuralists expected. On his view, no scientific ("practical and mechanical") discovery procedure can be found (1957, ch. 6). Even Harris, whose work was more careful than most, hadn't succeeded in defining one. The best we can hope for (and what Harris had actually provided), said Chomsky, is an evaluation procedure: a method for deciding, given a finite set of sentences, which of two candidate grammars is preferable. Even this is difficult to define formally, for grammars—like all scientific theories—are evaluated largely in terms of their simplicity, a notoriously elusive notion.

A candidate grammar for a natural language must generate all and only the grammatical sentences. But how do we know which these are? No search of an existing corpus can identify them. Statistics are inappropriate, since most sentences in any reasonable corpus will be one-offs: uttered on only one occasion. And if a sentence isn't there at all, so what? Any native speaker can, and frequently does, come up with new ones.

This is a matter not merely of observation, but of syntax. (At this stage, it was syntax, not semantics—still less, reason or imagination—which was given the credit for the creativity of language: see Section iv.f, above.) One can produce new sentences, for instance, by conjoining two or more old ones, or by recursively nesting one inside another. (Whether the result will always be intelligible was addressed in Chapter 7.ii.b.)

It follows, said Chomsky, that judgements of grammaticality must be left to the intuitions of native speakers. For they can reliably say whether a given word sequence is grammatical even if they can't explain their judgement.

Data-respecting critics soon complained—and still do—that by *native speakers* he meant *a single native speaker whose intuitions one trusts*—in Chomsky's case, Chomsky. Such a source hardly seems reliable: Chomsky himself changed his mind twice about his famous example "Colourless green ideas sleep furiously". And how were these armchair intuitions to be monitored? The structuralists, too, had used native informants to assess grammaticality, but had insisted that the conditions in which evidence is elicited from them be carefully controlled, to prevent experimental bias of various kinds (Z. S. Harris 1957, sect. 4). Disagreement arose, in psychology as well as linguistics, over the role of extensive sampling as against the consideration of individual cases: see Chapter 7.iii.d. Chomsky himself, however, remained content to rely on his natural, untutored, intuitions.

Assuming that we've agreed on a set of grammatical English sentences, we must ask "what sort of device can produce this set". This requires us, said Chomsky, to compare the power of different conceivable grammars. He addressed this task by starting from Claude Shannon's information theory (4.v.d).

c. Beyond information theory

Shannon had defined a number of artificial languages in the 1940s, suggesting that:

> These artificial languages are useful in constructing simple problems and examples to illustrate various possibilities. We can also approximate to a natural language by means of a series of simple artificial languages. (Shannon and Weaver 1949: 13)

Chomsky agreed that artificial languages are useful comparison points for natural language. But, with his grammar hierarchy lurking in the background, he saw the prospects for Shannon's serial "approximations" as hopeless.

The simplest example Chomsky considered, lying at the lowest ("regular") hierarchical level, was a *finite-state grammar* (*language*, *machine*), or FSG. This is a grammar—of which there are infinitely many—that describes a device with a finite number of states, including an initial state and a final state, and a finite set of rules for passing from one state (considered in isolation) to the next (cf. Shannon and Weaver 1949: 15–16). In a linguistic context, "passing from one state to the next" would involve either emitting or accepting a word, depending on whether the FSG was being used to produce word strings or to parse them, respectively.

Taking up Shannon's discussion, Chomsky pointed out that some FSGs could produce only a finite number of "sentences"—in some cases, only two (see the first state-diagram in Figure 9.2) (Chomsky 1957: 19). Clearly, such examples couldn't model the apparently infinite potential of natural languages. But a more powerful type of FSG could be defined by adding one or more closed loops, so that instead of passing directly from state n to state $n+1$, the device may—optionally—return to state n again, and again . . . before finally leaving it. As a linguistic analogy, the sentence *The man comes* can be extended to *The old man comes*, *The nasty old man comes*, etc. by inserting one or more adjectives at the relevant point. This type of FSG is recursive, so can produce infinitely many sentences (compare using five adjectives, or fifty, or . . .).

Because of the potentially infinite number of sentences of English (French, Kawi . . .), Chomsky had the extended type of FSG primarily in mind (cf. Chomsky and Miller 1958). Of the two FSGs shown in Figure 9.2, then, he was less interested in the first than in the second, which contains a closed loop. Indeed, the simpler type is now sometimes forgotten, or anyway ignored (as an uninteresting special case). So FSGs *as such* are sometimes said to be capable of producing infinitely many word strings, or sentences.

Shannon had pointed out that a specific probability could be assigned to each possible state transition allowed by an FSG, and therefore that different artificial languages could be defined by assigning distinct sets of probabilities. Such probabilistic FSGs are called "Markovian". In natural languages, too, the successor probabilities for both letters and words vary. In English, though not in Polish, the state *z* is highly improbable as a successor to *c*. Similarly, the state *man* is fairly probable, given the state *old*, whereas the state *because* is highly improbable as a successor to *the*. If realistic probability measures were added for each state transition, Shannon said, something resembling natural language would result.

To illustrate this point, Shannon suggested a number of simple rules to produce various Markovian letter strings and word strings. These strings approximated English more and more closely as the number of previous letters or words considered (zero,

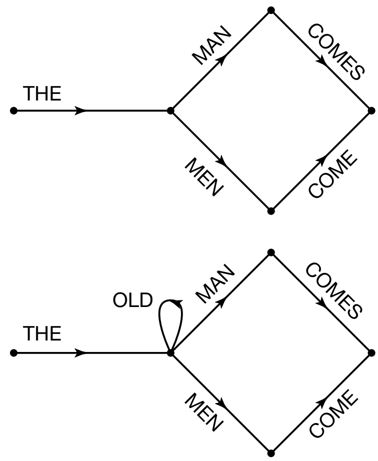

FIG. 9.2. State-diagrams for two FSGs. The first can produce only two sentences, whereas the second—because of the loop—can produce infinitely many. Redrawn with permission from Chomsky (1957: 19)

one, or two) increased. For instance, choosing words independently of each other (but guided by their individual frequencies) resulted in this:

REPRESENTING AND SPEEDILY IS AN GOOD APT OR COME CAN DIFFERENT NATURAL HERE HE THE A IN CAME THE TO IF TO EXPERT GRAY COME TO FURNISHES THE LINE MESSAGE HAD BE THESE. (Shannon and Weaver 1949: 14)

Not all of the two-word sequences included here would actually occur in English, and only one of the four-word sequences (AND SPEEDILY IS AN). By contrast, allowing the choice of each word to depend upon its immediate predecessor produced this:

THE HEAD AND IN FRONTAL ATTACK ON AN ENGLISH WRITER THAT THE CHARACTER OF THIS POINT IS THEREFORE ANOTHER METHOD FOR THE LETTERS THAT THE TIME OF WHO EVER TOLD THE PROBLEM FOR AN UNEXPECTED. (p. 14)

This passage contains many sequences of four or more words that could occur in real sentences. (Anyone but an information theorist would say ". . . that could make sense".) Indeed, the twelve-word sequence from FRONTAL to POINT could occur in a guidebook on country walks, in a sentence such as "It is because of the savage frontal attack on an English writer that the character of this point on the pathway has changed."

The method Shannon used to compose the latter word string was a simple one. Taking a book from his bookshelves, he opened it at random, and wrote down a word selected randomly from the open page. Next, he opened the book at another randomly chosen page, and read on until he encountered the previously recorded word. At that point, he wrote down the immediately following word. Then he repeated the process again and again, always using the most recently recorded word as his guide.

Clearly, he didn't pick *Alice's Adventures in Wonderland.* Indeed, he may have deliberately avoided picking a 'literary' text as his sample source. The reason is that this method would grind to a halt if any newly chosen word occurred only once in the entire book.

(i) *Sentence* $\rightarrow$ *NP* + *VP*
(ii) *NP* $\rightarrow$ *T* + *N*
(iii) *VP* $\rightarrow$ *Verb* + *NP*
(iv) *T* $\rightarrow$ *the*
(v) *N* $\rightarrow$ *man*, *ball*, etc.
(vi) *Verb* $\rightarrow$ *hit*, *took*, etc.

FIG. 9.3. Rewrite rules for a simple phrase structure grammar. Reprinted with permission from Chomsky (1957: 26)

Even this simple method was time-consuming. It would be interesting to go further, said Shannon, by considering more than one previous word. But the labour involved in hand-searching the sample text would become enormous even at the two-word stage. (George Miller, instead of searching texts, asked people to volunteer 'the next word' after having been given one, two, or . . . six words: the higher-order, more redundant, strings were remembered more easily: G. A. Miller and Selfridge 1950.)

If computers had been available at mid-century, to collect the necessary statistics, many structuralists would have been interested. Think of the textual studies that might have been done on the basis of Harris's discourse analysis, for instance. Today, such studies are possible. But in the 1950s, computing technology was still in its infancy. In practice, then, Shannon's approximations weren't followed up by those linguists whose theoretical sympathies were similar to his.

Chomsky, in any case, wasn't one of their number. He saw the statistical approach as a dead end in theory, not just in practice. He believed he could prove, as a matter of principle, that FSGs, although they can generate infinitely many new sentences, cannot produce all the examples of everyday English. Specifically, they cannot generate sentences involving nested expressions, where the selection (in Shannon's terms, the probability) of word $n + 1$ depends not on its immediate predecessor, word n (nor on the m immediate predecessors), but on some word indefinitely many places earlier. Consider this sentence, for instance: *The cat with black fur and long whiskers was sitting on the mat*. The ninth word here depends not on the eighth, but on the second: replace *cat* by *cats*, and you must change *was* to *were*. It's structure which is doing the work here, not statistics.

Such nested dependencies, Chomsky argued, can in principle occur on infinitely many levels. (We saw in Chapter 7.ii.b, however, that *in practice* they cannot.) They require a "phrase-structure grammar", in which sentences are derived by a series of ordered "rewrite rules". Rewrite rules *as such* were invented not by Chomsky, but by the logician Emil Post (1943: see 10.v.e). But Chomsky was the first to apply them to natural language. He used them to produce phrases, including terminal elements (words), on various hierarchical levels (see Figure 9.3).

Unlike Jespersen twenty years earlier, Chomsky aimed to account for every single word in the sentence. So he analysed nominal phrases like *the man* and *a man* into two parts—and when he came to discuss transformations (see below), he analysed auxiliary phrases such as *has taken*, *will take*, and *is taking*, and showed the underlying relations between them.

The complete grammatical structure of the sentence, though not the order in which the rewrite rules were applied, can thus be represented by a tree diagram in which every

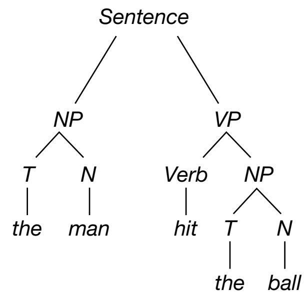

Fig. 9.4. Phrase-structure diagram showing the derivation of "The man hit the ball". Redrawn with permission from Chomsky (1957: 27)

word is separately considered (see Figure 9.4). This diagram shows how the grammatical categories are linked: from top to bottom, not—as in Markovian grammars—from left to right.

d. Transformational grammars

Phrase-structure grammars weren't new. They implicitly underlay immediate-constituent analysis, in which a sentence is recursively broken into contiguous constituents. This method had been used by many people, from the Port-Royal logicians to Harris, not only to parse unproblematic sentences but also to explain ambiguities. Linguists had long known, for instance, that the phrase structure of *The old men and women* could be either *The (old men) and women* or *The old (men and women)*, and that the meanings differed accordingly.

Similarly, the intuitive notion that different grammars might have different computational power wasn't new. Shannon, after all, had already contrasted FSGs having finite or infinite string sets.

The novelty in Chomsky's argument—as considered so far—was to define phrase-structure grammars as a general class, to prove that they're more powerful than Markovian (probabilistic) approaches, and to show that *natural* languages require grammars whose computational power is at least as great as that of a phrase-structure grammar. Significantly, he did the latter by relying, not, as Shannon had done, on some intuitive notion of computational power, but on his new classification of grammars. Each level in the hierarchy could generate all the strings generated by the level below, and more. FSGs lay at the lowest level, and phrase-structure grammars lay above them.

Chomsky was speaking here about *context-free* phrase-structure grammars. In his previous mathematical analysis, he'd distinguished between context-free (CF) and context-sensitive (CS) phrase-structure grammars.

In a CF grammar, each rewrite rule can be applied whenever the one-and-only symbol on the left-hand side is present. In a CS grammar, more than one symbol occurs on the left-hand side of the rewrite rules; a rule may rewrite one of them, and carry the others over unchanged. In the hierarchy of computational power, CS grammars had been located much higher than CF grammars. It was already clear that CS grammars included many "languages" of interest only to mathematicians, not to linguists. For linguists, the more interesting, more restrictive, and more plausible hypothesis was that natural languages have CF grammars. Indeed, the term "phrase-structure grammar" is often used to mean CF grammar.

At this point in the argument, Chomsky went further: he claimed that grammars of even greater computational power than phrase-structure grammars are needed for natural language. (My use of the word "claimed" here, instead of "proved", will be justified in Section ix.d–e.) In other words, natural languages involve a grammar located somewhere between phrase-structure grammars and universal Turing machines.

Chomsky admitted: "I do not know whether or not English is itself literally outside the range of [context-free phrase-structure] analysis." But he claimed that it could be so described (if at all) "only clumsily", by a complex, ad hoc, and unrevealing theory (p. 34). The reason he gave was that certain simple, and intuitively obvious, ways of describing sentences can't be expressed in terms of phrase structures, as then understood.

Everyday examples that require something more than a phrase-structure grammar, said Chomsky, include sentences involving auxiliary verbs (*The man has read the book*, *The man has been reading the book*); passive sentences (*The book is read by the man*); interrogatives (*Does the man read the book?*, *Will the man have been reading the book?*); *and* wh-questions (*Why/where/when/how does the man read the book? Who reads the book?*). It's intuitively obvious that there are close grammatical relations between the sentence *The man reads the book* and all these other sentences. But, Chomsky claimed, these relations can be simply expressed only by rules of the general form: *If the derivation of a grammatical sentence S-1 is such-and-such, then another grammatical sentence, S-2, can be produced by altering S-1 thus-and-so*. (*Sentence*, here, is a technical term, that covers any legal structure within a grammatical derivation. So *The man VP* is a sentence in this sense, for it is a structure derivable on the way to the terminal structure, *The man reads the book*.)

Intuitively, all these sentences seem to be related to the last one: *The man reads the book*. What's therefore required, said Chomsky, is a set of rules that can start with this sentence and derive all the others. Because rules like this define ways of transforming one sentence, or tree structure, into another (S-1 into S-2), grammars that contain them are called transformational grammars, or TGs.

A TG consists of a "base component"—a phrase-structure grammar that generates the initial trees—plus one or more transformational rules. This general definition covers many examples, including Harris's work and perhaps even Port-Royal grammar (see Sections iii.c and v.d–e). But the term TG is widely used to refer only to Chomsky's grammar, or variations of it—a fact that has aroused angry criticism, as we shall see (in Section ix.d).

TGs in general can't be located at any specific point in the grammar hierarchy, because the base component needn't be context-free (though it usually is), and because it's not clear how much—if any—computational power is added to it by the various transformations. The latter point makes it difficult to place even a particular TG in the hierarchy. The assumption implicit in *Syntactic Structures* was that a TG must lie somewhere between Turing machines and CS grammars—but just where was unclear.

In Chomsky's 1957 terminology, the simplest of the English sentences given above, and the point of reference for all of the others, is a "kernel" sentence. In other words, *The man reads the book* is derivable from its underlying grammatical form (which is derived by phrase-structure rewrite rules) by using only obligatory transformations (p. 45). These are the transformations that must be applied if the terminal sentence is to be grammatical at all. Non-obligatory transformations are applied either to the forms underlying kernel sentences, or to previous transforms thereof. In deciding which transformations are obligatory in English, and which optional, Chomsky relied on grammatical intuitions such as the one just remarked.

Chomsky's general claim, here, was that sentences of natural language must be represented on more than one theoretical level. In broad terms at least, many linguists were quick to agree. One later recalled Chomsky's argument as having had a "dramatic input" at the time:

> By God, native speakers DID associate active and passive counterparts . . . Yet the two were different and even unrelated in a phrase-structure analysis. His ideas seemed salient, dramatically salient, from the outset. (Hymes 1972)

As a result, "within a few years, quite a number of linguists were working on transformational grammar" (Chomsky 1975: 4).

Within a few years, also, the philosopher Hilary Putnam noticed that transformational grammars as defined above have the same power as a Turing machine (Putnam 1961: 101 ff.). If we allow just anything to count as S-1 and S-2, then this class of grammars has potentially infinite power. Any conceivable language, whether natural or artificial, recursive or non-recursive, could be derived by some TG (if it's computable at all). The set of prime numbers, for example, can be TG-generated.

This point was awkward for linguists claiming that TGs underlie natural languages. A scientific theory should not only explain what *does* happen, but also restrict what *could* happen (see 7.iii.d).

A grammar, for instance, should generate all *and only* the acceptable sentences of the language concerned. If any conceivable language, even including the (highly un-natural) set of prime numbers, can be 'explained' by some TG, then the class of such grammars can't exclude any possibilities. To be sure, a given TG might explain English and exclude French. (To someone seeking a TG to fit *all* natural languages, as Chomsky later did, this would be a weakness rather than a strength: see Section vii.d.) But Chomsky's supposedly surprising claim in 1957 was that each natural language requires *some TG or other*, and that *some TG or other* will suffice to explain it. Putnam's work suggested that this amounted merely to saying that natural languages are Turing-computable. That had been assumed for years by logicist philosophers (see Chapter 4.iii.c), so was hardly exciting.

The Turing-equivalence of transformational grammar was to be discussed in detail in the 1970s (Peters and Ritchie 1973). Partly because of this, by 1980 some linguists had rejected transformations altogether. They offered more restrictive scientific theories of natural language, relying on grammars low down in Chomsky's hierarchy.—But that was for the future (see Section ix.d–f, below).

Meanwhile, Putnam's theoretical point was shunted into the background for over twenty years, as linguists tried to discover *which transformations in particular*, and in which order, are needed to represent a given natural language—usually, English. The specific transformations that Chomsky hypothesized for English included, for instance, rules for converting a kernel sentence into a question either by moving the auxiliary verb to the beginning (so *The man will read* becomes *Will the man read?*), or by inserting the appropriate form of the auxiliary *do* at the beginning, and altering the form of the main verb (so *The man reads* becomes *Does the man read?*).

The details don't concern us (pp. 61–84). Nor need we discuss the rather different account of transformations that Chomsky was to give in his third book, in which kernel sentences, with their compulsory/optional transformations, were nowhere to be seen (Chomsky 1965). (Transformations as such became rarer in Chomsky's later work, as many functions previously effected by transformations were transferred to other rules of the grammar: see Section viii.b.)

More important, for our purposes, is the general form of the argument in *Syntactic Structures*. For this had implications far beyond linguistics. It alerted philosophers of language, psycholinguists, and the early computational psychologists. (One might say that it didn't alert psycholinguists so much as *create* them; the countless studies of "verbal behaviour" were focused on learning, not language—word strings, not sentences: see Chapter 6.i.e.) But it *didn't*, yet, alert psychologists in general.

e. So what?

Chomsky's analysis had radical—and to many, highly unwelcome—implications. For it followed, as he took pains to point out, that utterances (i.e. "sentences" in the everyday, non-technical sense) must be theoretically represented on several levels.

On the one hand, there is the surface structure: namely, the grammatical form of the sequence of words (morphemes, phonemes) that constitutes the sentence. The surface structure is interpreted phonetically, to produce a spoken utterance. On the other hand, there is the deep structure: the derivational history (including rewrite rules, kernel forms, and transformations), which will usually have many levels. The deep structure is interpreted semantically, to give the sentence's meaning.

(Although the technical terms "deep/surface" were introduced in Chomsky's second book, a related distinction was clearly made in the first. Similarly, the terms "competence/performance" didn't feature there, but the relevant distinction did.)

From the point of view of Bloomfieldian linguists (and behaviourist psychologists, too), this added insult to injury. Having already been told that statistical theories can't describe language, they were now being told that the observable aspects of language are underlain by a complex unobservable structure that must be represented in any adequate theory. Mentalism had returned, with a vengeance.—Mentalism, but not introspectionism: Chomsky agreed with Bloomfield that the speaker has no direct access to inner mechanisms.

One might argue that grammar is a mathematical exercise having nothing to do with mentalism. Indeed, theoretical computer scientists, who were much influenced by Chomsky's analysis of the computational power of different types of "language", gave no thought to psychology. And Chomsky himself said nothing, here, about the broader mentalistic implications that were to be so controversial in the 1960s (see Section vii.c–d).

In other words, *Syntactic Structures* contained no explicit comment on behaviourism, although Chomsky's anti-Markovian arguments were clearly relevant to it. Moreover, there was no mention of universal grammar, and therefore no hint that linguistics has nativist psychological implications, nor any relevance for the philosophy of mind. The theory of generative grammar wasn't yet being explicitly presented as "a particular sub-branch of cognitive psychology", still less as a study of "the human language faculty as such" (Chomsky 1975: 9).

The reason these "Cartesian" hypotheses weren't mentioned wasn't that Chomsky hadn't yet thought of them, but that he was deliberately suppressing them. They would have clashed with structuralist assumptions about the diversity of language and the emptiness of talk about language-and-mind—and the book was radical enough, even without them. Indeed, its ideas were so unconventional that, as he later recalled: "The one article I had submitted on this material to a linguistic journal had been rejected, virtually by return mail" (Chomsky 1975: 3). Understandably, then, he felt it to be "too audacious to raise the psychological issues which were in the background of my mind" (p. 35).

However, psychology wasn't ignored entirely. Linguistics, he said, is relevant to psycholinguistics—specifically, to the study of meaning. He was concerned not with vague claims like the Sapir–Whorf hypothesis, but with clearly specified theories about the psychological abilities (though not the processing details) involved in understanding:

> [My] formal study of the structure of language . . . may be expected to provide insight into the actual use of language, i.e. into the process of understanding sentences. (p. 103)

> [The] notion of "understanding a sentence" must be partially analyzed in grammatical terms. To understand a sentence it is necessary (though not of course sufficient) to reconstruct its representation on each level, including the transformational level where the kernel sentences underlying a given sentence can be thought of, in a sense, as the "elementary content elements" out of which this sentence is constructed. (p. 107–8)

The last remark occurred in the context of a discussion of the prospects for semantics. Here, the book was rather more acceptable to Chomsky's Bloomfieldian predecessors. For meaning was sidelined. Any theory of syntax, Chomsky argued, must be independent of semantics. Indeed, semantics is secondary to syntax, for understanding the meaning of a sentence rests on grammatical analysis.

Even so, structuralists were being challenged. Although Chomsky agreed with them that a science of meaning can't be based on vague appeals to introspection, or on unknown past associations, he did say that a (syntax-based) science of meaning is in principle possible. Indeed, semantics would play a fundamental role in his next book, in which he described a grammar as a set of rules relating the meaning of a sentence to its phonetic structure (Chomsky 1965).

These passages alerted psychologists, some of whom were aghast and others inspired. The repercussions in psycholinguistics, and the relevance of Chomsky's distinction between competence and performance, were discussed in Chapter 7.ii–iii.

In Chapters 5 and 6, we considered the growing revolt against behaviourism—to which Chomsky was an enthusiastic latecomer. Now, let's look more closely at what he had to say about the then prevailing psychological orthodoxy.

9.vii. A Battle with Behaviourism

Chomsky initiated a battle with behaviourism, but not the war itself. Others were fighting at the same time, and some had reached the battlefield earlier (see 5.iv and

6.i–iii). But it was Chomsky who flourished the sword most cuttingly and wounded his opponents most bloodily. And it was he who returned to the attack over and over again, in both his scientific and his political writing. Consequently, he's been awarded most of the victory medals, even though others merited them too.

(Not being one for half-measures, he also rejected Piaget's "epigenetic" compromise between nativism and behaviourism: see Chapters 7.vi.g and 14.x.c. Contributions to the Chomsky–Piaget debate are collected in Piatelli-Palmarini 1980.)

Chomsky's training in descriptive linguistics had been informed by behaviourist assumptions, as we've seen (in Section v.a). But in the early 1950s, he ignored this psychological movement. He looked at it in detail only after he'd finished his basic theoretical research on language, in 1956–7. Indeed, he said later that the critique of finite-state languages with which he'd opened *Syntactic Structures* was "an afterthought", not included in his larger manuscript (Chomsky 1975: 40).

From the late 1950s on, however, he pursued the behaviourists relentlessly. By the mid-1960s, he had rejected—or rather, expanded—the definition of linguistics given in *Syntactic Structures*. Now, he identified the goal of linguistics in explicitly nativist terms—with radical implications for psychology, and for the philosophy of mind.

a. Political agenda

In his pursuit of behaviourism, Chomsky was driven at least as much by political passion as by abstract argument. For he saw it in political terms, and didn't like what he saw.

He linked behaviourism with the social-scientific 'experts' whose advice to the US government, and especially to the military, he—and countless others—regarded as political anathema. AI scientists were suspect too, despite their non-behaviourist approach, for their work had made 'smart' bombs and aerial reconnaissance possible (Chapter 11.i).

Chomsky expressed this complaint on many public platforms at the height of the Vietnam war. Indeed, he spoke in the very first public demonstration against the war, held on the Boston Common in October 1965. He spoke, but he wasn't heard:

> the mobs were so hostile that none of us could say an audible word. The only reason we weren't killed, I suppose, was that there were hundreds of police—who didn't like what we were saying one bit, but didn't want to see anyone murdered on the Common. (quoted in Swain 1999: 29)

Besides braving mobs on the Boston Common, he was put in prison on more than one occasion (Swain 1999: 24). He was thus a powerful voice in the counter-culture (Chapter 1.iii.c).

He still is. For, unlike his MIT colleague Joseph Weizenbaum (11.ii.d), he continued—and intensified—his complaints long after the 1970s. He repeated them, with meticulous documentary evidence, all around the world in connection with various other events—most recently, those of 11 September 2001 in New York, and their grisly aftermath in Afghanistan and Iraq. He still berates "respected intellectuals" for justifying the actions of "violent and murderous states"—including the USA (Chomsky 2001: 73; 2005). And he still sees political engagement as a responsibility of the intellectual (1996*c*).

His speeches continue to draw a multitude of listeners: his Royal Institute of Philosophy Lecture in 2004, for instance, saw about 3,000 youngsters queuing along the London streets (Chomsky 2005). And his writings have attracted adulatory praise from political sympathizers (Barsky 1997). They doubtless drew some people to his scientific writings who wouldn't otherwise have been interested in them.

Given the combination of his political and linguistic work, he eventually became the most-quoted living writer, and the eighth most quoted in history (Barsky 1997: 3). (The other seven were Marx, Lenin, Shakespeare, Aristotle, Plato, Freud—and, in fourth place, the 'author' of the Bible.)

In making these politico-scientific links, Chomsky repeatedly criticized what he saw as the philosophical assumptions underlying the science. Specifically, he claimed that empiricist and rationalist views of humanity inherently tend to promote political oppression and freedom, respectively (e.g. Chomsky 1972*b*: 45–54 and *passim*; cf. N. V. Smith 1999).

The justice of this general claim isn't obvious; some have argued that the reverse is true (Sampson 1979*a*). For instance, Locke's political philosophy—which underlay the English, French, and American revolutions—hardly suggests that empiricism is incompatible with liberty. Indeed, Locke saw doctrines of innate ideas as politically dangerous, since they encourage "blind credulity" whereby the populace becomes "easily governed" by a "dictator of principles and teacher of unquestionable truths" (J. Locke 1690: I. iv. 25). One of his followers, Lord Chesterfield, even wrote to his son that "A drayman is probably born wyth as good organs as Milton, Locke, or Newton" (Strachey 1924–32, pp. ii–136). True to his time, however, when Locke framed the constitution of Carolina in 1669 he gave slave-owners full jurisdiction over their slaves (Porter 2001, pp. xxii–xxiii). Lockean liberty had its limits.

However that may be, this dual significance helps explain the virulence with which Chomsky attacked behaviourism in general, and Burrhus Skinner in particular. Skinner—who wrote the first book on "verbal behaviour"—not only theorized language in a manner Chomsky saw as scientifically vacuous, but also rejected traditional assumptions about the way to the good life (Skinner 1948) and humanist conceptions of freedom and dignity (Skinner 1971).

These views didn't endear him to the counter-cultural Chomsky (1.iii.c). He attacked them in typically uncompromising terms:

> Consider a well-run concentration camp with inmates spying on one another and the gas ovens [visibly] smoking in the distance, and perhaps an occasional verbal hint as a reminder of the meaning of this reinforcer. It would appear to be an almost perfect world . . . In the delightful culture we have just designed, there should be no aversive consequences . . . Unwanted behavior will be eliminated from the start by the threat of the crematoria and the all-seeing spies . . . Nevertheless, it would be improper to conclude that Skinner is advocating concentration camps and totalitarian rule (though he also offers no objection). Such a conclusion overlooks a fundamental property of Skinner's science, namely, its vacuity. (Chomsky 1973: 129–30)

The familiar vocabulary of freedom and dignity, said Chomsky, far surpasses Skinner's terminology in discussions of politics. Indeed, it's all we have: there's no scientific theory of politics, and perhaps there never can be. In refusing to use such humanistic expressions, therefore, Skinner was being not scientifically scrupulous but politically irresponsible.—Perhaps merely politically neutral? No, Chomsky insisted, for that comes to the same thing: to "offer no objection" is, in effect, to support the status quo.

Later, Chomsky widened this attack to include all quietist academics. He contrasted Albert Einstein's "very comfortable life" of research, interrupted by "a few moments for an occasional oracular statement", with Russell's passionate espousal of nuclear disarmament and vociferous critiques of the Vietnam war, which landed him in prison on more than one occasion (Barsky 1997: 32–3). (Russell was one of the first public critics of the H-bomb, and in 1958 became founding president of the Campaign for Nuclear Disarmament; his pacifist speeches and writings around the time of the First World War had also got him jailed—see Monk 1996: 525–40; 2000: 367–90, 405–13.) In general, Chomsky argued that intellectuals should actively, if perforce riskily, confront "privilege and authority"—both on public platforms and in their personal lives. Certainly, he himself has never stopped doing so.

For the rest of our discussion here, let's ignore the politics. If this brands us as irresponsible quietists, so be it. For Chomsky also gave non-political arguments against behaviourism.

b. That review!

Politics aside, Chomsky made three main claims in his ongoing critique of behaviourism:

* First, that behaviourist theories are in principle inadequate to represent grammatical structure, which exists on several theoretical levels.
* Second, that Skinner—the most influential behaviourist in this area—used covertly mentalistic terms to explain language, while having no theoretical right to do so.
* And third, that human babies, and *only* human babies, can acquire language only because they have innate knowledge of its fundamental structure.

One could coherently admit the first two claims while rejecting the (more controversial) third. Nevertheless, by the end of the 1960s, many cognitive scientists had accepted all three.

The first claim was the theoretical core of Chomsky's dispute with behaviourism, and rests on his argument in *Syntactic Structures* (presented there without explicit reference to behaviourism). The structure and "creativity" of language can't be described by Markov processes, but must be represented as a hierarchy of theoretical levels (see Section vi). The central idea here wasn't new: Karl Lashley had expressed it in the 1940s, in relation to speech and other motor skills (Chapter 5.iv.a). But Chomsky put it in mathematical terms.

He took this criticism to apply to behaviourism in general. As regards those behaviourist theories which (unlike Skinner's) posited internal Ss and Rs, he was justified: mathematically, it doesn't matter whether the Ss and Rs are observable or not. (Compare the objection that production systems are merely an internalist form of behaviourism: Chapter 7.iv.ii.)

Whether he was justified as regards all possible forms of behaviourism was less clear. Some empiricist philosophers argued that behaviourism, or (as they put it) scientific psychology, shouldn't be defined so restrictively as to include only Markovian theories based on conditioned response (e.g. Quine 1969: 96–7). (It turned out, later, that simple statistical methods can enable a connectionist network to learn the past tense, even generating the detailed errors made by children: see Chapter 12.vi.e and x.d.)

The second prong of Chomsky's attack was unsheathed in his notorious review of Skinner's book on the psychology of language (Skinner 1957; Chomsky 1959*b*). This book was published in the same year as *Syntactic Structures*, but had been circulating in draft for some time. It was based on Skinner's William James Lectures, given at Harvard in 1947, and in his own mind represented his crowning achievement. (He'd been working on it for twenty-three years—Skinner 1967: 402.)

Chomsky allowed that in his animal research Skinner had been scrupulous in defining his terms, and had made genuine scientific discoveries. On turning to language, however, he had abandoned both experiment and scruple. His central theoretical concepts of *stimulus*, *response*, and *reinforcement* were being applied so loosely as to be vacuous. And his new, specifically linguistic, concepts (such as *tact* and *mand*), though defined in putatively observational terms, were actually being understood mentalistically (*mand* as an indiscriminate amalgam of *command*, *request*, *question*, *prayer*, *advice*, and *warning*, for instance).

This was hardly surprising, Chomsky said. For if one struggled to interpret Skinner's vocabulary in a strictly behaviourist fashion, his theory instantly lost all plausibility. Moreover, Skinner had made no serious attempt to test his theory of language experimentally, relying instead on anecdote and speculation.

Chomsky did acknowledge that some operant-conditioning experiments on language had come up with surprising and non-trivial results. For instance, speakers can be—unknowingly—conditioned to produce more or fewer plural nouns, to use the personal pronoun more or less often, or to talk about one topic rather than another (Krasner 1958). The first of these is especially interesting, since it's defined in terms not of a single response, like uttering the word *I* or *we*, nor even of a phonemic pattern such as words ending in *-s*, but of a syntactic class. But Chomsky was sceptical: "Just what insight this gives into normal verbal behavior is not obvious" (Chomsky 1959*b*, n. 7).

This review, one-third as long as Chomsky's little book, attracted enormous attention. Its many readers were not only gripped by the argument, which was detailed and careful, but also amused and/or outraged by the rhetorical style. For this essay was very different from the dry and symbol-ridden *Syntactic Structures*.

Chomsky's pen had been dipped in vitriol, as well as in ink. Words such as *pointless*, *confused*, *gross*, *absurd*, *delusion*, *dogmatic*, *arbitrary*, *useless*, and *empty* leapt out from the pages. Skinner's fundamental concept (reinforcement) was scornfully said to have "totally lost whatever objective meaning it may ever have had", and Skinner himself to be "play-acting at science". There was delectable ridicule, too. According to Skinner, said Chomsky, the best way to show one's appreciation of a prized work of art owned by a friend is to shriek "Beautiful!" repeatedly in a loud and high-pitched voice, without ever pausing for breath.

This was welcome light relief from the daily academic grind. Small wonder that the piece was so widely read. Only Skinner avoided it—or so he claimed: "I have never actually read more than half a dozen pages of Chomsky's famous review of *Verbal Behavior*. (A quotation from it which I have used I got from I. A. Richards)" (Skinner 1967: 408).

Rhetoric apart, however, Chomsky's second point was unassailable. Skinner was guilty as charged: he was misusing his own terminology and betraying his own scientific method, by tacitly relying on everyday mentalistic intuitions. In that skirmish, Chomsky won hands down.

c. Nativist notions

Chomsky's third salvo caused even more sound and fury—and is still echoing today (see 7.vi, 12.vi.e, and 14.ix.c–d). More intellectually daring than the first two points, and arguably less well grounded, it was a combination of a negative claim and a positive one.

Negatively: that the child's language acquisition can't be fully explained by experience, even if this is conceptualized in non-Markovian terms. Positively: that babies must therefore have innate knowledge of the structure of language—which is to say, of the rules of some universal grammar.

The positive corollary, that there's some inborn "language acquisition device" specially apt for learning grammatical patterns, was even more obviously heretical than its negative ground. It had been "too audacious" to be included in *Syntactic Structures* (see above), and was merely hinted at in the notorious review, where Chomsky was more concerned to criticize Skinner's theory than to present his own. But it was made fully explicit—and defensively related to his august "Cartesian" precursors—in Chomsky's publications of the 1960s (Chomsky 1964, 1965, 1966, 1968). Indeed, he now built it into the very definition of linguistics as such:

> A theory of linguistic structure that aims for explanatory adequacy incorporates an account of linguistic universals, and it attributes tacit knowledge of these universals to the child. (Chomsky 1965: 27)

> Given a variety of descriptively adequate grammars for natural languages [which can be achieved if one sees the goal of linguistics as I defined it in *Syntactic Structures*], we are interested in determining to what extent they are unique and to what extent there are deep underlying similarities among them that are attributable to the form of language as such. *Real progress in linguistics* consists in the discovery that certain features of given languages can be reduced to universal properties of language, and explained in terms of these deeper aspects of linguistic form. Thus *the major endeavor of the linguist* must be to enrich the theory of linguistic form by formulating more specific constraints and conditions on the notion "generative grammar". (Chomsky 1965:35; italics added)

The negative nativist claim rested partly on Chomsky's anti-Markovian arguments, and partly on his assertion that the language the infant hears is inadequate to allow grammar to be induced so quickly. The child, he said, may hear a certain syntactic construction only very rarely. Moreover, everyday speech abounds with unfinished sentences, restarts, and grammatical errors. (People may get lost inside subordinate clauses, for instance.) So the child very often hears utterances that are grammatically flawed. Given such patchy and contaminated data, rapid learning of a perfect grammar simply couldn't happen.

This negative assertion was immediately criticized by those of an empiricist cast of mind, as being an argument from ignorance. The fact that no one has yet come up with an explanation of how children learn language, they said, doesn't mean that it's impossible to do so. Induction (as remarked above) needn't be conceptualized in the simple terms of traditional empiricism (Quine 1969: 96–7; Harman 1967, 1969). Moreover, the notion of "experience" was said to be richer than Chomsky allowed. It was no longer thought of as passive or atomistic, and with further psychological research might become richer still (M. Black 1970: 458).

This neo-empiricist shaft hit its mark, but left Chomsky standing. Facing only promissory notes from his opponents, his argument from ignorance remained in play. (It was soon followed by a formal proof that 'nested' languages can't be learned on the basis of *positive* evidence only: Gold 1967.)

As for Chomsky's comment that the infant's heard corpus is largely degenerate, this seemed obviously true to many people. But—like Cordemoy's remarks (see Section iii.a) about nouns preceding adjectives, preceding verbs—it hadn't actually been tested.

When it was, psycholinguists reported that mothers typically use a restricted dialect ('motherese') when speaking to babies and young infants, employing sentences both syntactically simpler and more grammatically correct than those of adult speech (R. Brown 1973). On the other hand, they also found that the child's syntax develops in predictable stages, two-word utterances appearing first, and the complexity increasing with age (7.vi.a). This was generally interpreted (perhaps wrongly: see Chapter 12.viii.c–d) as evidence of an innately driven developmental process, supporting the spirit, if not the letter, of Chomsky's nativism.

The positive nativist claim caused huge controversy. Much of the initial scepticism concerned what Chomsky—or indeed anyone—could mean by "innate knowledge" or "innate ideas". All of the questions, and most of the answers, that had been hurled at Descartes, Locke, and Leibniz resurfaced.

Some philosophers objected that innate knowledge is impossible, because "knowledge" implies justification (Edgley 1970; Harman 1969). Chomsky replied that unconscious knowledge (competence), unlike what Gilbert Ryle (1946) had called "knowledge that", requires neither verbalization nor justification (Chomsky 1969; 1980*a*, ch. 3).

Even when the debate was put in terms of innate ideas instead of innate knowledge, or dispositions instead of ideas, the problems sketched in Section ii.c (above) arose—and were debated with passion. High-visibility symposia pitting Chomsky against leading epistemologists and philosophers of language occurred from the mid-1960s on, and innate ideas became a hot topic of scientific and philosophical debate (e.g. *Synthese* 1967; Hook 1969, pt. ii; Stich 1975).

The discussions were often ill-tempered, and many of Chomsky's adversaries rivalled his rhetorical armoury in their attack. One leading philosopher, Gilbert Harman, said that Chomsky "misrepresents [my comments] at almost every point", to which Chomsky testily retorted: "I see no reason to try to trace the various confusions Harman develops, none of which have any relation to the views I actually hold . . . " (Harman 1969: 143; Chomsky 1969: 154). His irritation was doubtless fuelled by the fact that, some years earlier, Harman had denied the need for transformations (Harman 1963). Another influential philosopher dubbed Chomsky's theory 'The Emperor's New Ideas', and remarked:

> The theory of innate ideas is by no means crude. It is of exquisite subtlety, like the gossamer golden cloth made for that ancient emperor. But the emperor needs to be told that his wise men, like his tailors, deceive him; that just as the body covered with the miraculous cloth has nothing on it, the mind packed with innate ideas has nothing in it. (Goodman 1969: 141–2)

Willard Quine, in characteristically gentlemanly fashion, mildly declared that the behaviourist is "knowingly and cheerfully up to his neck in innate mechanisms of learning-readiness" (Quine 1969: 95–6). Reinforcement, for example, depends on "prior inequalities in the subject's qualitative spacing . . . of stimulations". And "unquestionably much additional innate structure is needed, too, to account for language learning".

But there was a sting in the gentleman's tail. Quine ended his paper thus:

> Externalized empiricism [which makes no reference to "ideas"] or behaviorism sees nothing uncongenial in the appeal to innate dispositions to overt behavior, innate readiness for language-learning. What would be interesting and valuable to find out, rather, is just what these endowments are in fact like in detail. (Quine 1969: 98)

Chomsky could answer that question only by saying: universal grammar, whatever that turns out to be.

d. Universal grammar?

What universal grammar will turn out to be—if it exists at all—is still unclear. Indeed, the very notion of *innateness* is now interpreted in a much more sophisticated way (Chapters 7.vi.g and 14.ix.c). Added to that is the fact that Chomsky himself changed his mind more than once about just what the "universal" base of language is.

Chomsky's initial postulation of universal grammar had depended only on argument, the main premiss being the supposed inadequacy of learning theory to explain language acquisition. But, as Quine had said, it needed empirical evidence also.

From 1965 onwards, Chomsky suggested a number of abstract grammatical principles that appeared to apply to several languages and might apply to all. Some concerned aspects of the base component (for example, that all languages share the same syntactic categories: noun, verb, NP, etc.). Others concerned the transformational rules.

For instance, in *Aspects of the Theory of Syntax*, the first major publication in which he made his nativism fully explicit, Chomsky said:

> Although a language might form interrogatives, for example, by interchanging the order of certain categories (as in English), it could not form interrogatives by reflection [reversing the order of words in the sentence], or interchange of odd and even words, or insertion of a [syntactic] marker in the middle of the sentence. (Chomsky 1965: 56)

Later, he posited the *A-over-A* principle. This forbids any language-specific (English, French, or . . .) transformation from picking an embedded noun phrase out of the noun phrase in which it is embedded—or more generally, from extracting any phrase of category *A* out of some larger phrase of the same category. Another example was a "principle of cyclic application" which Chomsky supposed to govern the way in which noun phrases are deleted and replaced by pronouns.

However, each of Chomsky's suggestions was challenged as applying only (if at all) to English, or to a small set of languages. Thorough testing would require detailed descriptions of a multitude of tongues.

This, of course, is what the out-of-fashion structuralists had aimed to provide. But Chomskyans didn't. One critic has described them as being as obsessed with English as the Port-Royalists were with French (Itkonen 1996: 487; cf. Section iii.c). Indeed, Chomsky himself would defiantly declare that "I have not hesitated to propose a general principle of linguistic structure on the basis of a single language"—an admission dubbed "preposterous" by this critic (Itkonen 1996: 487).

Some of Chomsky's "universals" were criticized even with respect to English. The *A-over-A* principle, for instance, was soon decomposed into several independent "island constraints" (J. R. Ross 1968), which covered the data better (and some of which hadn't been covered by the original principle). In the years that followed, Chomsky tried to integrate the island constraints into a single rule. He came up with the "Subjacency Principle", but even this didn't work for all of the island constraints. Again, Chomskyans tried to find some even more abstract principle underlying the variety of surface forms.

But non-Chomskyan linguists weren't persuaded. Worse (for Chomsky), they would eventually accuse him of constantly redefining his position over the years so as to make it, in effect, unfalsifiable. Sometimes, this would be said in waspish exasperation, caused by frustration at the still-continuing dominance of Chomskyans in the linguistic profession (see Section viii.a):

> I [have become] convinced that there is nothing, absolutely *nothing*, that could make Chomskyans admit that there is or has ever been anything amiss with their theory. In the game of linguistics, truth is a secondary consideration: not to lose face has top priority. (Itkonen 1996: 497; cf. pp. 490–4)

On this view, the passage from A-over-A to island constraints wasn't a step forward in a healthy Popperian progression of conjectures and refutations, but one of many intellectual retreats in a degenerating research programme (K. R. Popper 1935; Lakatos 1970). Today, half a century after Chomsky came on the scene, linguists are divided between these two judgements (see Sections viii & ix).

In short, Chomsky's universal grammar of the 1960s was, at best, a promissory note. Twenty years later, and largely due to Chomsky's influence, nativism would be expressed more acceptably and backed by considerable *non-linguistic* evidence (see Chapter 16.iv.c–d and Fodor 1981*b*). Twenty years later still, 'straightforward' nativism would be replaced by epigenesis, and modular theories of the mind reinterpreted, or rejected, accordingly (Chapters 7.vi and 15.x.a–c). Meanwhile, Chomsky couldn't meet Quine's challenge.

It's important to recognize, however, that (whatever one might say about his later theories) Chomsky's early suggestions on this matter had the Popperian merit of being mistaken. They weren't vague claims unamenable to testing—which isn't to say that the Chomskyans were eager to test them.

Still less were they a priori arguments from first principles, with no obvious relation to reality. On the contrary, they were empirical, falsifiable, *scientific* claims. Chomsky was saying "Languages are like *this*—but they could, conceivably, have been like *that*." As he put it:

> There is no *a priori* consideration that lends plausibility to a theory of [universal] syntactic operations [such as mine] that precludes the formation of interrogatives by left–right inversion of the corresponding declarative, or innumerable other perfectly conceivable, and quite efficient operations. It is just this fact that constitutes the scientific interest of such a theory. (Chomsky 1970: 468)

In other words, Chomsky wasn't a rationalist in the strict sense. The Cartesian philosophers of the seventeenth century took language to be close to reason, being informed by principles of necessary truth. And even Kant held that no alternative mental structure (system of intuitions) is conceivable by us (see Section ii.c). But Chomsky shared neither of these beliefs. Whether a language-universal grammar exists, and if so what it is like, are empirical questions.

On those points, Chomsky's behaviourist opponents were willing to agree. But even if he had identified a grammar suited, as a matter of fact, to all natural languages, they wouldn't have conceded defeat. For universality doesn't guarantee innateness. Max Black put the point thus:

> In science in general, reference to dispositions and powers is usually a promissory note, to be cashed by some identifiable internal structure . . . But there is no serious question at present of finding such internal configurations in human organisms: we hardly know what we should be looking for, or where to look. So far as stimulation of research goes, 'nativism' looks to me like a dead end . . . (M. Black 1970: 458)

Black's charge that no interesting research can be prompted by nativism fell wide of the mark. Cognitive scientists excited (whether for or against) by Chomsky's nativism did much interesting work as a result, the many studies of the development of grammar in children being just one example (see Chapter 7.vi). But Black was right to insist that, strictly, the nativist requires some independent evidence of internal mechanisms. Not until the 1990s would the debate on innate ideas, and inborn "dispositions", be illuminated by reference to specific neurological processes (see Chapter 14.vi.b and ix.c).

Not even Chomsky, of course, suggested that babies are born knowing French—or perhaps English, if destined for a life of persuasion, emotionalism, and deceit? (see iii.d, above). But their knowledge of universal grammar, he said, acts as a framework which guides them to attend to certain features, certain distinctions, in the language spoken around them. In syntax as in phonetics, the specific value of those distinctive features varies across natural languages: hence their apparent diversity.

On this view, the child is, in effect, like a scientist. Instead of collecting data by pure induction (which is impossible), the scientist formulates theories and hypotheses which suggest what to look for, and where to look for it. This, essentially, is what the baby has to do in learning its mother tongue.

The view of the speaker/hearer as a hypothesis tester had always been implied by Chomsky's work, quite irrespective of nativism. It was implicit in *Syntactic Structures*, in his claim that the speaker/hearer must ascribe unobservable, many-levelled, grammatical structure to utterances in order to understand them, and was made explicit in the first review (Lees 1957: 406–7). As he himself admitted, his theory that language users generate grammatical hypotheses owed much to Jerome Bruner's "New Look" in perception (6.ii), which swept cognitive psychology in the late 1940s and 1950s (Bruner 1980: 81).

What Chomsky's nativism added (in 1965) to the widely current idea of hypothesis testing was the claim that babies may not have to create their linguistic hypotheses out of thin air, nor even out of infantile dreams and visions. Rather, he said, they can produce them on the basis of a powerful theoretical framework—a "Language Acquisition Device"—already present in their minds.

9.viii. Aftermath

Chomsky's intellectual footsteps were greatly amplified in the two decades after his appearance, and are still clearly audible today.

His early papers had a huge, and lasting, influence on pure computer science. Virtually every introduction to compiler design cites Chomsky's hierarchical classification of languages (Edmund Robinson, personal communication). And a leading textbook on theoretical computer science remarks that "[Chomsky's] notion of a context-free grammar and the corresponding push-down automaton has aided immensely the specification of programming languages" (Hopcroft and Ullman 1979: 9; cf. 217–32). That's why I said (in Section vi.a) that the 'Three Models' paper was his most original and most well-founded contribution.

For cognitive science in general, his crucial writings were the formalist *Syntactic Structures* and the nativist *Aspects*—plus, for light relief, his coruscating review of Skinner. These three publications had a huge impact on psychology and philosophy, and a significant influence on AI (see 6.i.e, 7.vi.a–d, 10.i.g, and 16.iii–iv). In effect, cognitive science in the 1960s had a love affair with Chomsky: one historian of linguistics has remarked on "the sweeping and unrequited optimism of the honeymoon years of cognitive psychology and transformational grammar" (R. A. Harris 1993: 257).

With respect to linguistics as such, the sequel was clear: all linguists came to situate themselves with respect to Chomsky (Lyons 1991: 9). This was true even of those whose specialism was in some other area, such as sociolinguistics, historical linguistics, descriptive linguistics, and anthropological linguistics—all of which, and especially the last two, declined in status post-Chomsky (Sampson 1980: 78 ff., 146–7). All linguists had to decide whether to adopt some version of his account in their own work. And all had to allow that he'd set new standards of clarity for theoretical linguistics.

Whether his many followers lived up to those standards is questionable. Trouble was brewing even in the 1960s. A champion of formalization in science—echoing Leibniz's "calculemus" as the only way of achieving objectivity (see Chapter 2.ix.a)—praised Chomsky for seeding "one of the healthiest and most important controversies in psychology in this century", but complained that his leading disciples couldn't *prove* their claim that behaviourism is in principle inadequate (Suppes 1968). Twenty years later, things were even worse. One critic pointed out that, of the "thousands" of papers published on Chomsky's grammar between 1970 and 1986, *only one* (in a relatively obscure journal) attempted a mathematical statement (Gazdar 1987: 125). Indeed, Chomsky himself would eventually be fiercely criticized for lack of rigour (see Section ix.e).

In addition, he was accused of being mistaken in various ways even about *syntax*, never mind arcane philosophical topics such as innate ideas. This fact should be no great surprise. It's obviously possible to be influential without being right. What is surprising is the extraordinary emotional tone of many of those criticisms. Disinterested discussion of Chomsky's views was—and still is—hard to come by, as we'll now see.

a. Polarized passions

For linguists who specialized in syntax, semantics, or phonetics, Chomsky soon became a constant presence. Too much so, perhaps: the sociology of science hindered the science itself, as Chomskyan cliques came to dominate various conferences and journals.

Bruner, who as a non-linguist has no professional need to 'take sides' (and who'd influenced Chomsky deeply in the late 1950s: see vii.d, above), is one of many who've complained about this. He recently remarked:

> [Chomsky is a] systems builder, and ruthless systems at that. And it's so funny, because the fact of the matter is he claims to be a deep believer in democratic values. But the ways in which he goes about it, and the ways in which they, the Chomskians, have gone about it by a kind of taking over of the apparatus of linguistic scholarship in America is nothing less than just a hostile takeover of the whole damned system. Everybody else is out. (Shore 2004: 51)

Naturally, this phenomenon didn't go unchallenged within the profession. Eventually, linguists' complaints about Chomsky's hegemony in linguistics became even more heated than philosophers' debates about his theory of innate ideas (see Section vii.c). One observer recently remarked that "the level of enmity is truly stunning". As he put it, "there are people who genuinely wish that Chomsky would die, or retire, or move exclusively into political or philosophical domains, and just leave poor little linguists alone" (R. A. Harris 1993: 256).

This "blood-boiling animosity" arose from professional frustration. An English linguist surveying the international scene in 1980 saw it like this:

> The discipline of linguistics seems to be peopled by intellectual Brahmanists, who evaluate ideas in terms of ancestry rather than intrinsic worth; and, nowadays, the proper caste to belong to is American. The most half-baked idea from MIT is taken seriously, even if it has been anticipated by far more solid work done in the "wrong" places; the latter is not rejected, just ignored . . . To the young English scholar of today, the dignified print and decent bindings of the *Transactions of the Philological Society* smack of genteel, leather-elbow-patched poverty and nostalgia for vanished glories on the North-West Frontier, while blurred stencils hot from the presses of the Indiana University Linguistics Club are invested with all the authority of the Apollo Programme and the billion-dollar economy. Against such powerful magic, mere common sense . . . and meticulous scholarship (in which the London School [e.g. Firth, Halliday, Hudson] compares favourably, to say the least, with the movement that has eclipsed it) are considerations that seem to count for disappointingly little. (Sampson 1980: 235)

Comparable complaints have been made more recently, if less colourfully. A Finnish linguist in the mid-1990s remarked that Chomskyans often identify "linguistics" with "generative linguistics", and that "there are nowadays relatively few publications which subject generative linguistics to explicit critical scrutiny". The lack of publication was attributed to sociological factors:

> A lengthy discussion [on the Internet] concerning "mainstream linguistics" . . . was started by the observation that people who had to criticize the generative paradigm preferred to stay anonymous. This was interpreted as reflecting the opinion that open criticism of "mainstream linguistics" might jeopardize a person's career prospects and possibilities for publication. Although such a view was heatedly denied by representatives of the generative paradigm, at least my own experience confirms it. In several informal meetings I have found out that linguists agree with some or even all aspects of the criticism [that I am about to present]; they just do not want to say it publicly. (Itkonen 1996: 471)

In a nutshell, the "representatives of other schools seem anxious to maintain what might, depending on one's point of view, be called either 'peaceful coexistence' or a 'balance of terror' " (p. 471).

Similarly warlike language was occasionally heard on Chomsky's side of the Atlantic, too. One leading American linguist, a colleague of Chomsky's at MIT in the late 1950s and 1960s (see Section x.b), had lost patience with him by the 1980s. Victor Yngve (1920–) , arguing that linguistics should focus on people (communicators) rather than language, referred to "puffery, empty polemics, intellectual bullying, and the great-man syndrome", and bemoaned "unscientific" a priori reasoning "in support of philosophical preconceptions and maintained by early ecstatic reviews, political acceptance, largely unquestioned personal authority, and the abuse and contempt . . . poured on other positions" (Yngve 1986: 7, 43, 108). Chomsky's name wasn't mentioned. Clearly, however, the cap fitted and he was being asked to wear it.

In short, Chomsky was the high priest of a new orthodoxy, almost a new paradigm (Kuhn 1962). Most young linguists aspired to be his devoted acolytes. Heretics (if noticed at all) weren't treated lightly—a situation due largely to Chomsky's personality, which thrives on embattlement.

For example, the MIT linguist who defined island constraints (see Section vii.d) was systematically reviled and excluded by his so-called colleagues (R. A. Harris 1993: 245–6). And George Lakoff, a pioneer of generative semantics (see below), was venomously accused by Chomsky himself of (among other things) having "discussed views that do not exist on issues that have not been raised, confused beyond recognition the issues that have been raised and severely distorted the contents of virtually every source he cites" (quoted in R. A. Harris 1993: 157). Skinner, then, wasn't the last to be lacerated by Chomsky's pen.

Nevertheless, heretics there were. Not everyone agreed with him. Indeed, even Chomsky disagreed with Chomsky. In other words, he had second thoughts—and third, and fourth . . . and more. Before considering his linguistic critics (in Section ix), let's look briefly at his own revisions of his ground-breaking theory of 1957.

b. Revisions, revisions . . .

Revisions weren't slow to come, for the grammar of *Aspects* differed significantly from Chomsky's earlier approach. The main differences were its terminology of deep and surface structure, its new treatment of transformations, and its inclusion of semantics. (Besides the new treatment of *grammar*, there was also a new emphasis on nativism, as we've seen.)

The 1965 account—known as "standard" theory—lasted, with relatively minor revisions, for fifteen years, while Chomsky devoted much of his time to politics. These revisions reduced the number of transformations in his theory: in 1970, for example, he suggested that lexical rules should replace morphological transformations (Bresnan 1978: 5). But the revised standard theory wasn't his last gasp. In the early 1980s, he provided a new approach, the theory of "government-binding" (GB) (Chomsky 1980*a*,*b*, 1982).

GB theory was even more unlike *Aspects* than that had been unlike *Syntactic Structures*. Chomsky had already suggested, in the late 1970s, that what had previously been thought of as a number of different transformations (involving wh-questions and various other matters) could be seen as special cases of a more general one. By the early 1980s, only a single, highly general, transformation remained. (Known as "move alpha", its pivotal notion was subjacency.) Much of the explanatory weight was now carried by innate "principles" and "parameters" (Chomsky and Lasnik 1977).

Principles are unvarying linguistic universals. Parameters are like variables: each has a limited number of possible values, which are partly interdependent. The diversity of actual languages is explained by differences between their sets of parameter values. So infants, in acquiring language, must discover which values characterize their mother tongue, and set their internal parameters accordingly (Lyons 1991: 184–8). As Chomsky put it:

> If the system of universal grammar is sufficiently rich, then limited evidence will suffice for the development of rich and complex systems in the mind, and a small change in parameters may lead to what appears to be a radical change in the resulting system. (Chomsky 1980*a*: 66)

This theory is reminiscent of claims made by biologists who see the range of possible adult forms as highly constrained, yet different, with no "great chain of being" filling the gaps. Conrad Waddington, and his student Brian Goodwin, have argued that small changes in epigenesis can tip the embryo into one developmental pathway rather than another: see Chapters 14.ix.c and 15.ix.a–c.

Eventually, in the early 1990s, GB theory gave place to "minimalism" (Chomsky 1993, 1995). "Deep structure" was abandoned. Still more shockingly, the previously pivotal notion of grammaticality was dismissed as being "without characterization or known empirical justification" (Chomsky 1993: 44). And several new principles—including Greed, Procrastinate, and Last Resort—were introduced (Chomsky 1995: 200–12).

But minimalism was too much for some of Chomsky's critics. One reviewer remarked that it was so very different from its GB predecessor that Chomsky was here "contriving to reclaim the role of the lone revolutionary", without acknowledging that his "new" position owed much to the generative semanticists of twenty years before (see below)—Pullum 1996: 137. As for the core theoretical ideas of minimalism, these were "sketched so hesitantly as to be hard to describe", and afforded "a level of explication [that] is risible" (Pullum 1996: 140–1). He mocked the new principles of "Greed" and the like, and complained about "anthropomorphic" accounts of "phrases moving in a bid to get their needs satisfied, and abstract nodes yearning to discharge their feature burdens" (Pullum 1996: 142). Minimalism, this critic declared, involved "a complete collapse in standards of scientific talk about natural language syntax".

These heretical judgements cut no ice with Chomsky's followers. The mantle of intellectual guru had settled firmly on his shoulders in the 1960s, and sits there comfortably still. Late in 1998, for example, his theory of minimalism was reported as a quarter-page news item—not a book review, nor even a feature article—in a British national newspaper. This largely explains his reviewer's ill-tempered use of vocabulary such as "risible".

In truth, the rot had set in long before minimalism. Chomsky's own standards of rigour had always been much lower than was generally believed. This fact, which became clear (to those with eyes to see) in the mid-1970s, is important for cognitive science in general, and is discussed in Section ix.e.

The many theoretical changes in Chomsky's later writings, whether rigorous or not, don't concern us. The huge impact of Chomsky's work on cognitive science resulted from his first three books, and was already integral to the field by the 1980s.

However, two of Chomsky's post-1957 theory changes do have a wider relevance, so merit mention here. The first was his increasing stress on "modularity". His style of linguistic nativism always implied that the language "faculty"—or, as he also says, "organ"—is a self-contained part of the mind, functioning in independence of others. Over the years, he made this more explicit (now, he analyses the language faculty itself into distinct sub-modules: Chomsky 1986). Moreover, he speculatively generalized it to other mental "faculties" (Chomsky 1980*a*).

The idea of modularity didn't originate with Chomsky. Conceptualized as "hierarchy", it had already been stressed by Simon, in his widely read discussion of the design (and evolution) of complex computational systems (Simon 1962/9). Chomsky's championing of it influenced (and drew support from) research in the psychology of vision and developmental psychology (Chapter 7.v and vi); ran in parallel with the incorporation of expertise (as opposed to general reasoning methods) in AI (see Chapter 10.iv.b–c); and inspired an influential philosophy of mind developed by Fodor (16.iv.c–d).

Nevertheless, the general relevance of modularity is controversial (see Chapter 7.vi.d–i). It has been challenged, for instance, by wide-ranging research in developmental psychology (Karmiloff-Smith 1992). And Simon's arguments about the evolutionary necessity of modularity have recently been questioned by the philosopher Tadeusz Zawidzki (1998). He argues that Simon's desideratum that evolution pass through "stable intermediate stages" is met by Stuart Kauffman's models of genetic regulation (see 15.ix.b), which are *not* decomposable into separate, hierarchical, parts.

The second broadly influential change was that Chomsky included semantics in *Aspects*, having previously ignored it.

c. Semantics enters the equation

By introducing semantics into the discussion, Chomsky was trying (for example) to account clearly for the deviance of sentences like "Colourless green ideas sleep furiously", and to decide whether they should be regarded as truly grammatical.

This word string *seems* to be grammatical: two adjectives and a noun, making a nice NP, and a verb and adverb providing the necessary VP. From the syntactic point of view, then, it appears to be fine. (Some people even claimed to be able to give it a meaningful interpretation.) Nevertheless, there does seem to be something wrong with it—but what, exactly?

To deal with that question, among others, Chomsky now (in *Aspects*) said that any generative grammar must have both a syntactic and a semantic component. And he regarded the latter as "purely interpretive". That is, each deep-structure (syntactic) expression is sent to a semantic rule system, which gives it a formal description in terms of (universal) semantic primitives. These include the distinction between mass and count nouns, and between human, animate, inanimate, or abstract things.

Because the semantic component was supposed to be only interpretative, "it follows that all [this] information . . . must be presented in the syntactic component of the grammar" (Chomsky 1965: 75). But there is no a priori answer, he said, to the question whether—and if so, to what extent—it should influence the generation of syntactic structures. He did include various semantics-based "selectional rules" restricting the structures that his syntax could generate. But he pointed out that these could be transferred to the semantic component; conversely, all of the semantic interpretative rules might be applied before some of the syntactic generative rules, "so that the distinction between the two components is, in effect, obliterated" (Chomsky 1965: 158–9). In short, Chomsky regarded questions about the relation of syntax to semantics as a matter of judgement, not principle.

His close MIT colleagues Jerrold Katz and Fodor (1963) agreed that syntax and semantics are to some extent intertwined. Nonetheless, they insisted that we need a specifically semantic theory to describe and explain the role of meaning in language. Moreover, they said, such a theory would contribute to (and draw on) the psychology of language. Our ability to understand the meanings of novel sentences must depend on the meanings of the constituent words (morphemes).

This implies, they argued, that we need a semantic "dictionary" of morphemes, and also an understanding of the principles by which meanings can be sensibly combined. A dictionary and grammar alone cannot explain understanding. The prime reason for this is that many words are multiply ambiguous (*bank*, *bill*, *seal*, *bachelor*), and the dictionary must include all the possible senses. Syntax cannot always do the disambiguating for us: *He banked the bill* isn't ambiguous, but *They were approaching the bank* is. In addition, then, we need "projection rules" for using the dictionary and grammar, which take account of the meaning relations between morphemes in generating semantic interpretations of sentences.

The burgeoning interest in semantics took many forms. One of these was "generative semantics". This label, originated by Lakoff in 1963 (before the publication of *Aspects*), was attached to a number of theories in the late 1960s to mid-1970s (Dean Fodor 1977; R. A. Harris 1993, chs. 5 and 6; McCawley 1995). The single label obscured various differences, both theoretical and political.

Some generative semanticists criticized Chomsky's reliance on mathematical models, as opposed to detailed linguistic data. Some even saw Chomskyans as "scientific Calvinists" out of touch with the anti-elitist counter-culture of the 1960s (McCawley 1995: 344–5). Politics aside, the charge of mathematical affluence combined with data poverty would be levelled by many other critics too. But those generative semanticists who did focus on mathematical models argued that the basic generative system was semantically driven and interpreted by syntactic rules, rather than the other way around (see above).

It was as though they were saying "Meaning first, syntax afterwards"—which, at least on first hearing, is intuitively plausible. However, after "some years of involved and at times acrimonious argument", it was eventually agreed that there was less difference between the two positions than had been supposed (Lyons 1991: 93). Both "generative" and "interpretative" semantics concerned (timeless) linguistic competence, not performance. Giving the generativity to the syntax or to the semantics made little difference in the types of sentence that could be (non-procedurally) accounted for.

In general, a semantic theory should give us a principled account of synonymy, and explain the (non-syntactic) ambiguity of *The bill is large*, and its resolution in *The bill is large but need not be paid*. Katz and Fodor assumed that concepts are analysable into distinct semantic components, and posited semantic primitives universal to all natural languages—and all human minds. They explained synonymy in terms of shared entries in a semantic dictionary, and paraphrase in terms of shared semantic structure between sentences that might be lexically and syntactically very different (*The oculist examined me/I was inspected by the eye-doctor*). Different senses of one word (such as *bachelor*) falling in the same syntactic category (*noun*) were identified by differing "semantic markers" (primitives such as *Human*, *Animal*, *male*) and "distinguishers" (for instance, *never married*, *young knight*, *first academic degree*, *young fur seal*).

The componential analysis of meaning is a tenet of classical empiricism—found in Locke, for instance. But there are difficulties about how to identify semantic primitives (for example, how to differentiate Katz–Fodor markers from distinguishers—Dean Fodor 1977: 144–55). Worse, it's not obvious that the componential assumption is true. Even in apparently simple cases, such as the concept of *cousin*, it's not clear what the analysis should be. If one uses the 'obvious' constituents *mother*, *father*, *son*, *daughter* (and perhaps *brother* and *sister*), one can't represent someone's being a cousin without committing oneself on the sex of the various people involved (unless disjunctions are included). This problem disappears if one analyses in terms of *parent*, *child*, *sibling*, *male*, *female*; but then one can accept only blood cousins, not cousins by marriage (which would require *spouse*). Moreover, suppose the word *cousin* actually was used in this restrictive way: so what? Someone who creatively used it (in an appropriate context) to include cousins by marriage might raise some eyebrows, but would nevertheless be understood. This example illustrates what the philosopher Friedrich Waismann (1955) had called the "open texture" of language.

Scepticism about componential analysis and the identification of semantic primitives arose in linguistics, philosophy, and AI (e.g. Fodor 1970; Kempson 1977; Wittgenstein 1953: 31 ff.; Wilks 1978; Sampson 1979*b*). It was one reason why generative semantics went out of fashion. Fodor, for instance, abandoned his "primitivist" account, and later suggested—following the psychologist Eleanor Rosch (1978—see Chapter 8.i.b)—that certain psychologically salient concepts may be the semantic focus of language (Fodor 1983).

Besides these criticisms, however, a very different account of semantics—an account based in mathematical logic—began to gain ground by the mid-1970s (Dowty *et al.* 1981). Componential analysis, in the most general sense, was retained. But the components were now conceptualized as abstract ontological entities and mathematical relations, not as familiar notions such as *Human*, *Animate*, *parent*, *child*, or *male*. The assumption that the distinction between syntax and semantics is a matter of judgement and emphasis was roundly rejected. Moreover, the psychologism of Chomsky and his followers was rejected too.

In short, the Chomskyan paradigm was being challenged. This approach to semantics is outlined in the next section, along with some other important anti-Chomskyan work. Some of this would cast doubt not only on his *grammar*, but on his position on cognitive science in general.

9.ix. Challenging the Master

Some of the new theories challenging Chomsky would undermine only his linguistics, strictly so called. People not especially enamoured of NPs and VPs might not be much interested. Indeed, they might be downright bored.

But other challenges would also reject his close juxtaposition of language and mind, with its supposed implications for both philosophy and psychology. And one would drive a coach and horses through his claim that phrase-structure grammars are inadequate—so hugely improving the power of computer models of language.

In this section, I'll highlight these points of general interest, rather than concentrating on strictly linguistic nit-picking. Some nit-picking, however, there will have to be.

a. Linguistic wars

The grammarians who disagreed with Chomsky did so for a variety of reasons. Accordingly, the "linguistic wars" of the 1970s and early 1980s involved many different skirmishes (R. A. Harris 1993). One linguist in the mid-1980s identified forty-two competing grammars by name, ominously adding "among others" at the end of the list (Yngve 1986: 108).

Broadly speaking, the non-Chomskyan combatants fell into two armies. On the one hand, there were people who, perhaps even before Chomsky's first publications, took a fundamentally different approach to syntax. They might be spurred to greater clarity by his highly formal example. But they didn't accept his theory—or even his goal.

The London School, for example, didn't aim at a generative grammar from which all possible sentences could be derived (Sampson 1980: 212–35). Founded in the 1920s by J. R. Firth (1890–1960), these linguists focused on the functional properties of language as communication.

Where grammar was concerned, they asked how syntactically different types of sentence relate to different communicative contexts. They were much less interested in (Chomskyan) questions concerning word-by-word derivations of individual sentences, or decisions about whether a particular word string is grammatical. Like the Port-Royalists, they saw grammar as a communicative system that happens to be formalizable. Chomsky, by contrast, saw grammar as a formal system that happens to be used for communication. (His prioritizing of formal syntax was criticized also by philosophers working on speech acts, whose research dealt with issues—of meaning and speaker's intention—he left untouched; Searle 1972.)

Michael Halliday (1925–) was one of the London group. A specialist in Chinese, he had an early interest in machine translation, and was associated with Richard Richens and the Cambridge Language Research Unit, or CLRU (see Preface, ii). But his main contribution to linguistics was "systemic" grammar—later used in one of the first impressive automatic parsers (see Section xi.b).

Halliday classified sentences into a limited set of syntactic types. The speaker has to choose one of these, in deciding how to communicate what they want to say. Each type was defined in terms of the syntactic "features" included in it, and each feature was chosen from a feature set of mutually exclusive alternatives. The features were largely interdependent (hence the name, systemic grammar): choice of a feature not only ruled out its immediate alternatives, but also constrained the allowable feature choices from other feature sets.

Whereas the speaker must make the choices, the hearer uses them to aid interpretation. (An example of how syntax can help understanding is discussed in Section xi.c.) And both speaker and hearer are guided by context: if one syntactic type is more appropriate in context than another, then it will (or should) be chosen. Some linguists applied Halliday's approach to practical problems of language teaching, rhetoric, and literary criticism—hardly grist to the Chomskyan mill.

On the other hand, there were those who followed Chomsky onto his own ground and challenged him there. Unlike the London School, whose general approach pre-dated Chomsky, these linguists couldn't have done their work without him. They agreed that the goal of linguistics is to find some generative grammar—but not necessarily his.

Many merely quibbled about this transformation or that one. Someone could do that, yet still be playing on Chomsky's team. Others risked the charge of heresy by offering a very different transformational grammar.

But some went much further. They excommunicated themselves, by rejecting transformations altogether. And some of these, in turn, criticized Chomskyans' mathematical claims—and even Chomsky's formal skills—in uncompromising, often contemptuous, terms.

b. Who needs transformations?

Chomsky had argued that context-free phrase-structure (CFPS) grammars can't generate natural language, so must be supplemented by transformations. This strategy was theoretically inelegant, especially when—as in the early versions of Chomsky's linguistics—a long list of transformations was involved. But, for a quarter of a century, it was widely assumed to be unavoidable.

Some murmurings, however, were afoot. Even before *Aspects*, Harman had outlined a generative grammar without transformations (see Section vii.c). And the suspicious fact—first pointed out in 1961 (see Section vi.d)—that the class of transformational grammars is unconstrained, being equivalent to a Turing machine, was clarified a decade later by the Stanford logician Stanley Peters (1941–)—Peters and Ritchie (1973). Chomsky himself started to rely less on transformations (see Section viii.b). Eventually, then, some theorists stopped asking which transformations are needed, and asked instead whether they're needed at all.

One person who posed this question was Joan Bresnan (1945–), initially a student of Chomsky's at MIT. Bresnan's linguistics was clearly an example of cognitive science, and was highly influential at Stanford's (early 1980s) interdisciplinary Center for the Study of Language and Information (CSLI). Together with the computational linguist Ronald Kaplan (1946–) she developed "lexical-functional grammar", or LFG—so named because it stressed lexical rules for word morphology, and functional rules governing relationships such as *agent* and *passive* (Bresnan 1978; Bresnan and Kaplan 1982).

These two types of rule replaced some of the transformations defined in *Aspects*. Bresnan still felt some structural transformations to be necessary, and sometimes described her grammar as "transformational" accordingly (Bresnan 1978: 36–40). But she conceptualized them procedurally as online operations on a single string, not as changes in one (deep) string to turn it into another (surface) one. That is, transformations in the literal sense had disappeared.

This was no accident, for the main motivation underlying LFG was to avoid altering already built structural descriptions during the derivation or parsing of a sentence. Bresnan and Kaplan saw this strategy as computationally clumsy and psychologically implausible. Instead of (sequentially ordered) transformations, LFG provided several levels of description that apply simultaneously. In generating a sentence structure, each partial description could only add to, not cause changes in, the partial descriptions already accepted on other levels.

Bresnan took Chomsky's psychologism even further than he had done. In accordance with his structuralist training, Chomsky had developed his grammar first and only then suggested that it had psychological implications. Moreover, when psycholinguistic evidence went against his theory, he retreated into grammar as such: "[my] generative grammar does not, in itself, prescribe the character or functioning of a perceptual model or a model of speech-production" (Chomsky 1965: 9). But LFG was conceptualized from the beginning as the ground of detailed psycholinguistic hypotheses. As Bresnan put it:

> [A realistic grammar requires that we] define for it explicit realization mappings to psychological models of language use. These realizations should map distinct grammatical rules and units into distinct processing operations and informational units in such a way that different rule types of the grammar are associated with different processing functions. (Bresnan 1978: 3)

A realistic grammar, she also said, should be tested by computational methods, as well as by psychological experiments. A prime reason for her collaboration with Kaplan, who also saw grammars as "mental representations of language", was that he'd written computer programs—using ATNs (see Section xi.b)—intended to simulate what goes on in people's minds when they understand a sentence (R. M. Kaplan 1972, 1975). Similar models, and a related programme of psycholinguistic studies, were developed by two of Kaplan's co-researchers—who showed, for instance, how relative clauses could be parsed without backtracking (Wanner and Maratsos 1978; Boden 1988: 100 ff.).

Some years later, the computational linguist Martin Kay (a one-time member of CLRU: see Preface, ii) located Bresnan's work—and that of others discussed below—within the overall space of possible human parsing strategies (M. Kay 1980). He argued that the psycholinguist needn't be strictly constrained by considerations of computational elegance, still less by a devotion to step-by-step (sequential) algorithms. There are many reasons for thinking that people process language in parallel, in the sense that a number of different parsing strategies are at work at the same time, and are somehow integrated in generating the completed parse tree. And there are reasons for thinking that both top-down and bottom-up methods may be involved.

Each point in Kay's abstract space defined an *algorithm schema*, identifying a function to be computed but not saying just how this should be done. Actual algorithms could be generated in a principled way by combining a schema with an *agenda* listing various psychological strategies. These could direct both depth-first and breadth-first search (see Chapter 10.i.d). In addition, Kay discussed in general terms how parsers (using *charts*) could be constructed to avoid unnecessary duplication of effort, such as repeating prior computations during backtracking. When computer parsers proliferated in the 1980s and 1990s, this seminal attempt to see the wood as well as the trees was to be highly influential.

c. Montagovian meanings

Whereas Bresnan had insisted that grammar and psychology should be very closely related, some others who challenged Chomsky's account of language made a point of avoiding that claim. Richard Montague (1930–71) at UCLA was an important example (Dowty *et al.* 1981).

Montague was a logician and philosopher of language, working in the strongly anti-psychologist tradition of Frege (see Chapter 2.ix.b), and inspired by Carnap rather than Chomsky. His work wasn't an instance of cognitive science. He had no interest in the mind or mental processes, nor in computational linguistics. And his theoretical concepts were drawn not from computer science, but from mathematical logic. However, his approach appealed to some linguists whose views were highly relevant to cognitive science, as we'll see. In addition, it was taken up by a highly influential psychologist working on language and reasoning (Chapter 7.iv.e).

His influential paper on "universal grammar" had nothing to say about the relation between language and mind, still less innate ideas (Montague 1970). By invoking a universal grammar he meant, rather, that all languages, both natural and artificial, should be described in the same way. In this belief, he was echoing Carnap (see Section v.a). What was novel about his approach, and what commended it to some linguists, was the unusually close theoretical relation between syntax and semantics.

His system was called "intensional logic", because it dealt with meanings as well as logical formulae. It contradicted Chomskyan assumptions about the autonomy of syntax. It also rejected all semantic theories that merely offered translation into a more basic language—whether this was some form of logic, or a language of semantic primitives. For Montague, to translate one language into another isn't to address the central problem. The crucial questions of semantics concern the relation between linguistic expressions (of whatever kind) and entities in the world.

Logicians had long defined semantics in terms of truth conditions: what would have to be the case in the world for the expression to be true. And they had long assumed compositionality, so that the truth conditions of a complex expression depend recursively on those of its component parts. So far, so good—but just how were truth conditions to be conceptualized?

The logical positivists had answered this question in terms of (pure) observation protocols, but by mid-century it had become clear that this approach had intractable problems. In the 1960s (though not published until after his death in 1970), Montague developed a more abstract answer, and applied it to various types of sentence in English (Montague 1970, 1973).

Criticizing Chomskyan grammar as mathematically imprecise and unsystematic, he went back to Russell's set theory. With this as his ground, he defined "the set of all possible worlds" in terms of an abstract ontology of individuals, properties, *n*-ary relations etc. The semantics of a linguistic expression was then defined as its denotation (its model) in some possible world. That model was found by applying recursive mapping rules, such that each syntactic form (NP, VP, Det, etc.) had a corresponding semantic form. A proper name, for instance, always maps onto some individual.

This 'rule-for-rule' approach coupled syntax and semantics much more closely, precisely, and systematically than Chomsky and his followers had done. The theory of semantic markers, for example, had posited "primitives" such as *Animate* and *Human* (see Section viii.c). But to capitalize a familiar term of English isn't to display its meaning. Moreover, it wasn't clear just how to interpret the bracketed lists of semantic primitives offered by such theories: their syntax didn't establish their meaning. They were understood intuitively, much as the higher-level words (such as *bachelor*) were. In Montague's hands, by contrast, some specific—albeit highly abstract—meaning was definitively implied by the syntax.

Montague's theory was mathematically elegant, but couldn't solve most of the problems about meaning that had long plagued linguistics. He held, for example, that if a rule-for-rule mapping of a given English sentence succeeds in all possible worlds, it is necessarily true—and semantically equivalent to every other such sentence. Yet the component words of these distinct sentences may arouse very different associations in the hearer's mind. If, with Humboldt (or even Bloomfield), one regards these as part of the "meaning" of language, then Montague's theory is inadequate.

Again, semantic relationships such as synonymy, implication, sub/superordinacy, and consistency/inconsistency were rigorously defined by Montague. Synonymy, for instance, requires that both expressions be true in the same set of possible worlds. However, this abstract definition may not help us to decide whether two actual words are synonymous. (Montague agreed with Humboldt that accurate translation from one natural language to another is impossible—not because of different mental associations, but because it's unlikely that any two sentences in the different languages will share the same mapping in model theory.) Nor did his approach help in defining *cousin*: all the problems noted in Section viii.c, including the open texture of natural language, remained.

The new semantics offered clear definitions for everyday words such as *the*, *every*, *some*, *all*, *any*, *never*, *ever*, all of which are notoriously difficult to define in dictionary style. They were interpreted by Montague as set-theoretic expressions defined over possible worlds, whose logical–mathematical relations could be precisely stated.

However, most of the long-standing problems about assimilating natural language to logic had been brushed aside, rather than solved (see Chapter 4.iii.c). As for sentences about propositional attitudes, these were as intractable as ever (Dowty *et al.* 1981: 170–5). No semantic mapping for *Mary believed that the bracelet had been lost* could be completed, because the bracelet's fate still had to be left open (see Section v.a).

Model-theoretic semantics was a further step along the road of formalism pioneered by Frege, Russell, and the early Wittgenstein. This road had been followed also by Carnap and Reichenbach. But whereas in the 1930s–1940s few linguists had paid much attention to Carnap's work on language, by the 1970s linguistics itself was largely formalized, and had been strongly linked (by Chomsky) with the analysis of artificial languages. In other words, the ground had been prepared for Montague.

Even so, persuading linguists to read Montague took some time and effort. His work was so fiercely abstract, and so tersely written, as to border on unintelligibility. Most linguists tackled it by way of some introductory account, preferably one relating set theory (more familiar to philosophers of language than to linguists) to transformational grammar. Barbara Partee (1975) was especially influential in introducing Montague's ideas to other linguists. But even four years later, professional journals were still prepared to publish explanatory notes on Montague rather than original research, defending their decision by reference to his forbidding writing style (Halvorsen and Ladusaw 1979: 185).

After the mid-1970s, when (thanks to Partee) linguists in general became aware of him, Montague's work soon came to dominate theoretical semantics, and various theories of syntax too. (Ironically, Chomsky himself now puts much less stress on formalization than he used to, and even queries the relevance of "most of the results of mathematical linguistics"—Lyons 1991: 199.)

Psycholinguists, however, virtually ignored Montague. (Although some would take up his theories in the early 1980s: see 7.iv.e.) Being ignored by the psycholinguists wouldn't have bothered him at all. As remarked above, his theory was a purely logical–ontological one, making no claims about psychology.

d. Transformations trounced

Among the linguists inspired by Montague in the mid-1970s was Gerald Gazdar (1950–), of the University of Sussex. Together with Ewan Klein, Geoffrey Pullum, and Ivan Sag, Gazdar developed a new syntactic theory: generalized phrase-structure grammar, or GPSG (Gazdar 1979*a*, 1981*a*, 1982; Gazdar *et al.* 1985). GPSG adopted Montague's model-theoretic approach, and applied it to a much wider range of English syntax than he had done.

Like Montague, Gazdar treated language as a purely formal system, not as a psychological phenomenon. Nevertheless, he was inspired also by the psychologically oriented Bresnan. What drew him to Bresnan's work wasn't her use of grammar to relate language and mind, but her rejection of syntactic transformations.

Another formative influence was Peters—who in 1973 had expanded Putnam's insight about the Turing equivalence of transformations in general (see above). Gazdar took this mathematical discussion still further. Besides co-developing GPSG, he directly challenged some of Chomsky's formal claims about the power of various types of grammar. In so doing, he implicitly cast doubt on arguments that had influenced cognitive science in general (see Section ix.e–f).

In formulating GPSG, the prime aim of Gazdar and his associates was to develop a single-level (non-transformational) tree-based grammar that would describe English elegantly. That task could be, and often is, approached without any concern for the abstract mathematical properties of language. But two of the authors (Gazdar and Pullum) had already claimed that the widely accepted arguments against CFPS grammars were either formally invalid or based on false empirical premisses. Indeed, their work had revived interest in this long-neglected question, and led to some improved arguments for the opposing view (G. Gazdar, personal communication).

Partly because of this interest (which not all syntacticians shared), and partly as a matter of methodological discipline, the GPSG group took pains to prove that their new account of syntax was mathematically equivalent to a CFPS grammar.

The GPSG authors were careful not to claim that GPSG can describe every natural language, although they pointed out that it seemed to fit about twenty diverse tongues (Gazdar *et al.* 1985: 15). But they did assume that it could describe the whole of English.

Soon afterwards, it became clear that this was almost true, but not quite (see below). Nevertheless, it was evident by the early 1980s that GPSG could successfully describe a host of English sentences which Chomsky had said require appeal to transformations. Moreover, no extra rules had to be added to link each syntactic form with its semantic interpretation. These relations were transparent, by virtue of a model-theoretic account of the mapping between syntax and semantics.

GPSG captured the grammatical intuition noted in Section vi.d, that *The man reads the book*, *The book is read by the man*, and so on, are closely related. Nevertheless, it considered only the surface string, so didn't need transformations (which were introduced to derive surface-level from deep-level structures). It specified only a set of phrase-structure rules. GPSG was more flexible than the phrase-structure grammars considered by Chomsky, because in addition to the familiar syntactic categories (S, NP, VP, Det, and so on) it contained three other formal devices: slash-categories, metarules, and linking rules.

A slash-category marks a constituent with a syntactic gap: so S/NP, for instance, represents a sentence with a noun phrase missing. As this example shows, the nature of the gap was defined in terms of the basic (and familiar) phrase-structure rules. Given slash-categories, the problem arose of defining how the grammar should deal with them. Consider S/NP: this must denote either *an NP-missing-an-NP followed by a VP*, or *an NP followed by a VP-missing-an-NP*. These are the only possible interpretations, given that the basic grammar prescribes that S $\rightarrow$ NP + VP. Other slash-categories may allow more than two possibilities.

One might have expected, therefore, that GPSG would include an inelegant profusion of extra rules, several for each slash-category. Not so: instead, Gazdar's grammar contained a small number of metarules. Each of these was a general rule schema, from which (together with the basic rules) the new rules required for a given slash-category could be derived. Finally, the (more numerous) schematic linking rules dealt with the housekeeping: they defined how to introduce and delete slash-categories, and enabled the gap to be carried down to lower levels of the parsing tree as necessary.

This new grammar not only dealt with all the sentences generated by transformational grammar, but also explained some things simply which Chomsky could explain only in tortuous ways. For instance, consider these two sentences: (1) I think *Fido destroyed the kennel*, and (2) The kennel, I think *Fido destroyed*. Most linguists (including Chomsky) had assumed that the two italicized expressions fall into the same syntactic category—namely, a (subordinated) sentence. But because the second expression isn't a complete sentence (it cries out for a noun phrase telling us what Fido destroyed), they had to give a complicated account of (2) in order to show this. GPSG, by explicitly labelling the gap, placed the italicized strings in different syntactic categories. But it enabled one to give equally simple descriptions of how to generate the two whole sentences (Gazdar 1981*a*).

GPSG had a significant influence on linguistics, being taken up by a number of syntacticians in the early 1980s. Clearly, it could achieve a great deal—but how much? It seemed to encompass English, and at least twenty other languages too. But there were growing doubts. It was already known that some European languages contain phrase-structure trees lying outside GPSG, and in 1984 two further languages—one from West Africa, another a Swiss dialect of German—were found to contain recalcitrant sentences (Gazdar *et al*. 1985:16; Gazdar 1998). Indeed, English itself, as Klein had discovered, contains some sentences—involving nested comparatives—that couldn't be described by GPSG.

Accordingly, Sag went on to develop an improved, but no longer context-free, version: "head-driven" phrase-structure grammar, or HPSG (Pollard and Sag 1994). And Gazdar showed that both GPSG and HPSG were special cases of "indexed" grammar. This is a general type located just above context-free grammar in the abstract Chomskyan hierarchy, but still appreciably below context-sensitive grammar (Hopcroft and Ullman 1979: 389–92).

Even within linguistics, however, GPSG didn't attract attention as widely as it deserved. This was largely due to the sociological factors cited in Section viii.a—including the *not invented here* syndrome that still pervades MIT. Stanford, to be sure, was open to Gazdar's theory—but CSLI didn't rule the world.

Today, much of the best work on non-Chomskyan syntax (including LFG, GPSG, and HPSG) is done in departments of computational linguistics, not of linguistics as such. This is only partly because the theorists concerned are interested in computer modelling. More to the point, they are "locked out" of the many departments of linguistics still dominated by the Chomskyan paradigm. One indication of this dominance is the fact that the term "generative grammar" is sometimes used as if it referred only to Chomsky's work—the current version of which is arguably not generative at all (Gazdar *et al*. 1985: 6).

e. Why GPSG matters

In cognitive science *as a whole*, GPSG was even less well known than in linguistics. In a sense, it was its own worst enemy. For it was yet more fiercely abstract than Chomsky's early publications had been. Non-specialists would need plenty of black coffee.

Moreover, the GPSG linguists, unlike Chomsky, had no desire to discuss broad issues of "language and mind". And, unlike Bresnan and Kaplan, they had no interest in psycholinguistics. They drew no psychological morals from their grammar, and no psychological discovery could either support or falsify their (purely formal) work. Some psycholinguists, including Janet Fodor and Rosemary Stevenson, did experimental research inspired by GPSG (G. Gazdar, personal communication). But because of the GPSG group's explicitly anti-mentalist stance (and their limited visibility in professional linguistics), most psychologists were unaware of their work.

Nonetheless, it was—and is—potentially important for cognitive science in five different ways. (Four are discussed in this subsection, and the fifth in the next.)

First, GPSG questioned Chomsky's fundamental critique of CFPS grammars. He had admitted that he couldn't strictly prove that English lies beyond any conceivable phrase-structure grammar. Now, his claim (his hunch) that it could be so analysed, if at all, "only clumsily" had been challenged. GPSG, which covers most if not quite all English sentences, is a formally elegant theory, not a clumsy one. It didn't deserve Chomsky's contemptuous accusation that it was "simply a needlessly complex variant" of a transformational theory, supplemented by "a class of superfluous devices" (Gazdar 1981*a*: 280–1).

Moreover, if natural languages can indeed be described by some context-free phrase-structure grammar (a CFPSG, for short), then a huge mathematical literature becomes potentially relevant. This literature was developed (partly as a result of Chomsky's papers of the early 1950s) in theoretical computer science, to deal with the parsability and learnability of programming languages.

Compiler programs, for instance, have to parse context-free programming languages in order to translate them into machine code. This is "perhaps the most researched and best understood area of formal language theory" (Gazdar 1981*a*: 275). In other words, and as Montague had already shown, the mathematical analysis of language—and, significantly, the comparison of natural and artificial languages—can be taken much further than Chomsky took it.

Third (a corollary of the previous point), the standards of rigour set by Harris and raised by Chomsky had been raised further still. Indeed, Chomsky's own standards had already been criticized by people outside the GPSG group. The Stanford-based logician Montague didn't even deign to criticize them, but contemptuously ignored "the attempts emanating from the Massachusetts Institute of Technology" (Montague 1973: 247). He was presumably offended by (among other things) Chomsky's basing his core claim about the necessity of transformations not on a proof, but on a hunch.

Others agreed, and accused Chomskyans in general of not having done their mathematical homework. As remarked in Section vi.a, the technical evidence behind *Syntactic Structures* wasn't published until 1975. Meanwhile, the famous mimeograph ("three thick volumes of faint purple typewriting with handwritten annotations") had probably been read only by a handful of those who had bothered to get hold of it (Sampson 1979*c*: 356).

One reviewer of the published version confessed that he himself had for years taken on trust Chomsky's hints that the theoretical lacunae in *Syntactic Structures* had already been filled in by the work presented in those purple pages. He confessed also that when he did finally get hold of a copy (while waiting to receive the published book for review), he "rapidly laid it aside" because of its near-illegibility. And he acidly commented:

> The publication of this book [in 1975] symbolizes a remarkable situation in the recent history of linguistics, a situation which can hardly have many parallels in other disciplines . . . [For the best part of two decades], during the heyday of Transformational Grammar, its hundreds of thousands of advocates in the universities of the world not only didn't but *couldn't* really know what they were talking about. (Sampson 1979*c*: 355–6)

Part of the explanation for this unhealthy state of affairs was that most linguists couldn't have understood Chomsky's manuscript even if they had read it. Realizing this, they'd been content to leave its arcane mathematics to the "high priests" at MIT, assuming that it answered all their theoretical questions. But they were mistaken. Those with mathematical eyes to see would find, when they did actually read it, that Chomsky's argument was often "maladroit" and "perverse", and sometimes "just plain wrong" (Sampson 1979*c*: 366).

(I must confess that I can't justify this claim at first hand, for I *don't* have mathematical eyes to see. Several specific examples have been pointed out to me, but I have to take them on trust. However, I'm a colleague of two of Chomsky's major 'mathematical' critics, Gazdar and Sampson, and I've pressed both of them hard on whether they really mean what they say in the passages I've quoted. They do.)

Many of Chomsky's mistakes, according to Sampson (1979*c*), were "elementary", and some were crucial. For example, he'd repeatedly claimed that the syntactic phenomenon of "Affix Hopping" can be stated as a single transformation (though he never showed just how to do so). That claim had persuaded many linguists into his camp. Yet it now appeared, Sampson complained, that one of his own formal definitions rendered it impossible. In other words, Affix Hopping had arguably been "a standing refutation of [his] theory throughout its history". Yet Chomsky had never discussed this problem (Sampson 1979*c*: 365).

In light of such points, the professional adulation of Chomsky was—or anyway, should have been—distinctly embarrassing. To be sure, most linguists weren't mathematical animals. But their misplaced admiration for Chomsky's formal work was due to more than mere ignorance. It was encouraged by sociological factors: his by-then-established grip on departments of linguistics, and his towering status as a worldwide guru.

Similarly negative judgements of Chomsky's work and influence have been expressed for twenty years by Gazdar and his colleagues. Indeed, it was Pullum who recently dismissed Chomsky's theory of minimalism as "risible" (see Section viii.b). Admittedly, Gazdar had earlier declared—and still does (personal communication)—that *if* any work in syntactics is to be called "foundational", as Frege's work was foundational for mathematical logic, then it is Chomsky's—especially his hierarchy of grammars (Gazdar 1979*b*: 197). But that's not to say that he saw all of Chomsky's "proofs" (in Chomsky 1975) as equalling Frege's in respect of precision and accuracy. To the contrary, he didn't.

Commenting on Chomskyan linguists in general, Gazdar's group pointed out that "mathematically respectable" proofs of general claims about grammars are very difficult to obtain. For instance, new versions of transformational grammar had been proposed (by Chomsky and others) which were held to be formally equivalent to, though more elegant than, some previous version; and linguists often claimed that such-and-such a structure cannot be generated by this or that grammar. But proving it was a different matter. Since most Chomskyans didn't even try to do so, the GPSG theorists were less than impressed:

> Such claims [about the formal equivalence and computational power of different grammars] are made in many contemporary linguistic works without there being any known way of demonstrating their truth. In some works we even find purported "theorems" being stated without any proof being suggested, or theorems that are given "proofs" that involve no definition of the underlying class of grammars and are thus empty. (Gazdar *et al.* 1985: 14)

Rigour was necessary, they said, not just for clarity and a good mathematical conscience, but for providing explanation. Thus any proposed "universal" should be a necessary consequence of some formal definition of the class of natural grammars. Otherwise, it is (at best) a description of some feature found, as a matter of fact, to be universal—without any understanding of why this is so (pp. 2 ff.). This point was similar to Marr's claim that we can explain visual processing only if we can relate it to (ideally, derive it from) the abstract constraints on vision as such: Chapter 7.iii.b.

A fourth point of interest for cognitive science as a whole is that GPSG implied that Chomsky's nativist 'argument from ignorance' against behaviourism must be reconsidered. Even if the simple learning theories popular at mid-century are inadequate to explain language acquisition, because they cannot parse phrase structure, some more sophisticated—but still purely surface-level—version might succeed. In other words, GPSG might be learnable (without the need for any dedicated acquisition device), even if transformational grammar isn't.

To be sure, the framework for this more powerful type of 'induction' might be innate: even Quine had allowed that "unquestionably much additional innate structure is needed . . . to account for language learning" (see Section vii.c). Even so, and although linguistic nativism hadn't strictly been disproved by Gazdar's work, the empirical evidence demanded years before by Black had become even more necessary.

One reason why GPSG didn't spread widely throughout cognitive science was that evidence for some sort of language-specific nativism was by then more abundant. Besides the developmental studies mentioned in Section vii.c, it included analysis of the many detailed features of human anatomy and physiology seemingly evolved specifically (*sic*) for language (Lenneberg 1967), and the apparent impossibility of teaching even simple grammatical structure to non-human primates (Chapter 7.vi.c).

In addition, neuroscientific evidence for *visual* nativism had—seemingly—been accumulating since the 'Frog's Eye' discoveries in the late 1950s (Chapter 14.iv & vi). And the new popularity of modular theories of mind (see above) discouraged reliance on general learning mechanisms to explain language acquisition.

That's not to say that nativism had been conclusively proved, for it hadn't. Despite the best efforts of Chomskyans to marshal their evidence (Pinker 1994), the facts didn't—and still don't—show that language, even linguistic universals such as coordination and hierarchical structure, can't be learned and/or evolved (Sampson 1997, esp. chs. 3 and 4). Furthermore, even if the nativists were right, Black's point still stood: the nature of the innate dispositions supposedly concerned, and of their neurophysiological implementation, were—and still are—unclear.

Indeed, the notion of nativism is itself unclear. Recent research in both psychology and neuroscience has shown how over-simple it is to label behavioural or anatomical features as 'innate' (see Chapters 7.vi.g and 12.viii.c).

The fifth important aspect of GPSG is perhaps the most significant of all. It has deep implications for both psychology and software technology, and especially for NLP.

f. Computational tractability

Because of its equivalence to a CFPS grammar, GPSG is less computationally demanding than transformational grammar. And that means, in a nutshell, that more can be achieved by relatively simple systems—whether minds or machines—than Chomsky believed.

With respect to psychology, GPSG suggested (for instance) an explanation of why people can parse natural language so rapidly (Gazdar 1981*a*: 276). And it lessened the difficulty of seeing language as the product of evolution, since context-free parsing algorithms are less evolutionarily improbable than transformational ones. More generally, if natural languages are indeed CFPS structures, then psycholinguists don't need—so shouldn't propose—psychological theories with the power of a context-sensitive grammar.

This is a special case of Lloyd Morgan's canon, framed in the late nineteenth century to promote intellectual hygiene in comparative psychology (see Chapter 2.x.b). Conwy Lloyd Morgan had forbidden explanation in terms of "a higher psychical faculty" if the behaviour in question could also be explained in terms of "one which stands lower in the psychological scale" (Lloyd Morgan 1894: 53).

For sixty years, this hugely influential advice could be followed only by relying on some intuitive sense of what counts as a "higher" psychical faculty. But Chomsky's hierarchical classification of grammars had, in effect, defined "higher" in terms of distinct levels of computational power, requiring processing mechanisms of specific types—with or without push-down, for example. (This enabled 'extra' levels to be inserted in the hierarchy: indexed grammar, for instance, lying above CFPSGs but still significantly below context-sensitive phrase-structure grammars, or CSPSGs.)

In short, the linguistic hypothesis that natural languages can be described by CFPSGs implied a psychological hypothesis about the minimum computational power required by the human mind/brain. Humboldt's "creative spirit of humanity" would have to rise as far as CFPSGs to generate language, but—if the GPSG theory was correct—need rise no further.

As for the software implications of GPSG, these were quickly recognized and highly influential. By the early 1980s, this grammar had already been adopted in various NLP projects in Europe, Japan, and the USA.

One of these was the "Alvey Tools Grammar", developed for the UK's Alvey Project (11.v.c) and still in use in various places today. And Sag's HPSG, which shares many features with GPSG although it isn't context-free (it permits unbounded recursion in certain circumstances), is now probably the most widely employed grammar formalism in NLP, especially in Europe (G. Gazdar, personal communication). (Very recently, Gazdar (1998) has defined a class of grammars, which includes GPSG, that is mathematically equivalent to a type—known as "linear tree adjoining grammars"—now gaining popularity in NLP circles.)

These NLP projects of the 1980s fell clearly into "technological" rather than "psychological" AI (see Chapter 1.ii.b). GPSG's psychological plausibility was irrelevant. So was the 'pure' linguist's question whether it could describe *every* syntactic construction in *every* human language. From the point of view of NLP research, that question is comparable to theological disputes about angels dancing on pinheads. What was important about GPSG, besides its success in describing almost the entire range of English (and some other languages), was its computational tractability.

Even devotees of GPSG, however, don't deny Chomsky's seminal importance. His work, besides affecting computer science as such, profoundly influenced NLP. Or rather, his classification of different types of grammar did so. His ever-changing syntactic theories have had less influence here. Partly because of his own lack of interest in, even hostility to, computer modelling, very few Chomskyan programs have been written (but see Chapter 7.ii.b). And, for reasons remarked above, many computational linguists are explicitly anti-Chomskyan. However, to be anti-Chomskyan isn't to be uninfluenced by Chomsky: LFG, GPSG, and HPSG were all developed in reaction to his pioneering efforts.

Moreover, Chomsky's formal–generative approach to linguistics in the late 1950s (and his linking of different grammars to different automata) buoyed the spirits of people already doing computer modelling of language, and encouraged others to start trying. (Section x will recount the early development of this field.)

g. Linguistics eclipsed

The last item within the tenfold Chomsky myth (i.a, above) was that linguistics is as prominent in cognitive science today as it was in the 1950s–1960s. That's not true. Ironically, its eclipse was largely due to Chomsky himself.

Part of the problem was his continual recasting of his own theory of syntax, described above. But that alone wouldn't have sufficed: if the price of doing good cognitive science had been keeping up with Chomsky, then that price would have had to be paid. More important than his inconvenient changes of mind was his mid-1960s distinction between *competence* and *performance* (Chapter 7.iii.a). This put a theoretical firewall between the psychology of language and linguistics as such. The firewall prevented commerce in both directions. Linguists, in effect, had been instructed to take no heed of psychology. But by the same token, psychologists were tempted to regard abstract linguistics as largely irrelevant to their concerns.

Researchers in non-linguistic disciplines didn't stop working on language, of course. But they stopped looking to Chomskyan theory for their key inspiration. As for the people who weren't working on language, they no longer gave linguistics a second thought. The general lessons (about formalization and generativity) that Chomsky had taught had been well learnt, and were no longer thought of, at least by the youngsters entering the field, as having any special connection with linguistics. By the 1990s, the discipline was "arguably far on the periphery of the action in cognitive science" (Jackendoff 2003: 651).

Recently, things have started to change. For instance, Pinker has put linguistics in the context of cognitive psychology, and in particular of evolutionary psychology (Pinker 1994, 1997, 2002). Moreover, the late 1990s saw a new field being named: cognitive linguistics. Its adherents are *linguists*, but linguists who take special note of the cognitive processes involved in using language (see 7.ii, preamble, and 12.x.g).

Similarly, the Brandeis (now Tufts) linguist Ray Jackendoff (1945–) has recently tried to integrate linguistics with psychology, neuroscience, and evolutionary theory (Jackendoff 2002, 2003). An ex-pupil of Chomsky, Jackendoff is still wedded to the idea of a universal grammar. But he claims to have shown (what Chomsky questioned) that it's possible for this to have evolved *incrementally*. He also argues that semantics doesn't need to be "paralysed" by a failure to solve the philosophical problem of intentionality (2002: 280). And he couches his argument in computational terms, describing a parallelist architecture (blackboard-based: see 10.v.e, and xi.g below) in which the rules of grammar are directly involved in language processing.

Jackendoff's book is described as a "masterpiece" by one *BBS* commentator, namely the philosopher Daniel Dennett (2003*b*: 673). Others disagree. For instance, another philosopher (F. Adams 2003) complains of its cavalier attitude to semantics and intentionality (although Dennett defends Jackendoff on this point—2003*b*: 673–4). And a neuroscientist objects to its assumption that the brain has evolved specialized components of language, as opposed to a small number of general capacities (he names seven) that make it possible to discover such "components" over the course of many millennia and/or to learn them within a few years (Arbib 2003: 668). Right or wrong, however, Jackendoff's theory is a far cry from Chomsky's chastely firewalled linguistics.

Or perhaps not? Employing the revolutionary analogy cited in Section i.b, Edelman has described Jackendoff's book as

> one of several recent manifestations in linguistics of the Prague Spring of 1968, when calls for putting a human face on Soviet-style "socialism" began to be heard (cf. the longing for "linguistics with a human face" expressed by Werth 1999: 18). (S. Edelman 2003: 675)

Edelman's prognosis for Chomskyan theory isn't hopeful:

> In a totalitarian political system, this may only work if the prime mover behind the change is at the very top of the power pyramid: Czechoslovakia's Dubcek in 1968 merely brought the Russian tanks to the streets of Prague, whereas Russia's Gorbachev in 1987 succeeded in dismantling the tyranny that had sent in the tanks. In generative linguistics, it may be too late for any further attempts to change the system from within, seeing that previous rounds of management-initiated reforms did little more than lead the field in circles. . . . *If so, transformational generative grammar, whose foundations Jackendoff ventures to repair, may have to follow the fate of the Communist bloc to clear the way for real progress in understanding language and the brain*. (S. Edelman 2003: 676; italics added)

To be sure, Edelman isn't a disinterested critic. For he argues, contra the Chomskyans, that the inductive learning of hierarchical structure is in principle possible. He and his colleagues have devised a pioneering "ADIOS" algorithm (Automatic DIstillation Of Structure), which can induce both context-dependent and context-free grammars (Solan *et al*. forthcoming). It uses a combination of statistics and structured generalization to extract hierarchical regularities from input sequences without knowing what patterns to expect, and without being given clues as labels on sequence parts (e.g. part-of-speech tags on the input words). Its only presupposition is that the sequence contains "partially overlapping strings at multiple levels of organization" (p. 3).

ADIOS has been applied to large sets of 'grammatical' sentences (e.g. the Bible and the *Wall Street Journal*), and also to the CHILDES corpus of spontaneous—and largely 'ungrammatical'—speech. (Those scare quotes are needed because Edelman rejects Chomsky's view that only strings fitting some set of abstract syntactic rules can be termed grammatical: language, for Edelman, is what people actually speak.) The system works even better with CHILDES than with the *WSJ* corpus, which Edelman (personal communication) explains in terms of Jeffrey Elman's stress on the importance of "starting small" (see Chapter 12.viii.c): whereas CHILDES contains many short word strings, the *WSJ* contains many longer ones.

In addition, ADIOS has coped well with six natural languages, including English, French, and Chinese. It has also been tested on artificial context-free languages, some having thousands of rules. And it has even been applied to DNA and protein sequences from several species. In each case, it has learnt to recognize the hierarchical patterns involved, and to reject anomalous sequences.

As its success with CHILDES illustrates, it has done this *despite* having ungrammatical strings in the input (which Chomsky saw as a huge barrier to inductive learning). Moreover, simulating the "creativity" of language, it has generated new (and legal) structures too—the first learning algorithm to do so. (The patterns it classifies in the learning phase are transformed into rewrite rules, which are then used for the generation phase.)

It doesn't follow that this is what infants do. Indeed, the authors point out that ADIOS has no access to conceptual knowledge, nor any "grounding" of the verbal input in current action and/or environment. (They also remark, however, that babies appear to use both statistics and rule-learning in acquiring language: Saffran *et al*. 1996; Seidenberg 1997; G. F. Marcus *et al*. 1999.) But ADIOS's success does dispatch arguments for the *necessity* of linguistic nativism.

In sum, linguistics may regain its place in cognitive science—if not as a *root* of theorizing in the other disciplines, at least as an equal, and collaborative, partner. If that happens, however, linguistics will be a very different enterprise from that engaged in by Chomsky.

9.x. The Genesis of Natural Language Processing

At mid-century, Harris wasn't the only person hoping to apply computer technology to linguistic problems. On both sides of the Atlantic, there were people "enchanted by the idea that [machine-based experiments to test linguistic hypotheses] could now be performed in the flesh rather than only in the spirit" (Bar-Hillel 1970: 293). And some were already doing so.

The late 1940s and early 1950s saw the first computer models for NLP. These attempted machine translation (MT), automatic classification, information retrieval (IR), text generation, and (for a while) the induction of grammars.

As it happened, these topics weren't the focus of the early research in any of the three pioneering AI labs at MIT, Stanford, and Carnegie Mellon (see 10.ii.a). Consequently, when people talk about the origins of AI they often ignore work in MT which pre-dated their foundation. By the same token, however, when MT suddenly fell into disfavour in the mid-1960s (a story told in Section x.e–f, below) AI as a whole—although it suffered—wasn't so badly affected as one might have expected.

a. Ploughman crooked ground plough plough

Hopes for automatic translation long pre-dated the computer age. It had been envisaged in some of the "universal language" projects of the seventeenth century (see Section iii.d, above). And the first (purely mechanical) MT patents had been taken out, in Russia and France, in 1933.

Whereas the French patent merely described a simple paper-tape dictionary that stored equivalent words in several languages, Petr Smirnov-Troyanskii's (1894–1950) machine could transform a grammatical analysis of a sentence in one language into its equivalent in another. Moreover, he claimed that it should also be possible to automate the (two-way) conversion between these analyses and actual sentences. But he wasn't able to demonstrate this, for lack of funds.

As late as 1944, the Institute of Automation and Telematics refused his bid for support; and his 1948 design for an electromechanical machine similar to the Harvard Mark I (see 3.v.b) was similarly ignored. (He died two years later, so had no chance to develop it.) This lack of appreciation was perhaps inevitable, for his ideas about MT were far ahead of his time:

> In retrospect, there seems to be no doubt that Troyanskii would have been the father of machine translation if the electronic digital calculator had been available and the necessary computer facilities had been ready. History, however, has reserved for Troyanskii the fate of being an unrecognised precursor; his proposal was neglected in Russia and his ideas had no direct influence on later developments; it's only in hindsight that his vision has been recognised. (W. J. Hutchins 1986: 24)

With the development of computers in the UK and USA, their use for various language-related purposes soon followed. In 1946, for instance, Andrew Booth (1918–) of Birkbeck College, London, suggested using computers for translation—and had designed and built a computer by 1947 (Lavington 1975: 5). In the late 1940s he started work with Richard Richens on what would become a lifelong project (Richens and Booth 1955; Richens 1958; Booth 1967, p. vi), and in the early 1950s he co-edited the first volume on MT (W. N. Locke and Booth 1955).

Richens, who was later attached to Margaret Masterman's Cambridge Language Research Unit (CLRU), has been credited with "the first serious contribution" to MT (Bar-Hillel 1959: 303; 1970: 303). His work (initially carried out by hand simulation using punched cards) was interesting not least because it considered grammar as well as vocabulary: the input verbs were split into stem and affix, so that *start*, *started*, and *starting* would have only one vocabulary entry, while *-ed* and *-ing* could be attached to indefinitely many different verbs. Booth and Richens's first experiments on MT were mentioned at a conference (on 'Science Abstracting') in Paris in June 1949, and featured briefly in the *Scientific American* six months later. But they became more widely known thanks to Warren Weaver's memo on MT, written after Booth's visit to the USA in 1947.

Booth's discussions in 1947 with the information theorist Warren Weaver, then Director of the Natural Sciences Division of the Rockefeller Foundation, indirectly influenced the initiation of MT research in America. MT programmes were set up at several US universities in the early 1950s, as a result of an influential memorandum written by Weaver two years after Booth's visit (Weaver 1949; W. J. Hutchins 1986: 24–30).

Financially, the burgeoning of NLP was largely driven by Cold War funding. This was especially true of machine translation. For military purposes, the prime languages were English and Russian, but in the USA they were soon joined by Vietnamese (Newquist 1994: 115).

The first public demonstration of an MT system, in January of 1954, translated forty-nine Russian sentences into English (using a 250-word vocabulary and six rules of grammar). Despite the six rules of grammar, this was basically a word-for-word translator. As such, it was hugely fallible. Nevertheless, it was used right up to the mid-1960s by the USA's Atomic Energy Commission (which was monitoring nuclear sites in Italy, as well as America), and by other governmental agencies too. In other words, it was *still* state-of-the-art: nothing better (for practical use) than word-for-word translation had been achieved.

That program, developed with CIA funding at Georgetown University, was one of many MT projects initiated in the USA in the 1950s. Even in the UK, much of the money for MT and other types of NLP came from various parts of the American defence programme. For instance, CLRU (founded in 1954) was partly supported by the US Office of Naval Research.

Predictably, NLP was developed in the Soviet Union too. Following the visit of a Russian computer scientist to the USA in 1954, for whom the Georgetown demonstration was proudly repeated, several research programmes were set up in the USSR (Hutchins 1986: 37, 133–45). By 1959, there were many hundreds of Soviet researchers in MT alone.

Intellectually, the field was driven by linguistics, by various logical and philosophical theories of language, and by the recent discussions of communication in cybernetics and information theory (see Chapter 4.v). Much early NLP research made a serious attempt to think about language systematically and/or to work towards practically useful ends.

But to say it was serious isn't to say it was successful. The well-known story—or rather, the group of mutually inconsistent stories—about "The spirit is willing but the flesh is weak" being rendered (after translation and retranslation) as "The whisky's fine, but the meat is rotten" is almost certainly apocryphal (W. J. Hutchins 1986: 16–17). However, there were certainly many such early-MT howlers. In the mid-1950s, for instance, Virgil's precisely inflected Latin sentence *agricola incurvo terram dimovit aratro* was once translated at CLRU as *ploughman crooked ground plough plough* (Masterman *et al*. 1957/1986). As remarked in the Preface, ii, this happened because CLRU used a thesaurus, not a dictionary.

With no computable theory of syntax—as opposed to a few simple programmed grammatical rules—available at the time, that's hardly amazing. (A fairly modest dose of syntax would have sufficed to deliver *A/The ploughman ploughs the ground with the crooked plough*.) And with no adequate theory of semantics either, it's not surprising that the CLRU's computational work on meaning didn't prevent this infelicity. Not until the early 1970s would there be powerful computational models of syntax, or of syntax allied with semantics (see xi.b, below).

b. Shannon's shadow

Shannon's theory of information was an important early influence on NLP. He himself used it in the late 1940s to produce "approximations" to English, as we saw in Section vi.c.

With hindsight, it's easy to see that these were word strings rather than sentences, because neither grammatical structure nor meaning were represented in information theory. At the time, this wasn't so obvious. Karl Lashley's (1951*a*) arguments against Markovian theories (see Chapter 5.iv.a) were unknown to most linguists and logicians, and Chomsky's more formal critique hadn't yet been published. Accordingly, many people were enthused by Shannon's ideas about the automatic generation of language.

Besides attempts to generate English text probabilistically, a number of people in the 1950s tried to induce grammars by statistical programs. In effect, they were aiming at the automatic discovery procedure sought by structuralism (see Section v). They focused on artificial rather than natural languages, not least because natural syntax was both complex and unclear.

Chomsky, for instance, cooperated with the psychologist George Miller (then at Stanford University, but soon at Harvard) in describing the formal properties of finite state grammars (Chomsky and Miller 1958). They also did experiments to find out what strategies people use, consciously or otherwise, to discover them (G. A. Miller 1967). Letter strings were labelled by the experimenters as grammatical or ungrammatical, and the subjects tried to learn to distinguish the two classes. If they could actually state the regularities involved, so much the better.

Their Cambridge colleague Bruner had investigated the information strategies used in concept formation (see Chapter 6.ii.b). Moreover, when Miller and Chomsky first described their experimental work (at the University of Michigan in 1957), they alerted the information scientist Ray Solomonoff, a participant at the Dartmouth meeting in the previous year, to define ways of inducing (artificial) grammars automatically (Solomonoff 1958, 1964). (These methods underlie the 1990s work on statistical grammar induction mentioned in Section v.d.)

That there should be linguists, psycholinguists, and information theorists at one and the same venue in 1957 was no accident. Communication between these groups had been growing throughout the 1950s. The Dartmouth meeting had caused an extra upsurge of interest, especially in AI models of learning and problem solving (see Chapter 6.iv.b).

But even earlier, in 1951, the information-theoretic approach to language was already predominant at Harvard and MIT—where Chomsky and his wife, Carol, respectively, were then working:

> Few linguists in Greater Boston at that time dared not use freely "message" and "code", "information" and "bits" in their shop talk, and nobody was "in" if he did not master, or at least professed to master, a good amount of probability theory and statistics. Everybody who was somebody in the field would sooner or later show up at MIT . . . All of us were enormously impressed by Shannon's well known [probability-based] experiments in what he called "approximations to ordinary English" and were convinced that speech, in English or any other language, was a Markov process. From this to the conviction that the English language, i.e. the set of all English sentences, can be generated by a Markov source, was only a small step, and I am not sure that we noticed at the time that this was a step at all. (Bar-Hillel 1970: 294–5)

The person reminiscing here, and quoted above as initially "enchanted" by the possibilities of the new technology, was the logician Yehoshua Bar-Hillel (1915–75). He'd encountered the logical positivists' approach to language in 1935, while studying at the Hebrew University in Jerusalem. He experienced their work as "nothing short of a revelation", later describing Carnap's volume on the logical analysis of language as "the most influential book I read in my life" (Bar-Hillel 1964: 1). And Bloomfield's linguistics "kept the fire of my interest burning".

So Bar-Hillel shared the structuralists' dream of an inductive discovery procedure for grammars. His hope was intensified when Harris, on a visit to Palestine in 1947, remarked that he was considering using the new electronic computers for this purpose. And, at close of the 1940s, he became "the first prophet in Israel" of cybernetics, including its potential relevance to the mind–body problem (Bar-Hillel 1964: 5).

With these views firmly in place, in 1950 Bar-Hillel accepted a fellowship at the University of Chicago, where he got to know Carnap personally. In the following year he visited MIT, well primed to be drawn into the enthusiastic information-theoretic community described above. Indeed, he was very soon appointed the first director of MIT's MT research. His remit was to survey the nascent field, to assess its prospects, and to plan MIT's research accordingly. His initial survey—of which, more below—was submitted in 1951, and in 1952 he organized the first MT conference (Hutchins 1986: 34–6).

Bar-Hillel didn't stay at MIT very long. On his return to Jerusalem in 1953, he was succeeded by Yngve, also from the University of Chicago. Yngve, now in his eighties, has been described by one NLP expert as "still the most original of all computational linguists" (Y. Wilks, personal communication).

In the 1950s, Yngve used both cybernetic and symbolic approaches. Besides doing early work on MT (Yngve 1955), he studied statistical methods for generating English (Yngve 1961) and developed the COMIT programming language, the first to be designed specifically for NLP (Yngve 1958). In the 1960s, he wrote a *Scientific American* article describing MT to the general public, and a technical survey defending MT against a damaging attack from an official committee (see below) (Yngve 1962*c*, 1967).

Yngve also made an early, and influential, attempt to relate syntactic theory to specific hypotheses about how people process language (Yngve 1960). That was an indication of the difference between his interests and those of the more austere grammarians, whether Chomsky or Gazdar. Over the years, his interests moved more towards "people" and away from "language" (Yngve 1986). And as remarked in Section viii.a, he attacked Chomsky on sociological as well as intellectual grounds.

During Bar-Hillel's brief stay in Massachusetts in the early 1950s, he met Chomsky. The two men interacted regularly, and Chomsky expressed his gratitude to Bar-Hillel several times in his early manuscript on the logical properties of language (e.g. Chomsky 1975: 31).

By 1955, Chomsky had accepted an appointment at MIT's Research Laboratory of Electronics (jointly with Modern Languages). In 1957, as remarked above, he and Miller were doing psychological experiments that immediately prompted information-theoretic work aimed in part at the development of NLP. And his hierarchy of grammars, as we've seen, helped to suggest what type of computational device would be needed to compute natural language.

Nevertheless, Chomsky never shared Bar-Hillel's enchantment with NLP. On the contrary, he was deeply sceptical from the outset:

> My personal reaction to this particular complex of beliefs, interests, and expectations [that information-theoretic computer modelling, combined with empiricist psychology, would make NLP possible, and further the positivist unification of science] was almost wholly negative. The behaviorist framework seemed to me a dead end, if not an intellectual scandal . . . I had no personal interest in the experimental studies and technological advances. [I felt the latter to be] in some respects harmful, [leading people to focus on] problems suggested by the available technology, though of little interest and importance in themselves. As for machine translation and related enterprises, this seemed to me pointless, as well as probably quite hopeless. As a graduate student interested in linguistics, logic, and philosophy I could not fail to be aware of the ferment and excitement [in the early 1950s]. But I felt myself no part of it and gave these matters little serious thought. (Chomsky 1975: 40)

When he did become interested in them, soon after completing his *magnum opus*, he wrote his fierce review of Skinner (see Section vii.b). His only foray into NLP work was a program schema that used transformational grammar (rewrite rules), not statistics, in its processing (G. A. Miller and Chomsky 1963: 464–82).

Nor was he a fan of AI in general. Quite apart from any intellectual reasons for scepticism, there appears to have been some unpleasant rivalry between him and Marvin Minsky—both young, brilliant, famous, and ambitious. In the mid-1960s, when the *Alchemy* scandal was at its height (see 11.ii.b), he went over to the MIT AI Lab, to sit in on one of the heated debates between Weizenbaum and Hubert Dreyfus on one side and Minsky and Seymour Papert on the other. David Waltz, an AI student at the time, now recalls:

> I remember once Noam Chomsky came over [to these debates] also. There was personal animosity between him and Minsky, and people were very rude to Chomsky when he came to the AI lab. They booed when he talked, and he was very miffed. (interview in Crevier 1993: 123–4)

As for Bar-Hillel, and partly because of his discussions with Chomsky, his love affair with—though not his interest in—NLP was to be short-lived, as we shall see.

c. Love letters and haikus

Despite the "ferment and excitement" aroused at mid-century by information theory and statistical cybernetics, some NLP pioneers chose instead to use the newly available digital computers as symbol manipulators.

Even very early on, these machines could be programmed with rules (written in binary notation) for selecting words from distinct grammatical classes. But with the introduction of list-processing languages, such as IPL and COMIT, in the mid-1950s (see 10.v.b), hierarchical syntactic structures could be represented more easily.

Probably the earliest computerized text generator was Turing's playful love-letter program. This was written in the late 1940s for MADM, the world's first electronic stored-program digital computer (Chapter 3.v.b). Using random numbers to choose the words, MADM produced this (Lavington 1975: 20):

Darling Sweetheart,

You are my avid fellow feeling. My affection curiously clings to your passionate wish. My liking yearns to your heart. You are my wistful sympathy: my tender liking.

Yours beautifully

M.U.C. [Manchester University Computer]

The program hasn't survived. But presumably the last two lines, apart perhaps from the adverb *beautifully*, were provided in 'canned' form, while some overall template instructed the machine to select an adverb here, a noun there, and perhaps to pick two endearments (*Darling*, *Dearest*, *Sweetheart*, *Love* . . .) for the first line. Template fillings of this type were soon to be used at CLRU to generate texts fitting the strict constraints of a Japanese haiku (Masterman and McKinnon-Wood 1968; Masterman 1971). Two examples are:

All green in the leaves
I smell dark pools in the trees
Crash the moon has fled

All white in the buds
I flash snow peaks in the spring
Bang the sun has fogged

As the CLRU team realized, the apparent meaningfulness of these mechanically generated haikus was due primarily to the human reader, whose "effort after meaning" (Bartlett 1932: see 5.ii.b) projected significance onto the initially puzzling lines. But if the CLRU realized this, many others didn't. The program was exhibited at the first international exhibition of computer art, and impressed the visiting public more than it should have done (J. Reichardt 1968).

d. Wittgenstein and CLRU

Some of the intellectual sources of early NLP were surprising, being very far in spirit from structuralist linguistics and information theory, and from symbolic computing too. This applies, for instance, to the pioneering research done at CLRU under the direction of Masterman (1910–86).

Their computational work was informed by the anti-positivist philosophy of the later Ludwig Wittgenstein. In scientific circles, this approach to language was nothing if not unorthodox. Wittgenstein himself had likened it to Goethe's views on morphology—see Chapter 2.vi.e–f (Monk 1990: 303–4, 501).

Although these new ideas weren't published until after his death, Wittgenstein had lectured on them—and his lecture notes had circulated—in Cambridge for many years. Moreover, he'd dictated some of them to Masterman herself (see Preface, ii). The lectures provided a radical critique of his own earlier (logicist) position (Wittgenstein 1953), and a very different view of language. Whereas he had once declared that "Everything that can be said at all can be said clearly" (Wittgenstein 1922: 27, 79), he now saw an indefinable penumbra of meaning surrounding every statement.

One of his main points was that words don't have cut-and-dried (essentialist) definitions, in terms of necessary and sufficient conditions. Rather, the items falling under a given word (*game*, for example) are linked by a network of "family resemblances" (Wittgenstein 1953: 31 ff.). Analogously, relatives may share the family nose, the family eyebrows, the family fingernails . . . without any one person having all these characteristics. Admittedly, some items are better examples of the concept concerned, so can function as "paradigm cases". (These have Rosch-typicality ratings close to 1: see Chapter 8.i.b.) But there's no clear cut-off point.

Masterman was convinced by the doctrine of family resemblances, and disturbed by the all too evident weakness of word-for-word dictionary translations (first attempted by Richens and Booth 1955 and Yngve 1955). Her critique of the early word-for-word efforts (Masterman 1967) was backed up by her own thesaurus-based approach to NLP (Masterman 1957, 1962). One of the early AI workers influenced by her research was M. Ross Quillian, who visited King's College, Cambridge, in 1961 to give a talk about his early ideas on semantic networks (Chapter 10.iii.a).

The thesaurus was envisaged as a semantic interlingua, through which the translator could pass from one natural language to another. (For an early application of CLRU's interlingua approach, see the discussion of "catataxis" in Parker-Rhodes 1956.) Many examples of semantic ambiguity, which would defeat a word-for-word MT procedure, could be resolved by this means. The semantically ambiguous word would fall under at least two different heads in the thesaurus, and the one actually selected by the program would be the one under which some other words in the sentence fell also. So *I put my money in the bank* and *I know a bank whereon the wild thyme blows* would be recognized as dealing with financial and rural matters, respectively. (Syntactic analysis would be needed to deal with *I drew some money from the bank to buy some wild thyme*.)

Initially, Masterman used a thesaurus derived by human intuition, namely, a cut-down version of Peter Roget's pioneering work published 100 years earlier. But her group also developed procedures for constructing thesauri automatically. Formal clustering methods were used to identify word classes, in terms of the co-occurrence of various words. Those word classes determined lexical substitutability for the purposes of machine translation. In addition, they aided in the automatic classification, indexing, and retrieval of documents (Sparck Jones 1988). (The pioneering librarian Gabriel Naudé would have been intrigued: see Preface.)

CLRU's thesaurus approach offered flexibility of various kinds. It could be applied to texts of any length, not just to isolated sentences. It was a source of semantic primitives that could be used to define meaningful messages (or "gists"), based on *actor–action–object* patterns, that were helpful for single-language interpretation and précis as well as for translation. And, not least, it enabled Masterman's group to take some account of the unpredictable extensibility of language. This had been stressed by Wittgenstein and Waismann—and, as Masterman often remarked, by the philosopher Ernst Cassirer (1874–1945), who followed Humboldt in highlighting the unceasing development of language (Cassirer 1944).

The extension of language was modelled, for instance, by Yorick Wilks (1939–). Like Masterman, he was especially interested in the interpretation of metaphysical texts—dismissed as "meaningless" by the logical positivists fashionable at mid-century. He wrote a program in the 1960s to assign semantically coherent representations to textual snippets drawn from the writings of a wide range of philosophers.

Wilks's program could do this successfully for some test paragraphs from Descartes, Leibniz, and David Hume, *without* any need to extend word meanings. But other test paragraphs did require that. Accordingly, his program would locate the semantically problematic word in a chunk of text (not a trivial matter), and then use thesaurus-driven methods to identify its meaning with some other term or phrase within the passage (Wilks 1972: 166–72). If the problematic word was an extension of sense relative to some interpretation already stored in the (thesaurus-based) dictionary, Wilks's EXPAND algorithm could develop the rules for 'literal' interpretation so as to make sense of the anomalous word in context.

This procedure wasn't foolproof. What if there were no other suitable word in the text, and/or some major sense of the problematic word had been omitted from the dictionary? And what is to count as a "major" sense, anyway? (Bar-Hillel, clearly, was hovering in the background.) Nevertheless, it gave acceptable readings of some notoriously tricky texts, including passages drawn from Wittgenstein's *Tractatus Logico-Philosophicus* and Spinoza's *Ethics*. Short of torturing it with extracts from *Finnegans Wake*, one can hardly imagine a more taxing test. In short, this early NLP model tried to escape the logicist straitjacket by acknowledging the creative extensibility of language. (Some of Wilks's later work did so too: his "preference semantics" was used in automatic parsing, interpretation, and inference—Wilks 1975.)

The methods developed by CLRU weren't intended as theories of how human beings translate, interpret, or classify. As remarked in Chapter 1.ii.b, this NLP group was doing technological, not psychological, AI. (Quillian, by contrast, was at least as interested in simulating human psychology as in producing useful technology: 10.iii.a.) But the practical demands were taken seriously from the start. One of the strengths of CLRU was its emphasis on careful testing and experiment to compare IR (information-retrieval) systems (Sparck Jones 1988: 14–17, 25–6). Mere plausibility wasn't good enough—and was sometimes found to be misleading. In short, Drew McDermott's well-deserved criticisms of much early AI didn't apply to Masterman's group (see 11.iii).

Whether Wittgenstein himself would have approved of any computerized approach to translation or classification, even one (such as Masterman's) part-inspired by his own ideas, is another matter. He didn't explicitly discuss any of the budding AI work. Nor do we know of any informal meeting between him and Turing, still less any discussion between them about the possibility of AI. (For an entertaining account of an imaginary meeting, see Casti 1998.) But when Turing attended some of Wittgenstein's lectures on the philosophy of mathematics, the two men repeatedly disagreed on fundamental points (Monk 1990: 417–22). The whole tenor of Wittgenstein's mature philosophy suggests that he wouldn't have welcomed computational work on language.

In part, this follows from his view of language as a network of social conventions rooted in the human "form of life", a notion that can hardly be applied to a computer. But in part, it follows from his stress on the flexibility and open texture of language (and concepts), which seems to lie beyond any scientific explanation.

This flexibility may be approximated by some computational methods, such as CLRU's thesaurus. But even if anti-logicist NLP is in practice less inadequate than logicist approaches, the philosophical problems remain. For Wittgenstein, presumably (S. Shanker 1998)—and for his follower Dreyfus, certainly (H. L. Dreyfus 1972; Dreyfus and Dreyfus 1988)—neither type of NLP can escape the fundamental limitations of AI in general. The Wittgensteinian position agreed with what Descartes had argued long ago (2.iii.c): machine mimicry of language use can only be highly imperfect.

e. Is perfect translation possible?

However, in this area of AI as in others, the question whether some task could in principle be performed (or mimicked) *perfectly* by a machine must be distinguished from the question whether it could in practice be performed (or mimicked) *well enough to be useful*.

The first question is especially difficult where translation is concerned, because it's not even clear what—if anything—would count as perfection in the human case.

Humboldt had claimed that no human translator can achieve perfect equivalence (see Section iv.b, above). In scientific texts, he allowed, translators could hope to do their work with no important loss of meaning. But in literary contexts, they couldn't (Novak 1972). In discussing the (many) possible criteria for a good literary translation, he suggested that the translator should choose words and sentence structures that somehow indicate the original language. The more one does this, however, the less acceptable (in the derivative language) the new sentence will become. Mark Twain's spoof of the German habit of delaying the verb illustrates the point:

> I am indeed the truest friend of the German language—not not [*sic*] only now, but from long since—yes, before twenty years already. And never have I the desire had the noble language to hurt; to the contrary, only wished she to improve—I would her only reform. It is the dream of my life been . . . I would only some changes effect. I would only the language method—the luxurious, elaborate construction compress, the eternal parenthesis suppress, do away with, annihilate; the introduction of more than thirteen subjects in one sentence forbid; the verb so far to the front pull that one it without a telescope discover can. With one word, my gentlemen, I would your beloved language simplify, so that, my gentlemen, when you her for prayer need, One her yonder-up understands . . .
>
> After all these reforms established be will, will the German language the noblest and the prettiest on the world be. (Twain 1897)

Moreover, it's not even clear that this particular criterion of fidelity to the source language should be considered at all. Humboldt himself was well aware that there are conflicting views on what counts *in principle* as a high-quality translation. In short, "perfect" translation is a chimaera. And even high-quality translation is often very difficult.

If this is true for expert human translators, the difficulties facing machines (or rather, their programmers) are so much the greater. Both meaning and grammar stand in their way.

Meaning is notoriously elusive: if it can be pinned down in principle, which even empiricists often deny (Quine 1960), it doesn't follow that it can be captured in practice. Semantic ambiguity and vagueness, not to mention metaphor, are obvious problems. Moreover, a translation machine (eschewing word-for-word translation and statistical methods) needs a universal grammar or an artificial interlingua to mediate between languages, and/or full descriptions of the relevant pair of natural-language grammars. But defining a grammar to cover a single language, never mind a universal grammar, is no mean feat, as we saw in Section ix. And to define a grammar isn't to program it: successful parsers weren't available until the early 1970s (and true computational effectiveness had to await GPSG, more than a decade later).

Most of these theoretical points were made in the 1950s by an increasingly disillusioned Bar-Hillel (1951, 1953, 1960). Despite having been enchanted by the linguistic promise of the new technology in the 1940s, he later expressed deep pessimism—not only about machine translation, but about computational linguistics in general (Bar-Hillel 1970: 298 ff.). He even apologized for his own early influence on the field:

> I myself was led into confusion by the strong surrounding currents [of cybernetics] and was responsible to a degree for increasing this confusion and leading others into blind alleys from which some never returned. (Bar-Hillel 1970: 289)

In recanting his earlier beliefs, Bar-Hillel didn't merely lament the unexpectedly slow progress. He claimed to prove that certain things, their feasibility largely taken for granted by the young NLP community, simply cannot be done by automatic means.

For example, Harris's suggestion that texts made up of syntactically complex sentences can be represented as transformations of several much simpler kernel sentences had led many to hope that NLP could proceed by normalizing texts to some simpler form. Bar-Hillel proved, by contrast, that "Not everything that can be said at all can be said, in a given language, by using syntactically simple sentences exclusively" (Bar-Hillel 1963: 31).

As for semantic ambiguity, this often calls for world knowledge as well as knowledge of language as such. The simple sentence *The box is in the pen*, for instance, can be understood only if one knows that playpens are large enough to contain boxes whereas writing pens are not (Bar-Hillel 1960, app. iii). An MT program concerned specifically with such topics could of course be given this information beforehand. But, Bar-Hillel insisted, such priming can't be done in the general case.

In short, what he called FAHQT (fully automatic high-quality translation) is impossible.

f. Is adequate translation achievable?

Bar-Hillel was complaining about the "science-fictional claims" made by some proponents of NLP, namely those who were promising FAHQT. He wasn't arguing that computer models of language are wholly useless.

In his first report to MIT, he'd said that whereas high-accuracy, fully automatic, MT isn't feasible, "there appear to be less ambitious aims the achievement of which is still theoretically and practically valuable" (Bar-Hillel 1951: 154). Almost a decade later, when he surveyed the progress of MT in the USA and UK (and USSR), Bar-Hillel again stressed the impossibility of human-quality MT (Bar-Hillel 1960). Instead of aiming for this unattainable goal, he said, AI should aim for imperfect-but-intelligible automatic translations, possibly supplemented by human post-editing.

Alongside this potentially hopeful advice, however, he argued that even this less ambitious project should be undertaken in a different way. In his second report, after MT had been under way for some years, he rejected approaches based on statistics and information theory, which he'd previously thought so promising. Nor did he have much time for the then-fashionable methods of GOFAI (Good Old-Fashioned AI: see Chapter 10). He criticized virtually all the major MT groups by name, and attacked the most common methodologies.

The immediate effect of Bar-Hillel's second report was almost to destroy faith in MT on the part of the general public, including scientists not working in the field. A best-selling popular book on *Computers and Common Sense* by Mortimer Taube (1910–65), for instance, took up Bar-Hillel's negative remarks while ignoring his positive ones (Taube 1961).

Taube's book announced in highly emotional terms that MT was impossible and MT research—indeed, AI in general—a waste of taxpayers' money. The nation's monetary resources, Taube said acerbically, would be better devoted to "research looking toward the Second Coming" than to research aiming to build machines with "intelligence, knowledge, and knowledgeability". His dismissive conclusion was that "One may wonder why reputable scientific journals publish material of this sort and why it should have an audience beyond the readers of the Sunday supplements."

Taube, an internationally famous librarian, knew some of his computer onions: he'd pioneered powerful new forms of indexing and information retrieval. Even so, his attack cut little ice with the AI community. Being called "ignorant" and "jejune", and being accused (repeatedly) of "scientific aberration", led to so much offence that they hardly bothered to marshal a defence. Moreover, the book was—as one early cognitive scientist put it—"neither reliable nor responsible", being largely comprised of "allegations presented as facts, of misunderstanding, of debaters' tricks identical to those he decries in others, and of statements about the work of others which are simply untrue" (Reitman 1962: 718).

However, Taube's attack encouraged an attitude of scepticism, not to say ridicule, in the general reader. And the "general readers", in this case, included not only counter-culturalists such as Theodore Roszak (1969: 295) but also people who might at some point have to make decisions about funding policies for MT.

As if that weren't damaging enough, Bar-Hillel's critique also dampened the optimism of MT researchers who were aiming to approach human-quality results. Those who were willing to tolerate many linguistic infelicities, provided that these didn't compromise understanding, were less set back. Even so, and even though significant (military-led) funding continued for over a decade, many MT workers lost heart. At Harvard, for example, almost all research in this field had ceased by 1964.

In that year, the scepticism deepened further. A survey had just been conducted by the US government's Automatic Language Processing Advisory Committee (ALPAC), chaired by the Bell Telephones executive John Pierce (Hutchins 1986: 164–7). Their report was thirty-four pages of dynamite—plus ninety pages of smouldering appendices. It concluded that previous MT research had been a failure, that fully automatic MT was impossible, and—even worse—that there was "no immediate or predictable prospect of useful machine translation".

This negative judgement wasn't a purely scientific one. It was partly based on ALPAC's view that not enough customers would want to use MT to make it commercially viable. Machine aids for human translators, however, might well be feasible.

The effect on informed (or rather, "semi-informed") public opinion was predictable. Yngve described it like this:

> The [general] public is now where the pioneers were many years ago, vaguely aware of the difficulties but allowing that the thing is possible, while the workers, with more than a little knowledge now, see quite clearly that there is very much yet to be done. And the semi-informed public gives indications of swinging back to [their] original position, that the task is virtually impossible, therefore no proper area for research. In this they may be echoing a few despairing noises coming from some of the workers who had expected a quick victory. (Yngve 1967: 453)

Despite criticisms that the ALPAC report was "narrow, biased, and shortsighted", and imbued with a "hostile and vindictive attitude", it had a devastating effect on MT research in the USA. The activity was virtually halted for over a decade. And the devastation was near-instantaneous: "Funding for [MT] projects dried up within weeks of the ALPAC report, and several research labs shut down soon thereafter" (Newquist 1994: 116).

It had a negative influence in the UK and Soviet Union, too. Work on translation at CLRU, for instance, ceased in the late 1960s—even though the Unit itself continued, and did valuable work on various aspects of information retrieval (Sparck Jones 1988; Wilks forthcoming).

If the negative aura of ALPAC could cross oceans, it could cross some intellectual boundaries too. It threw a shadow over AI in general, and NLP in particular. Although the three main AI departments weren't much affected (they weren't doing NLP anyway), several US universities that had been planning to start departments of AI decided not to do so (Newquist 1994: 117).

Nevertheless, ALPAC didn't end NLP as a whole. On the contrary, it favoured increased support of *basic* research in computational linguistics. If the embarrassingly prolific MT cousins of *ploughman crooked ground plough plough* were ever to be avoided, this would require a better understanding—and effective computational implementation—of theoretical linguistics.

9.xi. NLP Comes of Age

NLP would come of age (in the 1970s) with the acceptance of more realistic goals for MT, with the appearance of effective computer parsers, and with the recognition that, besides processing single sentences, one must also model the rhetorical coherence of entire texts. The last two lines of development—which required advances in general AI—are still under way.

Moreover, it's now clear that improved statistical methods, let loose on huge samples of real-life linguistic data, can go much further than Shannon's early critics imagined. Even as late as 1987, that was less clear. At a statistics/linguistics conference in Oxford, sponsored by the Engineering and Physics Research Council (EPSRC), the atmosphere was civilized but there was no real communication (G. Gazdar, personal communication). At a similar meeting held at the Royal Society in 1999, there was (I witnessed that for myself). What's more, while the EPSRC may have expected all the benefit to go from the statisticians to the linguists, in fact it went in both directions.

For instance, Markovian three-word chunks can now be used to make word predictions almost as well as people can, although they can't generate grammatical sentences as reliably (Pereira 2000). These probabilistic models typically induce "hidden" rules from huge databases, and some rely on symbolic rules or tree structures derived from theoretical linguistics (Gazdar *et al*. 2000). Many are trained on collections made up of several hundreds of millions of words. Even so, not all sentences (or newly coined words) can be included. Chomsky's complaint that Markovian theories can't allow for the creative use of language is countered by "smoothing algorithms" that avoid assigning zero probabilities to unencountered events.

Some advances, whether symbolic or statistical, are of primarily technological interest. They will affect our daily lives, but not necessarily our understanding of the mind. Others are of interest only to highly specialized linguists. Below, I outline a few post-1960 landmarks, selected for their relevance to cognitive science *in general*.

Strictly, a certificate of maturity for NLP would also require advances in speech processing—both understanding and synthesis. The former involves the analysis of continuous speech into individual words, and the classification of acoustically different sounds as one and the same phoneme. It had to await the development of vocal-acoustic technology, and also required an integration of several theoretical levels: acoustic, phonetic, morphemic, syntactic, and semantic.

Since I've virtually ignored phonetics throughout this chapter, I'll ignore speech systems too. An early machine for learning to recognize phonemes was mentioned in Chapter 6.ii.c, but this was merely an exploratory toy. The pioneering HEARSAY program of the early 1970s will be mentioned in Chapter 10.v.e, because of its innovative "blackboard" architecture, which integrated processes based in syntax and semantics with processes grounded in phonetics. And the 1980s connectionist system NETtalk is discussed in Chapter 12.vi.f, because of its methodological interest. But speech processing as such isn't crucial for our purposes. Apart from a few remarks at the close of the chapter (subsection g), it won't feature here.

a. MT resurrected

As for machine translation, the ALPAC authors were shown in the long term to have been over-pessimistic. But their suggestion that basic research in computational linguistics would be helpful was justified. Bar-Hillel, by contrast, turned out to be correct on both main counts: although human-quality MT isn't achievable in the general case, practically useful MT is. Masterman's key problem of word-sense disambiguation, for example, can be approached today by methods fundamentally similar to hers but much more powerful (Ide and Veronis 1998).

There are now many MT systems in daily use (W. J. Hutchins 1994, 1995). Most, as Bar-Hillel had predicted, deal only with a highly restricted area, but some can cope with a fairly wide range of topics. They are used, for example, to scan foreign-language news media or scientific publications, or to express political debates and legislation.

Their translations are typically good enough to be understood by informed human readers, and/or to show whether it would be worthwhile to ask a human translator to improve them. Sometimes, only minimal post-editing is required. But sometimes (for instance, when Japanese is involved), significant pre-editing and post-editing are needed.

The SYSTRAN program is one well-known example (P. J. Wheeler 1987). A descendant of an early Russian–English system funded by the US Air Force, it was written in the late 1960s by a team led by Peter Toma, a participant in the famous Georgetown project. The European Community adopted it for English and French in 1976, since when it has been broadened to include all the official languages of the European Union. It is used also by NATO and the International Atomic Energy Authority, and by commercial companies such as Xerox and General Motors.

Some of these applications appear at first glance to evade Bar-Hillel's criticism. For many documents in English can be translated by SYSTRAN into other European languages with near-perfection. The trick is to use only a small subset of English for the original document. A number of other commercially available programs can also provide near-perfect translation of technical manuals and the like, by using highly restricted vocabulary and syntax.

What might well surprise Bar-Hillel is that some very recent MT systems rely heavily on statistical pattern matching (W. J. Hutchins 1995: 440–1; 1994). Rule-based approaches have given way to corpus-based ones, and the emphasis has shifted from syntax to the lexicon (Hutchins 1994, sect. 9). Instead of careful syntactic analysis, these systems rely on probabilistic methods based in some huge corpus of paired source/translation texts. Shannon, one might say, has returned with a vengeance.

IBM's CANDIDE system, for instance, draws on the voluminous (and multi-topic) French–English 'Hansard' of the Canadian Parliament. In the mid-1990s this program contained no grammatical rules whatsoever, relying purely on statistical matching of words and phrases. Its performance amazed most observers, given that the analytical approach had been largely taken for granted in NLP for thirty years. Even ALPAC had seen detailed computational linguistics as essential for automatic translation. Almost 50 per cent of phrases were acceptably translated, being matched either with their database originals or with equivalent expressions.

However, one must not forget the other 50 per cent. To deal with those, future versions of CANDIDE will include some morphological and syntactic information, as well as more sophisticated statistical methods. But grammar and morphology will be used as sparingly as possible. In other words, the team expect the statistics to trump the syntax. It remains to be seen whether they are right, and to what extent MT can afford to ignore theoretical linguistics.

Certainly, grammatical correctness is MT's Achilles' heel. The general assumption, *pace* CANDIDE, still is that this demands painstaking attention to syntax (gender, number, tense, and so on). Measures of intelligibility and correctness have shown a dramatic improvement in the former, but much less progress on the latter.

For instance, in the two-year period 1976 to 1978, the intelligibility of translations generated by SYSTRAN rose from 45 to 78 per cent for the raw text, and from 95 to 98 per cent for the post-edited text (W. J. Hutchins 1986: 261). Human translation, it's worth noting, gave not 100 per cent but only 98–9 per cent.

SYSTRAN's correctness, where every tiny error counts, scored much lower. In 1976 the measure for grammatical agreement was only 61–80 per cent; and in 1978, only 64 per cent of words were left untouched by the human post-editors. Even so, human post-editing of a page of SYSTRAN output took only twenty minutes in the mid-1980s, whereas normal (fully human) translation would have taken an hour. However, over half of the amendments involved substituting a different word, not simply altering a word ending. In both cases, the main source of errors seemed to be the dictionary, which in 1978 contained only 45,000 entries. Accordingly, the computerized dictionaries have been gradually enlarged.

The more ambitious EUROTRA system was multilingual as opposed to severally bilingual, dealing with forty-two different language pairs (King and Perschke 1987). It held 140,000 words in its prototype stage, in 1988: 20,000 words for each of seven languages, with the expectation of at least two more to come. But no operational version was ever built. EUROTRA was influential, nevertheless. It was recently recognized in an official report as providing much of the basis for later work in MT across Europe (*Euromap Report* 1998: 59).

More ambitious still would be an MT system that could switch between languages in very different language groups, such as English, Japanese, and Hindi. In Japanese, for example, the words aren't segmented as they are in English (no equivalent of our *post-ed*, for the past tense of *post*), and the phrase orderings in the parse trees are reversed (Powell 2002: 112). Although there are MT programs combining Japanese and English, and also for switching between several of the many languages of India, they aren't as efficient as the best European-language systems.

(I've mentioned corpus-based work only in MT, but similarly statistical approaches are increasingly being used in other areas of computational linguistics too: see Sampson and McCarthy 2004.)

b. Automatic parsing

If computerized dictionaries are relatively easy to improve, automatic parsing is a different matter.

NLP in the 1950s and early 1960s, as we've seen, was hampered by the lack of a powerful theory of syntax. Computational work on syntax started to show results in the early 1970s. This development was largely due to the post-Chomsky interest in formal grammars. (This is *not* the same thing as an interest in Chomsky's formal grammar: as remarked in Section ix.f, very few people used Chomsky's theory as the basis of their NLP programs.)

The first impressive computer parser was written by William Woods at Bolt, Beranek & Newman (BBN), using "augmented transition networks", or ATNs (W. A. Woods 1970, 1973). The computational advantage of ATNs, which soon became widely used in NLP, was that they considered the input sentence in one pass, working left to right on one word or syntactic constituent at a time. Nevertheless, they could deal—recursively—with nested sentences or noun phrases (such as *the judgement of the court*), and with nouns embellished by several adjectives.

In effect, they worked top-down, continually making syntax-driven predictions about grammatical form and testing the input word to see whether it fitted the current prediction (see Boden 1988: 91–102). On encountering the word *the*, for example, the ATN would predict either an adjective or a noun, in that order; but if an adjective were found, it would immediately predict another one before looking for a noun. This simple procedure would enable it to recognize, for instance, *The girl*, *The clever girl*, and *The clever French girl*.

Woods used his parser in his LUNAR program, which answered questions about lunar geology, drawing on NASA's data about the mineral samples collected from the moon on the Apollo 10 mission. Its answers were in 'written' English (though Woods soon worked also on the HEARSAY speech system). This early version couldn't handle relative clauses in a theoretically elegant manner. Nevertheless, LUNAR was a huge advance on the question-answerers of the 1960s (surveyed in Simmons 1965, 1970).

These included the BASEBALL program, co-authored by Carol Chomsky (B. F. Green *et al.* 1961). This could search and reason about its database so as to answer questions such as "How many games did the Yankees play in July?" (see Chapter 10.iii.a). To deal with the English-language input, BASEBALL and its contemporaries had relied on a menu of ELIZA-like pattern matches (10.iii.a), not on parsing. Simple rules enabled ELIZA to switch pronouns so that (for example) the input *I ***** you* would elicit *WHY DO YOU ***** ME*. Woods's program, by contrast, modelled syntactic structure in some detail.

ATNs had originally been defined by a research group in Scotland (Thorne *et al.* 1968). Their NLP program was successfully tested on Lewis Carroll's 'Jabberwocky', among other things. It was based on transformational grammar, and built syntactic representations of the input sentence on both deep and surface levels. Woods adopted the general approach of ATNs, but eschewed Chomsky's grammar.

Nor was he the only one to do so. Because of the computational load involved in mapping between two entire syntactic structures, and thanks to the development of non-Chomskyan grammars (see Section ix), very few NLP projects have implemented transformations. The most interesting exception is Mitch Marcus's PARSIFAL, a program inspired not only by Chomsky's syntax but also by his views on language-and-mind (see Chapter 7.ii.b and M. P. Marcus 1980).

The Scottish team, like Marcus, had been doing psychological AI. They saw Chomsky's theory, and their left-to-right ATNs, as modelling some of the mental processes involved in language. Woods wasn't much interested in whether his parser was psychologically plausible. But some people used his approach to formulate specific psychological hypotheses about how people use language—and memory, too (see Chapter 7.ii.d and iv.d–e). The first to do so was Kaplan (1972), who later went on to co-author a psychologically motivated grammar, LFG, that has been borrowed extensively for technological purposes (see Section ix.b). Another was David Rumelhart, who used ATN models of grammar to study the psychology of reading errors (Stevens and Rumelhart 1975).

This swinging pendulum of intellectual influence illustrates a general point made in Chapter 1.ii.b. The boundary between psychological and technological AI, and therefore between what is cognitive science and what is not, is often fuzzy. ATNs were first devised (in Scotland) with psycholinguistic intent, soon adapted (by Woods) for technical purposes, and then picked up (by Kaplan and others) for use in psycholinguistics, memory research, and theoretical syntax. The new formal grammar that eventually resulted was later adopted by a variety of technological NLP researchers—some of whom would hardly recognize a mental process if it punched them on the nose.

A further illustration of this point was provided by the most famous achievement of early NLP: Terry Winograd's program SHRDLU (Winograd 1972; Boden 1977, ch. 6). The name, by the way, wasn't an acronym but a slyly subversive joke. In the publishing technology of the 1960s, one row of the keyboard of a standard linotype typesetting machine consisted of these letters. Typesetters would often signal a mistake by inserting them in a faulty line, so that the proof-readers would easily spot that a mistake had been made. Bad proof-reading might result in this deliberate gibberish being printed in the final text. That fact was made much of in the counter-cultural *MAD* magazine, which was deliberately peppered with multiple occurrences of this nonsense word. As a devotee of *MAD*, Winograd (1946–) decided to use it as the name of his program (T. Winograd, personal communication).

Winograd's program was written, at MIT's AI Laboratory, in the heyday of NewFAI. In 1961 George Ernst (with Minsky and Shannon on his thesis committee) had started to build a robot that would pick up blocks from a table, build them into towers, and put them into and out of a box. And by the late 1960s, the MIT robotics team were trying to integrate computer vision with their robot's problem solving, as well as working on a better robot hand (L. J. Fogel and McCulloch 1970: 256–65). It was in this intellectual environment that Winograd's doctoral research began.

The overall aim was to enable the team to give instructions to the robot in English, and for the robot to respond in real time. But for that to be possible, AI needed to advance in English as well as robotics.

Winograd's thesis title, 'Procedures as a Representation for Data in a Computer Program for Understanding Natural Language', showed that he wasn't interested only in English, or even NLP. To the contrary, he was largely concerned with questions about virtual architectures for AI. Indeed, his concepts of "heterarchy" and "procedural programming" had a huge impact on GOFAI (see Chapter 10.iv.a).

What's more, he wasn't doing psychological AI—except, perhaps, in the most general sense. Although his opening sentence was "When a person sees or hears a sentence, he makes full use of his knowledge and intelligence to understand it," he was careful to stress that SHRDLU wasn't intended as a detailed model of what goes on in people's minds.

Nevertheless, his work was considered so significant by the cognitive science community that an entire issue of the journal *Cognitive Psychology* was devoted to it—and it was simultaneously published in book form by a leading university press. In explaining their unprecedented decision, the psychologist editors said:

> Winograd's system is not a "simulation", but it incorporates important ideas about human syntactic, semantic, and problem-solving abilities, and, in particular, about their interactions in understanding natural language. Human intelligence goes far beyond this system, and human

language comprehension may turn out to differ in major respects from the means employed here. At the very least, however, Winograd's system should prove an invaluable tool for thinking about what we do when we understand and respond to natural language.

(Winograd 1972, p. vii)

Their reference to "interactions" between syntactic, semantic, and problem-solving abilities, and Winograd's opening sentence (quoted above), indicated the sense in which SHRDLU went far beyond previous NLP work.

Like Woods, Winograd provided a powerful computer parser (based on Halliday's systemic grammar: see Section ix.a). It could even parse long sentences with a syntactic sting in the tail, such as: *How many eggs would you have been going to use in the cake if you hadn't learned your mother's recipe was wrong?* But the most important NLP novelty was that the parser was closely integrated with semantic analysis, problem solving, and world knowledge (see 10.iv.a).

SHRDLU's world knowledge—of a table, a box, and various coloured objects that could be moved by a robot arm—had to be laboriously programmed in. So Bar-Hillel's argument citing *The box is in the pen* still held. As Winograd himself pointed out, many obvious implications of English sentences about boxes, blocks, and tables were invisible to the program.

This was a prime reason why, in the 1980s, he rejected the approach underlying his early work (Winograd 1980*a*; Winograd and Flores 1986). He'd been persuaded, by Fernando Flores and Dreyfus, that various neo-Kantian thinkers were better guides to language than the logicist philosophers whose views imbued GOFAI—and most computational linguistics, too (see Chapter 16.vi–viii). So his 1986 book, co-authored with Flores, highlighted the hermeneutic philosophers Martin Heidegger (sixteen index entries) and Hans-Georg Gadamer (nine), the autopoietic theorist Humberto Maturana (fifteen), and the later Wittgenstein (two). None of these had figured in his earlier work—and many of his erstwhile admirers were aghast. (For more on Winograd's volte-face, see Chapter 11.ii.g.)

The cognitive integration, in SHRDLU, went beyond the fact that syntax, semantics, reasoning, and world knowledge were all included in the one *program*. The crucial point was that they could interact in the processing of a single *sentence*. When interpreting the syntactically ambiguous instruction *Put the blue pyramid on the block in the box*, for instance, the program checked to see whether there was one and only one blue pyramid already sitting on the block, or (if not) whether there was one and only one block already inside the box. (Compare this with Quillian's semantic network, which used *purely lexical* information to disambiguate sentences like *I threw the man in the ring*: 10.iii.a.) And in obeying the instruction, and deciding how to reply to it, SHRDLU might have to do some problem solving, to enable the robot arm (which could pick up only one thing at a time) to get at the blue pyramid concerned.

With the help of predicate logic ("one and only one thing such that . . ."), also included in the program, Russell's theory of definite descriptions (see 4.iii.c) had been implemented in computational form. However, Winograd defined the program's lexicon, and its syntactic and semantic terms, not as formulae of the predicate calculus but as mini-programs. So his definition of *the* didn't simply assert (as Russell had done) that this word was apt only if there was exactly one thing that fitted the description given. Rather, it instructed the system to go and look for such a thing on encountering the word. As a result, when SHRDLU was asked to "Grasp the pyramid", there being *three* pyramids in the scene, it sensibly replied, "I don't understand which pyramid you mean." However, if a specific pyramid had already been mentioned in the conversation, it assumed that "the pyramid" referred to *that* one. Similarly for *pyramid*, whose definition was a procedure telling SHRDLU to consider—and, if appropriate, to look for—a thing of a certain sort. The syntactic definitions, of *noun*, *adjective*, and the like, were also expressed as procedures rather than assertions.

An ATN too, of course, would look for a 'suitable' word on encountering *the*, or *pyramid*, and would employ some specific procedure to find a noun, or a verb. But these syntactic categories weren't *defined* procedurally. This gave ATNs a generality that SHRDLU lacked, for *some* ATN could be devised for *any* grammar.

SHRDLU thus constituted a pioneering example of "procedural semantics", an approach to meaning and understanding that became widely influential in cognitive science. As we saw in Chapter 7.ii.d and iv.d–e, procedural semantics was taken up in studies of language and problem solving. It also affected work in practical AI (10.iv.a). With respect to technological NLP, the specifics of Winograd's parser were less influential than Woods's ATNs. But Winograd's work had shown the possibility of integrating syntax and semantics (and world knowledge, when available) in understanding language.

This general lesson could be applied by those who came after him, even if they used a different grammar and method of processing. For example, the author of the speech program whose many errors betrayed underlying anxieties (7.ii.c) singled out Winograd, for having enabled him "for the first time . . . to get a handle on how to think about and represent cognitive and linguistic processes" (Clippinger 1977, p. xv). That stuttering program was very different from the grammatically perfect SHRDLU. Nevertheless, SHRDLU was crucial in its ancestry.

Awesome though SHRDLU was, it wasn't quite so impressive as my description, above, has suggested. For one thing, the "conversation" wasn't really a conversation:

> I believe that in the process of debugging I got it to go through the whole dialog in a single run, but I wouldn't want to state that for sure. Most of the work was done in a more fragmentary manner. (T. Winograd, personal communication)

(Each fragment was relatively speedy: the system, when running compiled, was "fast enough to carry on a real-time discourse", with between 5 and 20 seconds needed for the combined interpretation and response; and the display was designed to move at the speed of a real arm: personal communication.)

For another, the system couldn't be used 'off the shelf':

> The program was at times run effectively by others (including Stu Card who was there for a summer and helped get out many of the bugs), but only after they took some trouble to become familiar with it. It wasn't at a level of robustness for walk-up users. (T. Winograd, personal communication)

In this, SHRDLU was far from unique. It was a common failing of early GOFAI programs that they couldn't be run—or developed—by others, because of bugs. Indeed, this was one of the complaints made by McDermott in his famous criticism of AI work in the mid-1970s (11.iii.a).

c. 'What I did on my holiday'

The growing interest in automatic parsing throughout the 1970s and 1980s, which fed and was fed by the theoretical work on grammars outlined in Section ix, wasn't matched in respect of automatic composition. Even a young child can write an essay on 'What I did on my holiday'. But a computer, even if it could go on holiday in the first place, would be very hard put to do so.

The output of many (non-MT) NLP programs, including SHRDLU, was based on pre-assigned templates. Although these could be syntactically varied to some extent, they were essentially similar to the 'canned' responses of very early programs such as ELIZA. Indeed, the problem of how to enable computers to generate syntactically elegant text was rarely addressed. The reasons were part-practical, part-theoretical.

For most practical purposes, the automatic composition of elegant syntax was, and still is, a stylistic luxury. Many NLP programs, such as the human–computer interfaces used by the general public, can get by with very simple syntax. Even MT programs can acceptably simplify the original syntax, provided that intelligibility is retained. Often, the original text (of technical manuals, for instance) can be written in a deliberately simple fashion without loss of meaning. And even programs that generate the text—not just the plot—of stories can 'succeed' by emulating the syntax of stories written for 5-year-olds, not of Marcel Proust.

The theoretical obstacle was a version of Bar-Hillel's problem: subtle use of syntax requires subtle world knowledge. When people use language, they typically generate syntactic structures that are both apt (with respect to the situation being described) and helpful (with respect to intelligibility). In doing so, many questions arise. For instance:

* When is clause subordination appropriate,
* and which event should be referred to by the subordinate clause?
* When are two separate sentences preferable to a single sentence in which two clauses are conjoined?
* When should one employ subjunctives and conditionals?
* How should one do so?
* And how can one choose *appropriate* referring expressions, determiners, modifiers, tense, aspect, and modal verbs?

These intriguing theoretical questions were investigated in the late 1970s by Antony Davey, who related them to various psycholinguistic phenomena. Here, the relevant point is not the psychology, but the fact that he implemented some of his answers in an NLP program (Davey 1978). He showed how syntax could be used, in a principled way, to signal the strategy driving individual games of noughts and crosses (tic-tac-toe).

Thus his program produced the following description of the game depicted in Figure 9.5:

> I started the game by taking the middle of an edge, and you took an end of the opposite one. I threatened you by taking the square opposite the one I had just taken, but you blocked my line and threatened me. However, I blocked your diagonal and threatened you. If you had blocked my edge, you would have forked me, but you took the middle of the one opposite the corner I had just taken and adjacent to mine and so I won by completing the edge.

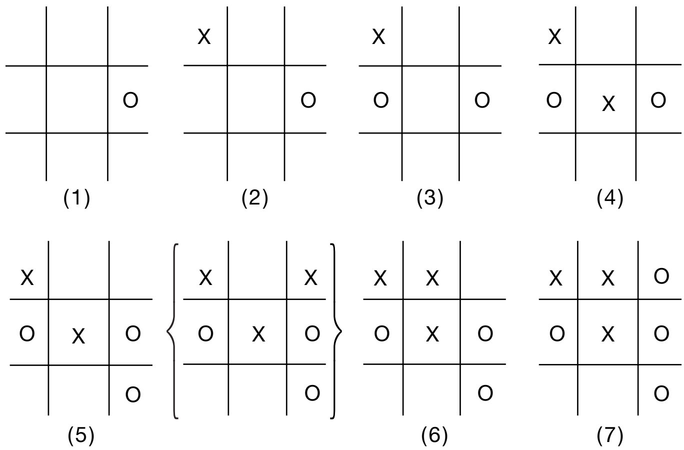

Fig. 9.5. Game of noughts and crosses (tic-tac-toe). The move in brackets wasn't actually made, but was 'imagined' by the program when it described the game depicted in the numbered frames. (Based on an example in A. C. Davey 1978: 18.)

No post-editing was done by Davey: this passage was the actual output of his program. The syntax nicely reflected the structure of attack, defence, and counter-attack informing the game, and helped distinguish strategy from tactics. For instance, it would have been less apt to reverse the last two ideas in the second sentence (as in "... but you threatened me and blocked my line"), or to start it by saying "I took the square opposite the one I had just taken and so threatened you." Many other superficially equivalent alternatives were specifically—and rightly—avoided by the program.

This was the first automatic system capable of generating complex, semantically appropriate, syntactic structures. As such, it was a significant achievement. But, for the reasons outlined above, it had little influence on the development of NLP. Its unprecedented power was unnecessary in most practical contexts, and wasn't achievable in the general case—for composing essays on holidays, for example. Davey had chosen noughts and crosses as his domain precisely because the rules are easily statable, the games are fully describable, and the strategy is readily intelligible. It would be difficult, and often impossible, to adapt his program to other domains.

Different approaches to grammar generation were sometimes considered. For instance, rules governing shifts in the focus of attention (see below) were used in choosing the active or passive voice, pronouns or definite descriptions, and the sequence of sentences within a paragraph (McKeown 1985). But these didn't match the detail of Davey's work. Consequently, today's NLP programs are asymmetrical in their grammatical abilities, much as SHRDLU was. Their expertise in parsing belies their simple-mindedness in sentence construction.

d. Semantic coherence

The maturation of NLP also required a concern for the semantic coherence and rhetorical structure of entire texts. Let's consider the first topic here (the second is discussed in subsection f).

Impressive though it was, Winograd's program had virtually no ability to deal with a text, as opposed to a series of single sentences. Admittedly, anaphora and definite descriptions were interpreted by noting what objects had been referred to in previous sentences. But there was no representation of the theme of the conversation as a whole, nor any prediction as to what the human might say next.

Still less was there any systematic representation of conversational etiquette, or of the distinction between the words uttered and the communicative intention behind them. Eventually, and partly driven by the problems involved in designing usable natural-language interfaces, these issues of semantics and pragmatics came to the fore (see 13.v).

One early attempt to identify the theme of an entire text had been made by Wilks, using CLRU's thesaurus approach (see Section x.d, above). Another, even earlier, was the "General Inquirer", initiated around 1960 by Philip Stone (1936–) at Harvard and colleagues (Stone *et al.* 1962). The method relied on an "affective" classification of the English dictionary, based on tags drawn from Fred Bales's small-group psychology. For example, *union*, *cooperation*, and *love* were coded under the Affiliation tag, whereas *fight* and *war* were classed as Hostility. Counting tag words was straightforward. And hierarchical structures, wherein one semantic tag seemed to be providing the context for another, could be found by list processing—using Yngve's new list-processing language, COMIT.

This approach provided only a very broad analysis—and could be highly misleading, to boot. The computer analysis might show Affiliation governing Hostility, for instance, or Hostility governing Affiliation. However, to decide whether these seeming contradictions reflected actual incoherence, as opposed (for example) to a threat followed by conciliatory remarks, the researcher would have to go back to the text itself.

I myself used a prototype version of the Inquirer in October 1962, as a student in Stone's team analysing the ongoing Khrushchev–Kennedy interchange about the Cuban missile crisis. (The texts were being made immediately available to us in electronic form by an international press association.) The hope was that implicit affective changes in Nikita Khrushchev's attitude might be picked up even before they'd been made explicit by him.

The attempt wasn't successful. For example, Khrushchev's speeches, but not John Kennedy's, scored very high on Affiliation. On checking the original transcripts, the explanation was clear. What Kennedy called "the USA" and "the USSR", Khrushchev (or his translator) called "the *United* States" and "the Soviet *Union*". The problematic words, of course, were then removed. But they might not have been identified in the first place, if the initial scorings hadn't been so highly counter-intuitive. In addition, it was unclear what significance—if any—should be attached to the fact that frequency counts showed one tag hierarchically dominating another.

Both Wilks's system and Stone's suffered from a broad-brush approach. They could identify general themes and overall affective tone, respectively, but couldn't follow the development of a theme from one sentence to the next. And there was no question of their being able to predict the likely content of sentences yet to come.

The first people to model these matters were the social psychologist Robert Abelson and the computational linguist Roger Schank. One reason for their collaboration was that Schank was doing psychological, not technological, AI. He did eventually produce a number of commercially marketed NLP tools, but he saw them—correctly or not—as reflecting how humans process language (see Chapter 7.i.c and ii.d).

By the mid-1960s, Abelson (at Yale) had simulated individual systems of political beliefs, predicting responses to a variety of new inputs. Soon afterwards, he outlined a computational theory of social roles, of motivational–emotional "themes", such as betrayal and cooperation, and of "scripts", such as escape (see Chapter 7.i.c).

By this time, Schank—then at Stanford, though soon to join Abelson at Yale—was doing NLP based on his conceptual dependency (CD) theory. This combined a semantic primitive analysis of verbs with a version of case grammar (Schank 1973; Boden 1977, ch. 7). He aimed not only to represent the meaning of an input sentence, but also to predict the likely topic/s of the following sentences. The verb *hit*, for example, involves an "instrumental" case. If this case slot was left open (as in the sentence *John hit Mary*), the CD representation enabled/predicted the follow-up query "What with?"—where the default inference was that the instrument was the actor's hand.

In their collaborative work at Yale, Schank and Abelson (1977) used the term "scripts" in a new way, to represent the behaviour of various actors in culturally stereotyped situations. Their restaurant script, for example, codified the roles of customer, waitress, and cashier in a hamburger bar. From the early 1970s, Schank and his students combined CD theory with this new theory of scripts to generate questions and answers about (specially composed) texts.

For instance, Wendy Lehnert (1978) wrote a question-answering program that integrated CD representations of verbs with world knowledge about hamburger restaurants. Given a mini-story including the sentence "When the hamburger arrived, it was burnt", the program would infer—what was not made explicit in the input—that the customer who had ordered it neither ate it nor paid for it. These texts provided the story snippets that would soon be used as examples by John Searle (1980) in his discussion of the Chinese room (16.v.c).

Meanwhile, Jim Meehan at Yale, and researchers in other places, had been using Schankian ideas in modelling the generation and summary of simple story plots (Meehan 1975; Rumelhart 1975; Schank and Riesbeck 1981; Lehnert and Ringle 1982). And up to the early 1980s, Schank's student Michael Dyer (at Yale and then UCLA) considered more complex types of story, involving developments of Abelson's ideas about motivational and emotional structures (Dyer 1983).

These Yale-based programs combined linguistics with GOFAI, for they relied heavily on AI ideas about planning in interpreting texts. In this, though in little else, they resembled Winograd's SHRDLU.

For example, a key concept in Dyer's NLP approach was the TAU, or thematic abstraction unit. TAUs were used to organize memory, direct the process of understanding, support analogical reasoning, and enable one story to remind the system of a different one. They were defined as abstract patterns of planning and plan adjustment, involving aspects such as enablement conditions, cost and efficacy, risk, coordination, availability, legitimacy, affect, skill, vulnerability, and (legal) liability. Those dimensions were used by the system to recognize individual episodes in the text as examples of one TAU or another, and different story plots would involve different sets and/or sequences of TAUs. The TAUs included (for instance) *incompetent agent*, *a stitch in time saves nine*, *too many cooks spoil the broth*, *red-handed*, *hidden blessing*, and *hypocrisy*.

As these labels indicate, TAUs were abstractly defined as general planning schemata, applicable to a wide range of texts. As such, they could in principle be used to describe the internal coherence of many different stories. But because of the specific world knowledge needed to consider individual plans in actual texts, Dyer's approach in practice fell foul of the Bar-Hillel problem. (It also fell foul of the McDermott problem: using meaning-rich English phrases, such as 'a stitch in time . . .', as the names for semantically impoverished technical terms: see Chapter 11.iii.a.)

Dyer's program had to be specially designed to anticipate a specific range of stories—which in turn usually had to be specially written. So this approach to NLP, or to knowledge representation in general, was limited in terms of its potential applications. If the text domain wasn't laboriously mapped onto a specific set of planning problems, a Schankian program couldn't generate questions and answers appropriate to it.

In Winograd's (unpublished) invited lecture at the 1973 international AI conference in Los Angeles, when his own name was still on the lips of everyone interested in cognitive science, he pointed out—with characteristic modesty and intellectual generosity—that Schank was addressing important problems which he himself hadn't touched. As for Abelson's work, this was being recommended at much the same time in Minsky's influential, and widely pre-circulated, paper on "frames" (see 10.iii.a). A few years later, Minsky (1977, 1985) would draw on Abelson's ideas again, and on Schank's as well, in his "society" theory of mind (see 12.iii.c).

In short, Schank and Abelson's ideas eventually influenced AI in general (and psycholinguistics too: 7.ii.d), not just NLP.

e. The seductiveness of semantic networks

To say—as Winograd did—that Schank was addressing important problems isn't to say that he was doing so successfully. Quite apart from doubts about semantic primitives in general (see Section viii.c), his own list wasn't drawn up in a principled fashion. It dropped from fourteen to twelve, to eleven. Moreover, his work suffered from an ailment that was all too common in the AI of the time: a logical and linguistic vagueness, grounded in the intuitive use of semantic links.

This charge may seem strange, since computer models can't function by intuition. Any semantic link implemented in a computer program must have some specific definition. But the case is different when one considers the human researcher's interpretation of *diagrams* of semantic networks, such as Figures 9.6 to 9.8. Many such diagrams adorned the NLP literature of the mid-1970s. They flourished in the AI work on knowledge representation, too (see Chapter 10.iii.a). Indeed, they'd been originated by Quillian (1961, 1968) to model the structure of long-term memory.

Quillian's networks represented conceptual associations of *various* kinds, including class membership and similarity (see 10.iii.a). His general approach was taken up by many NLP researchers, including Schank, to represent the meaning of sentences. (It

$$\text{John} \Leftrightarrow \text{hit} \overset{o}{\Leftarrow} \text{dog}$$

FIG. 9.6. Conceptual-dependency diagram representing "John hit the dog." Reprinted with permission from Schank and Colby (1973: 193.)

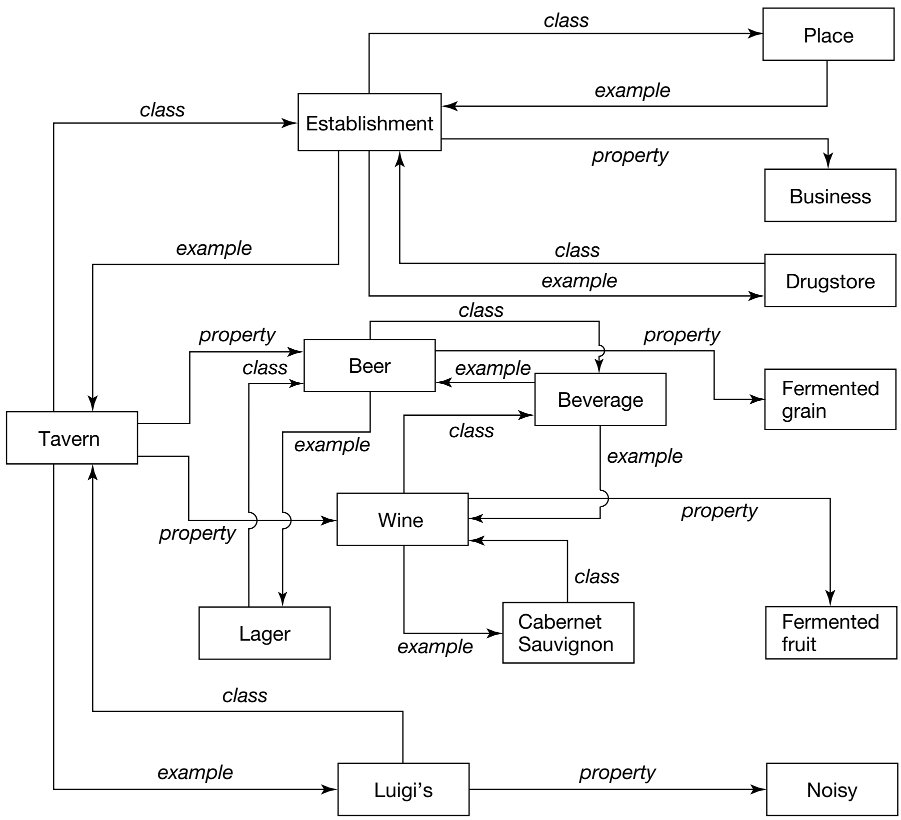

FIG. 9.7. Semantic network representing the concept of "tavern". Redrawn with permission from Lindsay and Norman (1972: 389)

was also applied to vision and to concept learning, by Patrick Winston and John R. Anderson, for instance: see 10.iii.d and 7.iv.c.) But, as semantic networks became increasingly popular, W. A. Woods (1975) rang a warning bell.

Woods pointed out that these representations were usually ambiguous, and—in their naive form—ill-suited to capture many crucial semantic distinctions. In particular, there were many problems concerning relative clauses and quantification:

> [When] one does extract a clear understanding of the semantics of the notation, most of the existing semantic network notations are found wanting in some major respects—notably the representation of propositions without commitment to asserting their truth and in representing various types of intensional descriptions of objects without commitment to their external existence, their external distinctness, or their completeness in covering all of the objects which are presumed to exist in the world. I have also pointed out the logical inadequacies of almost all current network notations for representing quantified information and some of the disadvantages of some logically adequate techniques. (W. A. Woods 1975: 79–80)

Additional problems that needed to be addressed, he said, included (among others) the representation of mass terms, probability, time, tense, and the use of adverbial modification.

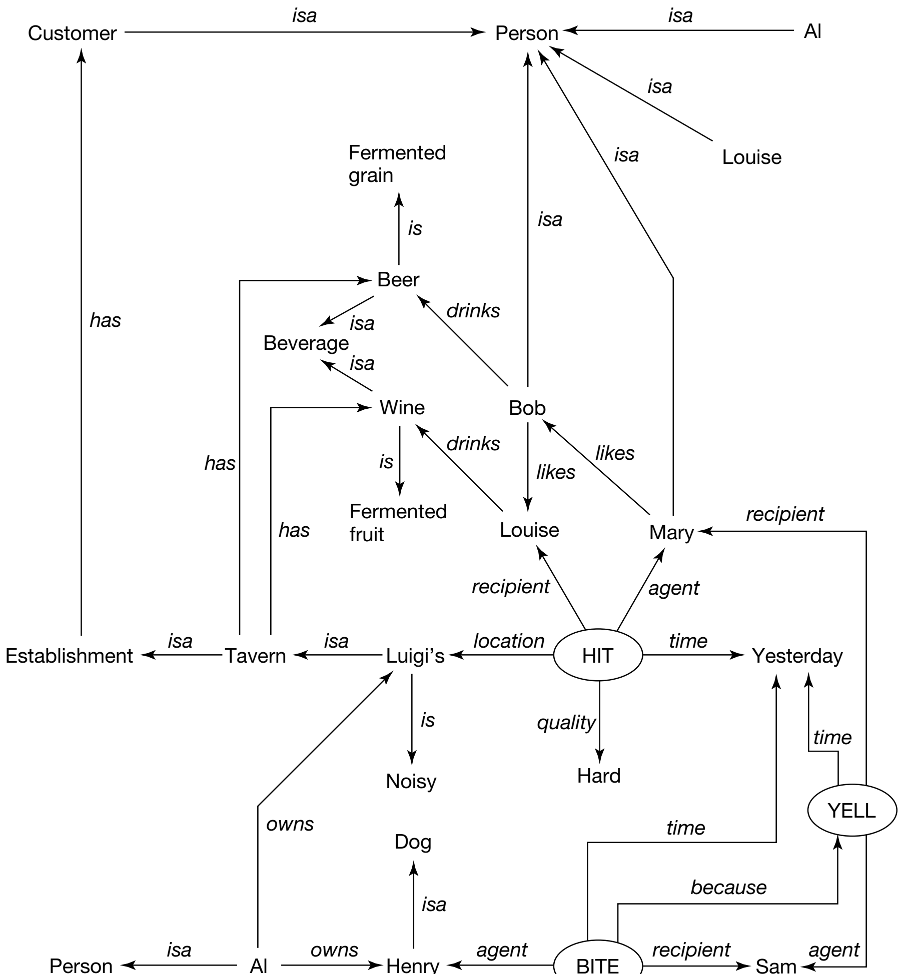

FIG. 9.8. Semantic network representing data about several people—and a dog. Redrawn with permission from Lindsay and Norman (1972: 400)

The justice of Woods's critique can be illustrated by the Schankian CD network shown in Figure 9.6. The link between "hit" and "dog" is labelled as being one of a specific kind, denoting the objective case. And Schank glosses this diagram accordingly, as being equivalent to "John hit the dog". But it could equally well be interpreted as "John hit *a* dog". If Winograd's SHRDLU had relied on this type of representation, it could not have queried the meaning of "Grasp the pyramid" when no specific pyramid had been indicated, nor interpreted that same phrase correctly later in the conversation. Moreover, if even this simple diagram is ambiguous, then one may expect more complex ones (such as Figure 9.7) to be highly problematic.

Where Schank's system was concerned, semantic ambiguity wasn't the only weakness. The system's syntactic power was grossly limited in comparison with that of SHRDLU, or of Woods's ATNs. It couldn't cope with complex auxiliary verbs and nested sentences, as in the query concerning the eggs in the cake (see above). And because it had no representation of logic, it couldn't interpret quantifiers such as *all* or *some*—nor, as we've just seen, definite versus indefinite articles.

Accordingly, those NLP workers who had a healthy respect for logical semantics and grammatical niceties weren't much influenced by Schank's work. Rather, they paid careful attention to syntax, and tried to fill the semantic gaps listed in Woods's critique.

Woods himself, for example, soon improved his LUNAR system in many ways, such as enabling it to interpret the natural-language quantifiers *all*, *every*, *some*, and *most* (W. A. Woods 1978). And others soon improved ATNs by defining a procedure (the "HOLD" function) that enabled them to parse relative clauses in an efficient, and theoretically elegant, way (Wanner and Maratsos 1978). From the early 1980s on, much NLP research implemented highly detailed syntactic theories such as GPSG and its computational cousins (see ix.d–f, above). And some developed theories of logical semantics broadly inspired by Montague, but better fitted to the constraints of actual language use (e.g. Barwise and Perry 1984).

f. Whatever will they say next?

The actual *use* of language involves not only syntax and semantics, but pragmatics too. This became increasingly clear through the 1970s, as computational linguists tried to design human–computer interfaces for interactive tasks (13.v). These included querying databases, planning (of travel itineraries, for instance), and giving/seeking advice on ongoing action (as in repairing a car).

Such applications require a rhetorically coherent conversation, as opposed to a string of isolated sentence pairs. Moreover, the human should be free to use language in everyday ways, and the computer should converse 'naturally' also.

Accordingly, NLP researchers in the mid-1970s began to model how people plan what they are going to say, how they use language to do things other than state facts, how they give or request information in a way appropriate to the interlocutor's state of mind at that moment, and how they keep track of shifts in conversational focus. In doing this, they drew on previous work in the philosophy of language.

Both Wittgenstein (1953) and John Austin (1962*a*) had shown that language can be used to do many different things, and Searle (1969, 1975) had recently formalized some of Austin's ideas. Austin (1911–60) had pointed out, for instance, that some verbs are used not to state facts but to promise, to command, to warn, or to marry. (Consider "I'm warning you . . .", "I promise", and the bride's "I do".) He believed that there's a finite number of speech acts, perhaps a few hundred, in terms of which language use could be systematically classified.

However, Austin (and Searle) didn't assume a one-to-one match between words and speech acts, because people often use language well suited to one speech act in order to perform another. For example, the verb "I suggest" can be used not to suggest, but to command. An indicative sentence can be used to ask a question ("I don't know the time"), or to make a request ("It's cold in here"). And a Yes–No question can convey a command ("Can you pass the salt?"), or elicit substantive information ("Can you tell me the way to the station?").

It follows that human speakers can—and interactive computers should—not only recognize different speech acts, but also distinguish the literal meaning of the sentence from the communicative intention of the speaker. Consequently, Searle's theory of speech acts was applied by Philip Cohen (a colleague of Woods at BBN) and Raymond Perrault to the computer modelling of conversation (P. R. Cohen and Perrault 1979).

The intellectual benefits flowed in both directions. This NLP work uncovered some flaws in Searle's theory, which was later developed—and axiomatized—as a result (Gazdar 1981*b*; Searle and Vanderveken 1985).

Cohen and Perrault drew on other philosophical work, too. H. Paul Grice (1913–88) had noted that people choose what to say—and what to leave unsaid—by considering not only truth, but also helpfulness, relevance, and brevity (Grice 1957, 1967/1975, 1969). These "conversational postulates" are involved also in understanding someone else's remarks. If they are clearly contravened, the remark will be interpreted differently: as a joke, or sarcasm, for instance. In order to apply them, both speaker and hearer must consider each other's beliefs and interests. What is helpful to one person may be unnecessary or confusing for another, or for the same person at a different time. (Grice's seminal work eventually led to a more elaborate theory of "relevance": see Chapter 7.iii.d.)

An interactive NLP system, then, should be able to adjust its output to suit different human individuals, or one individual at various points in the conversation. It should also include procedures for recognizing and correcting *misunderstandings*—on its own part, or the human's.

In implementing Grice's ideas, Cohen and Perrault used AI planning (Chapter 10.iii.c) to show how the multilevel plans of two conversationalists can be mutually adjusted so that communication takes place as intended. Each of these plans included a (continually updated) model of the other speaker's beliefs and intentions. (One might say that the programmers had sketched a "Theory of Mind" for AI systems: see 7.vi.f and 13.iii.e.) And each plan was used to guide the way in which different topics were 'naturally' introduced, or dropped, as the conversation progressed.

Similarly, Richard Power (1979) modelled the ongoing conversation between two robots cooperating in opening a door, where the relevant information wasn't directly available to both of them (see Chapter 13.iii.e). Only the robot on the bolt-side of the door could see whether the bolt was up or down. Opening the door involved problem-oriented planning concerned with how to get the door open (by moving the bolt). It also required *communicative* activities such as:

* attracting the other robot's attention;
* suggesting,
* and then negotiating, an agreed common goal
* (followed by a series of sub-goals);
* communicating or requesting information accessible to only one robot;
* confirming that this information has been duly noted;
* instructing another agent to do something which one cannot do oneself;
* . . . and so on.

From time to time, a robot would have to find out what the other robot knew and compare that with its own knowledge. This required processes that modelled each robot's changing knowledge and its (continually updated) model of the other's state of mind.

Related work was being done at much the same time by Barbara Grosz (1977; Grosz and Sidner 1979). For instance, she modelled the changing reference of terms such as "it" as the conversational focus shifted. As remarked above, focus shifting was later used in generating appropriate syntax, as well as in planning *when* to talk about *what* (McKeown 1985).

One of the general trends in 1980s NLP research was to integrate the two non-linguistic constraints of *attention* (related to focus of interest) and *intention* (related to plans and goals). An interdisciplinary workshop devoted to this aim was held in Monterey, California, in 1987 (Cohen *et al.* 1990). Many of the papers presented there showed how far NLP had moved on since Power's model of the conversation between the door-opening robots. Others were highly relevant, also, to AI work on planning—and on plan recognition, which involves the identification of the other agent's beliefs and intentions.

Several of the Monterey talks were devoted to one or another aspect of speech act theory. And Searle himself gave a paper in which he argued that "collective intentions" can be formally modelled, but can't be analysed in terms of "individual intentions" (Searle 1990*c*). Indeed, some of his remarks could be paraphrased as asserting the existence of something akin to a "group mind" (see 8.iii, preamble).

In addition, Grosz's (and other) work on the structure of conversations would eventually feed into AI teaching programs (Rickel *et al.* 2002). This enabled (for instance) virtual-reality agents to converse with human technicians about how to operate complex machinery (Chapter 13.vi.b).

None of these examples, of course, could match the human use of language. Never mind fancy syntax. The following interchange (Nicholas Negroponte's ultimate goal for NLP) could well make sense for two intimate friends, but would challenge all but the ideal example of "personalized" computers:

"Okay, where did you hide it?"

"Hide what?"

"You know."

"Where do you think?"

"Oh."

(quoted in Brand 1988: 153)

Evidently, sensible conversation depends on much more than *language*. It often needs knowledge of the situation, and of the speakers, too. Flawless computerized conversation is as unattainable as "perfect" translation and interpretation, at least in the general case.

Nevertheless, the attempt to attain these unattainable goals, and to enable computers to parse sentences of indefinite complexity, led to results of both theoretical and practical importance. Some relevant psychological research was discussed in Chapter 7.ii, and the benefits for philosophy included advances in speech act theory (see above). As for the practical aspects, applications burgeoned.

By the mid-1980s, a fairly superficial survey of "technological" NLP required no fewer than 460 large pages (T. Johnson 1985). Now, it would need many more. For significant progress has been made since then. Today's survey, in addition to updating the older topics, would need to add work on non-verbal pragmatics: not just inflection and tone of voice, but eye-gaze, hand gestures, eyebrow movements and other facial expressions, and general body posture.

All these things, which involve significant cultural variations (think of the Indian way of indicating "Yes": not by nodding, but by inclining the head from side to side), help us to interpret conversations in real life. And all are being mimicked, with more or less success, in applications of virtual reality (VR)—see below, and Chapter 13.vi.

g. A snippet on speech

Some of the technological advances in NLP over the past thirty years concern speech processing, which I've chosen not to discuss. Suffice it to say that a great deal was learnt from the blackboard-based early speech-understanding systems, such as the single-user HEARSAY and its speaker-independent successor HARPY (Reddy *et al.* 1973; Newell *et al.* 1973; Erman and Lesser 1980; Lowerre and Reddy 1980). Indeed, one of today's most successful commercial applications, a voice-recognition program marketed by Dragon Systems, was developed by Janet Baker—whose DRAGON program was a component of HARPY (J. K. Baker 1975).

Many of the difficulties that plagued these pioneering attempts (for an overview, see Barr and Feigenbaum 1981, ch. 5), and which led DARPA to halt their funding in 1976, have now been overcome. This has been done largely by combining rule-based knowledge (of phonological tree structures, for instance) with statistical pattern recognition, and by strengthening the phonetics (e.g. Rowden 1992, chs. 6–8; Stolcke 1997; P. A. Taylor 2000). Sometimes, speech recognizers have relied on self-organized "maps" of quasi-phonemes, rather than built-in phonetic representations (Kohonen 1988; see 14.ix.a).

The results have benefited both speech recognition and speech generation. They've also allowed for these to be combined in speech-to-speech translation.

Today's commercially available speech recognition systems can accept menu-based inputs from virtually any speaker on first hearing, so are widely used in telephone-answering services. HEARSAY's notorious slowness—which caused some disillusionment with AI in official circles at the end of the 1970s (Klatt 1977)—is a thing of the past. (Current speech recognizers rely on adaptive statistical models, not on GOFAI: cf. Chapter 12.) Some inexpensive desktop systems today allow one to dictate at normal speeds, without any unnatural pauses between the words. Their powers of recognition are flexible, to some degree: they can learn extra items to enlarge their vocabulary, and adapt to the individual accent of the user.

Visual speech recognition may be feasible in the near- to mid-future, since only sixteen lip-movements are needed to represent English—all of them used in saying *I thought you really meant it*. Already, "talking heads" can be generated (to 'read' input text) which pronounce words with highly effective lip-synchronization (Lucena *et al.* 2002). The sixteen lip positions may be generic, but can also be based on photographs of a specific person's face (cf. Chapter 13.vi.e).

Speech translation is progressing too. A program is being marketed which can deal with telephoned conference registrations, switching between English, German, and Japanese. Research throughout the 1990s sought to aid face-to-face commercial transactions in English between Germans and Japanese who don't speak the language fluently (W. J. Hutchins 1994, sect. 8). Indeed, the new century saw a detailed report on a speech-to-speech translation system which, unlike its few rivals, works in real time. It's not yet (as I write this page) commercially viable—although it may be, by the time you read this book. But a trustworthy reviewer has described it as highly promising, and refreshingly free of hype (Sampson 2001). This achievement is a long way from HEARSAY, whose linguistic knowledge often outweighed its phonetics—so much so, that it might emit a whole sentence in 'reply' to a cough.

Even virtual reality is taking speech on board (see Chapter 13.vi.d–e). In some computer games, one can ask a dragon, "Can you fly?"—and it does. This VR dragon is no SHRDLU: it's merely recognizing the word *fly*. But its future descendants may be able to use syntax and speech act theory to interpret the input sentence either as a question *or* as a request. Certainly, plausible interfaces for virtual reality will demand no less.

Meanwhile, a system called TESSA has been developed for the British Post Office to enable counter-clerks to communicate with deaf people whose native language is BSL, or British Sign Language (Cox *et al.* 2002). This program translates the clerk's speech into sign language, which is visibly expressed as the finger movements, bodily gestures, and facial expressions of a VR avatar. (The screen-creature even manages to look "rueful" when explaining that there are no more first-class stamps.)

By early 2003, about 400 pre-designed translations were being used by the avatar. The team had discovered early in their research that human clerks can't be trained to speak *only* the precise words defining these 400 phrases. So TESSA listens to what the clerk says and then offers a menu of up to half a dozen 'equivalent' English sentences, from which the person chooses one. It's that one which is displayed in BSL form via the avatar. In short, TESSA combines speech recognition with MT and advanced computer graphics.

Automatic speech synthesis is improving also. The first example, Ray Kurzweil's reading machine for the blind (gratefully used by Stevie Wonder, among others), was announced in January 1975. It was immediately featured on America's TV news: Walter Cronkite even allowed it to read the sign-off message for that evening's newscast. Given that it could read virtually any printed font, it was a superb achievement at the time. But it was most unnatural to listen to. The voice of its Xerox successor (Kurzweil sold the company to Xerox in 1980) is a good deal more pleasant.

In addition, there are now many more types of AI-voice application. For instance, a system recently developed for use in a hospital cardiac unit employs near-naturalistic intonation to reflect the relative importance of many different items of medical data. These are passed automatically from the operating theatre to the nurses busily preparing for the patient's arrival in intensive care (McKeown and Pan 2000). And in March 1999, my daily newspaper reported that the physicist Stephen Hawking (current holder of Isaac Newton's and Charles Babbage's Lucasian Chair) had acquired a new speech synthesizer, much more 'human'—and more British—than the one he'd been using for many years.

By the time this book is published, the choices available will doubtless be better still. I say that not just because technology inevitably moves on, but because of a specific research advance. By the close of the century, NLP researchers at Edinburgh University had produced a "dialect independent" lexicon suitable for synthesizing spoken English in many different local accents (Fitt and Isard 1999; Fitt 2003).

In this lexicon, which is based on the work of the descriptive linguist John Wells (1982), speech sounds are classified in terms of the words in which they occur—as in the "boot" vowel, the "foot" vowel, and so on. The description of a dialect for synthesis purposes specifies which of these vowel classes to merge (for instance, the vowels of "father" and "bother" for many American dialects) and which to keep separate (such as the vowels of "tide" and "tied" in most Scottish dialects). The sounds are 'glued together' to form the sentences required—"sentences", not "words", because the pronunciation of a particular word often varies according to the word that follows it.

The sounds themselves aren't synthesized from scratch, but are retrieved from the recorded speech of someone asked to read a script containing examples of each of the sounds required. In May 2004 the accents that had been synthesized in this way included received pronunciation of British English, several American dialects, and a Scottish, an Irish, and an Australian dialect (S. D. Isard, personal communication). More can, and will, be added. The collection of key phonetic symbols (in 2004, just thirty-four vowels and twenty-seven consonants) may turn out to be adequate. But it can be expanded if necessary.

Whether Hawking would be pleased to hear of this advance—which was licensed for commercial use in 2001, and is already being employed in the 'rVoice' product—is unclear. The newspapers in April 2004 reported that he was distressed about his familiar voice system wearing out, as he felt that its Dalek-like tones had become part of his identity. (As he put it when Intel Chairman Gordon Moore donated £7.5 million for a new science library in Cambridge, "I'm Intel inside myself"—Mialet 2003: 453.) In other words, he seems *not* to want his speech synthesizer to pass the Turing Test (16.ii.c).

The Edinburgh-based synthesizer doesn't quite do that, anyway. For example, dialects also vary in intonation and segment duration, but these features (which are independent of the lexicon) aren't represented in the system. So although it's clear that *this* synthesized voice is Scottish and *that* one Australian, neither sounds quite right to anyone with a good ear for accents. Nevertheless, speech processing has come a long way since HEARSAY.

From artificial voices to artificial intelligence: our next topic is the history of AI. *This* chapter, of course, has already begun that narrative. Language may be less central to intelligence than early AI took it to be (see 13.iii.b and 15.vii.a). Nevertheless, NLP is crucial to the AI project. And Chomsky's wider influence affected AI, as well as psychology and philosophy—as we'll now see.

10

WHEN GOFAI WAS NEWFAI

Difficult though it may be to believe, even one's grandparents were young once. They too knew the excitement of youth, and that first fine careless rapture. Likewise, even "good old-fashioned AI" was newfangled AI, once. And if not quite rapturous, certainly very exciting. (Sometimes careless too, as we'll see: 11.iii.a.) In short, GOFAI started life as NewFAI.

John Haugeland's GOFAI label (1985: 112–13) carries patronizing overtones absent from its alternatives: "symbolic", "classical", or "traditional" AI. It suggests a dismissive attitude all too often directed to this area of cognitive science, not to mention grandparents. My own label, NewFAI, also has a negative air. (For the record, it's my coinage, dating from the early 1980s; but others have picked it up and used it in print.) The word "newfangled" is an ancient one: I was taken aback, on a plane trip a few years ago, to encounter it in *The Canterbury Tales*. Geoffrey Chaucer used it to mean simply something *new*, but since then it has acquired a depreciatory tone. For several centuries past, according to the *OED*, it has implied *the love of novelty for its own sake or for purposes of gaudy show*. In our times, it also carries a hint of addiction to technological gizmos. All in all, then, it's hardly flattering.

My justification for using the label here is not that early AI was essentially meretricious. It wasn't. It did, however, often involve over-enthusiastic appraisals, over-optimistic predictions, premature efforts to address very complex issues, and—it must be admitted—self-deception or even dissimulation in describing what AI programs could do (see Chapter 11.iii). In brief, excitement led to overexcitement.

However, the excitement didn't spring from a shallow fascination for novelty or gadgets. It was grounded in an ambitious intellectual vision, which saw the future of theoretical psychology as the design of computational models isomorphic with (all kinds of) mental processes. Clearly expressed by Warren McCulloch and Walter Pitts in the 1940s (4.iii.e), this vision was echoed by several others in the 1950s (6.iii.c and iv.a–b). Hubert Dreyfus later traced its philosophical roots as far back as Plato (16.v.c). In its computerized incarnation, however, it was refreshingly new.

Moreover, it was seemingly endorsed by one of the first working AI programs, which found a proof for a theorem in *Principia Mathematica* more elegant than the one given by its eminent authors (6.iii.c, and i.b below). Small wonder, then, that people were excited.

A caveat, before we begin: It's not clear that all NewFAI researchers believed human thinking to be *constituted by*, or *identical with*, symbolic processes. Perhaps most did, but this was rarely made explicit. (For an early exception, see Newell and Simon 1961.) Even Alan Turing had sidestepped the issue (16.ii). "Strong" and "weak" AI (Searle 1980) hadn't yet been named, and the distinction wasn't always recognized by people at the NewFAI coalface. However, we don't need to worry about these matters until later (Chapter 16). When I speak of NewFAI/GOFAI, I'm referring to a programming methodology, not to the researcher's philosophical position. (So my usage differs from Haugeland's: in his definition, "GOFAI" includes a commitment to strong AI.)

Long though it is, this chapter would have been even longer had not much of the relevant research been discussed already. Natural language processing (NLP) was described in Chapter 9.x–xi; any NLP programs mentioned here are considered only for their relevance to AI in general. Similarly, NewFAI models of belief change and/or personality and emotion (see Chapter 7.i.a–d) are here ignored. And Allen Newell and Herbert Simon's initial work on problem solving was described in Chapter 6.iii.

The very earliest NewFAI research is described in Section i. The first AI labs and publications are noted in Section ii. Sections iii and iv, respectively, deal with the early search for generality and the later use of world knowledge in AI programs. (If asked to locate the maturing of NewFAI into GOFAI, I'd place it there.) And last, in Sections v and vi, I explain why much of the creative effort of NewFAI went into the design of new programming languages—including one which later inspired the revolutionary technology on our desks (and laps) today.

This chapter focuses on work in symbolic AI done before 1980. (In Chapter 12.vi–vii, we'll see why 1980 is a reasonable cut-off point.) As for how GOFAI fared after 1980, that story is taken up in Chapter 13. We'll see there that much of what we regard today as highly modernistic information technology was specifically inspired by visions first expressed within grandparent—or, in one case, great-grandparent—NewFAI.

10.i. Harbingers

The first paper in cognitive science, McCulloch and Pitts' 'Logical Calculus of the Ideas Immanent in Nervous Activity' (1943), was neutral as between symbolic AI, connectionism, and cybernetics. The cybernetics/symbolics schism happened later (Chapter 4.ix), largely driven by the 1950s harbingers of NewFAI.

These mid-century programs and programmatic visions implied that symbolic AI had a bright future. For some toe-in-the-water programs were capable of doing surprisingly 'intelligent' things. Moreover, the symbolic approach was better suited than the early network models to represent goal-directed action and propositional meaning. AI, it seemed, could model—maybe even match—human thought.

a. When is a program not a program?

If Gertrude Stein had said "A program is a program, is a program . . . ", she'd have been wrong. Or anyway, she'd have been wrong if she'd said this in the 1950s. For the sense in which people used the term shifted over the years.

That's not to say that there's a right sense and a wrong sense: most concepts don't have clear semantic boundaries, and this one is no exception (see 8.i.b and 9.x.d). Even today, people sometimes disagree about whether something is a program or merely an outline for a program, and about whether AI researchers should honour only the former. But the historical point, here, is that what NewFAI people were happy to count as a program changed, as implementation became more feasible.

The strong sense of *program* is a list of instructions which can—repeat, *can*—be run on some computer. (Never mind bugs: a buggy program is a program, in this sense.) But a weaker sense would cover a list of rules or instructions *written on paper and 'executed' by hand*. Such a program may not be capable of being fed to a computer. Even a *programming language* may be a purely paper-and-pencil exercise, if it hasn't yet been provided with a suitable compiler/interpreter (e.g. Newell and Simon's "Logic Language": Section v.b, below).

A yet-more-attenuated sense of the term would include a broad *design* for a program, without specification of the individual rules. In that sense, the first AI programs date back to the Second World War, when Turing—as early as 1941—wrote about how to solve problems by searching through the space of possible solutions, guided by what would later be called "heuristics". He even circulated a typescript on these matters to some of his Bletchley colleagues, including Donald Michie. Jack Copeland and Diane Proudfoot (2005: 15) describe this lost typescript as "undoubtedly the earliest paper in the field of AI", and I agree with them. However, an AI *paper* isn't the same as an AI *program*. For something to count as a program, even in the weak sense defined above, it needs to specify individual instructions, in some suitable order.

In the 1950s, weak-sense programs were often important. One example was what's *still* often referred to as "Shannon's chess program". In the late 1940s, Claude Shannon identified many of the basic problems which would have to be faced by anyone programming a computer to play chess (Shannon 1950*a*,*b*). This was highly influential work. Some ten years later, Newell and Simon acknowledged that "the framework he introduced has guided most of the subsequent analysis of the problem" (1958: 42). But their word "framework" was well chosen, for Shannon *didn't even provide a paper-and-pencil program*. What his 1950 papers provided, rather, was an abstract analysis of the task. (A paper-and-pencil chess program had already been written by Turing, but this wasn't yet well known—1947*a*: 23, 1950. It was implemented in 1951. It lost against a weak human player, was "rather aimless", and made "gross blunders"; however, it "reached the bottom rung of the human ladder"—Newell and Simon 1958: 46.)

Another example of a historically significant weak-sense program was the family role playing of Newell and Simon's Logic Theory Machine, or Logic Theorist (LT). In his autobiography, Simon recalled the historic occasion:

> *While awaiting completion of the computer implementation of LT*, Al and I wrote out the rules for components of the program (subroutines) in English on index cards, and also made up cards for the contents of the memories (the axioms of logic). At the [CMU] building on a dark winter evening in January 1956, we assembled my wife and three children together with some graduate students. To each member of the group, we gave one of the cards, so that *each person became, in effect, a component of the LT computer program*—a subroutine that performed some special function, or a component of its memory. It was the task of each participant to execute his or her subroutine, or to provide the contents of his or her memory, whenever called by the [relevant] routine . . .

So we were able to simulate the behavior of LT with *a computer constructed of human components*. Here was nature imitating art imitating nature. The actors were no more responsible for what they were doing than the slave boy in Plato's *Meno*, but they were successful in proving the theorems given them. Our children were then nine, eleven, and thirteen. The occasion remains vivid in their memories. (Simon 1991: 206–7; italics added)

Given enough children, perhaps NewFAI could have rested content with this (weak-sense) type of program?—No. For people can't be relied on to act as though they were "a component of a computer program". Even 6-year-olds will bring their intelligence to bear, following the intention behind an instruction rather than its literal meaning and/or effortlessly (perhaps unconsciously) resolving ambiguities. I was convinced of this when watching my own small son as a LOGO novice in the mid-1970s (see Section vi.a), with Stephen Salter 'playing turtle' and helping him to get the point by deliberately misinterpreting his instruction to TURN (direction unspecified, because—so my 6-year-old son thought—'obvious').

Indeed, if people didn't do this sort of thing as a matter of course then buggy programs—ignoring syntax errors and typos—would hardly exist. Even the great Turing was a culprit, here. Newell and Simon, admitting that there's "no *a priori* objection to hand simulation of a program" but pointing out that it's usually unreliable, said:

For example, there is an error in Turing's play of his [chess] program because he—the human simulator—was unwilling to consider all the alternatives. He failed to explore the ones he "knew" would be eliminated anyway, and was wrong once. (1958: 46)

Why were they bothering to argue for the superiority of strong-sense programs over weak-sense programs as late as 1958? The reason was that most researchers still didn't have easy access to a computer, so were willing—or even forced—to rely on paper and pencil instead. Herbert Gelernter's famous geometry program, for instance, was sketched (by someone else) long before he managed to implement it (see subsection d, below). And John McCarthy started designing LISP while miles away from a suitable computer (v.c). (Many *neuroscientists* still needed to be convinced of the usefulness of functioning programs as late as 1988: Chapter 14.vi.c.)

A further reason for graduating from weak-sense to strong-sense programs was that, in the 1950s, it really wasn't clear just how much was actually achievable by a computer. It was one thing to say, with Turing, that *any* computation could in principle be computed by something like the Turing machine. But what was doable in practice might be very limited. So it was an act of creative exploration, as well as a matter of intellectual hygiene (the avoidance of self-delusion), to find out.

As soon as sufficiently powerful machines were produced by IBM (and, following McCarthy's invention of time-sharing, by DEC, the Digital Equipment Corporation), mere paper-and-pencil programs became less and less persuasive. In any case, there never would be enough "children": one very early NewFAI program contained 20,000 instructions, as we'll see.

Today, then, Stein would be applauded. A program which isn't a program in the strong sense attracts little interest from AI researchers. That's why speculative work on computational architectures, as opposed to executable specifications of psychological processes, is often undervalued (Chapters 7.i.e–f and 12.iii.d). And it's why John Holland's seminal work on genetic algorithms was ignored by many AI people for nearly twenty years, given that he'd written no GA programs himself and that no computer at the time would have had the power to run them in any case (15.vi.b).

b. The first AI program—not!

The Gertrude Stein ambiguity is one reason why identifying "the first AI program" is problematic. Another concerns what people are (or were) prepared to count as *intelligent*. Again, there's no 'right' answer: the concept of intelligence is as fuzzy-bordered as any other, and perhaps more fuzzy than most.

Received opinion holds that the first AI program was the Logic Theorist (Newell and Simon 1956*b*; Newell and Shaw 1957; Newell *et al.* 1957). This is stated baldly in many places: not just in popular accounts (e.g. Crevier 1993: 44) but in scholarly ones too (e.g. H. Gardner 1985: 145; Edwards 1996: 124; Bechtel *et al.* 1998: 53 . . . and more). Arguably, it's also implied by the historian James Fleck (1982: 177), and even by Edward Feigenbaum (1936–) and Julian Feldman (1931–), both of whom were around at the time (1963: 108).

For all that, the oft-repeated claim that LT was the first working AI program is open to challenge—not to say false. Several programs, on both sides of the Atlantic, preceded it.

Newell and Simon began thinking about LT in autumn 1955 and, having been role-played by Simon's family in the New Year vacation, it was fully implemented some nine months later. Their first computer proof, of theorem 2.01 of *Principia*, was achieved in August 1956. And their first computer printout was triumphantly presented—right at the last minute—at the Dartmouth Summer Project in August 1956 (Chapter 6.iv.b). The triumph was deserved. This was the only computer printout to be shown at Dartmouth. And it was, *so far as most of the participants knew*, the first functioning program devoted to a task normally thought of as requiring significant intelligence. Moreover, it's clear with hindsight that it was hugely influential for the development of NewFAI as a whole (not *immediately*, however: see subsection g, below).

Newell had been inspired to start work on it by Oliver Selfridge's talk on pattern recognition, given at the RAND Corporation, Santa Monica, in November 1954 (Chapter 6.iii.b). Selfridge (1926–) had described not merely a programme for a (better) program, namely Pandemonium (Selfridge 1959), but also an already functioning, albeit primitive, system. This was a program written by Selfridge's colleague Gerald Dinneen to recognize letters of the alphabet (Dinneen 1955; cf. Selfridge 1955). It's relevant, here, that Newell later said:

> *Now I'd call it an artificial-intelligence program.* It was not just a simple pattern-recognition device, but it actually carried out transformations and had several levels of logic to it. (interview in McCorduck 1979: 132; italics added)

What's more, the Selfridge–Dinneen program was already known about by the cognoscenti at the time of the Dartmouth event (which happened two years after that RAND seminar). Selfridge himself was one of the Dartmouth participants. However, the early alphabet-recognizer wasn't 'sexy' enough to be thought of as modelling *intelligence* or, to use RAND's preferred terminology, to be seen as a paradigm case of *complex information processing*. Pattern recognition was assumed to be relatively straightforward, at least if—as in this case—generalization wasn't involved (cf. 12.i.c).

The Logic Theorist, by contrast, was modelling one of the peaks of human thought: Bertrand Russell's logical reasoning. Accordingly, it got the historical credit for being the first AI program *even though* it owed its existence to Selfridge's ideas and Dinneen's early system.

Selfridge's Pandemonium was successfully implemented by 1958, and is described in detail in Chapter 12.ii.d. It could well have featured as an extra harbinger, here. For Selfridge's 1954 account of it not only inspired the Logic Theorist, but gave NewFAI two important concepts: parallelism and demons. Instead of writing an ordered sequence of interconnected instructions the programmer could define a set of logically independent procedures; since they didn't depend on each other, these were *in effect* parallel—even though they had to be executed one by one in a von Neumann computer. Moreover, instead of being executed immediately these procedures (demons) could *lie in wait* to be activated by a specific cue. These ideas, too, were later taken up by Newell and Simon, in defining production systems (Section v.e, below). Indeed, the demons in Pandemonium were intellectual ancestors of Simon's famous ant (7.iv.a). Considered as a harbinger, then, Pandemonium was second to none.

The Dinneen and Selfridge pattern-recognizers aren't the only rivals for the accolade of "first AI program". Arthur Samuel's (1901–90) program for playing checkers/draughts (see subsection e) is another—with an even stronger claim to the honorific label.

It was envisaged as early as 1947. At that point, it was seen as a moneymaking exercise, to raise funds for a large computer at the University of Illinois:

> We would build a very small computer, and try to do something spectacular with it that would attract attention so that we would get more money. It happened the next spring there was to be a world checker champion meeting in the little neighbouring town of Kankakee, so somebody got the idea—I'm not sure it was mine, but I got the blame at least—that it would be nice to build a small computer that could play checkers. We thought checkers was probably a trivial game . . . Then, at the end of the tournament we'd challenge the world champion and beat him, you see, and that would get us a lot of attention. We were very naive. (A. Samuel, interviewed in McCorduck 1979: 148)

Naive, yes. But unlike Charles Babbage, whose similar 'moneymaking' scheme never resulted in anything (3.iv.c), Samuel did manage to make a machine play the game. His first program was implemented in 1949 at IBM (where he'd migrated from Illinois), on a '604' commercial calculating machine—and in 1951, on the brand-new IBM 701.

As for the *learning* version of the checkers program, this was up and running early in 1955 (Samuel 1959: 72). In Samuel's words:

> [My program] achieved this aim—to improve its playing ability through [a] learning process involving heuristics—fairly early in its existence, certainly well before 1956 . . . Except for the fact that no publicity was made of the existence of my checker program, one could argue that a program employing learning heuristics had been "fully realized" by this time . . . My checker program was one of the first programs of any size to be run on the first experimental model of . . . the IBM 701. (interview in Copeland 1993: 253)

Despite his reference to "no publicity", Samuel had demonstrated his learning program on American TV on 24 February 1956, six months before the Dartmouth event (Samuel

1959: 72). Unlike Newell and Simon, however, he attended that meeting without bringing along printout evidence. Perhaps that's why one of Marvin Minsky's first crop of AI students, whom one might have expected to know better, would later date Samuel's implementation as "1961"—a full five years after LT (Raphael 1976: 5).

Although checkers is doubtless trounced by Russell's logic as an example of intelligence, it's not 'mindless' in the way that pattern recognition apparently is. As Samuel said:

> checkers contains all of the basic characteristics of an intellectual activity in which heuristic procedures and learning processes can play a major role and in which these processes can be evaluated.
>
> Some of these characteristics . . . are:
>
> (1) The activity must not be determinate in the practical sense . . .
>
> (2) A definite goal must exist . . . and at least one criterion or intermediate goal must exist which has a bearing on the achievement of the final goal . . .
>
> (3) The rules of the activity must be definite . . .
>
> (4) There should be a background of knowledge concerning the activity against which the learning progress can be tested.
>
> (5) The activity should be one that is familiar to a substantial body of people . . . The ability to have the program play against human opponents (or antagonists) adds spice to the study . . . (Samuel 1959: 72–3)

In short, *organized* intelligence is needed for this game.

With respect to playing games (without learning to do better), others besides Samuel wrote programs several years before LT saw the light of day. Across the Atlantic, in May 1951, Christopher Strachey (1917–75) had coded a (buggy) heuristic draughts program for the pilot model of Turing's ACE machine at NPL (Chapter 3.v.c). Encouraged by Turing himself, he wrote an improved version for the Ferranti version of MADM. By the summer of 1952, he reported that this could "play a complete game of Draughts at reasonable speed" (Copeland and Aston n.d.). In addition, he showed that "non-mathematical" instructions outnumbered mathematical ones even in programs for doing numerical integration: in general, then, the *organization* of problem solving was the key to success (Strachey 1952). Samuel took some of his ideas from Strachey accordingly (Samuel 1959: 73).

As for chess, universally regarded as requiring intelligence (and often termed the *Drosophila* of AI, because it has attracted so much effort over the years), this too had already been programmed in Britain. Ferranti's Dietrich Prinz (1903–?)—who'd previously designed a rods-and-levers logic machine (see Preface, ii)—ran a brute-force chess program in November 1951. It played unimaginatively and slowly, and dealt only with the endgame (analysing all the several thousand possible moves in 'mate-in-two' problems).

Turing had been more ambitious. His TUROCHAMP chess program, begun (with the young Cambridge mathematician David Champernowne) in 1948 and still unfinished when he died, played a complete game—and used heuristics rather than brute force to do so (Turing 1953; Michie 1966: 37; Copeland and Aston n.d.). But Turing's ambition, here, didn't stretch to making his program known. He treated it as an entertaining, if challenging, project between friends, not as something to be touted at academic meetings. Being unknown beyond his immediate acquaintance, it couldn't have much influence even in England, still less in the USA.

One might mention even earlier cases, such as Turing's late 1940s program for writing love letters (Chapter 9.x.c). But that was just a toy, a joke. And it had no influence on the development of AI. Whereas it amused a few people, Selfridge's and Samuel's programs—and LT too, of course—excited many. Unlike them, it doesn't deserve (*sic*) to be regarded as a "discovery".

These examples bear out the general point made in Chapter 1.iii.f, that what's classed as a discovery is negotiable. At the dawn of AI, what counted as a program wasn't entirely clear, and what counted as intelligent (or even complex) wasn't clear either. So there was plenty of room for negotiation. There still is (Selfridge? Samuel? Strachey? Turing? Prinz? . . .). It's evident, nevertheless, that LT was/is widely *misperceived* as the first AI program.

c. How a program became a program

The history of Gelernter's geometry program nicely illustrates the shift from *program* (weak sense) to *program* (strong sense). It arose out of the Dartmouth conference. At that meeting, Minsky (having just seen the Logic Theory Machine) sketched a notional Euclidean "geometry machine", and got fellow organizer Nathaniel Rochester to persuade his young IBM colleague Gelernter to implement it (Chapter 6.iv.b).

The task took three years. Besides coding some 20,000 instructions, Gelernter's team at IBM had to invent a new programming language to describe geometrical 'diagrams' and operations (Gelernter 1959; Gelernter *et al.* 1960*a*,*b*). The operations included bisecting angles and dropping perpendiculars. This representation enabled his program to prune the search space drastically, since it tried to prove *only* those features which 'appeared' to be true in the 'diagrams'. (My scare quotes are a warning that this was *neither* computer graphics, *nor* a representation carrying the information that's available to a human being when looking at a diagram—see 13.iii.a.)

Technically, this was interesting because it showed how an internal model of a domain could be used in helping to solve problems about it. This idea, which Kenneth Craik had suggested—though in very different terms—in the early 1940s (Chapter 4.vi), would later be hugely important not only in GOFAI, but also in psychology and neuroscience (7.iv.d–e, 13.iii.a, and 14.viii).

Soon, over fifty different proofs, of up to ten steps, had resulted (Gelernter *et al.* 1960*b*: 143). But one above all attracted attention: an elegant (construction-less) demonstration of the equality of the base angles of an isosceles triangle. Gelernter himself already knew about this proof (McCorduck 1979: 188 n.). But he'd expected a different one, namely, the one used by Euclid. The unexpected proof ran as follows (see Figure 10.1):

> Consider triangles ABC and ACB.
>
> Angle BAC = angle CAB (common).
>
> AB = AC (given).
>
> Therefore the two triangles are congruent (two sides and included angle equal).
>
> Therefore angle ABC = angle ACB.
>
> QED.

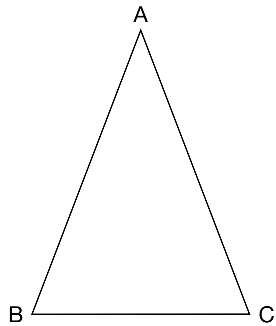

FIG. 10.1. Isosceles triangle

This proof is famous (in the history of mathematics, as in the history of NewFAI) not only because it's so elegantly simple, but also because it appears to be highly creative. A theorem concerning congruent triangles is used, which seems prima facie to be utterly inappropriate: after all, there is only the *one* triangle. Certainly, if a budding mathematician were to produce this proof spontaneously in the classroom, we'd be impressed.

(It was originally found by Pappus of Alexandria, six centuries after Euclid. But the program's computations differed significantly from those reported by Pappus himself. The reason is that, as noted above, its "diagrams" didn't carry the spatial information that real diagrams carry for human geometers. Careful comparison shows that the program was being less creative than it appeared—Boden 1990*a*: 104–10.)

What's relevant here is that Gelernter wasn't the first person to show that his program was capable of producing the proof. Indeed, he didn't even mention it in his 1959 paper. Rather, it was discovered by Minsky, using pencil and paper, long before the program was implemented.

The first public description of the incident was given by Minsky himself. This was in a 1958 forum from which, given the elegance of the proof and the identities of the participants, it was bound to spread far and wide (Minsky 1959 and Chapter 6.iv.b). And in the spreading, it was changed—by the sorts of communicative processes discussed in Chapter 8.vi. Ten years later, Seymour Papert set the record straight:

> The relevant history began at a Summer Program on Artificial Intelligence held at Dartmouth in 1956. At this meeting, Marvin Minsky proposed a simple set of heuristic rules for a program [weak sense, above] to prove theorems in Euclidean geometry. *Before any program* [strong sense] *had been written* these rules were tried (by "hand simulation") on the simple theorem (sometimes called the "pons asinorum") which asserts that the base angles of an isosceles triangle are equal. *To everyone's surprise and pleasure* these rules led to an elegant proof quite different from the one normally taught in high school courses . . .
>
> Although not entirely new, this proof is not well-known and strikes anyone with mathematical taste [in other words, not Dreyfus: Chapter 11.ii.b] as extremely elegant. So it is not surprising that *the story spread and very soon transformed itself, as stories do*, from "Minsky's rules suggested . . ." to "a program [sense ambiguous] generated a new proof" to "a computer [i.e. a strong-sense program] invented an elegant new proof". (Papert 1968: III-6; italics added)

In the meantime, Papert continued, Gelernter—"justifiably encouraged by this little success"—used Minsky's heuristics in a program which two years later was proving theorems of much greater (i.e. ten-step) complexity. In short, the hand simulation of the Pappus proof helped spur Gelernter to convert Minsky's 'program' into a genuine, executable, program.

So who should get the credit? Who *discovered* geometry programming? Hard-headed twenty-first-century AI scientists may insist that only computer-executable (strong-sense) programs count as *programs*. If so, then the prize will be awarded to Gelernter. And indeed, he and his team did most of the hard work. But someone with historical antennae will point out that he was given the general idea, and the crucial heuristics, by Minsky—and that the most famous 'Gelernter proof' was done on the back of an envelope by Minsky too. Since *the very idea* of a geometry program was revolutionary at the time, Minsky deserves much of the credit.

d. First-footings

First-footings in the New Year are, one hopes, auspicious. The lucky piece of coal at the Dartmouth Summer Project was provided by Newell and Simon, in the form of the Logic Theory machine.

We saw in Chapter 6.iii.c why LT was so exciting for psychologists. But it galvanized budding AI researchers too, who were especially interested in *how* it worked its magic. Its programmers were well aware that this magic was limited: "LT's power as a problem solver is largely restricted to problems of a certain class", namely, proving theorems in symbolic logic (Newell *et al.* 1957: 129). A few years later, then, LT gave way to a new system: the General Problem Solver, or GPS (Newell *et al.* 1959, 1962; Newell and Simon 1961).

The first two papers on GPS combined reports of what it had actually done, when implemented, with reports of hand simulations carried out (in early 1959) by the programmers. And the latter much outweighed the former:

> The program is on the RAND Johnniac. The work I am talking about here is all hand simulation. The GPS program is now being debugged, but is not yet solving any problems. Hence most of our information about it comes from extensive hand simulation. (Newell *et al.* 1962: 187)

Evidently, it was still acceptable to describe a program in the "weak" sense defined above. But the defensive nature of their comment shows that the GPS team themselves weren't happy with that: only strong-sense programs would really satisfy them.

What LT and—more powerfully—GPS did was to start with a symbolic representation of the desired object (what would normally be termed the "goal"), and identify differences between that and the current state. The differences would then be reduced one by one, until (with luck!) all had been eliminated. This was done by applying operators to the current state, which were chosen and/or ordered by heuristics. The two key ideas, here, were drawn from previous work: difference reduction from cybernetics (Chapter 4.iii.e and vii.a) and heuristics from Simon's research on decision making in management (6.iii.a).

The term "goal" was used by the GPS team in a way not exactly equivalent to normal usage:

> Each goal is a collection of information that defines what constitutes goal attainment, makes available the various kinds of information relevant to attaining the goal, and relates the information to other goals. There are three types of goals:
>
> Transform object A into object B,
> Reduce difference D between object A and object B,
> Apply operator Q to object A.
>
> (Newell and Simon 1961: 284)

Strictly, then, GPS couldn't have a goal without having some fairly definite idea of how to attain it. Whether that's also true of human beings is debatable (and relevant to the distinction between a wish and an intention).

Different goal differences required different operators. If the preconditions for applying a given operator weren't satisfied, action had to be taken to establish them. For example, a logical operator considered by LT might require that the 'current state' be a conjunction, or have the term *a* before *b* rather than the other way round. If the current state didn't match this precondition, some other operator would have to be found whose actions would alter the current state to match this precondition. The preconditions of the other operator would either have to match the current state or be capable of being made to match as a result of execution of yet another operator, and so on.

In this way, sub-problems (and sub-sub-problems . . .) in LT, and sub-goals (and sub-sub-goals . . .) in GPS, were set up as means to attaining the end. If a chosen strategy couldn't be made to work, LT/GPS would backtrack to the previous choice point and try an alternative pathway through the search space. Differing search strategies could be followed in different cases. For instance, breadth-first search involved following *every* possible branch on a given level, but each one only for a few levels down before switching to the next. Depth-first search, by contrast, picked a path and followed it to the bitter end before considering the next alternative. (The combinatorial explosion, as usual, was lurking in the background. The ability to specify sub-goals on indefinitely many levels could be too much of a good thing: relentless depth-first search to an increasing degree of detail could bog the program down.)

Success wasn't guaranteed, however: this was *bounded* rationality, after all (6.iii.a). A new understanding of "algorithm" ensued as a result.

Derived from the name of the Arab mathematician al-Khwarizmi (2.i.b), the term had come to mean a formally defined (so potentially automatic) mathematical procedure guaranteed to succeed in finding the answer. And the first computer programs, designed as they were for military use, were—or aimed to be—algorithms in this sense. But because LT relied on potentially fallible heuristics to prune the search space, its programmers *denied* that it was an algorithm (Newell *et al.* 1957: 113–14, 117–18). For all that, a heuristic program *was* a formally defined, automatable, procedure—which some people continued to call an "algorithm". So while weak-sense programs were becoming strong-sense programs, strong-sense algorithms were being joined by weak-sense algorithms. For some years, while heuristic programming was still a novelty, talk of "algorithms" was sometimes ambiguous and/or misleading for this reason. Minsky, for one, complained of the "pointless argument" that arose as a result (1961*b*: 438 n. 26). Nowadays, the ambiguity has disappeared, at least for AI professionals: anything that can be run on some computer is called an algorithm, even if it implements a heuristic program.

GPS wasn't limited to logic problems, as LT had been. Even so, the name "*General* Problem Solver" was misleading. To be fair, the programmers had said this themselves:

> GPS could really be better called GPSWP—sort of GPS with pretensions. By "general" we don't mean that GPS can solve all problems. "General" means that it is built in such a way that the specific content of the problem area is factored from the general problem-solving heuristics. Therefore it is capable of tackling a wide class of problems. I don't know how big the class is . . . (Newell *et al.* 1962: 189)

Any problem that could be represented in terms of goals, differences, actions, operators, and preconditions could in principle be solved by this program. The specific content was irrelevant. Moreover, some examples that human beings find tricky, such as the missionaries-and-cannibals puzzle, were solved by GPS (Chapter 6.iii.c).

However, it was the programmer who had to represent the problem in that form, which often required not only great effort but significant creativity. Arguably, that was the *real* problem solving—after which, the program itself merely 'turned the handle'. As the GPS team put it:

> The real gimmick, or the good trick . . . is inventing the right spaces so that the operators we found and the differences we found made these tables of connectives small enough so that there is not too much pointless search. Most of the information we put into the system . . . was introduced by constructing the right problem spaces for the program to work in. This I think was the big selection. (Newell *et al.* 1962: 187–8)

This fact would become increasingly evident over the following decade. It was clear, for example, in Saul Amarel's (1928–2002) masterly discussion of six representations for the missionaries-and-cannibals puzzle (Amarel 1968). The most powerful of these could cope with a very large number of cannibals, arbitrarily distributed on either side of the river at the initial and/or terminal stages, using a boat whose capacity could vary during the development of the solution, and allowing for several missionary 'casualties'. (Amarel had hoped to formulate general principles whereby AI programs could create improved representations for themselves, but he had to admit defeat—Boden 1977: 334–40.)

For NewFAI, the most relevant 'functional' ideas in LT/GPS were:

* heuristic programming (NB heuristics had already been used by Samuel to evaluate alternative choices, but not to generate the search tree itself: see i.b, above),
* choice of methods (in GPS, called operators),
* similarity testing (in GPS, goal differences),
* the hierarchical sub-problem tree (in GPS, means–end analysis and planning),
* backtracking (to compare/select alternative possibilities),
* separation of the 'solving technique' from the specific content,
* the representation of the problem, or
* the search space, and
* building representations of varying structure and unbounded complexity (as opposed to fixed-size vectors).

There were technical excitements too, for LT and GPS were implemented by a revolutionary programming method, made possible by new programming languages (Section v.a, below). These provided:

* recursion,
* list processing, and
* push-down stacks.

These ideas turned out to be incalculably significant for the history of GOFAI. Over the next twenty years, the field was largely focused on theorem proving, heuristic search, planning, and—increasingly—knowledge representation. Some developments, such as flexible planning (Section iii.c), were very much in the spirit of GPS. Others, such as production systems (Section v.e) and "filtering" by constraint propagation (Section iv.b), were new approaches aimed at preserving its strengths while avoiding some of its limitations.

e. The book of Samuel

Another auspicious first-footer was the IBM researcher Samuel (see subsection b, above), later a member of Stanford's AI Department. Taking advantage of IBM's test machines at night, when his saner colleagues were safely tucked up in bed, he wrote a 6,800-instruction program for playing checkers. This was less interesting to psychologists than LT was, because he didn't claim to be modelling human intelligence. Indeed, he thought that studying the way people solve a problem gives one insight into "what the real problem is", but *not* into the brain's method of solving it (McCorduck 1979: 152). To AI people, however, his program was thrilling.

Samuel described it as playing "a fairly interesting game, even without any learning" (1959: 73). But it was the learning which really excited his contemporaries. Eight years after it was implemented, it was still "the only really successful attempt at machine learning in problem-solving" (Feigenbaum and Feldman 1963: 38). When Dreyfus first fired his cannon at AI in the mid-1960s (11.ii.a), even he saluted Samuel. This was no grudging praise: Samuel, he said, had done "very impressive work—perhaps the most impressive work in the whole of artificial intelligence" (H. L. Dreyfus 1965: 5).

In *playing* checkers, the program normally used a lookahead of three moves to evaluate all the legal alternatives, before choosing the best. (Samuel discussed a number of ways in which the lookahead might be increased, depending on the dynamics of the game: pp. 77 ff.) What counted as "the best" was decided by a method in which the program chose the move *most* likely to lead to good positions for itself and *least* likely to do so for its opponent:

> It is not satisfactory to select the initial move which leads to the board position with the highest score, since to reach this position would require the cooperation of the opponent. Instead, an analysis must be made proceeding *backward* from the evaluated board positions through the "tree" of possible moves, each time with consideration of the intent of the side whose move is being examined, assuming that the opponent would always attempt to minimize the machine's score while the machine acts to maximize its score . . . Carrying this "minimax" procedure back to the starting point results in the selection of a "best move". (Samuel 1959: 76)

To *improve* its play, the program used two methods: "rote learning" and "learning by generalization". In the first, it stored all the past positions, together with its initial evaluations of them. (Samuel stressed the importance of indexing, and fast sorting and searching procedures to find the record required.) If the third move in the lookahead happened to be one for which it had already calculated an evaluation, the lookahead—in effect—was increased to *six* moves. So the system pulled itself up by its own bootstraps, with the recent evaluations benefiting from a search much deeper than the official limit of three.

The second learning method was a way of improving the evaluation decision itself, by continuously adjusting the mathematical weighting of the individual test parameters according to their success in play. The program had thirty-eight parameters marking strategic features of the game (such as "threat of fork" and "center control"). Starting with only sixteen of these, it experimented to see which were the most useful, and weighted them accordingly. The least helpful ones were replaced by others drawn from the reserve list. This method was soon called *Alpha–Beta* pruning, based on the names Samuel gave to the program and its opponent (1959: 83). It gave the program an impressive strength, namely, the ability to improve its game differently in response to different people. An opponent's idiosyncratic weak spots could be discovered, and the relevant parameters weighted accordingly—even if they weren't *usually* very helpful. (The machine's play could improve even without a human opponent, if Samuel set two copies of the program 'against' each other.)

Samuel's program was a milestone for NewFAI, in three senses. First, it provided heuristic techniques which would ground further developments for years to come. To use heuristics at all in AI was original. (Turing himself still regarded machine learning as *either* random *or* systematic, by which he meant exhaustive search: A. M. Turing 1950.) In particular, Samuel's minimaxing heuristic is still crucial in machine learning.

Samuel wasn't the first to define it (John von Neumann had done that by 1928), nor to suggest using it for computerized game playing (Shannon had done that by 1950). He wasn't even the first to implement it: Strachey had done that by 1952, using a lookahead of six moves and more. But he was the first to show how minimax could be achieved by a complex evaluation function, defined in terms of various features of game strategy—"center control", for instance. (Strachey had used a simple count of 'own' and 'enemy' pieces.) He was the first to show how that function could be continuously improved. And he was one of the first to suggest that future learning programs might be able to generate their own evaluative parameters (1959: 87, 95). (Selfridge had preceded him here; soon, a new version of Pandemonium would define its own feature detectors: see 12.ii.d.)

Second, in 1962 the program became a publicist's dream overnight, when it beat Robert Nealey, a blind chess player from Stamford, Connecticut—described in the press as a former state champion. (The match had been set up at the request of the editors of *Computers and Thought*, then still in draft.) Nealey himself was impressed:

> Our game . . . did have its points. Up to the 31st move, all of our play had been previously published except where I evaded "the book" several times in a vain effort to throw the computer's timing off. *At the 32–27 loser and onwards, all the play is original with us*, so far as I have been able to find. It is very interesting to me to note that *the computer had to make several star moves in order to win*, and that I had several opportunities to draw otherwise. That is why I kept the game

going. *The machine, therefore, played a perfect ending without one misstep. In the matter of the end game, I have not had such competition from any human being since 1954, when I lost my last game.* (Feigenbaum and Feldman 1963: 104; italics added)

The publicity generated was huge. (IBM weren't happy. They'd never really favoured Samuel's program, although it was useful for testing their new computers, because "it smacked too much of machine thinking, etc., and they wanted to dispel any worry people had with machines taking over the world and all that sort of thing": Samuel, in McCorduck 1979: 151.)

Journalists announced checkers to have fallen decisively to the computer. Most AI professionals apparently believed this too, since they abandoned it for chess (e.g. Newell *et al.* 1958*b*; A. Bernstein and Roberts 1958; Bernstein *et al.* 1958)—which soon provided NewFAI with yet another highly publicized success (see Chapter 11.ii.b).

In fact, Samuel's program wasn't so good—nor checkers so trivial—as this media-friendly achievement suggested. Not only was Nealey *not* an ex-champion of Connecticut (his rating was just below the 'master' level), but he'd made a careless mistake—perhaps because he wasn't taking his opponent seriously (Schaeffer and Lake 1996). In a return match a year later, he won all ten games roundly. Samuel himself wasn't misled. He knew the program had reached only near-master level, and worked hard on an improved version (Samuel 1967). (Nearly thirty years later, he admitted in a letter that he still "had no idea how he could make his program good enough to compete with the world champion": Schaeffer and Lake 1996. Victory at Kankakee remained as elusive as ever.)

Third, and no less compelling to the public eye, the program learnt to beat Samuel himself. This was even more significant, many people felt, than LT's feat of surpassing Russell in logical elegance. The fact that Samuel was a weak player was irrelevant. The sceptic's mantra that "a program can do only what its programmer tells it to do" now had to be seen in a new light. At that time, this was IBM's mantra too (McCorduck 1979: 159). They were so worried about the IBM 704 being seen as threatening that their salesmen were instructed to quote Ada Lovelace's deflationary remark—*[The computer] has no pretentions whatever to originate anything. It can do whatever we know how to order it to perform* (Chapter 3.iv.b)—as often as possible.

Add Samuel's claim that "one can say with some certainty that it is now possible to devise learning schemes which will greatly outperform an average person" (1959: 95), and the fuse had been lit. AI was on the way up.

f. Programmatics

Just how far up was "up"? Partly because it was still difficult to communicate *anything* to a computer (Section v, below), that question was being answered less by programs than by programmatics.

Over-optimistic predictions were rife. One in particular, that a machine would be world chess champion within ten years (i.e. by 1967), would be a prime target of Dreyfus's attack a few years later (Chapter 11.ii.a). Indeed, RAND's Paul Armer reported in his upbeat 'Attitudes Toward Intelligent Machines' (1960/1963) that even *that* prediction was regarded by some as "conservative". (Armer himself didn't agree explicitly, but his preceding sentence had been "Few would have believed in 1950 that man would hit the moon with a rocket within ten years'': p. 405.) This hype had such strong roots that by the mid-1960s it had abated only a little. Simon was then proclaiming, in a book on management, that ''Machines will be capable, within twenty years [i.e. 1985], of any work that a man can do'' (Simon 1965: 96). (We're now another forty years on . . . and still waiting.)

However, even over-optimists can sometimes be constructive. Eight of these early discussions were especially influential, and also remarkably far-sighted.

The earliest was Pitts and McCulloch's (1947) speculation about probabilistic networks and ''universals'' (Chapter 12.i.c). Soon after that came Shannon's (1950*a*,*b*) programmatic paper on chess, discussed above. Another was Selfridge's (1959) account of Pandemonium, in which (besides describing his program) he sketched future possibilities involving complex hierarchies of ''demons'' (12.ii.d). His vision inspired psychologists such as Jerome Bruner (6.ii.b–c), as well as AI researchers.

The fourth example of fruitful programmatics was Turing's (1950) paper in *Mind*. (His two papers of 1947 would have qualified here, had they been published; but they didn't appear until twenty years later: 1947*a*,*b*.) As explained in Chapter 16.ii.a, the *Mind* piece was *not* primarily about the Turing Test. That had been added as a jokey tease, which tantalized the media worldwide and diverted attention from the technical aspects. In fact, the paper was intended as an outline research programme for AI.

Turing gave only sparse hints about the results already achieved, some of which were still top-secret anyway. But what his text lacked in detail, it made up for in scope. Turing recommended AI work on intellectual activities such as chess, as well as on perception, language, and inductive learning—and pointed out that computers, like people, could make mistakes. He sketched the chess program which, when implemented a year later, would lose against a weak human opponent (Section i.a, above). And he outlined the fourfold classification of computational systems that's now normally attributed to Stephen Wolfram (15.viii.a).

Perhaps the most significant aspect of Turing's paper was that he saw AI (not yet named as such, of course) as a matter of programming computers, not building them. Quite a few people at that time were trying to produce machines capable of problem solving and/or learning, but they were doing so by means of engineering (12.ii.a–b).

However, Turing's ideas didn't immediately sweep through the scientific community: the arcane pages of *Mind* were rarely perused by them. The paper was first made more widely accessible in 1956 (see ii.b, below). Meanwhile, his equally prescient paper on 'Intelligent Machinery' (1947*b*), in which he'd declared that ''intellectual activity consists mainly of various kinds of search'' (of which ''genetical or evolutionary'' search was one possibility), remained unpublished until many years after his death. As a result, the notion that *programs,* such as the Logic Theorist, might be the royal road to AI struck many visitors to Dartmouth in the summer of 1956 as a revelation (McCarthy 1989). Even at the end of the 1950s, Frank Rosenblatt's ''Perceptron'' was a physical, not a virtual, machine (12.ii.e). (The capitalized word ''Perceptron'' names a specific piece of hardware built by Rosenblatt, whereas without capitalization it denotes a *class* of parallel-processing systems; although this class includes the Perceptron, most perceptrons are virtual rather than physical machines.)

Next, was McCarthy's 'Programs with Common Sense' (1959), which described a joint project also involving Minsky. Delivered at the seminal 1958 meeting in London (6.iv.b), this was the first published intimation of logicist AI—which would become both hugely influential and hugely controversial (Sections iii.b and e, and Chapter 13.ii).

McCarthy had been nurturing these ideas for a decade, ever since—as an undergraduate at CalTech—he'd gatecrashed the 1948 Hixon symposium and heard von Neumann's talk on automata theory (cf. 15.v.a). Today, he remembers being "turned on" to the idea of the brain as a machine by that talk, and perhaps by Wolfgang Kohler's too—although when he went back to look at their texts, he couldn't find any references to machine intelligence (personal communication). He did, however, beard von Neumann in his Princeton office, to suggest that the brain is an information-processing system *à la* Shannon. Von Neumann encouraged him to try to develop that idea. So where von Neumann's ultimate vision had been (artificial) self-reproduction, McCarthy's—from that moment on—would be (artificial) intelligence.

He soon became dissatisfied with his own equations, believing that logic must, somehow, be the way forward. One might be tempted to say that he was treading in McCulloch's footsteps. For McCulloch had used (a different type of) logic as a key idea in his 1943 paper, and had even tried to define the vocabulary of natural language in logical terms—before giving up in disgust at the difficulty of doing so (4.iii.c). But the young McCarthy didn't know about that.

Indeed, in 1955 he still knew nothing of Newell and Simon: "I had no idea that anyone was doing logic on computers" (personal communication). Meanwhile, he'd failed to persuade many people that automata theory had much to do with intelligence, and he was disappointed by the non-semantic, non-psychological, nature of the papers in the volume he'd co-edited with Shannon (6.iv.b). ("I was against behaviorism, because I used the IBM 704: lots of input/output, but also lots of internal state, which they (or anyway, Skinner) ignored": personal communication.)

So in the final section of the funding application for the Dartmouth Summer Project, he proposed "to study the relation of language to intelligence". In particular, he wanted to formulate a language that could express "conjectures" as well as proofs or instructions, and which would "contain the notions of physical object, event, etc." (McCarthy *et al.* 1955: 52–3). Now, he had his chance.

The 'Common Sense' paper described the *advice taker*, a "proposed [*sic*] program for solving problems by manipulating sentences in formal languages" (McCarthy 1959: 75). Since the inferential procedures and heuristics "will be described as much as possible [not in the particular program but] in the language itself", it followed that the *advice taker* would have a huge advantage over 1950s programs: "its behaviour will be improvable merely by making statements to it, telling it about its symbolic environment and what is wanted from it".

McCarthy's inspiration, here, was our own common sense. Most human intelligence involves natural language, where common-sense inferences are typically performed so easily that we're hardly aware that they've taken place at all. Programs, said McCarthy, should be able to do this too. Moreover, other desirable features depended on it. In particular, a program should be able to learn by taking verbal advice from a person—who needn't know anything about the structure of the program as such, and who certainly wouldn't have to *reprogram* it in order to provide an additional datum.

("Advice", here, meant telling someone a relevant fact, as opposed to instructing them on what to do.)

It followed that if a program is to be capable of learning something, it first has to be capable of being told it. How could that be achieved? The answer, McCarthy suggested, was predicate logic.

He wasn't merely saying (like the logical atomists and the young McCulloch before him: 4.iii.a–c) that natural language can be represented by some form of logic. He was saying that predicate logic could provide the common-sense inferences as well as the meaning. And the user wouldn't need to tell the computer what to do: the program would deduce not only declarative sentences, but also imperatives instructing the machine to do certain things (such as "printing sentences, moving sentences on lists, and reinitiating the basic deduction process on these lists").

As McCarthy defined his project,

> A program has common sense if it automatically deduces for itself a sufficiently wide class of immediate consequences of anything it is told and what it already knows. (ibid.)

(The example he chose to discuss was deciding how to get to the airport, given that one is sitting at home with one's car parked outside.) Much of the ensuing controversy—which continues today—concerned whether a "sufficiently wide class" of consequences could, in general, be deduced by logical means.

Already, in 1958, there were sceptics. The NPL discussants included the logician Yehoshua Bar-Hillel, who'd initially been sympathetic to formal/cybernetic approaches to language but who'd recently emerged as a major critic of machine translation, or MT (Chapter 9.x.b and e). He tartly remarked that McCarthy's ideas were "half-baked", philosophically problematic, vitiated by what would later be called the frame problem (see iii.e, below), and careless of people's capacity to change their minds—not to mention the importance of *time* in deciding how to get to the airport. He ended his many criticisms by saying:

> To make the argument [about getting to the airport] deductively sound, its complexity will have to be increased by many orders of magnitude. So long as this is not realized, any discussion of machines [such as that proposed] is totally pointless. The gap between Dr. McCarthy's general programme [i.e. program] . . . and its execution even in such a simple case . . . seems to me so enormous that much more has to be done to persuade me that *even the first step* in bridging this gap has already been taken. (in the 'Discussion' appended to McCarthy 1959; italics added)

McCarthy was unmoved. Or rather, he was moved to beef up his logic: ten years later, he admitted that the basic predicate calculus wouldn't be enough, that various modal logics would be needed too (iii.a, below). But his commitment to logicism endured—and it still does (13.i.a).

"Twin" examples of NewFAI programmatics which avoided such stringent criticism were 'The Processes of Creative Thinking' and 'Chess Playing Programs and the Problem of Complexity', both due to the LT team (Newell *et al.* 1958/1962, 1958*b*). These set out the general principles which had informed LT and would guide the writing of GPS: bounded rationality, heuristics, hierarchical structure, and so on. They caused great excitement in the small AI community and, like the other forward-looking papers mentioned here, would be cited by Minsky in his own triumph of programmatics (see below).

Soon, they'd cause excitement in other communities too. The RAND memo on creative thinking reached an interdisciplinary audience in 1962, when it appeared in a collection co-edited by the leading Gestalt psychologist Max Wertheimer (Chapter 5.ii.b). As for its twin, on chess and complexity, this was reprinted a year later in *Computers and Thought*.

Meanwhile, Simon had confidently declared in the management journal *Operations Research:* "It is not my aim to surprise or shock you . . . But the simplest way I can summarize is to say that there are now in the world machines that think, that learn *and that create*" (Simon and Newell 1958: 6; italics added). Some readers of *Operations Research* would, therefore, have been eager to see the RAND memo. But they might have been disappointed. The title mentioned "creative thinking", but the focus was on problem solving and game playing: creativity in its everyday sense was ignored. Likewise, Rochester's section on 'Originality in Machine Performance' in the proposal for the Dartmouth meeting hadn't discussed originality in the arts and sciences (McCarthy *et al*. 1955: 49). In the 1950s, that wasn't considered a fit topic for AI.

To be sure, quite a few people were working—with scant results—on "automatic programming", with the hope of avoiding some of the tedium of programming. Besides typical GOFAI programmers, these included the young Richard Laing, seeking automatic designs for cellular automata (Laing 1961*b*; cf. Chapter 15.v.b). And the 'Creative Thinking' harbinger itself predicted aesthetically valuable computer-composed music. But it said nothing specific about how this might be done. Its last-resort advice (after citing hints from George Polya: 1945), "When all else fails, try something counterintuitive", threw no light on Bach fugues, nor even on a saloon-bar pianist's mediocre efforts.

As things turned out, AI models of what's normally meant by creativity had to await the 1980s (Chapter 13.iv). Then, Simon himself would initiate work on scientific discovery (Langley *et al.* 1987). Later still, he'd consider artistic creativity too. Indeed, when invited by the *Stanford Humanities Review* to write a target article for peer commentary on the "foundational assumptions of AI", he chose instead to enter the postmodernist lions' den with a paper on literary criticism (Simon 1994*b*). But that was far in the future. In the harbinger period, it was enough if one could tackle chess or logic, or usher the missionaries and cannibals safely across the river. Creativity could wait.

g. First 'Steps'

The seventh, and most wide-ranging, example of fruitful programmatics was Minsky's 'Steps Toward Artificial Intelligence'. This paper itself developed gradually, step by step.

The earliest version (under the title 'Heuristic Aspects of the Artificial Intelligence Problem') was written in early to mid-1956, as the first draft of what would later become an MIT Technical Report. Although it was still unpublished, Minsky made the draft available informally to visitors at the Dartmouth meeting (Newell and Simon 1972: 884). It identified Minsky's major influences as Shannon, Selfridge, and Solomonoff (see 12.ii.a). Newell and Simon weren't mentioned, for the very good reason that Minsky hadn't yet heard of them.

The second draft, written after the meeting (and published by MIT's Lincoln Laboratory in December), did mention them—but only in passing (Minsky 1956*c*).

That's curious, for two reasons. First, the Logic Theorist was the only program to have been demonstrated at Dartmouth. Second, an Institute of Radio Engineers meeting held immediately afterwards (in September) had involved heated complaints backstage from Newell and Simon, who resented the fact that McCarthy—who had speculated creatively, but achieved nothing (i.e. no AI program)—had been asked to report on the Summer School. Minsky himself had been involved in the negotiations, and had agreed that this wasn't fair. The compromise reached at the IRE was that McCarthy's general report of Dartmouth was followed by Newell and Simon's detailed account of LT. But Minsky's December update of his paper still gave only scant attention to the LT team. It wasn't yet clear, at least to Minsky, that much of what they had to say might apply to intelligence in general, whether natural or artificial.

Five years later, it was. Now retitled as 'Steps . . .', and including extensive discussion of Newell and Simon's work, the paper was officially published for the first time by the IRE (Minsky 1961*b*). It's this version which was reprinted in the best-selling collection *Computers and Thought*. From that time on (i.e. 1963), it reached a wide, and ever-growing, audience.

Years later, Minsky allowed that the initial response to LT had been unfair: "like Darwin and Wallace, Darwin had done all this work and Wallace had gotten this bright idea, but they both got equal attention at the time" (in McCorduck 1979: 108). His explanation of his "perhaps surprisingly casual acceptance of the Newell–Shaw–Simon work" was that he'd sketched the Geometry Machine on the back of an envelope "in the course of an hour or so", so didn't realize just how difficult automated logic would turn out to be (McCorduck 1979: 106). Moreover, the LT team had presented their work at Dartmouth as a contribution to *psychology*, rather than to AI as such. A historical titbit, to be borne in mind when considering Minsky's later work (Chapters 7.i.e and 12.iii.d), is that he now sees the main thrust of his research and Newell-and-Simon's as reversed:

> I did not realize until much later [than the Dartmouth affair] the great joke; at almost every stage, I was in various ways more concerned with human psychology, they with artificial intelligence—but neither of us would have agreed at all with that description. (Minsky, interviewed in McCorduck 1979: 107)

Even today, 'Steps' should be highly recommended to new students of AI. They'd get a sense of some of the major, still largely unsolved, problems—as well as discovering how much 'new' research is reinvention of old wheels. At the time of its first publication, it provided not just intellectual dynamite but intellectual direction too.

Minsky provided a wealth of information, as well as analysis and speculation, for 'Steps' was backed up by a comprehensive annotated bibliography, published (also in 1961) in a different journal. Given the scattering of the relevant literature, this was very useful at the time, and helped to define the scope of the recently named new field (a revised version was included as an appendix when the discursive paper was reprinted in *Computers and Thought*).

In 'Steps', Minsky reviewed the first decade of research, and prophesied future developments. Many of his prophecies have come true—not least because he forecast problems as well as achievements. He had an eagle eye for the combinatorial explosion, for example (although he didn't use that label in discussing how to avoid it). Much as a good way of gauging the success of current cognitive science is to compare it with what was envisioned in *Plans and the Structure of Behavior* (see 6.iv.c and 17.iv), so in evaluating modern AI one could do worse than consult 'Steps'.

The outstanding characteristic of 'Steps' was that it adopted a mathematical, analytic viewpoint. (Regrettably, very few NewFAI people would follow that example: 11.iii.a.) Like McCulloch and Pitts (1943) before him, Minsky was doing what McCarthy called "meta-epistemology". That is, he was trying to identify *general* representational or computational constraints on the sorts of mechanisms that are *in principle* capable of computing particular notions.

Accordingly, Minsky defined and compared various general classes of program, mentioning specific cases only as illustrations. Samuel's checkers player, for instance, wasn't considered merely as having an ingenious learning rule, but as an example of the general class in which (*a*) evaluation depends on the estimation of "imaginary" situations, or planning, (*b*) reinforcement happens "when the actual outcome resembles that which was predicted", and (*c*) there is "some way of evaluating nonterminal positions" (1961*b*: 430–1).

Minsky considered both sides of the incipient cybernetic schism (Chapter 4.ix). He himself had experience of both: he'd started as a connectionist, combining spare parts from a B24 bomber to make a pioneering learning network, but was diverted/converted to NewFAI in 1955 by his MIT colleague Solomonoff (1926–), then working on the induction of grammars (12.ii.a). So in 'Steps', he discussed adaptive "self-optimizing" systems and early connectionist machines, and also highlighted NewFAI icons such as LT/GPS and the checkers player. Significantly, he tried to analyse the weaknesses of various AI methods, as well as their potential strengths.

His section on 'Hill-Climbing', for instance, was followed by one on 'Troubles with Hill-Climbing'. This mentioned both "local peaks" (12.v–vi) and "mesas", in which "the more fundamental problem lies in finding any significant peak at all", and which are especially likely if the evaluation procedure (or "Trainer") can detect only the *solution* of a problem (1961*b*: 411, 429; cf. Minsky and Selfridge 1961).

Another knotty problem highlighted in 'Steps' was credit assignment. In a complex program, each ultimate success is "associated with a vast number of internal decisions", so we must find some way of assigning "credit for the success among the multitude of decisions" (p. 432). In LT/GPS, this was done by breaking the problem into distinct sub-goals (later, it would be dealt with also by back-propagation in PDP connectionism, and by the bucket-brigade algorithm in evolutionary programming: 12.vi.c–d and 15.vi.a).

Property-list descriptions, too, were shown to be problematic (pp. 422–5). In particular, they were problematic if the "properties" were *unary* (defined in terms of only one object) rather than *binary* or *ternary* or . . . Consider the three diagrams shown in Figure 10.2, for instance. These structures (and substructures) can be described, and therefore compared, using familiar spatial words. A computer capable of describing/comparing them, said Minsky, would need some symbolic notation that includes (1) terms for binary relations such as *inside of, to the left of*, and *above* (and, with respect to Figure 10.2 as a whole, the ternary relation *between*), and (2) a way of specifying, and shifting, the hierarchical level at which these relations were being considered. In diagram (*c*), for instance, the triangle is inside the oval, and the circle is inside the triangle. In other words, *inside of* is a recursive relation. But being recursive doesn't necessarily mean being transitive: for some purposes, it wouldn't be

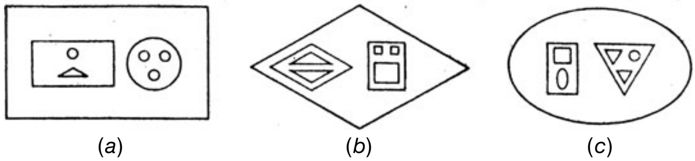

Fig. 10.2. Three diagrams for description and comparison. Reprinted with permission from Feigenbaum and Feldman (1963: 423)

appropriate to describe the circle as being inside the oval, although for other purposes it would. (These points would later be clarified in the ground-breaking ANALOGY program, written by one of Minsky's students: see 13.iv.c.)

Again, Minsky pointed out the difficulty of implementing hierarchy in neural nets (cf. 12.viii.b and ix.a), and the need for carefully ordered training sequences "to insure that early abstractions will provide a good foundation for later difficult problems" (pp. 428, 434 n. 23; cf. 12.viii.c–e and x.e). And with respect to the (general) need for recursive use of previous results, he suggested that future AI programs might use heuristic mechanisms (as in "meiosis and crossing-over") providing for "the segregation of groupings related to solutions of subproblems", and emulating "the fantastic exploratory processes found perhaps only in the history of organic evolution" (p. 434; cf. 15.vi). (John von Neumann had already said that copy errors could ground evolution in cellular automata, but he hadn't discussed how this could be achieved in practice: 15.v.a.)

Minsky discussed the various types of internal "model" (e.g. "analogous, semantic, and abstract": p. 435) which AI programs could use—and, perhaps, construct for themselves. He showed, for example, that planning depends on simplified models of the problem (pp. 442–3). And, sometimes citing his own mid-1950s work, he stressed *general* conditions regarding what would soon be called "knowledge representation" (KR). Minsky saw KR as "crucial":

> The structure of the [representation] will have a crucial influence on the *mental world* of the machine, for it determines *what kinds of things can be conveniently thought about.* (412–13; italics added)

In short, he was asking what types of *virtual* world would enable machines to perform various tasks (see Sections iii.a and v, below).

To take just one example, what kind of "mental world" must a visual program have if it is to be able to see *two* objects?

> [The] property-list scheme is limited (for any given set of properties) in the detail of the distinctions it can make. Its ability to deal with a compound scene containing several objects is critically weak, and its direct extensions are unwieldy and unnatural. If a machine can recognize a chair and a table, it surely should be able to tell us that "there is a chair and a table". (p. 422)

Besides choosing appropriate base-level property descriptors, he said, AI scientists would have to find ways of "subdividing complex objects and describing the complex relations between them". That quest would soon be the focus of MIT's programme of scene analysis, carried out under his direction (Section iv.b below, and 7.v.b–d). (It was also the key idea of Ulric Neisser's "analysis by synthesis", which eventually influenced some AI work on vision: 6.v.b.)

With hindsight, one of the most interesting aspects was Minsky's scepticism about Rosenblatt's "perceptrons", then being hyped in the press and on the airwaves (see 12.ii.e–f). This scepticism was expressed repeatedly throughout the text. For instance:

To recognize the *topological* equivalence of pairs such as those in [Figure 10.3] is likely beyond any practical kind of iterative local-improvement or hill-climbing matching procedure. (Such recognitions can be mechanized, though, by methods which follow lines, detect vertices, and build up a *description* in the form, say, of a vertex-connection table [i.e. scene analysis].) (p. 414)

How could one represent with a single prototype the class of figures which have an even number of disconnected parts? Clearly, the template system has negligible descriptive power. The property-list system frees us from some of these limitations. (p. 415)

[Rosenblatt's] nets, with their simple, randomly generated, connections can probably never achieve recognition of such patterns as "the class of figures having two separated parts", and they cannot even achieve the effect of template recognition without size and position normalization (unless sample figures have been presented previously in essentially all sizes and positions). (p. 421)

It is my impression that many workers in the area of "self-organizing" systems and "random neural nets" do not feel the urgency of this problem [of credit assignment] . . . For more complex problems, with decisions in hierarchies (rather than summed on the same level) . . . we will have to define "success" in some rich local sense. Some of the difficulty may be evaded by using carefully graded "training sequences" . . . (1961*b*: 432–3)

[The] work on "nets" is concerned with how far one can get with a small initial endowment; the work on "artificial intelligence" is concerned with using all we know to build the most powerful system that we can. It is my expectation that, in problem-solving power, the (allegedly brainlike) minimal-structure systems will *never* threaten to compete with their more deliberately designed contemporaries. (p. 446 n. 36; italics added)

And, after a careful mathematical comparison of various associative learning rules:

Incidentally, in spite of the space given here for their exposition, I am not convinced that such "incremental" or "statistical" learning schemes should play a central role in our models. They will certainly continue to appear as components of our programs [i.e. hybrid systems: 12.ix.b] but, I think, mainly by default. The more intelligent one is, the more often he should be able to learn from an experience something rather definite; e.g. to reject or accept a hypothesis, or to change a goal.

In light of the major scandal at the end of the decade, and its effects on the history of AI (Chapter 12.iii and vii.b), these early attempts on Minsky's part to counter the enthusiasm surrounding perceptrons were prophetic.

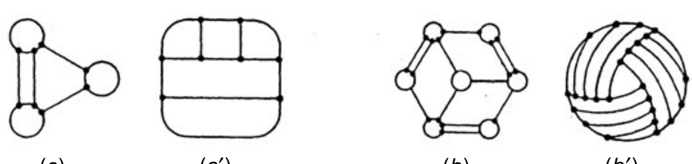

FIG. 10.3. The figures a, a' and b, b' are topologically equivalent pairs. Reprinted with permission from Minsky (1961*b*: 414)

Minsky's paper related the nascent AI to established areas of cognitive science. He cited the Gestaltist psychologists, Craik, Burrhus Skinner, Donald Hebb, Noam Chomsky, and George Miller—and Niko Tinbergen as well (4.vi and 5.ii.b–c). Twice, he praised MGP's *Plans and the Structure of Behavior* (6.iv.c). He recommended Bruner's New Look (6.ii) and Polya on heuristics (6.iii.b), and in comparing different learning strategies he mentioned mathematical psychology too (6.i.a). Neurophysiology and ethology were implicit when he defined various abstract "machines" for conditioning or noted the difficulty of "chaining" reflexes in lower animals having simpler brains (5.iii.a), and explicit when he spoke of "the bold pioneering work" of Nicholas Rashevsky (4.iii) and the "models based on brain analogies" described at the 1958 NPL gathering (6.iv.b). In addition, he remarked the recent experimental discoveries of visual feature detectors, at MIT and Harvard (14.iv.a–b).

Philosophy was included too, as when Minsky said that in thinking about "the 'mind–brain' problem" one should look to Craik and Gordon Pask, and that *freedom of will* depends on being able to distinguish our internal plan from intervention in our action (p. 447 n. 38; cf. Chapter 7.i.g). He devoted his penultimate section to 'Models of Oneself', arguing that an intelligent creature's model of the world would need to include a model of itself—which might well need to be "dual", as ours is (he'd explore this view further a few years later: Minsky 1965). The argument from Gödel's theorem (15.v. a) was based, he said, on a misinterpretation of Gödel. And the ineffability of "intelligence" and "creativity" may eventually be overcome. Programmers know, he said, that there's no mysterious "heart" in a program, only (at base) "senseless loops and sequences of trivial operations". Likewise, "[It] may be so with *man*, as with *machine*, that, when we understand finally the structure and program, the feeling of mystery (and self-approbation) will weaken" (p. 447). This was an early expression of functionalism, which Minsky's Cambridge colleague Hilary Putnam (1960) had just defined at length in an influential philosophical journal (15.iii).

In short, Minsky's attitude to these 'foreign' fields was interdisciplinarity, not condescension. He wasn't saying only that NewFAI had something to teach colleagues in other areas. It could learn from them, too.

It's relevant, here, to remark something which Minsky *didn't* say. Nowadays, he's regarded as one of the most optimistic champions of AI. He's tackling hugely difficult problems (Chapters 7.i.e and 12.iii.d), and is notorious for ebullient futuristic remarks. For instance, he once said to me that science would progress more quickly if *all* the funding money were given to AI, because AI programs will eventually surpass the intelligence of human chemists, geologists, biologists . . . and so on. That may have been tongue-in-cheek: he's nothing if not mischievous. But 'Steps' was carefully considered. Having opened by saying "we are on the threshold of an era that will be strongly influenced, and quite possibly dominated, by intelligent problem-solving machines" (p. 406), he could have closed with a vainglorious flourish. Instead, he forecast that AI programs, in the foreseeable future, would be no more than a powerful accessory to human thought:

> [With the advent of time-sharing machines] we can work toward programming what will be, in effect, "thinking aids". In the years to come, we expect that these *man–machine* systems will share, and perhaps for a time be dominant, in our advance toward the development of "artificial intelligence". (1961*b*: 450; italics added)

h. The harbinger in the Bush

That final quotation from 'Steps' had an important implication: if man–machine systems were to be thinking aids for anyone other than computer scientists, they'd need to be usable by the man/woman in the street—or anyway, in the laboratory and the library. Minsky didn't mention this fact. That's hardly surprising, for AI people in the 1950s had enough to do making computers usable by their colleagues, never mind Joe Bloggs. One computer pioneer, however, had already thought about this issue before mid-century: MIT's Vannevar Bush (1890–1974).

Bush's scientific feet were planted firmly in the ground. He'd invented the (analogue) differential analyser in 1930, and was President Roosevelt's chief scientific adviser—in which role, he supervised the Manhattan Project and other military technologies during the Second World War.

Nevertheless, his speculative paper 'As We May Think' (1945, sects. 6–8) was recently described by William Gibson as "so genuinely, so embarrassingly, so rawly prescient as to make a science fiction writer squirm" (W. Gibson 2001, p. xi). This is no small accolade: it was Gibson's hugely influential novel *Neuromancer* (1984) which introduced the public to the concept, and the potential, of cyberspace. (A copy of the magazine containing Bush's paper was recently sold for $2,200: not bad, for something bought to while away a train journey—J. M. Norman 2005.)

What Gibson termed "the weird acuity of this man's imagination" was concerned with what would now be called information technology, not AI as such. Nevertheless, the paper's insights were the first explorations of issues that were later made concrete by GOFAI and which are crucial for the practice of AI today. Accordingly, it was Bush whom I had in mind when I referred, in the preamble above, to "great-grandparent" NewFAI. His work was so hugely far-sighted that it came to look even more exciting as the years passed than it had done at the time.

Bush's declared concern was to enable people to profit from, instead of being overwhelmed by, the explosion of knowledge in the previous fifty years—not least, the research done for the Second World War. Towards the end of the war, Bush—then Director of the Office of Scientific Research—was invited by the widely read *Atlantic Monthly* to suggest what scientists might do, once they had time again for non-military pursuits. His response was a visionary essay on how they could help society cope with the information explosion (Bush 1945). In fact, his vision was already some 10 years old: the magazine contribution was based on a paper he'd written *before* the war, in 1937 (Nyce and Kahn 1989, 1991).

His essay dealt with the future recording, storing, and accessing of scientific records—indeed, of texts and images in general. He forecast many of the IT applications used in offices and libraries today. (Gabriel Naudé would have been fascinated! Indeed, research libraries would be the first institutions to use computers for handling non-mathematical information.) Bush even forecast the personal computer itself. He called this the "memex", or memory extender, and described it as "a sort of mechanized private file and library".

Bush was writing science-as-speculation, but not science fiction. He took pains to relate his suggestions to specific achievements of mid-1940s science and technology—including many examples drawn from cybernetics. He anticipated add-on gizmos (automatic cameras, scanners for storing handwritten text and images, and speech-typewriters) and interface gimmicks (a push-button that would take one straight to the first page of a document's index, or a sliding "lever" that could turn the—virtual—pages of a stored document one, or ten, or twenty . . . at a time). As you'll know from your own experience, the modern versions of these "gizmos" and "gimmicks" aren't mere toys: to the contrary, they're near-essential, today, for many kinds of intellectual research.

Even more to the point, he also anticipated much of the internal software, or functionality. For he was envisaging a machine to aid, and even to model, creative thinking as well as mere (mere??) data retrieval. The basic idea was that the memex, and its user, could create "trails" of associations: stored memory links (aka hyperlinks) that would become increasingly idiosyncratic with personal use. Bush was deliberately contrasting *flexible associative thought* with the mid-century librarian's rigid hierarchical indexing, and imagining a machine that would fit in with it.

Part of that machine would be what we now call a search-engine. One can hardly fail to be reminded of Google, for instance, on reading Bush's description of how a medieval historian might use his own personal memex (1) to find out about the Turkish and English bows used in the Crusades, (2) to compare—and (3) to explain—their efficiency, and even (4) to speculate on why the more effective (Turkish) weapon wasn't eventually adopted by *both* sides.

The need to make digital computers human-friendly would grow inexorably as their power increased. When Bush wrote his piece, however, they were only just being invented (or perhaps one should say "reinvented", with a salute to a crowded living room in pre-war Germany: Chapter 3.v.a). Very little, as yet, could be done to make the memex a practical proposition.

Indeed, it didn't become practical in the research-lab sense until the 1960s, nor in the commercial sense until the 1980s. As remarked in Chapter 1.iii.g, then, ideas (such as hypertext) crucial to the memex were born/reborn several times within a half-century.

In 1959 Douglas Engelbart's team at the Stanford Research Institute (SRI) started trying to put Bush's vision into effect. Engelbart (1925–) explicitly acknowledged that he'd been inspired by Bush (1962: 47–69). Indeed, he'd been fired up by Bush's ideas as early as 1945:

> At the end of the summer of 1945, just after the surrender of Japan, Engelbart was a twenty-year-old American naval radar technician, waiting for his ship home from the Philippines. One muggy day, he wandered into a Red Cross library that was built up on stilts, like a native hut. "It was quiet and cool and airy inside, with lots of polished bamboo and books. That was where I ran across that article by Vannevar Bush", Engelbart recalls. . . . [He] started designing computer-based problem-solving systems in 1951. (Rheingold 2000: 174–5)

Like Bush, he was thinking of a very wide range of users: "diplomats, executives, social scientists, life scientists, physical scientists, attorneys, designers". He'd also been influenced by his experiences with radar during the war, from which he concluded that a graphical display, changing in real time, might be linked to a computer—from which instructions could be fed back to alter the display.

His preliminary report on the project, prepared for the US Air Force Office of Scientific Research in October 1962, listed the team's goals partly as specific descriptions/predictions of technology (e.g. word processors), and partly as various futuristic dialogues (1962: 73–114). The latter featured an imaginary user and teacher:

> [You, as a neophyte user, will be talking to] a friendly fellow (named Joe), who is a trained and experienced user of such an augmentation system within an experimental research program which is several years beyond our present stage . . .
>
> Joe understands [that you don't know much about these matters], and explains that he will do his best to give you the valid conceptual feel that you want—trying to tread the narrow line between being too detailed and losing your over-all view and being too general and not providing you with a solid feel for what goes on. (Engelbart 1962: 73)

Those fictional dialogues with Joe are remarkable, now, for their 'modern' feel: similar interchanges go on every day in homes, computer shops, and introductory teaching labs. In addition, Engelbart foresaw graphic displays of structures which could be explored and inspected from different points of view and at different levels of detail—by an architect or a road designer, for example. (As it happened, Ivan Sutherland's *Sketchpad* was first described in the very year that Engelbart composed his report, 1962: see Chapter 13.v.c.)

At the time, however, the dialogues seemed not just fictional but science-fictional. Despite being selected as the opening paper in a forward-looking collection on information technology (Engelbart 1963), they didn't enthuse his colleagues:

> Total silence from the computer science community greeted the announcement of the conceptual framework Engelbart had thought about and worked to articulate for over a decade. (Rheingold 2000: 180)

However, ARPA's Joseph Licklider had the imagination—and the intellectual fellow feeling—to get the point. He supported (generously, as ever) Engelbart's efforts to turn some of this fiction into reliably functioning reality. It took almost a decade.

At the 1968 Fall Computer Conference in San Francisco, Engelbart's team were able to demonstrate their own memex—equipped with the ancestral computer mouse. They called it NLS—or oNLine System (Nyce and Kahn 1991). This was a personalized version of human–computer "synergy", or symbiosis (Engelbart 1962: 79 ff.; cf. Licklider 1960). Three thousand computer scientists, of whom Alan Kay (1940–) was one, attended a two-hour demonstration—followed by a standing ovation. The session is now seen as "a landmark event in the history of computing" (Packer and Jordan 2001, p. xvi). Indeed, a film of the event was screened at a thirtieth-anniversary meeting at Stanford in 1998, at which the 73-year-old Engelbart received another standing ovation (Rheingold 2000: 326).

But "reliably functioning reality" in a laboratory demo isn't necessarily a reality that the man in the street can rely on. Stewart Brand, who helped with the original demonstration, soon spread the word about personal computing in his hugely influential *Whole Earth Catalog* (Chapter 1.iii.d). But it would be many years before Kay and others would be able to turn Engelbart's ideas into *commercial* realities (13.v).

A list of the pioneering features of NLS is doubly familiar. Besides reminding one of IT facilities taken for granted today, it recalls the speculations in Bush's memex paper, now 60 years old—or 70, if one considers the 1937 draft. For NLS provided the first versions of

* text linkage (not called "trails of associations", but "chains of views");
* hierarchical hypertext (the term is Ted Nelson's, coined in 1963: cf. Nelson 1965, 1974), later used as the core of the World Wide Web (Berners-Lee 1989);
* keyword search;
* whole-text retrieval by keyword;
* links between text and graphics;
* annotation;
* message passing (i.e. email);
* word-processing (copying, reordering, and adapting written text);
* collaborative working;
* multiple (non-overlapping) windows;
* the screen cursor ("bug");
* and, last but not least, that now familiar animal the computer mouse ("I don't know why we call it a mouse. It started that way and we never changed it": Engelbart n.d.).

Some of these features were already being taken up in the ARPAnet—whose very first message was sent (from UCLA) to Engelbart's lab (Packer and Jordan 2001, p. xvi). Moreover, all were routinely used by Engelbart at SRI. And they caused a sensation at the San Francisco meeting, as we've seen. But they *didn't* immediately spread into the IT community as a whole, still less to Everyman. The mouse, for instance, wouldn't start reproducing merrily—and commercially—until the 1980s.

By that time (thanks largely to Kay), the mouse, windows, icons, and text-processing had not only been much improved but had been made accessible to anyone with a PC on their desk. At long last, historians really could use their private machines to do research on the Crusades.

A final word: the memex was a harbinger of more than desktop technology. Engelbart, though apparently not Bush, saw clearly that a memex/NLS machine would *change* human minds as well as aid them. For instance, word-processing would not only aid but also affect the creative process of composing texts (1962: 74 ff.). In general, it would enable the human computer user to have "the freedom and power of disorderly [thought] processes", which in the early 1960s was impossible (p. 89).

The psychologists Bruner and Miller had recently shown that we process differently structured concepts in different ways (6.ii.b). And in his early 1960s work on cognitive technologies (6.ii.c), Bruner was pointing out that pervasive systems of representation, or "technologies"—such as language, drawing, and writing—enter into the developing mind, shaping it as well as helping it. In 1962 Engelbart—besides remarking that the precise nature of future technologies would depend on "our [psychological] understanding of the human being", including how we process distinct "concept structures" (pp. 70, 85)—was saying much the same:

> In a very real sense, as represented by the steady evolution of our augmentation means [writing, printing, libraries . . .], the development of "artificial intelligence" has been going on for centuries. (Engelbart 1962: 79)

He predicted that in "augmenting" human intellect by using memex/NLS, information technology would provide the thinking processes listed above so as to enable people from all professions to solve "problems that before seemed insoluble", which may have lasted "for twenty minutes or twenty years". But increasing someone's capability "to approach a complex problem situation, to gain comprehension to suit his particular needs, and to derive solutions to problems" in this way wouldn't simply be adding more of the same, nor even providing a new box of tools. Rather, it would be changing the essence of how we think:

> *We do not speak of isolated clever tricks that help in particular situations. We refer to a way of life in an integrated domain* where hunches, cut-and-try, intangibles, and the human "feel for a situation" usefully co-exist with powerful concepts, streamlined terminology and notation, sophisticated methods, and high-powered electronic aids. (Engelbart 1962: 1; italics added)

Forty years later, some philosophers would take the notion of cognitive technologies to heart in a highly provocative way (Chapter 16.vii.d). Following the writings of Andy Clark rather than Bruner, they argued that the mind, the self, is part *constituted* by external technologies and systems of representation. The neo-Cartesian 'mind in the head', and even the phenomenologists' 'mind in the body, ending at the skin', was dismissed. Much as anthropologists—and Wilhelm von Humboldt—had long claimed that culture and language are integral to mind (see Chapters 8 and 9.iv.a–b), so Clark was now arguing that an Alzheimer patient's notebook, or a modern person's PC, are—literally—part of their mind, or self.

The philosopher Timothy van Gelder (a sceptic with respect to GOFAI: 16.vii.c) applied this idea to Engelbart's work. In a paper proclaiming Engelbart to be Turing's equal, when judged as "the most important pioneer in the general field of computing and intelligence", van Gelder said this:

> Engelbart's vision of computers augmenting human intelligence is, properly understood, *a vision of human self-transformation* through a bootstrapping process in which our current, technologically augmented intellectual capacities enable us *to refashion the spaces and practices within which we ontologically self-constitute*. Moreover, his crucial insight was that computer technology will be more profoundly and intimately connected with *the process of self-constitution through enhanced rational self-expression* than any previous technological forms. (van Gelder 2005, last page; italics added)

In other words, 'mind as machine' was being given an ontological, not merely an explanatory, air.

i. Spacewar

One harbinger seemed to many observers at the time to be trivial in the extreme. It was the first computer game, MIT's Spacewar (Levy 1994: 58–69).

It was also the first example of interactive computer graphics, where one could alter the picture on the VDU screen at will. Non-interactive graphics had been around for a decade or more. For instance, when Simon had visited RAND in 1952 he'd been met by "an eye opener. They had this marvelous device there for simulating [radar-blip] maps on old tabulating machines. Here you were, using this thing not to print out statistics, but to print out a picture, which the map was" (interview in McCorduck 1979: 125).

But you couldn't use RAND's "old card calculators" to change the picture before your very eyes.

Spacewar was seeded by Minsky's accidental discovery in about 1960 of how to make his PDP-1 display a circle. Initially, he used his Circle Algorithm to display particle interactions graphically on a cathode-ray tube screen. But the technique was soon adapted by playful MIT graduate students to allow them to pretend to chase and shoot down rockets in outer space.

The basic game was implemented by February 1962. But it was soon much improved, because the students spent most of their spare time playing it, and tinkering with it. By early 1963 (when I played with it on my first visit to MIT) Spacewar had rockets, torpedoes, explosions, sun, stars, constellations—and a joystick. You could use the sun's gravitational pull to increase your speed, provided that you didn't get too close. And you could escape into hyperspace by pushing a panic button, although you never knew just where you'd come out (if you were right next to the sun, it would gobble you up).

That wasn't the end of the line. The MIT hackers constantly advanced the program, the latest version being left in a drawer for the next person to upgrade. In fact, "the next person" might not even need to touch the drawer, for by 1963 the Spacewar code had been sent to the hackers' friends all over the USA. Eventually, the game spawned the "Intergalactic spacewar olympics" at Stanford, a heady meeting of enthusiasts reported in the magazine *Rolling Stone* and commemorated by the famous New York photographer Annie Liebowitz (Brand 1972). Minsky (1984*a*: 248) recalls that by 1965 the game had already become so addictive that daytime playing had to be banned, to leave the computer free for real research.

But how real was real? Spacewar may have seemed trivial to the outsider and trendy to Liebowitz, but over the years it would have a lot of highly practical spin-offs. For example, it soon contributed ideas to simulated displays for training pilots of aircraft and space vehicles. It was used by DEC as a diagnostic program for the PDP-1 (Levy 1994: 65). And it was a forerunner of the hugely more complex computer games we know today—indeed, of computer graphics and 'virtual reality', or VR, in general (see 13.vi).

j. The empty chair at the banquet

Computer graphics of a type hugely more sophisticated than Spacewar were already being seeded elsewhere in MIT—but the Spacewar hackers didn't know that. Indeed, even the specialists in computer graphics didn't know about it. They found out from an unscheduled talk, arranged at the last minute by Licklider, at their first official meeting in 1962 (Rheingold 2000: 149).

Ivan Sutherland, then a graduate student working in MIT's Lincoln Laboratory, had written a revolutionary computer-graphics program called Sketchpad (I. E. Sutherland 1963; Blackwell and Rodden 2003). Where Spacewar dealt with moving spots of light, Sketchpad enabled one to draw—or to instruct the computer to draw—pictures or geometrical diagrams of 2D or 3D structures. Amazingly, the diagrams could be moved, rotated, size-varied, shape-distorted, and even tidied up in various ways.

Sketchpad could well have been included here as yet another harbinger. However, it's described in Chapter 13.v.c instead. In short, there's an empty chair at our harbingers' banquet. (More accurately, there are two: remember Pandemonium.)

10.ii. Establishment

While cognitive science as a whole was being officially established by way of newly founded research groups and new publication practices (Chapter 6.iv–v), symbolic AI was coming into official existence too. But there was no rush to climb onto the bandwagon. Throughout the 1960s and early 1970s it would be studied in relatively few places, most of them in the USA—plus a handful in the UK and elsewhere (Edwards 1996, ch. 8; McCorduck 1979, chs. 5–7; Fleck 1982).

More accurately, it was being *bureaucratically recognized and officially funded* in only a few places. Interested individuals, of course, were scattered much more widely. In Bombay (Mumbai), for example, Rangaswamy Narasimhan (1926–), who'd directed the design of India's first operational digital computer, was doing early work on computer vision at the Tata Institute (Narasimhan 1964, 1966). (His interest in AI eventually led to the world-leading NCST: National Centre for Software Technology, now in a large building in Bombay's Juhu district; some twenty years ago, NCST won the international tender for the new train-scheduling program for the London Underground.)

Narasimhan wasn't the only one. Most computer science departments, in whatever country, contained one or two mavericks who spent some of their time on this new pursuit. A computer science department, however, wasn't the same thing as an AI department. And departments of electronics and/or engineering, which might also harbour a couple of AI 'oddballs', were different again. How did AI become established in its own right?

a. First labs

Several of the earliest AI workers were employees of IBM or RAND. These institutions weren't concerned with AI as an academic discipline, nor with encouraging youngsters into the field. Nevertheless, they both contributed greatly to it.

For instance, IBM supported Samuel (Section i.e, above) and RAND gave houseroom to Newell and Simon (6.iii.b–c). In addition, IBM played an important role in the Dartmouth Summer School, in the persons of Rochester, Samuel, Gelernter, and Alex Bernstein (6.iv.a). Besides IBM's regular employees, there were the occasional visitors—such as McCarthy. He'd spent the summer of 1955 at IBM Poughkeepsie, at the invitation of Rochester—who recommended the Dartmouth proposal because McCarthy "had been bending his ear about AI's potential for some time" (J. McCarthy, personal communication).

The consulting company Bolt, Beranek & Newman (BBN) was another very early AI player (Alperin *et al.* 2001: 7–37; Walden and Nickerson 2005). Temporarily lodged in two rooms inside MIT, BBN was founded in 1948 to develop the acoustic technologies initiated in the Second World War by (among others) the psychologists Licklider and John Swets—both of whom would join the company in its first ten years. (The start-up had been prompted by a vision of peace, not war: the United Nations building in New York. MIT's Richard Bolt won the architect's contract to advise on the acoustics, and decided that he needed Leo Beranek's help; and Robert Newman, then a graduate student in architecture, was soon enrolled too—Alperin *et al.* 2001: 13.) Psychology pervaded BBN from the beginning, both as informational theories of perception and attention (see 6.i and ii.a–b) and as a concern with man–machine integration. At first, that meant operator–tool environments like those studied by Kenneth Craik (4.vi) and Donald Broadbent (6.i.c). But in 1957, when digital computers came on the scene, Beranek hired Licklider specifically to move the firm nearer to them (Beranek 2005; Swets 2005). Licklider remained until 1962, and—given his key role in the history of AI (see below, and Chapter 11.i.b)—it's not surprising that BBN eventually employed several people mentioned in this book (including Oliver Selfridge, William Woods, and Ronald Brachman).

In 1966 the commercially oriented Stanford Research Institute (SRI) started an AI Center to do contract research. At first, most of its projects were government-funded, via ARPA. It soon became well known for its work on robotics and planning, and for vision research interestingly different from that done at MIT. Although these aspects are described below in separate subsections (iii.c and iv.b), and were studied separately in other labs, SRI's robot SHAKEY—so named because it wobbled—was one of the first attempts to integrate all three.

Another such attempt was the Edinburgh University robot FREDDY (Barrow and Salter 1969; Barrow and Crawford 1972; Michie 1973*b*). This was officially known as the Mark 1.5 project, but its more widely used name came from the acronym FREDERICK: Friendly Robot for Education, Discussion and Entertainment, the Retrieval of Information, and the Collation of Knowledge. (Edinburgh's leader, Donald Michie, was nothing if not ambitious!—see Chapter 11.iv.)

Soon afterwards, in 1970, Xerox set up their Palo Alto Research Center. (Largely because of Kay, Xerox PARC would eventually spawn a plethora of advances in human-centred AI: 13.v–vi.)

If NewFAI was to get off the ground at rapidly increasing speed, however, university-based laboratories—supporting graduate/undergraduate courses—would be needed. The first two were set up at the end of the 1950s: at CMU under Simon (6.iii.b–c), and at MIT under Minsky and McCarthy.

(In a different political climate, the honours might have gone to another Massachusetts institution instead, namely Tufts University. For a new department of "Systems Analysis" was opened there in the mid-1950s, of which Minsky was an early member. He was also one of the last members, for the department was closed by the Tufts authorities very soon after it had opened. The reason was that two of its founders, the philosopher Richard Rudner and the psychologist William Schutz, had been placed on the list of political "subversives" compiled by Senator Joseph McCarthy—Crevier 1993: 64. As a result of the witch-hunt at Tufts, Minsky left for the Lincoln lab in 1957; a year later, he transferred to MIT—initially to the maths department, but switching very soon to electrical engineering, where McCarthy was already a member.)

One might assume that MIT's first official AI project was planned at a pre-arranged meeting in someone's office, and shoehorned into official existence by several carefully crafted pages of pleas, promises, and justifications—circulated, in pristine folders, to a dozen busy committee members. Not a bit of it:

> It was all very informal. One day in 1958, Minsky and I met in the corridor of Building 26, and said "Let's have an AI project! Yes, that's a good idea!" Along came Jerry Wiesner, the head of

the Research Lab of Electronics [and President of MIT from 1972 to 1980], and he asked us—in the corridor—what we needed. We said: "A room, a secretary, a key-punch, and maybe two programmers?" He said, "And what about 6 grad. students?" MIT had just had a Joint Services (i.e. Army etc.) contract in electronics, related to defence, and he had all these extra students. A burnt-out computer—which was supposed to be ultra-safe!—gave us the room. (J. McCarthy, personal communication)

This was typical of Jerome Wiesner (1915–94). He was already renowned for having made the RLE, from 1952, not merely an electronics workshop but a wide-ranging interdisciplinary centre:

> At one stage we had twelve different fields represented in the laboratory. The Linguistics and Psychology departments grew out of groups that were started in the lab.
>
> [RLE's communication engineers were joined by] neurophysiologists and other biologists, linguists, economists, social scientists, and psychologists of the various persuasions . . . They explored each other's fields and slowly began to comprehend each other's lingo and exhibit that spirit of mental intoxication that characterizes the pursuit of an exciting idea . . . The two decades of RLE were like an instantaneous explosion of knowledge. (interviewed/quoted in Brand 1988: 134–5)

In short, MIT's AI Lab had an interdisciplinary home right from the start. It's little wonder that the second co-director (Papert) was a psychologist and (originally) a mathematician, not a computer scientist. And it's little wonder that MIT's Linguistics Department—headed by Chomsky (9.vi.a)—had a strongly computational slant. (Computational, but not computer *modelling*: not only did Chomsky eschew programming, but he was already distancing himself from his AI colleagues: 9.x.b.)

Generosity didn't come only from Wiesner, but—five years later—from ARPA too. Both Minsky and McCarthy had close ties with ARPA's first director, Licklider. An MIT psychologist with an early interest in computers, and in library science (Chapter 5.iv.f), Licklider had been on the Air Force's Scientific Advisory Board in the late 1950s, overseeing the ambitious SAGE project (11.i.b). As McCarthy remembers it:

> Licklider said "You're spending millions of dollars, but you're not looking at the (computer) science to support it." So in 1962 they said "OK, if you'll come to Washington to be involved, we'll do it." (personal communication)

Once he was involved, Licklider supported both hardware research and software research too. And his "support" was unstinting:

> [When] his office decided to support a project, that meant providing thirty or forty times the budget that the researchers were accustomed to, along with access to state-of-the-art research technology and a mandate to think big and think fast. (Rheingold 2000: 147)

For example, MIT's Project MAC received the equivalent of $25 million in mid-1990s values from ARPA between 1963 and 1970 (Edwards 1996: 269). It was directed by Edward Fredkin, a co-author—with Licklider and McCarthy—of the first paper on time-sharing (Boilen *et al.* 1963). (Later, from 1968, it would be directed by Licklider himself.) The MAC acronym was deliberately ambiguous, being variously interpreted as Multi-Access Computing (i.e. time-sharing), Man And Computers, and Machine-Aided Cognition—the last two of which recalled Licklider's "Man–Computer Symbiosis" (11.i.b).

As this catholicity implies, Project MAC covered a wide range of research, of which not all was AI—and not all of that, psychological AI. Nonetheless, NewFAI—whether psychological or technological—found shelter under the MAC umbrella. Indeed, the AI Lab set up by Minsky and McCarthy in 1959—with three whole floors of a modern building set aside for it—became a subdivision of Project MAC before graduating as a stand-alone department.

With hindsight, McCarthy sees Licklider's championship as the main reason why AI got established as early as it did, and why this happened in the USA rather than the UK—where early connectionist research, and computer science too, was at least as healthy as in America (Chapters 3.v.b–d and 12.ii.a–b). As he puts it:

> The "AI establishment" owes little to the general "scientific establishment". AI would have developed much more slowly in the U.S. if we had had to persuade the general run of physicists, mathematicians, biologists, psychologists or electrical engineers on advisory committees to allow substantial NSF money to be allocated to AI research.
>
> . . . AI was one of the computer science areas Licklider and his successors at DARPA consider relevant to Department of Defence problems. The scientific establishment was only minimally, if at all, consulted. In contrast European AI research long depended on crumbs left by the more established sciences. (McCarthy 1989)

(How those "crumbs" were first gleaned in the UK, and why they dried up in the early 1970s only to be restored ten years later, is described in Chapter 11.i.a, iv.a, and v.c.)

Initially, the MIT AI Lab was very much a joint enterprise between Minsky and McCarthy, who'd already worked together on organizing the Dartmouth meeting. Even in their 1955 funding application for that summer project, however, there'd been a clear difference between them. In a nutshell, McCarthy focused on logic, Minsky on robotics—including vision and anticipatory planning.

Minsky intended to study the machine learning of sensori-motor representations ("abstractions"), and problem solving by exploration of an internal model of the environment before experimental trials in the external world. (Because of this anticipatory exploration, he said, the behaviour would seem "rather clever", even "rather 'imaginative' "—McCarthy *et al.* 1955: 49.) McCarthy, by contrast, wanted to study "the relation between language and intelligence", in which "the trial and error processes at a higher level [than sensory data and motor activity] frequently take the form of formulating conjectures and testing them" (52–3). To do that, he'd need to construct "an artificial language" with some core strengths of English (i.e. LISP: see v.c, below). This would enable a computer to deal with conjecture and self-reference, to formulate short informal arguments, and to represent everyday notions like "physical object" and "event" (iii.e, below).

Eventually, this difference in research interests—"I never had rap sessions with Minsky" (J. McCarthy, personal communication)—led to McCarthy's decision to leave MIT in 1962 for Stanford, to establish the AI Group there a year later. (Papert took over as co-director of the MIT laboratory, and he and Minsky ran it together until 1972.) The East Coast versus West Coast rivalry that developed over the years wasn't merely about prestige or even money, but about two competing visions of what AI should aim to do. (Notoriously, papers from Stanford would be cited only rarely in work coming out of MIT.) Since AI didn't yet exist at Stanford, although computer science did, it could be moulded to suit McCarthy's own priorities.

Again, Licklider was crucial. When the Stanford AI Group was set up, "Licklider simply asked McCarthy what he wanted and then gave it to him" (Edwards 1996: 270). Later, he admitted: "It seemed obvious to me that he should have a laboratory supported by ARPA . . . So I wrote him a contract at that time." But Licklider was much more to McCarthy than an ARPA sugar-daddy. He was an intellectual partner too. As noted above, they both helped write the pioneering paper on time-sharing (Boilen *et al.* 1963). Indeed, Licklider—who put huge sums of money into the development of time-sharing as soon as he was appointed to ARPA—had been enthused by McCarthy's vision of it in the first place (see 11.i.b).

In fact, things didn't turn out quite as McCarthy had expected. For the department soon split. Largely due to Feigenbaum's presence there, a separate group—the Heuristic Programming Project—was set up in 1965, later metamorphosing into the Knowledge Systems Laboratory. McCarthy's group was now known as SAIL (the Stanford AI Laboratory). The emphases of the two research clusters were very different. McCarthy and his students were concentrating on highly abstract issues of logical reasoning and representation, based largely on "resolution" theorem proving—first formulated very soon after the founding of the department (Section iii.b). Feigenbaum's group, by contrast, were building practically useful expert systems, using facts and rules of thumb provided by domain specialists—medics, chemists, geologists, and so forth (Section iv.c).

CMU, too, benefited greatly from Licklider's largesse. But if Licklider was generous, he was also highly discriminating. When the J. Arthur Sloan Foundation provided $15 million for cognitive science in the late 1970s, they deliberately spread most of the money widely, and therefore thinly (Chapter 8.i.c). Licklider took a very different view. He felt that he knew who the top AI people were, and that between them they should get virtually all the ARPA money available. As a result, each favoured recipient got many times more than the average funding for university laboratories. That's why MIT, Stanford, and CMU quickly became *the* main university centres for AI research.

Licklider's faith in his small band of AI pioneers became doubly important in 1964, when the field suffered its first funding bombshell. A US government advisory committee blasted machine translation, declaring it well-nigh worthless—with dire consequences for MT researchers seeking to finance their work (see 9.x.e). The twenty-year shadow of ALPAC might well have been cast over other areas of AI too, whether language-based or not. And perhaps it was: the document was widely reported in the newspapers, and some university committees may have reconsidered the wisdom of embarking on AI as a result. In the few favoured labs, however, Licklider's support endured.

Meanwhile, the NewFAI gospel—in particular, its psychological version—was being spread across the seas (Chapter 6.iv.e). In 1963 Michie, enthused by his recent visit to the USA, founded a small research group with Bernard Meltzer. In 1966 this spawned Edinburgh's Department of Machine Intelligence and Perception, and (Meltzer's baby) its Department of Computational Logic. Other transatlantic visitors to MIT in this period included Ratio member Donald Mackay, and N. Stuart Sutherland—who founded Sussex University's Experimental Psychology Department in 1964 with NewFAI very much on his mind.

Visitors to the USA from even further afield included Narasimhan, who spent 1961–4 as a Visiting Scientist at the computing laboratory of the University of Illinois, Urbana (Narasimhan 2004: 250). On his return to India, he founded an AI group at the Tata Institute which soon became the National Centre for Software Technology. This was so successful that in 1986 it moved to a separate building, almost as large—if not so extraordinarily luxurious—as the Tata Institute itself.

b. The ripples spread

The AI harbingers described in Section i enthused the pioneers of cognitive science, psychologists included (Chapter 6.iv). But the NewFAI adventurers were a very small community. Moreover, they couldn't multiply the number of functioning programs overnight, since much of their effort had to go into designing new programming languages (Section v.a–e, below).

To make things worse, AI research was available only in informal laboratory research reports, or scattered across a bewildering variety of journals. Even by the end of the 1950s, then, its achievements still weren't widely known.

The possibility of NewFAI, however, was now in the air—thanks, in part, to the reprinting of Turing's daringly imaginative *Mind* paper in James Newman's *The World of Mathematics* (1956). At 2,500 pages, this boxed four-volume collection provided dozens of attractions to vie with Turing's essay—many of them already classics. But Newman's edition turned that paper into a classic too. By the time it was reprinted again in *Computers and Thought* (see below), it was already being described as "one of the best-known papers" about "the existence or nonexistence of various kinds of theoretical upper bounds on the intelligence of computing devices" (Feigenbaum and Feldman 1963: 9).

Some early programs, and their potential implications for psychology, were described in 1960, in the cognitive science 'manifesto' *Plans and the Structure of Behavior* (Chapter 6.iv.c). But the key surge of AI visibility occurred three years later. For in 1963 things changed suddenly. The very newest of NewFAI programs (the strong sense was obligatory at last: i.a, above) reached the public via Feigenbaum and Feldman's best-selling collection *Computers and Thought.*

Virtually every program later discussed by Dreyfus in his cat-among-the-pigeons RAND memo, for instance, was included there (see 11.ii.a). So were four crucial programmatic essays: 'Steps', 'Chess and Complexity', 'Attitudes Toward Intelligent Machines', and Turing's 1950 paper—the last, now placed in an appropriately *technical* context (but still mistakenly described, by the editors, as primarily concerned with the Turing Test: pp. 9–10). Admitting that AI programs were still at the low end of Armer's "continuum" of intelligence, the two young editors ended their Introduction with a rousing call to action:

> What is important is that we continue to strike out in the direction of the milestone that represents the capabilities of human intelligence. Is there any reason to suppose that we shall never get there? None whatever. Not a single piece of evidence, no logical argument, no proof or theorem has ever been advanced which demonstrates an insurmountable hurdle along the continuum. (Feigenbaum and Feldman 1963: 8)

This book was hugely influential, and is still reprinted regularly. The royalties would soon be enough to support a prize for outstanding new work, awarded at the biennial International Joint Conference on Artificial Intelligence, or IJCAI. As the editors had hoped, many readers made AI their profession as a result. It would be over twenty years before another AI collection would have such an explosive effect, on readers young and old (12.vi.a).

The same year saw a collection devoted to NewFAI models of motivation and emotion (Tomkins and Messick 1963). Although this created a flurry at the time, it was grossly premature and fairly soon forgotten (see Chapter 7.i.a–c). Five years later, Minsky (1968) edited *Semantic Information Processing,* which described the NewFAI research being done by his students at MIT. And in 1975 Patrick Winston (1943–), by then running MIT's AI Lab (which he continued to do until 1997), edited *The Psychology of Computer Vision.* This book was read by many people with scant interest in computer vision, because it contained Minsky's paper on "frames"—a hugely influential discussion of schemata in general, and how they could be implemented in AI (see iii.a, below). By the mid-1970s, a fifth widely read collection on psychologically oriented AI had appeared: *Computer Models of Thought and Language* (Schank and Colby 1973).

The floodgates had opened. NewFAI work was circulating outside the laboratory walls, and attracting responses from people in various non-AI departments, including some in the social sciences and humanities. The Association for Computing Machinery's SIGART (Special Interest Group on ARTificial Intelligence) had been publishing a newsletter since the early 1960s. In 1979–80 the American Association for Artificial Intelligence (AAAI) was set up, with Newell as its first President. (For a silver-anniversary retrospective on AAAI, see Feigenbaum 2005.) Meanwhile, AISB had already got started across the pond in the mid-1960s (Chapter 6.v.c). But largely because of a bold political move in Japan, AAAI was showered with money almost from the start (see 11.v.b). Unlike most academic or professional societies, it was able to do a great deal in encouraging its area of interest.

As for regular publications devoted to the new discipline, these were now well established. By the end of the 1960s, six volumes from Michie's Machine Intelligence workshops in Edinburgh had appeared, and a seventh was already in press. The journal *Artificial Intelligence* was about to be founded (in 1970), with Edinburgh's Meltzer as Editor-in-Chief and SRI's Bertram Raphael (1936–) as Associate Editor. The *International Journal of Man–Machine Studies* had made its debut in 1969—the year which also saw the first meeting of IJCAI, held in Washington DC. As befitted the Swinging Sixties, AI was in full swing.

The philosophers helped. Following on Putnam's highly abstract 1960 statement of functionalism (in which AI wasn't mentioned), Jerry Fodor (1968) defined psychological explanation in terms of computation and AI models (16.iv.c). The psychologists helped too: Bruner's Center for Cognitive Studies encouraged psychologists to take an interest in AI—and supported AI's claim to psychological relevance (6.ii).

So far, so Sixties. The Seventies saw the students of the true pioneers setting up specialist laboratories in particular sub-fields. For example, Newell's student Feigenbaum founded the Stanford Heuristic Programming Project and the Knowledge Systems Laboratory, also at Stanford, to focus on expert systems. And the first three monographs on AI appeared in the mid-1970s. These were Raphael's highly readable trade book *The Thinking Computer: Mind Inside Matter* (1976), which—among other things—gave an insider's view on the SRI robot SHAKEY; Winston's welcome textbook *Artificial Intelligence* (1977), which explained how students could use LISP to code the programs it described; and my own *Artificial Intelligence and Natural Man* (1977), which reported not only what AI programs could do and how, but also what they couldn't (yet?) do and why—and which related AI to psychology, philosophy, and social concerns.

Thanks in part to those three books, the general interest in AI, first aroused by *Computers and Thought,* grew phenomenally. During the last years of the 1970s, students were flocking to the already established laboratories, and others were being set up elsewhere. At the same time, the journalists were getting in on the act.

Such was the interest that Feigenbaum initiated a second, more systematic, publication on AI. Whereas *Computers and Thought* had been intended to whet people's appetites, *The Handbook of Artificial Intelligence* advised them on what to swallow—and how to chew it. "Most scientists and engineers," the editors said, "though very knowledgeable about the "standard" computing methods . . . simply had never heard about symbolic computation or Artificial Intelligence" (Barr and Feigenbaum 1981: 12). The *Handbook* should function as "A self-help encyclopedia to which the aspiring practitioner could turn for explanations of fundamental ideas, descriptions of methods, and discussions of well-known programs as case studies". The three volumes appeared close on each other's heels, a total of 1,466 pages in just over a twelve-month (Barr and Feigenbaum 1981, 1982; P. R. Cohen and Feigenbaum 1982).

In brief, the ripples had spread. But it's worth noting that connectionism wasn't mentioned in the *Handbook.*

Perceptrons (which had been prominent in Feigenbaum's *Computers and Thought)* were given only two pages, and the chapter on learning opened with a curt dismissal of the approach:

> [Perceptrons] failed to produce systems of any complexity or intelligence.
>
> Theoretical limitations were discovered that dampened the optimism of these early AI researchers (see Minsky and Papert, 1969). In the 1960s, attention moved away from learning toward knowledge-based problem solving. . . . *Those people who continued to work with adaptive systems ceased to consider themselves AI researchers*; their research branched off to become a sub-area of linear systems theory. Adaptive-systems techniques are presently applied to problems in pattern recognition and control theory. (P. R. Cohen and Feigenbaum 1982: 325–6; italics added)

The 'Vision' chapter included brief accounts of relaxation techniques (12.v.h) and Marrian low-level vision (7.v.b–d), but "parallel processing/search" had only eight index entries for all 1,466 pages.

These editorial judgements were made after consulting dozens of AI experts about the new publication (Cohen and Feigenbaum 1982, pp. xi–xii). In 1980, then, "artificial intelligence" was being perceived by most people simply as GOFAI. If connectionism was being ignored in the *Handbook of AI*, it's not too surprising that many people still use the term AI (wrongly) to cover only the symbolic variety.

c. New waves

The Journalistic ripples soon spread too. Omnibus vehicles such as *Artificial Intelligence* and the *International Journal of Man–Machine Studies* were supplemented in the 1980s by specialist journals devoted to particular sub-fields of AI.

In the 1990s, the numbers of such publications burgeoned. There are now several each in fields such as planning, problem solving, theorem proving, machine learning, computer vision, emotion modelling, legal AI, medical AI, diagrammatic reasoning, robotics, educational AI, virtual reality . . . and so on, and on. In addition, there are various journals in cognitive science, which often publish AI papers.

Most of these AI and interdisciplinary journals are complemented by their own conference series, regular workshops, and/or societies. In other words, a host of established GOFAI activities now aim to provide the cooperation and communication—including face-to-face conversations—necessary for scientific progress (2.ii.b–c).

Whether they ensure that sufficiently *widespread* communication takes place is another matter, for specialization has brought fragmentation. That's especially damaging if one's ultimate aim is to understand whole organisms, or "the whole iguana" (Dennett 1978*c*). Alan Mackworth (1945–), who entered AI at a time when virtually everyone in the field knew (not just knew *of*) everyone else, has put it like this:

> Unfortunately [given the AI dream of building integrated cognitive robots], current research in AI is highly divergent with little or no overlap between specialized subfields such as computational vision, knowledge representation, robotics, and learning. Each group has its own conferences and journals, and when they do all meet at a single conference, they diverge in parallel sessions. (Sahota and Mackworth 1994: 249)

In sum: the interdisciplinarity so characteristic of NewFAI survives, but under increasing pressure.

10.iii. The Search for Generality

The hopes pushing NewFAI forward in the 1960s were focused less on technology (*pace* Licklider, Engelbart, and Bush) than on a theory of intelligence as such. (That approach was still strong in the early 1970s, leading a well-known British AI researcher to say, "I'm not interested in programs!" M. B. Clowes, personal communication.) This is one reason why so many NewFAI ideas were taken up by psychologists. For example, the various forms of "knowledge representation" discussed below were (eventually) widely employed in theories of and experiments on human memory, and AI models were continually cited in the psychology textbooks (e.g. Klatzky 1980).

For many NewFAI workers, however, "intelligence" usually meant *intelligence in general*. In McCarthy's mind, for instance, human psychology was of no special interest, "except as a clue to possible effective ways of doing tasks" (McCarthy 1989). In drafting the Dartmouth proposal, he hadn't criticized "anybody's" (i.e. the behaviourists') way of studying human behaviour: "I didn't consider it relevant". In particular, he now disclaims being part of "the cognitive revolution":

> [Because I didn't consider psychology to be relevant to AI], whatever revolution there may have been around the time of the Dartmouth Project was *to get away from studying behavior* and to

consider the computer as a tool for solving certain classes of problem. *Thus AI was created as a branch of computer science and not as a branch of psychology*. (McCarthy 1989)

He allows, however, that Newell and Simon ("the only participants who studied human behavior") worked "both in AI as computer science and AI as psychology".

The belief—more accurately, the often unquestioned assumption—was that a relatively small number of general mechanisms (heuristics, search techniques, learning rules, representational methods, architectures . . .) would suffice to explain intelligence in all its forms. Whatever the domain of study, from logic and chess to language and vision, the aim was to uncover that generality. Special constraints might have to be added, if one was interested in modelling human minds—limits on short-term memory capacity, for example (7.iv.b). But the underlying principles would be untouched.

The commitment to generalism was strongest at Stanford, thanks to McCarthy. In the 1970s, Minsky would give it up, now arguing that many different interacting procedures were responsible for intelligence (Minsky 1979). Indeed, he later became known as the most eminent of the "scruffies", while McCarthy was acclaimed as the high priest of the "neats" (see 13.i.c). In the early 1960s, however, generalism was dominant.

Simon was someone who did take pains to examine the generalist assumption, and sought to justify it too. For example, he argued that the core mechanism of deliberation *must* be serial, so as to handle 'what-ifs' without confusion (e.g. Simon 1967). He soon became even more influential than the building of LT/GPS had already made him. His 1962 paper on 'the Architecture of Complexity', and his 1968 Compton Lectures at MIT on *The Sciences of the Artificial*, published in 1969 and never out of print thereafter, were an inspiration (7.iv.a). Together with Minsky's 'Steps', they helped set the NewFAI agenda.

I'll mention only a few examples of NewFAI generalism here. And I'll ignore chess, which isn't my thing. It's sometimes described as the fruitfly of AI, for a great deal of technical work was done on it right from the start—and still is (for some recent examples, see Berliner and Beal 1990). That's not because people wanted an excuse to spend their professional time on their favourite Sunday afternoon pastime, but because they believed that chess involved many of the major aspects of intelligence *in general*. As the GPS triumvirate put it: "If one could devise a successful chess machine, one would seem to have penetrated to the core of human intellectual endeavor" (Newell *et al*. 1958*b*: 39).

Apparently, Everyman agreed. These efforts continually whetted the public's appetite for AI. For example, the first "respectable" chess program was featured widely in the late 1950s media, from the *Scientific American*, through the *New York Times*, to *Life* magazine (A. Bernstein and Roberts 1958). The first exhibition game between the world champion and a computer took place in August 1974 (J. E. Hayes and Levy 1976: 49; see also Good 1968). The chess master David Levy's £500 bet, in 1968, that no program would beat him within ten years caused much publicity, culminating in 1977–8 in two widely reported matches (against Northwestern's Chess 4.5 and 4.7). In both cases, Levy won—much to the satisfaction of the readers of the *New York Times,* faced with the headline 'Chess Master Shows a Computer Who's Boss'.

All those programs were 'pure' software. Deep Thought—named after the computer in *The Hitchhiker's Guide to the Galaxy*—and its successor Deep Blue, which in 1997 did beat the world champion, were very different, for they relied on special-purpose chips. (These were designed by Feng-hsiung Hsu at CMU and then IBM: Hsu 2002.) The 480-chip Deep Blue could search hundreds of millions of chess positions per second. Even so, the chips were optimizing the very general AI technique of blind search, not supporting forms of representation specific to chess—as human players do (cf. Chase and Simon 1973). This enabled the public—and the defeated champion Gary Kasparov, too—to save face: the computer might now appear to be the boss, but only because it was, at base, a bully.

For NewFAI, as remarked above, chess *as such* wasn't the point. Indeed, Minsky deliberately discouraged his MIT students from working on it (interview in McCorduck 1979: 189). Chess interested some AI researchers because it could help them to develop general AI techniques. (Today, this motivation underlies the AAAI's General Game Playing Competition, which aims at programs that can play any formally described game by using general methods of representation, reasoning, and learning: see <http://games.stanford.edu>.)

Most of the 1960s NewFAI programs, in fact, weren't designed simply to achieve a specific task. Rather, they were aimed at the general problems identified by 'Steps'—and, in the late 1960s, even by Dreyfus's *Alchemy and Artificial Intelligence* (see 11.ii.a–b). In applying (so it was widely believed) to men, mice, and Martians, they were intended as contributions to cognitive science as a whole: the study of *all possible minds*.

a. SIP spawns KR

When computers were used only to do simple mathematics, the problem of knowledge representation (KR) wasn't too pressing. Enabling a digital computer to store the fact that "$2 + 2 = 4$", and even enabling it to do the sum, was relatively painless. But things got trickier when the machines began to be used to do goal-directed problem solving, theorem proving, pattern matching, visual scene analysis, diagrammatic reasoning, and—above all—interpretation of verbal texts. Enabling the human user to communicate with the machine in English, for example, was no small feat. "Semantic information processing", or SIP, required new forms of KR, appropriate for non-numerical data and inferences.

(Strictly, people should have spoken of BR, not KR. For the term "knowledge" assumes *truth*, whereas "belief" doesn't. NewFAI writers systematically ignored the K/B distinction. Later AI researchers sometimes allowed for it, especially when discussing how to revise previously drawn conclusions now seen to be false: see McDermott 1974, and 13.i.a. However, they usually retained the term "*knowledge* representation", which had become accepted AI jargon.)

With hindsight, it's surprising how long it took people, even in scientific circles, to realize that computers might be used for SIP. Babbage arguably, and Konrad Zuse certainly, had seen the potential for non-numerical computation (see 3.iv and v.a). Zuse had even suggested using computers to do CAD/CAM carpet design, allowing for deliberate weaving errors to make the carpets appear handmade (1993: 130). And (non-interactive) computer graphics had been used since the late 1940s—by the RAND team, for instance, for radar maps (see 6.iii.b). But none of these people had tried to coax their machines to deal with the meanings carried by ordinary-language sentences.

That possibility became clearer with the theoretical marriage of Turing and the *propositional* calculus in 1943 (Chapter 4.iii.e), with the 1950s efforts in machine translation (9.x.a–d), and with the development of programming languages capable of manipulating items that looked like English words (v.c, below). By the early 1960s, non-numerical computation was no longer left to isolated visionaries. It was being explored by Ph.D. students—at CLRU, MIT, and elsewhere.

Very few people outside the MT and NewFAI communities, however, had got the message. The opening page of *Computers and Thought* bore the sub-heading *What is a Computer? Is it just a "Number Factory"?*, followed by a declaration that a computer isn't just "a high-speed number calculator" but "a general symbol-processing device" (Feigenbaum and Feldman 1963: 1). Evidently, the editors felt that the point needed to be made. And despite the enormous popularity of that collection, it still needed to be made at the end of the decade. Minsky was able to shock his intended readers in the late 1960s by calling his new book "*Semantic* Information Processing", and he had to defend the very possibility of non-formal computing yet again (Minsky 1968: 11–12).

In the general public's eyes, the use of computers to do semantic information processing was most famously illustrated by Joseph Weizenbaum's ELIZA (1966; Boden 1977: 96–7, 106–11). The program's notoriety was based on the widespread beliefs that it had passed the Turing Test, and that this is the criterion for success in AI. Both those beliefs were mistaken (see 16.ii.c).

There was a third reason, however, why the program's high status in the public's perception of NewFAI was unearned—even ironic. For ELIZA *wasn't* an exercise in AI, or anyway not in psychological AI. On the contrary, it was a successor to the very simple game-playing program described in Weizenbaum's first paper (in the newly founded commercial magazine *Datamation* in the late 1950s), significantly titled 'How to Make a Computer *Appear* Intelligent'—the italics being Weizenbaum's (interview in Crevier 1993: 133).

ELIZA was a simple pattern-matcher, with 'canned' responses triggered by keywords or phrases. Weizenbaum assembled a number of "scripts", or sets of domain-specific keywords, one of which would be used by ELIZA on any given run. The most famous of these was the script intended to simulate the type of conversation characteristic of Rogerian psychotherapy—in which the patient's remarks are continually reflected back to them by the therapist.

If Rogerian ELIZA's human interlocutor mentioned their mother or father, sister or brother, it would reply "TELL ME MORE ABOUT YOUR FAMILY". If no keyword was available, ELIZA would say "WHY DO YOU THINK THAT", or pick some previous input of the form "MY *****", and ask "DOES THAT HAVE ANYTHING TO DO WITH THE FACT THAT YOUR *****". Occasionally, this produced startlingly appropriate remarks, such as the program's "DOES THAT HAVE ANYTHING TO DO WITH THE FACT THAT YOUR BOYFRIEND MADE YOU COME HERE" in response to the keyword-free input "bullies". But that was pure chance: ELIZA had no representation of the *meaning* of "father", never mind "bullies". And the nearest it got to syntax was to respond to "I ***** you" by spitting out "WHY DO YOU ***** ME", or to turn "My *****" into "YOUR *****" (as it did in generating the BOYFRIEND response).

It was already possible to do a little better than that. In 1960 an M.Sc. student at MIT, A. V. Phillips, had used ideas from Chomsky's (1957) grammar to write a pattern-matching question-answerer that 'parsed' simple sentences into subject, verb, object, time phrase, and place phrase—everything else being ignored (Bobrow 1968: 151). And M. Ross Quillian (see below) had indicated how linguistic meaning might be represented in a program. Yet Weizenbaum didn't try to soup up ELIZA's syntax, nor its semantics either. Why not? Because he wasn't aiming to make a computer 'understand' language—i.e. represent linguistic meaning. He thought that was impossible (and would say so at length in his 1976 book). He'd written ELIZA simply to demonstrate that a programming language designed for numerical computing (i.e. FORTRAN) could be used to handle words. In short, he wasn't interested in NLP.

He wasn't interested in KR either. He chose to model Rogerian psychotherapy because it's "one of the few examples of . . . natural language conversation in which one of the participating pair is free to assume the pose of knowing *almost nothing* of the real world" (Weizenbaum 1966: 42; italics added). Nor was he trying to produce a prototype of something useful, even though many expert systems would later use similar pattern-matching techniques for the human–computer interface. Indeed, he was appalled when "his" ideas—as he saw it: the priority was disputed (see 7.i.a)—were appropriated by Kenneth Colby for clinical use in psychiatry.

ELIZA was irrelevant for the advance of KR, because stored English sentences were rarely suitable for representing the information being processed by a machine. They were used by Phillips's question-answerer, to be sure, but this involved mere sentence-by-sentence matching—*not* inference. The few NewFAI programs that seemed to be solving problems in English weren't actually solving problems *in English*.

So, for instance, Bert Green's (1927–) pioneering BASEBALL program conversed in English with its users, answering their questions about the statistics of baseball teams/games—such as "How many games did the Yankees play in July?" (B. F. Green *et al.* 1961). But it didn't 'think' in English. It turned the input sentences into algebraic equations, and then solved those. Its algebraic answers were transformed into English output for the user's benefit, not for the machine's. Similarly, Daniel Bobrow's (1935–) STUDENT, one of the programs highlighted in Minsky's SIP book, solved English-language problems such as: *The distance from New York to Los Angeles is 3,000 miles. If the average speed of a jet plane is 600 miles per hour, find the time it takes to travel from New York to Los Angeles by jet*, and *Mary is twice as old as Ann was when Mary was as old as Ann is now. If Mary is 24 years old, how old is Ann?* (Bobrow 1968: 147, 213). But like its predecessor BASEBALL, STUDENT would translate the problem into a set of algebraic equations, to be solved mathematically. English had nothing, essentially, to do with it.

Evidently, then, solving problems and/or answering questions posed in English didn't necessarily mean using English to do so. In fact, English wasn't a good medium for computer KR. Raphael, in his thesis on 'Semantic Information Retrieval', put it like this:

> The most important prerequisite for the [machine's] ability to "understand" is a suitable internal representation, or model, for stored information. This model should be structured so that information relevant for question-answering is easily accessible. *Direct storage of English text is not suitable* since the structure of an English statement generally is not a good representation of the meaning of the statement. (Raphael 1968: 35; italics added)

If English text wasn't a good way of representing semantic information inside the computer, what was? Programs doing SIP had been written—by Samuel, for example—more than ten years before Raphael wrote those words. But those *very* early NewFAI programs hadn't aimed at representational generality, even if they'd aimed at inferential generality. Their data were expressed in a domain-specific form: for checkers, chess, or logic. If computers were to deal with a wider range of topics, some more neutral KR would be needed. Raphael, again: "models which are direct representations of certain kinds of relational information usually are unsuited for use with other relations. [AI needs] a model which can represent semantic content for a wide variety of subject areas" (ibid.). Likewise Minsky, announcing the key claim of his SIP book: "the route toward generality [in AI] must lie partly in . . . the representation of more and better kinds of knowledge" (1968: 13).

The most influential KR-for-SIP at that time, besides logic, was the method of semantic networks developed by Quillian (1931–). These were implemented in the mid- to late 1960s, when Quillian was working at Bolt, Beranek & Newman, or BBN (Quillian 1967, 1968, 1969). But they'd been envisaged when he was a graduate student of Simon's at Carnegie Mellon (Quillian 1961, 1962).

Quillian had come into AI after being trained in sociology. His AI aims were to enable automatic word disambiguation, comparison between word meanings, interpretation of anaphora, and associative inference. But his prime concern, doubtless encouraged by Simon, was to cast light on human memory and language understanding:

> The central question asked in this research has been: What constitutes a reasonable view of how semantic information is organized within a person's memory? In other words: What sort of representational format can permit the "meanings" of words to be stored, so that humanlike use of these meanings [by computers] is possible? (Quillian 1968: 227)

Indeed, over half of his Ph.D. thesis of 1966 would be based on experiments recording the thinking aloud of a woman interpreting language. A summary of the thesis appeared in the psychologists' journal *Behavioral Science* (Quillian 1967), and the writers he cited there included Frederic Bartlett on memory (5.ii.b), Miller on the "Magical Number Seven" (6.i.b), Bruner and Earl Hunt on concept learning (6.ii.b–c and v.a, and iii.d below), and Walter Reitman on thinking (6.v.b and 7.i.b). In addition, he drew on an up-to-date review of what psychologists knew about associative meaning (Deese 1962). And some years later, he did a systematic series of psychological experiments on memory and language (A. M. Collins and Quillian 1972). In short, he was "disposed to consider this model a psychological theory" (1967: 429).

The core insight—that word-ambiguity might be dealt with by looking for intersections of meanings—had been stated in the 1950s, by CLRU's Margaret Masterman and Robert Richens (see Preface, ii, and 9.x.d). And Quillian presented his earliest ideas at a 1961 colloquium in King's College, Cambridge, where the CLRU team reported on the latest version of their computerized thesaurus, or "semantic interlingua". But whereas their focus was solely technological (machine translation), his was primarily psychological. Moreover, his methodology was very different from the analyses/programs used at CLRU.

Specifically, Quillian pioneered localist connectionism (12.ii.i). (David Rumelhart, normally thought of as a guru of PDP connectionism, later recalled being "inspired" by Quillian to begin his own work on psychological simulation—J. A. Anderson and Rosenfeld 1998: 272.) A semantic network was composed of nodes and links between nodes. The nodes stood for concepts, objects, and events. The links represented relationships of various types, such as *superordinate*, *subordinate*, *isa*, *has-part* (and, if one wished, *aunt of*, *married to* . . . and so on). Such a network could represent both general concepts and individual instances: both cats and Tibbles, the latter linked to the former by an *isa* (IS-A) link.

On Quillian's view, both human long-term memory and the knowledge (data, meanings) possessed by a programmed network are implemented as nodes and links. Or rather, "denotative, factual information" is stored in this way. People's "plans for doing things", their "feelings about words", and their knowledge of "the conditional probabilities of word sequences" were specifically excluded (1967: 410). All of those were being explored by psychologists trying to capture the nature of meaning. Piaget, for instance, had discussed action plans in terms of sensori-motor schemas (5.ii.c); word sequence probabilities had been stressed by the informational psychologists (6.i.a and 9.x.b); and the feelings associated with words had been intriguingly highlighted by Charles Osgood's group in Illinois (Osgood *et al*. 1957). A complete theory of semantic memory, said Quillian, would have to include all those aspects too.

In a Quillian network, the inferences justified by the program's knowledge were drawn by a mechanism of "spreading activation". Whenever a node was activated, the activation would automatically spread along the links that connected it to other nodes—thus forming inferential pathways of various kinds. This simple arrangement met Raphael's demand: that the information required to generate the output from a KR be "easily accessible". (That wasn't true for logicist KR: there were no stored relevance links between propositions in the predicate calculus, only general rules of inference which could link them *if they could be found*.)

For example, consider property inheritance in semantic networks. If the class name *bird* was linked by *has* to *wings*, and if *robin* was linked as a *subordinate* to *bird*, then robins could easily (*sic*) be inferred to have wings too; and if Fred was linked by *isa* to robin, then Fred's wings could be easily inferred as well. Similarly, spreading activation enabled the network to make explicit comparisons and contrasts between the meanings of any pair of words, and to interpret ambiguous words according to the linguistic context—where the key factor in disambiguation was the *intersection* of activated pathways. Figure 10.4 shows two different pathways associating *plant* with *live*, and Figure 10.5 shows an associative structure leading to the intersection node (*sad*) for *cry* and *comfort*.

Quillian tested his networks on the English text used in the thinking-aloud experiment mentioned above. There were seven sentences, which between them contained nineteen ambiguous words. (This was pushing at the technological limits: because the program itself used up most of the computer's memory, there was room for no more than twenty definitions of English words—Crevier 1993: 82.) His first program interpreted twelve of them correctly. (It couldn't decide on four, so they remained ambiguous; and it got three wrong.) An improved version, developed in concert with Bobrow, dealt also with ambiguous prepositions. For instance, *I threw the man in the ring* was correctly interpreted, in context, as *While in the ring I threw the man*, or as *I threw the man who was in the ring*, or as *I threw the man into the ring* (Quillian 1968: 261–2).

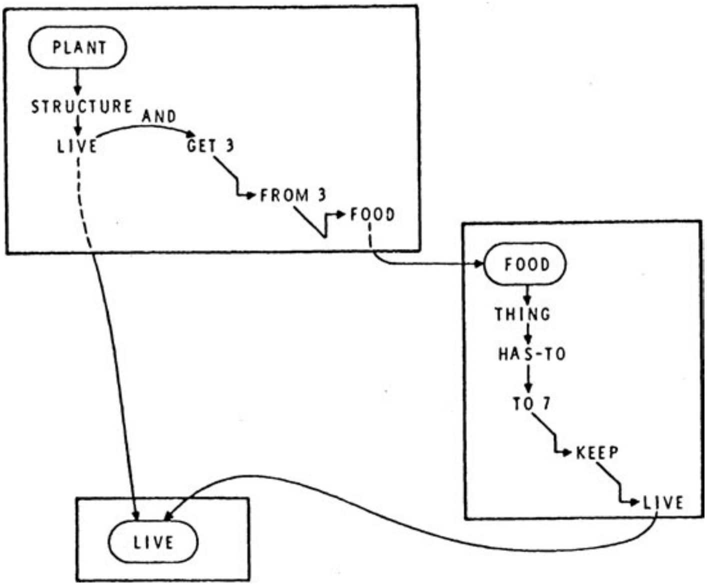

FIG. 10.4. Two paths direct from "Plant" to "Live". Reprinted with permission from Quillian (1968: 250)

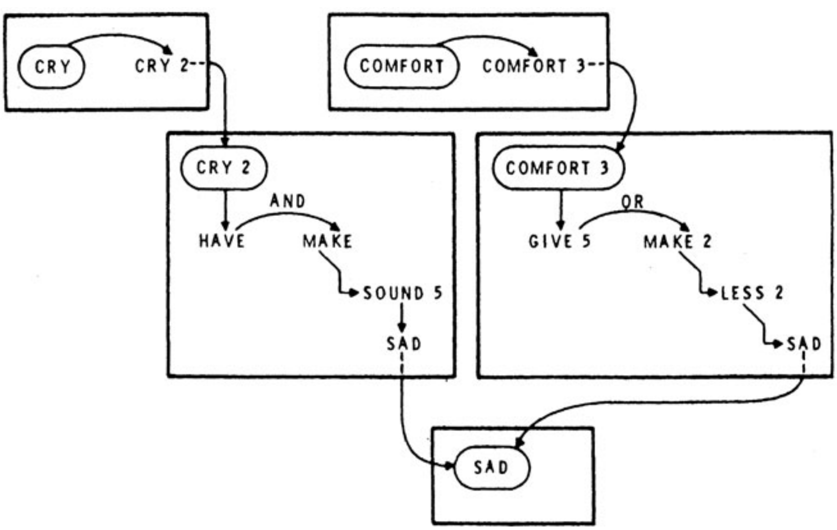

FIG. 10.5. A path from "Cry" and a path from "Comfort" which reach the same intersection node, "Sad". Reprinted with permission from Quillian (1968: 250)

In the late 1960s, semantic networks were seen as a liberation. Many people (in AI, psychology, and linguistics) adopted, or adapted, them. They weren't used only for language. For instance, they were applied to vision as well as concepts in John R. Anderson's ACT system (7.iv.c).

Granted, there were hazards lying in wait for the unwary. Various difficulties in using/interpreting semantic nets were detailed in 1975 by Quillian's BBN colleague William Woods (see Chapter 9.xi.e). Later still, some of these were elaborated by James Allen and Alan Frisch (1982), and by Ronald Brachman—another BBN colleague at the time (1977, 1979, 1983). But the difficulties didn't kill the interest. Indeed, nearly twenty years later the editors of a comprehensive volume on KR judged them to be "arguably the most popular of all techniques employed to represent knowledge in AI systems" (Brachman and Levesque 1995, p. xviii).

If Quillian's work inspired a huge amount of research over the years, so did McCarthy's harbinger project, logicism. Further claimants to the KR crown appeared as AI matured, some coming from other disciplines within cognitive science (social psychologists' *scripts* and linguists' *semantic primitives*, for instance: 7.i.c; 9.viii.c). By the mid-1980s, there was a thirty-page bibliography on the topic (Brachman and Levesque 1995: 335–65). In short, KR was a leading concern—many would say *the* leading concern—of symbolic AI.

One shouldn't conclude that people were faced with an *embarras de richesse*: a choice between myriad utterly different forms of KR. For the *richesse* consisted largely in superficial, not fundamental, differences.

This was made clear in a hugely influential paper by Minsky, circulated in draft (as was his wont) for some years before appearing as an MIT memo in 1974, and an official publication in 1975. 'A Framework for Representing Knowledge' unified the work of a number of scientists both within and outside AI. These people had said essentially similar things about how concepts work. The core idea was that concepts are structured, and that this structure—by storing co-relevant things together and by indicating just how they're related—enables sensible inference.

For example, Bartlett had posited structured "schemas" in the 1930s, and Hebb outlined hierarchical "cell-assemblies" in the 1940s (5.ii.b and iv.c). Quillian's semantic networks represented meaning structures too, although they could also depict merely contingent associations. AI vision researchers in the 1960s had defined structured object models for interpreting images (see iv.b, below). In the early 1970s, Robert Abelson had added "scripts" and "themes" defined as interpersonal concepts, and then (with Roger Schank) "scripts" understood as stereotyped ways of behaving (7.i.c). Meanwhile, Michael Arbib was describing sensori-motor schemas as well as conceptual ones (and he'd later attribute them to robots as well as to many animal species: 14.vii.b–c).

Minsky referred to some of that literature in trying to unify the superficially disparate work on KR "in Artificial Intelligence and Psychology" (1975: 211). That phrase "and Psychology" was crucial: "I draw no boundary", he said, "between a theory of human thinking and a scheme for making an intelligent machine." The paper's key claim was that common sense depends on structured "'chunks' of reasoning, language, memory, and perception". This claim was explicitly opposed both to behaviourist psychology (specifically, the first two tenets: see 5.i.a) and to AI logicism, which—Minsky said—tried "to represent knowledge as collections of separate, simple fragments".

Minsky added recommendation to unification. And what he recommended was the KR notion then favoured at MIT: the "frame". Frames were hierarchical structures ("networks of nodes and relations") representing complex objects. Each frame had fixed attributes at the higher levels, and many terminal "slots" for properties that could be filled in various ways. They occurred as "systems" of frames—for instance, the many images of a "scene from different viewpoints", or the different situations brought about by "actions, cause–effect relations, or changes in conceptual viewpoint". Since the various frames within a frame system share the same terminals, it's possible to "coordinate information gathered from different viewpoints"—in other words, to make inferences drawing on distinct sources/types of knowledge. (Later, these ideas would spawn object-oriented programming languages, in which frames were in effect treated as primitives: see v.c, below.)

Examples of frames included the concept of "arch" employed by Winston's learning program (subsection d, below), or the everyday concept of a room. A room typically has one door (occasionally, more), one or more windows, a roof, and a cuboidal shape; it normally contains furniture (distinct frames define tables, chairs, etc.); and it's usually contained in a larger building, such as a house.

However, "typically", "normally", and "usually" are weasel words. To be ultra-safe, the *number* in the *door* slot for *room* (for instance) could simply be left open, to be filled in by the programmer for each specific room considered. But that would be highly time-consuming; and it would also mean that a vision system looking for an unknown room or door, or trying to interpret an unfamiliar image which happened to depict a room, couldn't use one-door-ness as a cue. Alternatively, the number-of-doors in a *room* frame could be given a "default" value *(one)*, which would stand unless overridden by the programmer or, as a result of inferences, by the program.

In practice, said Minsky, much of the knowledge possessed by a frame-using program would be stored as default values. This was economical and efficient, but it could lead to problems. Consider exceptions, for instance. Cats have tails . . . but Manx cats don't. How could an AI representation—whether a hierarchical frame, or a set of logicist axioms, or a semantic network, or a Schank–Abelson script . . . —deal with that fact? It would be counter-productive simply to omit the tail slot from a cat frame; or to remove the axiom *If x is a cat then x has a tail* from a theorem-prover; or to delete the link between *cat* and *tail* in a semantic net; or to drop the rule, in a stereotyped script, that friendly visitors would stroke the tail of the family's cat. After all, the inference that a particular cat has a tail is far more often right than wrong. Minsky suggested various ways in which something could be assumed by an AI program unless it was specifically contradicted. Indeed, "default reasoning" soon became a key issue in AI (13.i.a).

Not for the first time, then, Minsky was surveying the land in preparation for core debates in AI. But whereas 'Steps' had (unavoidably) been programmatic, 'Framework' discussed many programming details. Its influence was due as much to the authoritative exposition of the MIT approach as to the general observations it contained.

Despite his efforts at unification, significant differences remained. Indeed, Newell (1982: 92) complained of "a veritable jungle of opinions" about KR, adding that "There is no consensus on any question of substance." Today, over twenty years later, KR is still a major concern. The early 1990s saw a 408-page special volume of the journal

Artificial Intelligence, and a further update appeared very recently (Brachman *et al*. 1991; Brachman and Levesque 2004). Evidently, KR and SIP were prizes which would be very hard-won.

b. A resolution to do better

Theorem proving had competed with checkers and chess as the first topic for real (i.e. implemented) programs. The fact that LT had found one proof more elegant than Russell's in *Principia Mathematica* had been hugely encouraging (Chapter 6.iii.c). And some, including the LT authors themselves, had been further encouraged by believing that they were modelling the thought processes of human logicians.

However, the mathematical logician Hao Wang (1921–95), then at Oxford but about to return to Harvard, soon criticized LT in pretty strong terms (H. Wang 1960). Not only could *Principia* proofs be generated more efficiently by other mechanized methods, but these methods—unlike LT—would eventually find *any* provable proposition within the relevant set. He concluded that LT wasn't a good ideal for mechanized theorem proving. More generally, he rejected human simulation as an approach to automated reasoning: it was logic that was important, not human thinking (cf. MacKenzie 1995).

Minsky disagreed, arguing in 'Steps' that whereas the *Principia* problems were simple enough to yield to exhaustive procedures, more complex problems wouldn't be. In particular, such procedures couldn't help with "the fundamental heuristic problem of *when to decide to give up on a line of attack*" (Minsky 1961*b*: 437).

In terms of Gottlob Frege's distinction between logical norms and psychological laws (2.ix.b), Minsky was in effect sitting on the fence. Unlike Wang, he wasn't restricting himself to pure logic—for he was considering the untidy practicalities of real-time computation. In terms of a distinction drawn 100 years later—and mentioned above, in contrasting McCarthy and Minsky—Wang was a neat whereas Minsky was a scruffy (see 13.i.c). On the other hand, he wasn't insisting that those practicalities be drawn solely, or even primarily, from human psychology: he was interested in the practical constraints on *any* complex computational system. He was happy to learn lessons from human psychology, when it seemed helpful. But unlike Newell and Simon (whom Frege would have accused of coming close to "psychologism"), he didn't believe that automatic theorem proving should necessarily mimic human thought.

The divide between theorem proving as logic and theorem proving as psychology was a special case of the divide between technological and psychological AI. And it endured, as this area of NewFAI advanced (MacKenzie 1995). Whichever side of this fence one favoured, the mere fact of such disagreement shows that while LT had kicked off the ball, it hadn't established the rules.

Broadly speaking, three different approaches to theorem proving developed, each of which is still with us today: logical/axiomatic, heuristic, and model-based. These were exemplified respectively by the resolution theorem-prover, the Logic Theorist, and Gelernter's geometry program.

Resolution theorem proving was driven by the same aim as Wang's: to discover a mechanized procedure that would be *guaranteed* to find a proof. It was defined in the early 1960s by the British logician J. Alan Robinson (1930–) at Rice University (J. A. Robinson 1963, 1965), and implemented by others soon afterwards (Wos *et al*. 1964, 1965). The immediate result, for Robinson himself, was a "spectacular rise to stardom in AI" (E. A. Feigenbaum, interviewed in McCorduck 1979: 219).

The reason why Robinson's work had such an impact was that it could deal with a relatively complicated form of logic. With respect to Russell's *propositional* calculus (the focus of McCulloch and Pitts: see 4.iii.c), there was no difficulty in principle. All proofs could be found by constructing truth tables. To be sure, the size of the search increased exponentially as the number of variables grew: if establishing *if (p and q) then (a or b)* was practically feasible, proving *if (p and q and r and s . . . and z) then (a or b or c . . . or n)* might not be. However, there was nothing intellectually deep about the methods, and almost any programmer could write programs for applying them. Russell's *predicate* calculus (the focus of McCarthy: see i.f, above) was a very different kettle of fish. It included existential and universal quantifiers of varying scope, and terms denoting relations of various degrees (binary, ternary . . . *n*-ary). Accordingly, it required more sophisticated methods of problem solving.

That's where resolution theorem proving came in, for it was a method for dealing with (first-order) predicate logic. Robinson wasn't the first to try to define some such method. The logician Jacques Herbrand, as long ago as 1930, had defined—though not implemented, of course—a basic algorithm for proof procedures (sometimes called "refutation procedures") which tried to establish a theorem by showing that its negation is inconsistent. In other words, the basic rationale was the assumption that not-not-X implies X.

That seems like common sense, although it was disputed by "constructivist" mathematicians (they claimed that X had to be proved directly, not inferred from a double negative: P. M. Williams, personal communication). However, non-constructivists were happy with it. Accordingly, after computers had come on the scene a number of people defined mechanizable versions of Herbrand's algorithm. One of these people was Robinson's ex-tutor Putnam (M. Davis and Putnam 1959/1960). (In his eyes, this was *logic,* not psychology; that's why he didn't mention it in his paper on functionalist philosophy of mind, written at the same time: 16.iii.b.)

Soon after Putnam's logic paper appeared, Robinson tried to implement the method defined in it—and discovered that it was highly inefficient. But he was also trying to implement another logician's suggestion at much the same time, and he found that a combination of ideas drawn from both papers was superior to either (MacKenzie 1995). That method was resolution, which—besides its relative efficiency—could deduce *new* statements from existing knowledge. That is, they could make information explicit which had previously been implicit and unrecognized. The other neo-Herbrand techniques, including Putnam's, couldn't do that: they produced only trivial consequences, by instantiating variables in logical expressions (Wos and Veroff 1987: 895).

In one respect, Robinson's theorem-prover was elegantly simple. For it used only one essential rule of inference. (The other rules, added over the years, provided the guidance/restriction strategies.) It always tried to infer a *contradiction* between the desired conclusion and the premisses. This may sound paradoxical, but it's a form of argument (*reductio ad absurdum*) that's common even in everyday chit-chat. If someone makes a statement, and their opponent can show that it contradicts their premisses and/or common knowledge, then (if the premisses are true) it must be false. So we often suppose—'for the sake of argument', as we may say—that something is the case, *precisely in order to show that it isn't*. If we can't find any contradiction between X and the shared premisses, then the disputed statement can stand.

A resolution theorem-prover aiming to prove X, then, would first try to show that X is impossible. And it would do *that* by seeking some contradiction between X and the premisses. If it found such a contradiction, then not-X (the negation of X) would have been proved. So in trying to find a plan enabling a robot (such as SHAKEY) to do something, for instance, the program would start by assuming that no such plan exists.

As usual, it wasn't all plain sailing. Robinson's initial version was very inefficient, tending to get bogged down in masses of valid-but-boring conclusions. These were drawn because they *could* be drawn, not because (in respect of the task) they *should* be drawn. In other words, it suffered from the "combinatorial explosion", a form of information overload that bedevilled many NewFAI programs (and which often bedevils human brains too). In general, the difficulty was that the computer might try to consider and/or infer too many items to make problem solving practically possible. Sir James Lighthill, in his savage attack on AI some ten years later, would write as though the combinatorial explosion was an unseen and insuperable obstacle (11.iv.a). It may have been insuperable: we'll come to that. But it certainly wasn't unseen. It was a bugbear familiar to all computer scientists, and had been mentioned many times in 'Steps' (though not under that name). And it could be ameliorated, if not wholly overcome.

At first, people assumed that better hardware (faster processing and larger memories) would enable resolution theorem-provers to scale up beyond the initial barrier of a few dozen items. But it soon became clear that better software would be needed too. Accordingly, several people tried to improve on the basic resolution algorithm. They included Robinson himself (1968), his collaborator Larry Wos (in several papers), David Luckham (1967), and Cordell Green (1969)—who applied it to question answering. These people (and their successors in later decades) defined increasingly efficient "strategies" for guiding and restricting the many inferences made by a resolution theorem-prover, so that the system knew where (not) to go and, as Minsky had demanded, when to give up.

Robinson's approach caused huge excitement in the early 1960s. One didn't have to be a logician to find it intriguing. McCarthy's harbinger paper, after all, had suggested that predicate logic could represent common-sense knowledge (and could be used to give advice while leaving the core program untouched)—so the new technique might be useful in any problem domain. Moreover, the resolution theorem-prover did what the *advice taker* had been proposed to do: it drew new conclusions. Tell it A (given that it already knew B, C, and D), and it might be able to infer E. A wide variety of resolution-based NewFAI programs were soon developed. In question-answerers, for example, the program's world knowledge was expressed as axioms, and questions were presented to it as theorems to be proved (C. C. Green 1969). Logic even entered robotics, in the STRIPS resolution system that planned actions for the SRI robot (see subsection c, below).

There was a time bomb hidden here, however. It sputtered into life about twenty years later, when a new programming language with resolution built into it was widely used in practical applications—namely, expert systems (v.f below, and 11.v.a). Non-logician users sometimes assumed that if their program *failed* to find a contradiction, then not-not-X hadn't been established so not-X had been proved. This so-called "negation by failure" was a mistake. Failing to find a contradiction meant nothing, because predicate calculus isn't what logicians term "decidable" (cf. 4.i.c).

In real life too, there's all the difference in the world between proving that something is false (real negation) and failing to prove that it's true (negation by failure). Just compare being able to prove that your partner isn't having an affair with not being able to prove that he/she is. The reason, of course, is that there are many potentially relevant pieces of evidence (premisses) of which you may be unaware, and which you have no realistic hope of discovering/deducing. (Even the private detective may fail to find all of them.) Indeed, you may even have difficulty in recognizing *just which* matters are "potentially relevant" (Chapters 8.vi.c and 7.iii.d).

Problems in very well-understood areas of science are less open to threat on this account. For one can hope (*sic*) to have identified all the relevant knowledge, and one can hope (again, *sic*) that the situation is relatively 'closed' against unpredictable complications. But even there, it's not obvious that the problems are in principle decidable. If they're not, then assuming that not-X had been proved merely because of the failure to find a contradiction isn't logically justified. In other words, proof of non-existence is very much more difficult than proof of existence.

So why wasn't resolution laughed out of court? Well, partly because expert logicians—the Putnams and Robinsons of this world—wouldn't be tempted to make that mistake. Moreover, in a logical system that's technically *complete* the drawback outlined above doesn't apply. All the required premisses and/or axioms are (by definition) given, and the rules of inference are capable of leading to every possible true conclusion. It follows (in principle) that if they *fail* to draw a particular conclusion then it's not there to be drawn, so cannot be true. And Robinson showed that resolution theorem proving is complete in this technical sense. Provided that the premisses suffice to imply the conclusion, it can *in principle* be found by the resolution method.

Even so, *in practice* it was often difficult, or impossible, to work through the deduction far enough to complete the proof. (Remember Minsky's point about knowing when to give up.) Robinson's star status waned, accordingly. Feigenbaum remembers:

> [Here] he was, [a logician] propelled to the front ranks [of AI], and suddenly felt heavy obligation to extract the AI researchers from the pit into which they were falling, the pit of the combinatorial explosion. He understood this, but was really helpless to do anything about it since he was a logician who invented a method, not an AI researcher interested in formalizing the world's knowledge. Finally he gave up, decided he was really sorry he'd got people into this trap, but he couldn't do anything about it. As AI moved away from the Resolution Method, he moved back to logic and resigned his position on the editorial board of the AI Journal, and retreated from the whole scene. (interview in McCorduck 1979: 219–20)

c. Planning progresses

AI planning sprang from Newell and Simon's mid-1950s work on LT and GPS (see Sections i.b and d above, and Chapter 6.iii.c). That work had been a revelation—indeed, a revolution.

Nevertheless, GPS had many weaknesses. One was mentioned in i.d, above: its tendency to get bogged down by forming sub-goals on too many levels. Another was its inability to outline a plan at an overall, abstract, level, leaving the details to be decided later (on execution). This made it especially ill-suited for use in robotics, where the real-world situation may change while the program is running. By the same token, it wasn't amenable to interrupts during processing. Nor could it learn from its mistakes: an error recovered by backtracking on Monday would be repeated relentlessly on Tuesday. (Some capability for learning was soon provided, however: Newell *et al.* 1960.) Certain errors, such as undoing a previously achieved (and essential) sub-goal, weren't even identifiable by the system.

In the 1960s and early 1970s, these weaknesses—and others—were overcome as means–end analysis was developed into planning programs of increasing power. Many of these were written for the Stanford robot, SHAKEY (and others for Edinburgh's FREDDY).

The STRIPS planner (an acronym for STanford Research Institute Problem Solver) used predicate calculus theorem proving to plan SHAKEY's movements in much the same way as GPS had done for abstract problems (Fikes and Nilsson 1971; Fikes *et al.* 1972*a*,*b*). It relied on a novel form of KR: a "triangle table" storing operators, their preconditions, and the newly true facts resulting from their execution: see Figure 10.6. All other facts were assumed to remain unchanged (an assumption which raised the spectre of the frame problem: see iii.e, below).

Triangle tables enabled STRIPS/SHAKEY to act, and also to learn to do so better. The key point was that they identified whole sets/subsets of actions, for achieving particular goals/sub-goals. One triangle table could be inserted (as a chunk) into another one, so representing several levels of plan complexity without having to reconsider each individual operator. Moreover, STRIPS could generalize its plans. For example, having worked out *how to get from Room 7 to Room 3 via Room 6, in order to open Window 2 (using Box 1 fetched from Room 4)*, it could express a plan schema representing *how to get from any room to any other, via some other if necessary, to open any window, using any box found in any place*. (In essence, this was done by replacing logical constants with variables.)

Since it identified the expected result of a given action, or set of actions, a triangle table could be used to monitor success—and to plan subsequent actions accordingly. It could even be (intelligently) broken up, the relevant portions being incorporated into new plans. And these, in turn, could be inserted into others.

However, STRIPS (in its first incarnation) was limited in a number of ways. As a result, successive improvements were developed in the early 1970s (see Boden 1977: 280–7, 357–70).

For instance, STRIPS (like GPS) couldn't produce an overall strategic plan of the problem before the detailed solution was started. For very simple problems, this didn't matter. But if there were many different operators, each with many preconditions, planning would be scuppered by the combinatorial explosion. What was needed was a further level (or levels) of abstraction, allowing a solution to be stated in very general terms. These would later be transformed into lower representational levels, each more detailed than the one above it—with the last having direct control of the robot's movements. (Similarly, one may plan a journey in terms of the towns to be visited, before worrying about the order in which to visit them—still less, just how to get from this town to that one.)

Initially True Preconditions (ITPs)

1	ITPs of Action 1	Action 1			
2	ITPs of Action 2 (if any)	Facts made true by Action 1	Action 2		
3	ITPs of Action 3 (if any)	Facts from cell above which are still true after Action 2	Facts made true by Action 2	Action 3	
4	ITPs of Action 4 (if any)	Facts from cell above which are still true after Action 3	Facts from cell above which are still true after Action 3	Facts made true by Action 3	Action 4
Last row		Facts from cell above which are still true after Action 4	Facts from cell above which are still true after Action 4	Facts from cell above which are still true after Action 4	Facts made true by Action 4
	Leftmost column	1	2	3	4

FIG. 10.6. Schema for a STRIPS triangle table. Adapted with permission from Fikes *et al.* (1972*a*: 259)

Accordingly, Earl Sacerdoti (1948–) developed ABSTRIPS, which solved its problems on a hierarchy of representational levels (Sacerdoti 1974). The first was the most abstract. Details were considered only when a successful plan in a higher-level problem space gave strong evidence of their importance. The crux of ABSTRIPS was that the lists of preconditions for the various operators were ordered for priority, so that the most critical preconditions were considered first. For example, if SHAKEY's goal was to push a box from one room into another, ABSTRIPS enabled it to get to the former room first (assuming that it had started out from yet another room), and then to open the relevant door (assuming that it was shut) before positioning itself by the box so as to be able to push it.

Like GPS's difference orderings, the criticality levels of the preconditions for each operator were provided in the database, not worked out by the program itself. ABSTRIPS could pass easily from one plan level to another, mapping more abstract onto less abstract representations, because the abstraction involved was merely a question of *ignoring* details in an operator's definition (details which, if necessary, could be taken up later). If the content of the definition had differed according to plan level, it would have been more difficult for the program to pass from one level to another.

Similarly, if—when considering the details—ABSTRIPS discovered that the sub-plan wasn't executable in the current circumstances, it could return smoothly to the *more* abstract level, much as GPS had backed up to previous choice points on failing to achieve a sub-goal. As Sacerdoti pointed out, this was especially important for robotics, since the real world can't in general be expected to stand still. A state of affairs that pertained at the outset might have changed by the time it became relevant.

In fact, the Stanford team deliberately teased/tested SHAKEY by occasionally moving a block to a different position. The robot wasn't capable of noticing this being done. But it might later realize that something was amiss when it came to execute a plan that assumed that the block was in its *original* position. In that case, SHAKEY would recompute the plan. (As the situated roboticists would later point out, this was very different from being in constant interaction with a dynamically changing world: e.g. R. A. Brooks 1991*b*, n. 1.)

While Sacerdoti was developing ABSTRIPS at Stanford, Gerald Sussman (1947–) at MIT was working on HACKER (Sussman 1975; Boden 1977: 286–97). This was a planner with a difference, for it monitored its own performance and corrected its mistakes. It did this by exploiting what Papert was already referring to as a "powerful idea": *bugs* (see vi.a, below). As Sussman put it:

> I believe that effective problem solving depends as much on how well one understands one's errors as on how carefully and knowledgeably one makes one's initial choices at decision points. The key to understanding one's errors is in understanding how one's intentions and purpose relate to his plans and actions . . . [So one needs a] teleological commentary about how the subparts [relate to the overall goals]. [And one needs] knowledge about how to trace out bugs and about the kinds of bugs that might be met in applying a given kind of plausible plan. (Sussman 1974: 236)

He identified five main types of bug: PCB, PM, PCBG, SCB, and DCB (that is: Prerequisite-Conflict-Brothers; Prerequisite-Missing; Prerequisite-Clobbers-Brother-Goal; Strategy-Clobbers-Brother; and Direct-Conflict-Brother). These concerned interactions between plan components, manifesting themselves (for instance) as unsatisfied prerequisites, unnecessary double moves, or failure to protect a condition that must continue to exist until a specific point in the plan. An unsatisfied-prerequisite bug differed from a prerequisite-missing one. The former was a hitch discovered only on actually trying to execute the plan; the latter would be discovered by a critical analysis of the plan's structure before any attempt was made to execute it. (Compare encountering roadworks on your way to the station with planning to reach it by a mistaken route.)

While engaged in planning, HACKER employed several CRITICS, self-monitoring procedures designed to spot/fix particular bugs. For instance, one CRITIC looked out for cases where the program, having achieved an essential sub-goal, later undid it in order to achieve another one. If such a case was found, the program would devise a "patch" for the original plan. (Besides spotting and fixing bugs, HACKER learnt to avoid them in future: see subsection d, below.)

Sussman's work helped Sacerdoti to make a further advance in planning. Part-inspired by HACKER, he abandoned ABSTRIPS for NOAH: Nets of Action Hierarchies (1975*a*,*b*). ABSTRIPS, like HACKER, had been a linear planner. Both programs assumed that sub-goals are additive, so could be considered independently—even if they were best considered in a particular order. However, sub-goals are sometimes non-additive: they interact, so that the achievement of sub-goal A may have to be deliberately undone before it's possible to achieve sub-goal B. This would happen, for example, if HACKER were asked to solve the problem shown in Figure 10.7 (Sacerdoti 1975*b*: 105–9).

ABSTRIPS could sometimes use backtracking to reach a clumsy solution to non-additive problems. But it couldn't achieve the optimal solution, because it couldn't take sub-goal interaction into account. NOAH, by contrast, could. It did this by ignoring temporal order in its initial plans. Sub-goals were represented merely as logical conjuncts to be achieved in parallel. When the plan was elaborated, on successively detailed levels, NOAH would scan for potential interactions between sub-goals and specify temporal order whenever this was needed to avoid them. The result would be a partially ordered plan, constructed so as to minimize backtracking in execution.

NOAH's secret lay in its CRITICS, inspired by HACKER's subroutines of the same name but constructive rather than destructive in nature. For these Stanford-based CRITICS added constraints to a partially specified plan, instead of rejecting incorrect assumptions that shouldn't have been made in the first place.

There were five general-purpose CRITICS to oversee the elaboration of NOAH's plans. They watched out for ways of resolving potential conflicts between sub-goals; of specifying existing objects for use rather than leaving their identity vague; of eliminating redundant preconditions; of resolving "double crosses" in which each of two conjunctive purposes denies a precondition for the other; and of optimizing disjuncts so that a choice between alternative sub-goals could be predetermined or postponed, whichever was the more sensible.

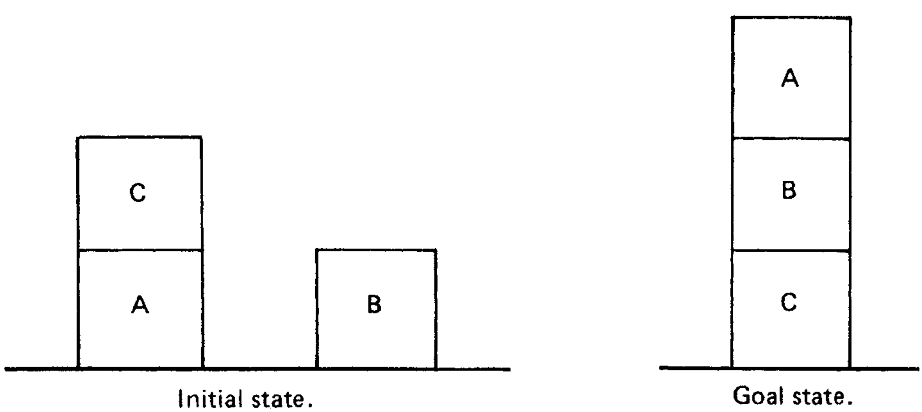

Fig. 10.7. A non-additive problem. Reprinted from Boden (1977: 360)

In addition, NOAH could be provided with task-specific CRITICS. This was done for Stanford's CBC project (Computer Based Consultant), an interactive program designed to give on-the-job advice on how to assemble a machine to novice mechanics having varied levels of expertise (Hart 1975; Sacerdoti 1975*b*: 90–109, 117–20). In order to give advice that was appropriate for the particular user, NOAH used the specific queries posed by the human mechanics as cues directing it to answer at one hierarchical plan level rather than another. So one mechanic might be told simply to "Replace the pump", whereas a less experienced person might be instructed to "Remove the 4 mounting bolts at the base of the pump using a $\frac{3}{8}$-inch open-end wrench." Similarly, the program could ask helpful questions when the user got into trouble, because it had some idea of just where in the overall task the human's difficulty might lie. In short, CBC was an early forerunner of today's "Steve", a VR system that enables mechanical advice to be given by a humanoid animation, bodily movements—and voice recognition—included (Chapter 13.vi.b).

NOAH managed to solve a problem which bemuses many humans, and which early 1970s theorem-provers had been quite unable to handle. Michie had recently identified the "keys and boxes" puzzle (too complex to state here) as a benchmark problem for AI, but NOAH worked it out in only twenty-one steps (Sacerdoti 1975*b*: 70; Michie 1974).

Similar work on non-linear plans was now being done in Michie's Edinburgh laboratory, by Austin Tate (1975). But problems remained. For instance, neither Sacerdoti's NOAH nor Tate's INTERPLAN could cope reliably with cases where each of two conjunctive goals denies a precondition for the other. (The "double cross" CRITIC could sometimes diagnose and resolve the trouble, but in other cases this wasn't possible.) As Sacerdoti put it, "the system must be creative and propose additional steps that will allow the two purposes to be achieved at the same time" (1975*b*: 42).

That sort of creativity was provided by BUILD, a program written by Scott Fahlman (1948–)—who, by the way, also invented the "smiley face" emoticon (Fahlman 1974). BUILD represented plan structures in such a way that it could solve the problems shown in Figures 10.8 and 10.9.

Both of these see-saw tasks require an additional manipulation early in the plan, which is later undone by the builder. Without going into the details of how BUILD worked (cf. Boden 1977: 366–70), let's just note that it 'knew' enough about weights and levers to foresee unwanted effects (i.e. the collapse of the structure being assembled),

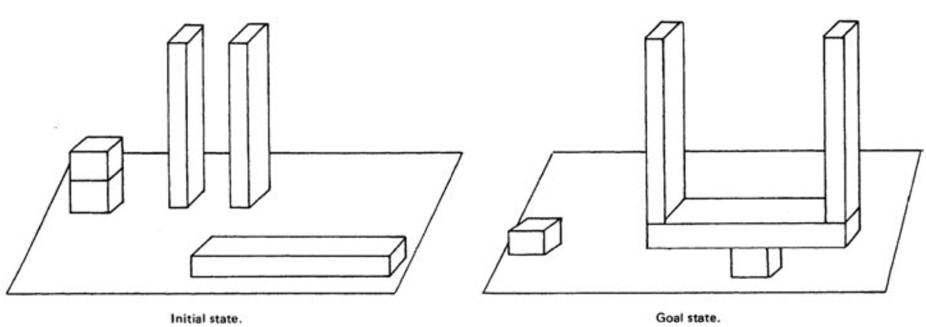

Fig. 10.8. Blocks-world problem (only one hand; no sliding). Reprinted from Boden (1977: 364)

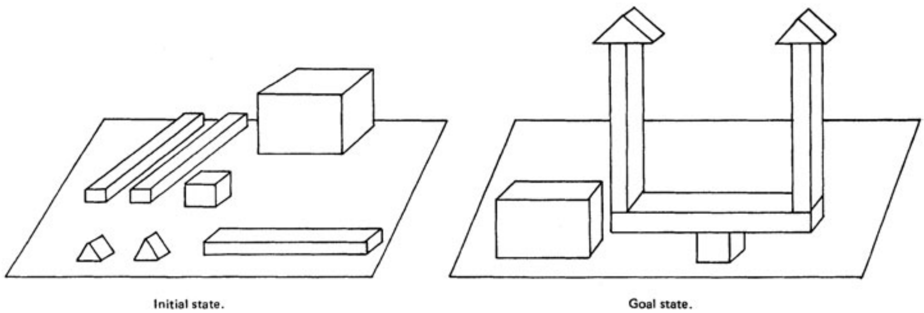

FIG. 10.9. Blocks-world problem (only one hand; no sliding). Reprinted from Boden (1977: 365)

and could forestall them—by adding steps into the plan—without introducing further contradictions. (Well, that's what Fahlman claimed, but it's not quite true: the cube used as a scaffold in Figure 10.8 can be removed at the end only by sliding, which is forbidden. When someone pointed this out on a sultry summer's day in 1978, during a talk I was giving at RAND, there was an appalled silence in the room—until a man at the back shouted "It's an ice cube!")

Ice cubes aside, it's clear that by the mid-1970s planning structures of some complexity were being handled in AI. Backtracking, generalization, abstraction, contingency planning, diagnostic critics, anticipatory corrections, on-the-spot adjustments, mapping of the current context of action, memory of past contexts . . . all these were now possible. Some programs (such as BUILD) could recognize that a current plan threatens to become overly complicated, and could interrupt it to switch to an alternative—with the option of resuming it *at that very point* if it turned out later that the first plan had been better after all. (This flexibility was due to new programming languages: Section v.d.)

By the mid-1970s, then, a number of planning techniques were available. General-purpose methods were sometimes supplemented by special-purpose data and tricks (NOAH's $\frac{3}{8}$-inch open-end wrenches, for instance). But the teleological structure of plans *in general* was the focus of all this GPS-inspired NewFAI work. And Newell and Simon's production systems provided further general features, such as tolerance of interrupts (7.iv.b and Section v.e below).

The generality was limited, however. In particular, there was no good way of modelling systems having several different, and potentially conflicting, goals. Research on multi-purpose planning had been done in the 1960s: Walter Reitman's Argus (7.i.b), and the Mars robot controller designed at MIT by William Kilmer and McCulloch. But the problems involved were by then insuperable. It was difficult enough, as we've seen, to model plans for achieving a single goal. Not until the end of the century would the Kilmer–McCulloch controller become a practical proposition (14.v.a), or multi-motive scheduling begin to be understood (7.i.e–f).

Moreover, the 1970s theoretical advances didn't prevent there being major problems in practice. The Stanford robot, for instance, spent an inordinately long time deliberating about what it should do—not because of any Hamlet-like indecision on its part, but because of plan-hierarchy complexity. (The combinatorial explosion, again.) Even when, thanks to Sacerdoti, the robot was able to recover from unexpected events, this wasn't the work of a moment. So in a constantly changing real-world environment SHAKEY, like all other NewFAI robots, was useless.

That's largely why many roboticists in the 1980s would reject planning *as such*, relying on insect-inspired reflexes instead (Chapter 13.iii.b). Nevertheless, SHAKEY had prompted a great deal of useful work—and not only in AI. The neuroscientist Arbib, for instance, was inspired by SHAKEY to start on a programme of research on visuo-motor control in frogs, which led eventually to an ambitious theory of human thought—even including religion (see 14.vii.b).

d. Early learning

During the early to mid-1950s, most AI research on learning was connectionist. Even Minsky had tinkered a connectionist learner in 1951, and devoted his Ph.D. to explaining why it worked (12.ii.a). In symbolic AI, learning machines were thin on the ground. By the mid-1950s there was only one of any real interest: Samuel's checkers player.

In the late 1950s, however, a number of people started to work in this area. One was Amarel (1962), who wrote a heuristic program which, in a sense, learnt *how to learn*: its task was to induce routines equivalent to the sixteen basic operations of the propositional calculus, but once a particular operator had been learnt it could help in learning others. (Much the same would later apply to STRIPS, as remarked above.) His draft paper was listed in Minsky's 'Steps' bibliography, but (perhaps because it wasn't officially published until 1962) it wasn't included in *Computers and Thought*. Three other early 1960s papers, however, were included—all intended as general theories, and all largely based on psychological ideas.

The first was a pattern-recognizer, an adaptation of Pandemonium (Uhr and Vossler 1961*a*/1963). It learnt its own "feature detectors", instead of having to be supplied with them. (The authors compared it with David Hubel and Torstein Wiesel's contemporary work on vision: Chapter 14.iv.b.) The paper in Feigenbaum and Feldman's collection described how the program learnt to recognize written letters and doodles (with respect to the latter, it surpassed human beings). But it had also learnt to deal with diagrams of speech acoustics, which aren't distinguishable by humans unless they're expert in the field (Uhr and Vossler 1961*b*). Its generality lay in the fact that a pixel is a pixel . . . that was all the program needed to know.

The second was Feigenbaum's (1961) EPAM: Elementary Perceiver and Memorizer, briefly mentioned in Chapter 6.iii.c. This had started out as an attempt to simulate aspects of decision making in business (Newquist 1994: 81). But it moved away from business towards psychology, and from decision making towards memory. The published paper described it as "an attempt to state quite precisely a parsimonious and plausible mechanism sufficient to account for the rote learning of nonsense syllables".

The program used its "elementary information processes" to build, and when necessary to revise, treelike "discrimination nets" representing the various syllable pairs. The details of the nets, and of the processes using them, were decided partly by general principles and partly by human psychology. For instance, *any* learning system needs to store more information about a stimulus if it has to reproduce it, as opposed to merely recognizing it. But only systems—such as EPAM—simulating human psychology need to notice the order of letters in syllables, since our tendency to be more influenced by end letters than by middle letters, and by first letters than by last letters, is presumably not a cognitive universal.

EPAM was more valuable for psychology than for AI. Feigenbaum (with Simon) had already used it to simulate some classic paired-associate experiments, when it had shown stimulus generalization and various types of interference (where later learning seems to undo earlier learning) even though these hadn't been specifically anticipated. And they soon applied it to explore the difficulties involved in learning serial lists where the same item occurs twice (Feigenbaum and Simon 1962). Even today, improved versions are still being reported in the psychological journals (e.g. Feigenbaum and Simon 1984; Gobet 1998).

The last of the *Computers and Thought* trio was valuable for psychologists and AI alike (Hunt and Hovland 1961; see also Hovland and Hunt 1960). Indeed, its ideas would eventually bear huge fruit in technological AI (13.iii.e). It was a model of strategies for learning from examples, based largely on Bruner's psychological work of the late 1950s (6.ii.b–c).

The senior author was Yale's Carl Hovland, whose mid-century analyses of the information available in concepts had inspired Bruner to work on that topic in the first place. The junior author was his student Hunt (1933–). Nowadays, their approach is normally attributed to Hunt, for Hovland died (in 1961) soon after their initial program was completed, and the work was taken forward by the younger man—who published an entire book on it just before *Computers and Thought* appeared (Hunt 1962).

Following Bruner, Hunt and Hovland defined strategies for learning both conjunctive and disjunctive concepts, given both positive and negative examples. And (again, like Bruner) they considered not only concepts whose instances share common properties, such as redness or triangularity, but also concepts defined by "common relationships"—such as having *a large figure on top and a small one below*, irrespective of the shape of either figure.

Broadly speaking, they modelled the inductive strategies informally described in *A Study of Thinking*—which they thought of as MGP's TOTE units (Hunt 1962: 184–5). In addition, they leant on the computer simulation of human memory that Hunt had presented for his Ph.D. in 1960, which featured—for instance—the limited size of STM. That was significant. For they were doing psychology, not technological AI:

> We have attempted to write a computer program which, when given as input coded representations of the stimuli, will give as output coded responses that can be used to predict the responses of a human subject. *Accurate prediction of the responses, not the development of a good hypothesis developer*, nor, solely, the reproduction of previously obtained protocols, is our goal. (Hunt and Hovland 1961: 146; italics added)

So, for instance, their model favoured "positive focusing", in which hypotheses are developed from positive instances rather than negative ones—even when this isn't the most efficient strategy. Why? Because BGA's experiments had found that human subjects favour positive focusing.

Hunt's (1962) book discussed a number of strategies—some implemented, others not. The way in which they were described was less 'logical', and more 'psychological', than in the Hunt–Hovland paper. Consider "conditional focusing", for example—a procedure for learning disjunctive concepts. In the *Computers and Thought* paper, this had been expressed as a recursive function operating on sets, an idea taken from McCarthy (1960). But Hunt described it as a method for building decision trees (see Figure 10.10). These two approaches were equivalent: logic had been re-expressed, not dropped. Indeed, Hunt still declared that "Concepts are essentially definitions in symbolic logic" (p. 8).

We needn't follow through this strategy in detail. But notice that step (3) involves a simple frequency measure, seeking the description *most commonly* applicable to positive instances. Later versions of this general inductive approach would employ increasingly sophisticated frequency measures (see 13.iii.e). Notice, too, that different random choices at step (3)—where no single description is "the most common"—would result in different decision trees for one and the same concept. Suppose, for example, that the training set was as follows (Hunt 1962: 234):

Positive instances	Negative instances
Large, black circles	Large, black triangles
Large, white circles	Large, white triangles
Small, black triangles	Small, black circles
Small, white triangles	Small, white circles

Two decision trees derived from those data are shown in Figure 10.11.

As Hunt pointed out, conditional focusing *as shown in Figure 10.10* was "an algorithm for producing answers", which "[clearly] will not do as a simulation" (p. 235). The Hunt–Hovland paper had already suggested limiting the number of recursions permitted, so restricting the maximum length of a path through the decision tree. Now, Hunt had done further experiments on human subjects, learning concepts of various kinds. As a result, he suggested changes to make the machine strategies more human-like—which sometimes, though not always, made them more efficient too.

For instance, a "positive focusing" modification could give quick solutions for conjunctive concepts (see Figure 10.12). This new routine was inserted between steps (0) and (2) of the procedure shown in Figure 10.10. It would seem at first sight, therefore, that conditional focusing had been made more complex. But that wasn't so. For the calculations shown in Figure 10.12 take less time (especially in list-processing languages) than those of step (2) in Figure 10.10.

Various other modifications were suggested as well. In short, this work was not only an achievement, but also an intriguing promise of further achievements. That promise would be fulfilled, for Hunt and Hovland's research led eventually to the ID3 algorithm (13.iii.e). (It was part-inspiration also for the NewFAI program that discovered geometric analogies, using the "common relationships" mentioned by H&H and by Minsky in 'Steps'—T. G. Evans 1968: 283, and 13.iv.c.) However, that didn't happen immediately.

Despite being honoured by inclusion in *Computers and Thought*, these early learners didn't set GOFAI learning afire at the time. In part, that was because they were so heavily biased towards psychology. Besides, NewFAI was concerned with other things: planning, theorem proving, and especially KR. McCarthy had said in his harbinger paper

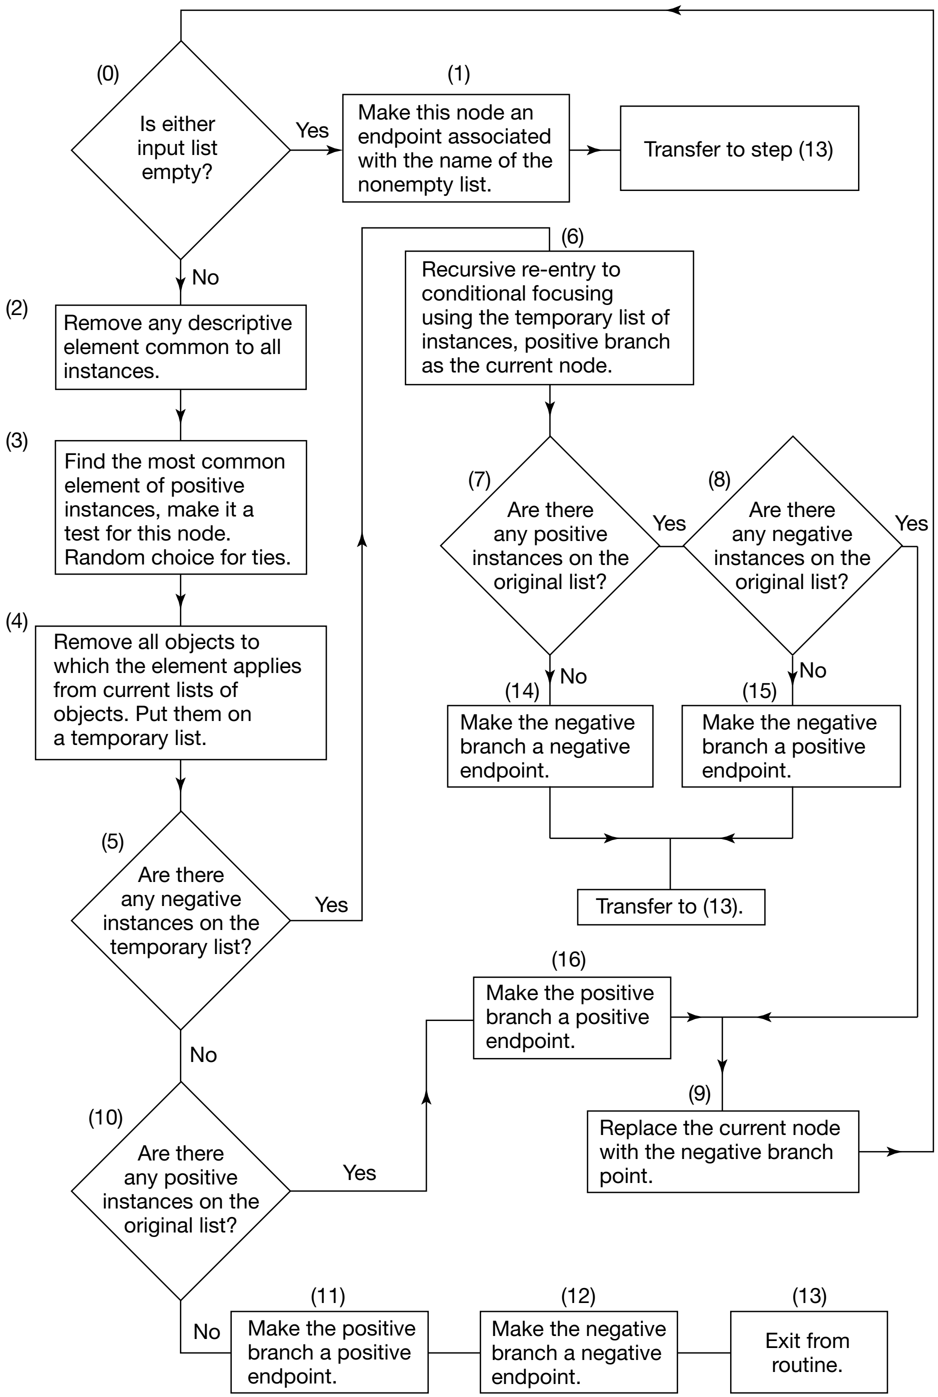

FIG. 10.10. Conditional focusing. Redrawn with permission from Hunt (1962: 232)

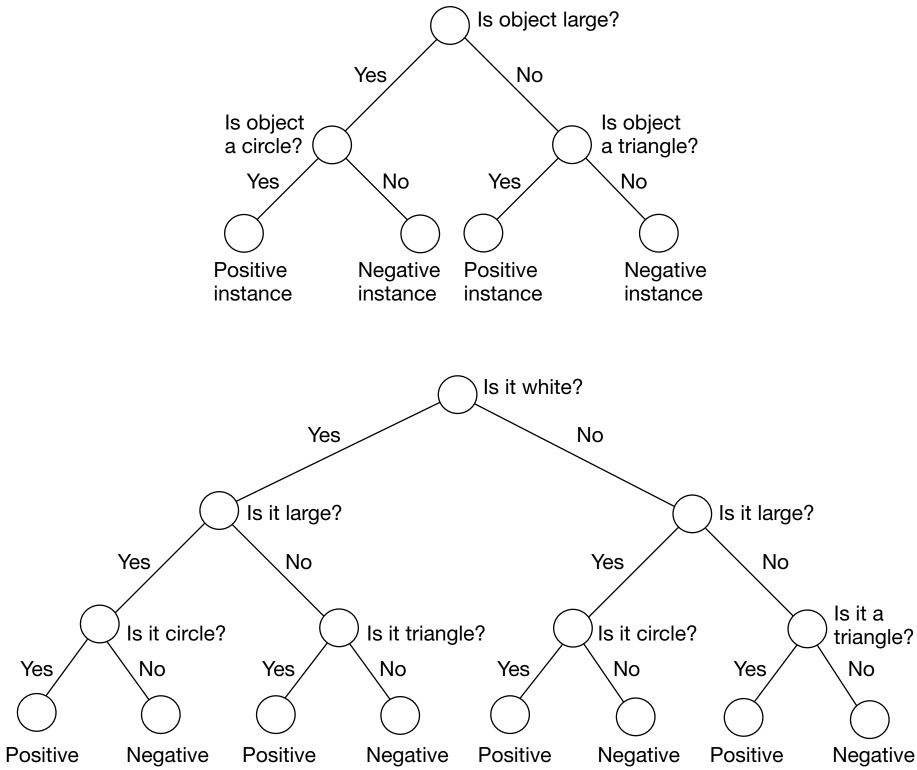

FIG. 10.11. Alternative decision trees defining the same concept. Redrawn with permission from Hunt (1962: 234, 235)

that if a machine were to learn something, it would first have to be able to represent that something—and the 1960s, as we've seen, were largely devoted to finding ways of representing things. Occasionally, creative efforts in KR were aimed at automatic learning: Michie's "Adaptive Graph Traverser", for instance, which extended Samuel's work from games to problem solving (Michie and Ross 1969). By and large, however, learning was put on the back burner.

In the early 1970s, a few pots were brought to the front of the stove. The first was Winston's concept-learner (1970*a*), the second Sussman's HACKER (1973/1975), and the third McDermott's TOPLE (1974). This trio addressed many interesting aspects of intelligence, for the programs learnt (respectively) by comparing examples, by doing, and by being told. They created some local warmth, especially at MIT. But they barely raised the temperature in the kitchen, as we'll see.

By the time Winston's program was officially published (in 1975), it was already well known. It had been developed during the late 1960s, presented to MIT for a Ph.D. in 1970, and circulated unofficially from then on—amid no little excitement. It was the first NewFAI learner since Samuel's to be widely lauded within the field (although I felt at the time, and still do, that its title to fame was largely due to the efficiency of the MIT publicity machine).

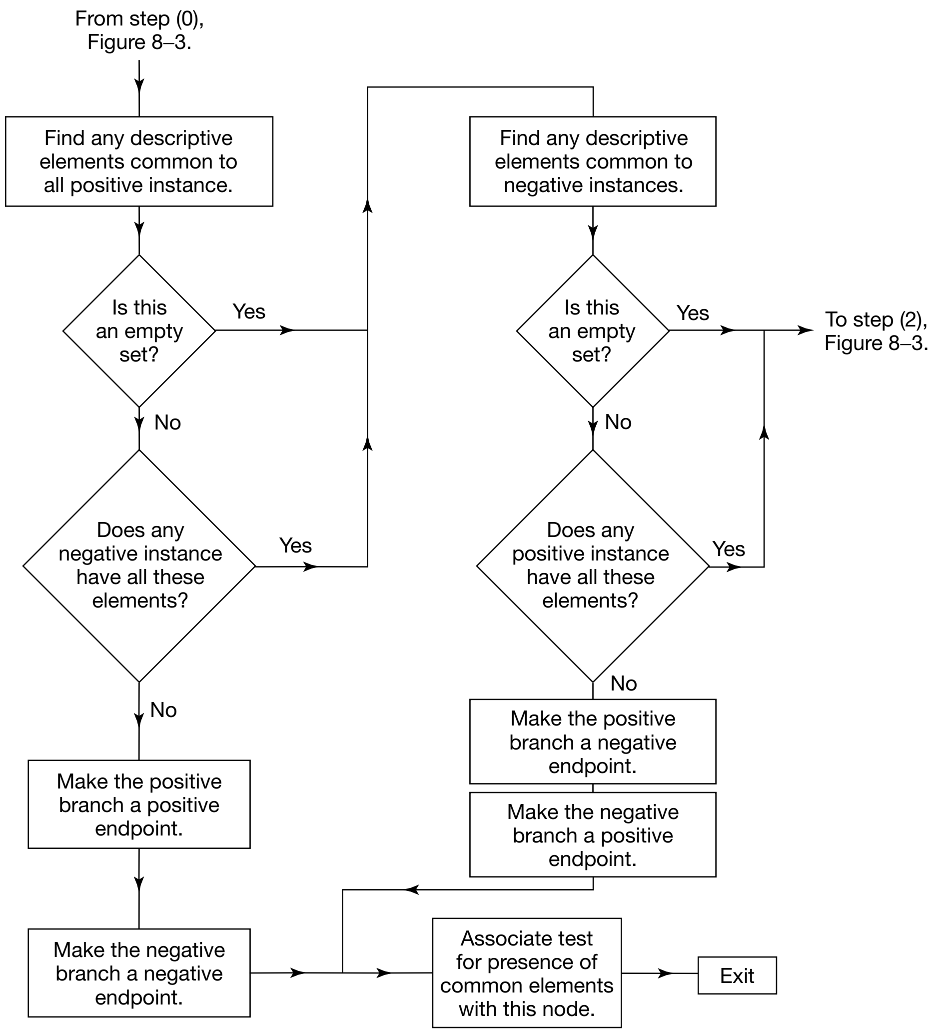

FIG. 10.12. Modification of conditional focusing for a rapid solution of conjunctive problems. Redrawn with permission from Hunt (1962: 236)

Winston, like Bruner and Hunt before him, assumed that concepts can be defined by lists of necessary and sufficient conditions (but cf. 8.i.b, 9.x.d, and 12.v–vi and x.b). His program learnt what counts as an *arch*, or an *arcade*, in the blocks world. On being presented with inputs labelled as examples or counter-examples (including near-misses), it generated an articulated description of each one: a hierarchical semantic network. Gradually, it modified the current candidate to construct a description matching *only* the examples.

That's easily said. In fact, the comparison and modification techniques were a significant KR achievement at the time (see Boden 1977: 252–67). Quillian had shown how to build semantic networks, and how to use them for simple inferences; but he'd said nothing about how to compare them. Winston's new network-matching techniques were designed to do just that. Indeed, they—not the program's power as a learner—were the main reason for people's interest.

An arch, for instance, consists of two vertical blocks with another block on top of them—not lying on the floor beside them. The shape of the top block is irrelevant: it may be a bulky cuboid, or a plate, wedge, or pyramid. Moreover, there must be a significant gap between the two vertical blocks: if they abut, it's not an arch but a near-miss. These facts wouldn't be evident on seeing just one arch. They'd become clear only after many different inputs—including some non-arches as well as various types of arch. The program's final concept is shown in Figure 10.13.

Much as Bruner and Hunt had found that the order of presentation matters when people learn concepts, so it mattered for Winston's program. And he had to avoid introducing several differences at once—hence the importance of the near-miss. But the inputs, and the list of candidate properties, were carefully tailored to suit the blocks world. Because this was so narrowly defined, Winston *couldn't* present the program with irrelevant information. For the same reason, it didn't have to decide which ones were *likely* to be salient. Real-life learning is different. It's possible only if one assumes that most possible descriptions are irrelevant, and (usually) that some relevant descriptions may be missing—or even false. Such issues were ignored by Winston. (And, to be fair, by most other AI workers until many years later: see 7.vi.d–f, 12.viii.c–e, and 13.iii.e.) Moreover, structural comparisons of complex semantic networks were difficult

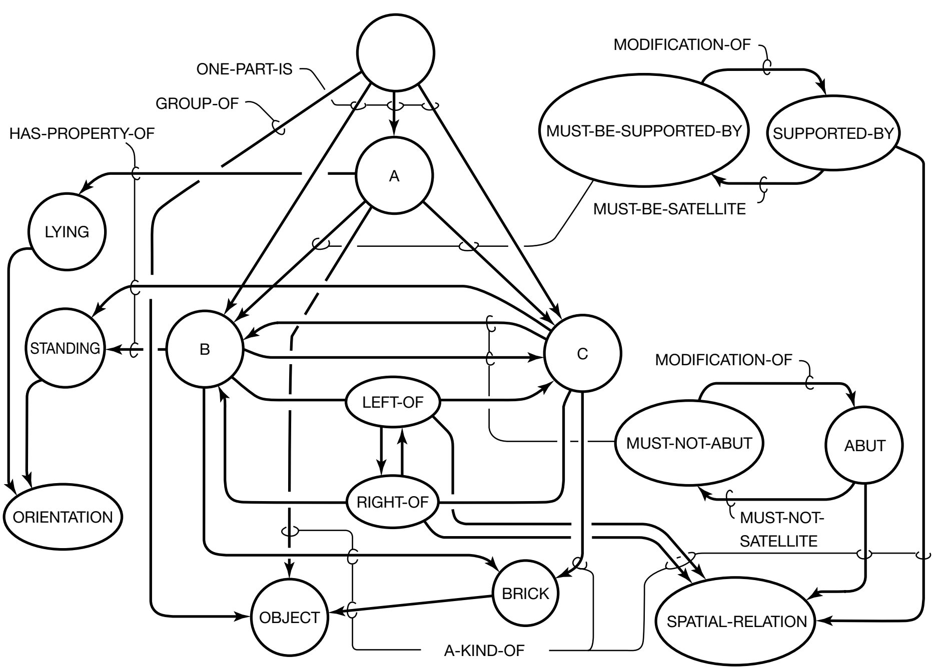

Fig. 10.13. Semantic network representing the concept of arch. Redrawn with permission from Winston (1975: 198)

to program, and to generalize (much more difficult than the property-counting done by Hunt's strategies). For both these reasons, Winston's program didn't hold much promise of practical applications.

Another issue ignored by Winston, and by most of his contemporaries, was *just why* certain programs did or didn't manage to learn. This question was an aspect of meta-epistemology, which most NewFAI scientists ignored—Minsky being an honourable exception (see i.g, above). It was highlighted in the mid-1970s, when researchers at Edinburgh not only proved that Winston's program had unsuspected limitations but also explained its successes in a principled way (Richard M. Young *et al.* 1977).

Their own concept-learning algorithm was a generalization of a focusing strategy earlier identified by Bruner. It could deal with hierarchical concepts (such as arch or arcade), and dealt uniformly with descriptive features (such as predicates, relations, and multi-valued dimensions) which Winston had treated as special cases. It worked irrespective of the order of presentation. And it explained the logical role of near-misses, which Winston had recognized intuitively. The key idea was to represent a candidate hypothesis by *two* nodes in the semantic network, one describing the specific instances already known to fall under the concept, the other holding the most general description known to be possible, given the instance encountered so far. So the two nodes set boundaries (identifying sufficient and necessary conditions) to the search-space within which the concept must lie. An efficient learning strategy would shift these boundaries until they met.

This Edinburgh algorithm was later used as the logical core of the widely used method of "version spaces" (T. M. Mitchell 1979; Mitchell *et al.* 1983). Its importance here, however, is as an early attempt to meet Drew McDermott's criticism of NewFAI in general: that it failed to analyse why programs were, or weren't, successful (see 11.iii.a).

Soon after Winston's 1970 memo weighed down the postmen's mailbags, his MIT colleague Sussman circulated a memo of his own (1973/1975). This described HACKER, a planning program engaged on a very different task: learning by doing. It wasn't the only NewFAI system that learnt by doing. Another was the Edinburgh pole-balancer (Michie and Chambers 1968), and yet another the STRIPS learner developed for the SHAKEY robot (Fikes *et al.* 1972*a*,*b*; Boden 1977: 280–6). But HACKER exhibited a capacity for deliberate self-criticism. Among other things, this suggested how Piagetian error-led constructive learning might be possible (see 5.ii.c, and Section vi.a below).

Much as Winston's program looked out for specific types of discrepancy, which it tried to reduce by relevant amendments to its conceptual models, so HACKER looked for discrepancies of particular kinds. As noted in Section iii.c above, it corrected its own mistakes by using a "teleological commentary" on its performance, couched in terms of various types of bug. But it didn't have to correct the same mistake repeatedly, because it learnt from its errors.

HACKER's learning took two forms. On the one hand, it stored its corrective "patches" in a central LIBRARY, indexing them according to the bugs they'd been written to correct. On the other hand, a patch devised in particular circumstances could be generalized to cover a general class of cases. (That had also been true of STRIPS, as we've seen.)

For instance, consider Figure 10.14. HACKER solved (*a*) instantly, using the primitive action for moving blocks. But (*b*) caused trouble, because the most nearly relevant primitive action required that the block to be picked up have no other block on top of it. However, HACKER classified this correctly as a prerequisite-missing bug, and patched the plan accordingly: A was moved off B, and then B could be put on C. This patch was stored in the LIBRARY, and brought out for problem (*c*)—which was therefore solved *immediately*, despite having the very same structure as (*b*). Moreover, problem (*d*) was also solved immediately, because the patch generated in response to (*b*) was sufficiently general to direct these steps (resulting in Figure 10.14.*e*):

Wants to put A on B
  Notices C and D on A
    Puts C on TABLE
    Wants to put D on TABLE
      Notices E on D
        Puts E on TABLE
      Puts D on TABLE
Puts A on B.

HACKER's learning-by-practice wasn't just a matter of repetition, where doing something several times makes it more likely to be done in future. (Think connectionism.) Rather, the program had learnt something about the teleological structure of what was being done, and used this to do something else—something better—next time. So when it used the primitive action to solve problem (*a*), it made a note that this was being done *in order to* get A onto B. Similarly, its comments on the patch noted that putting A on the table was done purely *in order to* clear B, *in preparation for* moving it onto C. In short, Sussman was following Papert's lead in proclaiming the "virtuous" nature of bugs (Sussman 1974; cf. vi.a, below).

As for learning by being told (McCarthy's dream for the Advice Taker), McDermott's TOPLE was intended to show that this is a highly active form of cognition. Besides interpreting the meaning of the input sentences, one has to make judgements on their truth. Indeed, the interpretation itself may depend on judgements about truth, as Winograd's SHRDLU had recently shown (see the discussion of *Put the blue pyramid on the block in the box*, in Chapter 9.xi.b). Those judgements are grounded in the cognitive system's world model.

So TOPLE didn't just add newly input sentences ("Advice"?) to a list, but interpreted them in the light of what it already knew—or believed—about the world being described. Ambiguities were resolved, and anaphora understood, by comparing the input sentence with the program's current world model. The model itself could be amended, if it conflicted with the facts provided in the input. For each input, a "tree of hypothetical worlds" would be constructed, capturing every possible interpretation. (That was done by using the CONNIVER programming language, co-developed by McDermott himself: v.d, below.) This tree would then be pruned, leaving only the "plausible" possibilities—i.e. those consistent with the world model. As McDermott put it:

> TOPLE is basically a very skeptical program. It wants to resist any change to the data base . . . so it forces itself to believe what it is told as cheaply as possible . . . [It] knows that some interpretations of the situations that it is told about are unlikely. It resists having to believe in such interpretations at all if more plausible interpretations of what it hears are available; and, if it must accept them, it demands some kind of compensating belief. (1974: 57)

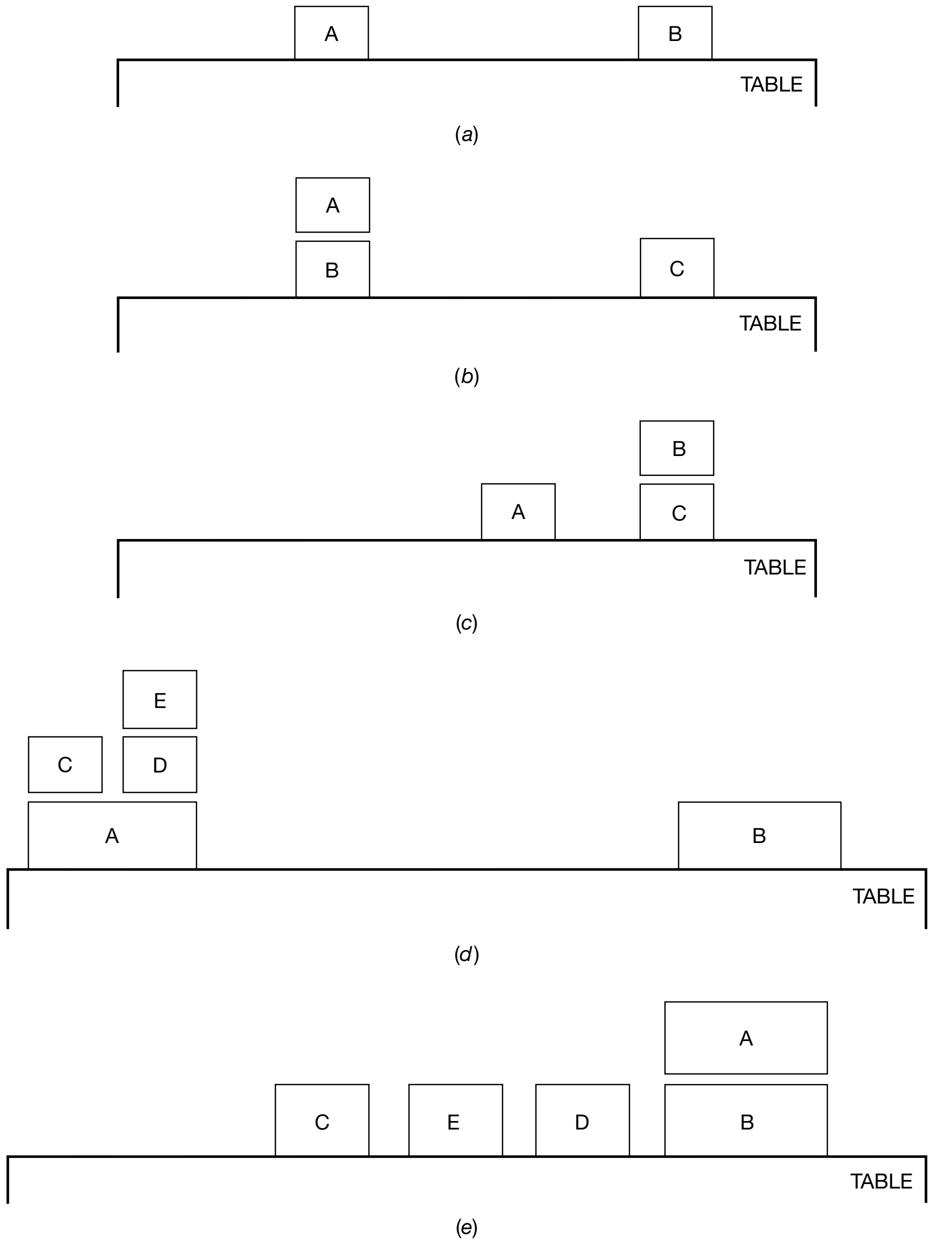

Fig. 10.14. Four problems solved by HACKER. Adapted with permission from Sussman (1975: 9–11) (*a*) Problem: Starting from this situation, put A on B. (*b*) Problem: Starting from this situation, put B on C. (*c*) Problem: Starting from this situation, put C on A. (*d*) Problem: Starting from this situation, put A on B. (*e*) HACKER's solution to problem (*d*).

The world model employed by TOPLE was a logical one, for McDermott was then still wedded to logicism (see 13.ii.a). But it was open to others to suggest non-logical versions, and the psychologist Philip Johnson-Laird soon did so (7.iv.d–e). He discussed the role of spatial mental models (and sentence–model comparisons, and even possible-worlds ontology) in reasoning and language understanding—not least, in learning by being told.

Despite these attempts to advance GOFAI work on learning, and despite the praise handed out to Winston's program (and, to a lesser extent, HACKER), the topic was still largely neglected. Ryszard Michalski, a key player in the revival of AI learning in the early 1980s, remembers that it was seen in the 1970s as "a 'bad' area to do research in (the dominant AI research was then on problem solving)" (R. S. Michalski, personal communication). What eventually brought it back to life was an exciting development of Hunt's work. But that's a story for a later chapter (13.iii.e).

e. 'Some Philosophical Problems'

In 1969 McCarthy and Patrick Hayes (1944–), then a Ph.D. student in Meltzer's Metamathematics Unit at Edinburgh, gave a paper at the fourth Machine Intelligence Workshop which very soon became a classic. Indeed, drafts had already been circulating for some time, and Hayes had been asked to give seminars on it in the months preceding the Workshop: "People were kind of primed for something important, and this was generally reckoned to be John's magnum opus in some sense" (P. J. Hayes, personal communication).

"John's" *magnum opus*, you'll notice. Why not "Pat's", too? Well, McCarthy was one of the three biggest names in NewFAI (alongside Minsky and Newell-and-Simon). Hayes was a mere research student. In fact, when he first impressed McCarthy with his ideas, he hadn't even achieved that far from exalted status: he'd just started a diploma in Machine Intelligence.

That was in 1966, when McCarthy came to Edinburgh for the second MI Workshop. Being too lowly a creature to be allowed to attend the sessions, Hayes begged Rod Burstall to arrange an audience with the great man. For McCarthy's grapevine-circulated memo on 'Situations, Actions, and Causal Laws' (1963) had excited him "hugely", as being "a natural way to put [my hero] Carnap into a computer". Burstall came up trumps, and scheduled the meeting:

> Rod warned me that John was a very busy man, I had 30 minutes at most, and not to make him cross. So I turned up at the appointed time . . . and I was so nervous that I had written out my questions on a piece of paper, in case I forgot them. So John snarled "Come in!" rather grumpily, obviously irritated at having to talk to this kid as a favor to Rod, and I sat down and started asking my questions. John tossed the first couple of answers off in a few words but then he started to get thoughtful, and by about the 5th question he figured I was reading from a list, and he suddenly stood, reached over the (tiny) desk and grabbed the list out of my hand, "Lemme see that!" And then he sat in total silence for several minutes reading it, and I sat in utter terror that I had committed some cardinal sin of intellectual discourse by having a list written out and would be banished from academic society for ever. And then he looked up and said "How would you like to come to California?" And I was so flabbergasted that I couldn't speak. And then I said "When?" and he said "Maybe in the summer" and I said "Wow! Great" and so on and then my 30 minutes was up and I didn't see him again . . . (Hayes, personal communication)

After several months of total silence, during which Hayes put it out of his mind as a dream, a telegram arrived summoning him and his wife and baby son to visit California—all expenses paid. That was in the spring of 1967, and Hayes remembers:

> While [I was] there we wrote the main draft of the paper. In fact, John had already written a lot of it, and my role was to be a kind of in-house critic/questioner, like a court jester, for most of the stuff; but I did write the section on situation calculus and modal logic (Section 4 of the paper) which, apparently, introduced the actual term "situation calculus" into the language though at the time this didn't seem like a big deal. (personal communication)

Their declared intention was to discuss some familiar philosophical problems *from the standpoint of* AI—and this, they did. But they also identified a huge philosophical problem *concerning* AI. Specifically, they defined the frame problem.

The roboticist Lynn Andrea Stein (1965–), some twenty years later, said that "a definition of the 'frame problem' is harder to come by than the Holy Grail" (L. A. Stein 1990). I'll offer one, nevertheless—or rather, two. To see why a dual definition is needed, one must first consider just how McCarthy and Hayes introduced the problem in their 1969 paper.

They didn't do this in a defeatist spirit. On the contrary, they located the frame problem in the context of a constructive discussion of how new forms of logic might be used for AI purposes. (Thirty-five years later, McCarthy's home page on the Web described it tersely as "the basic paper on situation calculus".) In other words, the generalities being sought by NewFAI were set alongside, and to a large extent identified with, the generalities sought by philosophical logic. And the McCarthyite faith in logic was undimmed: in their eyes, the frame problem was potentially solvable.

They weren't afraid of reaching for the skies. The philosophical chestnuts addressed in their paper were:

* causation;
* the nature and origins of knowledge;
* purpose, action, and ability;
* counterfactual conditionals;
* self-knowledge;
* and free will/determinism.

In addition, they discussed various modal (i.e. non-truth-functional) logics. These had been developed by philosophers in order to express certain highly general aspects of the world clearly, and to enable inferences about them to be deduced accordingly. The subject matter, ranging over metaphysics and mind, included:

* possibility and necessity;
* probability;
* ontology;
* knowledge and belief;
* tensed statements and time;
* decision and purposive action;
* commands;
* obligation and permission;

* interrogatives;
* and the conditions necessary for communication.

So McCarthy and Hayes were optimistic, not to say hubristic. Although modal logics were a twentieth-century invention (mostly pioneered after mid-century), the problems they were focused on were much older. As for the "chestnuts", these had puzzled philosophers for hundreds of years. Questions about the basic ontology of the universe (states, events, properties, changes, actions . . . ?), for example, had kept generations of grey-beard metaphysicians busy. Now, here were two NewFAI researchers, one of them a mere pipsqueak, brashly claiming to be able to illuminate them—even, *mirabile dictu*, to solve some of them. Causation and counterfactuals, for instance, could—so they said—be explicated by considering systems of finite automata interacting according to deterministic rules (McCarthy and Hayes 1969: 470–7, 479–80).

This was strong meat. As remarked in Chapter 16, philosophical problems don't get solved in a hurry. So their paper was nothing if not ambitious. Admittedly, their hubris had limits. For they were also claiming that AI "needs" philosophy. Even though most philosophy was declared by them to be "irrelevant", NewFAI scientists could learn a lot from some philosophers.

They weren't the only people who thought that philosophy and NewFAI needed each other. Others were saying that, too (Minsky 1965; Boden 1965, 1970, 1972; Newell 1973*b*). By the end of the 1970s this claim was even more common (e.g. Newell and Simon 1976). It was argued at length—and with no little passion—by Aaron Sloman, who declared that "within a few years philosophers . . . will be professionally incompetent if they are not well-informed about these developments" in AI (Sloman 1978, p. xiii). Moreover, some of the early cyberneticians—especially Craik (1943) and McCulloch (1948, 1961*a*; Pitts and McCulloch 1947)—had been equally bold in their claims to be able to help solve long-standing philosophical problems (see Chapters 4.iii.a–c and vi.b, and 12.i.c). So the coupling of philosophy with computers wasn't new.

However, McCarthy and Hayes were looking to philosophy in a more focused way. Their approach was distinctive in its heavy reliance on modal logics. Most of these had been developed very recently, in the 1960s, by philosophers such as Arthur Prior, Jaakko Hintikka, Georg von Wright, Saul Kripke, and Nicholas Rescher.

In recalling the many ancient philosophical disputes, McCarthy and Hayes reiterated the claim made in McCarthy's harbinger papers (1959, 1963), that natural language and common-sense knowledge could be represented in predicate calculus terms. And they promised that (their improved version of) resolution theorem proving could be used to explore the implications of all the highly problematic concepts listed above—and even to prove the correctness of complex action strategies. It followed that any philosophy of knowledge (epistemology) which could not, at least in principle, help AI "to construct a computer program to seek knowledge in accordance with it, must be rejected as too vague" (1969: 467).

For most AI scientists, however, what was especially interesting was the paper's relevance not for philosophy, but for the practice of AI. And there, despite the optimism, lurked a huge problem—one which would dominate the research of both men, and many of their AI colleagues, for decades. This was what they called "the frame problem" (p. 487).

McCarthy and Hayes introduced the frame problem by reference to their attempt to write an AI program that knew something about human communication: specifically, telephone conversations. When representing one person's ability to get into a conversation with another, they'd been "obliged to add the hypothesis that if a person has a telephone he still has it after looking up a number in the telephone book", and also to assume if someone looks for a number they'll know it, and that if they dial it they'll speak to their friend (pp. 485, 487, 489). Clearly, this spelled trouble.

Indeed, it spelled potentially endless trouble. It may not actually be the case that if Peter looks up John's number in the book, he will know it, or that if he dials the number he'll soon be talking to John. As the authors pointed out (on p. 489):

1. The page with John's number may be torn out.
2. Peter may be blind.
3. Someone may have deliberately inked out John's number.
4. The telephone company may have made the entry incorrectly.
5. John may have got the telephone only recently.
6. The phone system may be out of order.
7. John may be incapacitated suddenly.

Of course, they said, we could add terms contradicting any one, or even all, of these exceptions—"But we can think of as many additional difficulties as we wish, so it is impractical to exclude each difficulty separately."

They suggested three methods of escape, the first of which was to use the notion of a state vector, or "frame", associated with a theorem-prover. Here, various aspects of the (formally described) situation are listed, and the effect of any action is defined by stating which situational aspects are changed—all the others being presumed unchanged (p. 487). Earlier in the paper, for example, they'd mentioned a simple action sequence enabling a monkey to reach some bananas suspended from the ceiling: *Move the box under the bananas; climb onto the box; and reach for the bananas* (p. 481). A clear, though usually unstated, assumption of this strategy was that moving the box doesn't move the bananas. (That's usually true, of course. But others soon pointed out that it's not true in the situation depicted in Figure 10.15.)

Second, they said, modal terms like "normally" or "probably" could be introduced into the logic. This would act as a default assumption, yielding the expected conclusion unless there were a specific statement saying, for instance, that the phone system wasn't working (p. 489). (They rejected the idea that each sentence should be given its own probability measure, because in most cases we wouldn't know how to do that, and because it's not always clear how to match probabilities to people's subjective conviction: p. 490. Although they didn't say so here, this was a dig at fuzzy logic: Zadeh 1965—see 13.i.a.)

And third, they suggested using Rescher's (1964) recently published philosophical work on hypothetical reasoning and counterfactuals. His logic, they said, might enable a program to search for, and sensibly fix, inconsistencies arising from its (deliberately false) assumption that *nothing* would change as a result of a given action (p. 499).

None of these suggestions was spelt out in detail in their paper. And they made this telling confession:

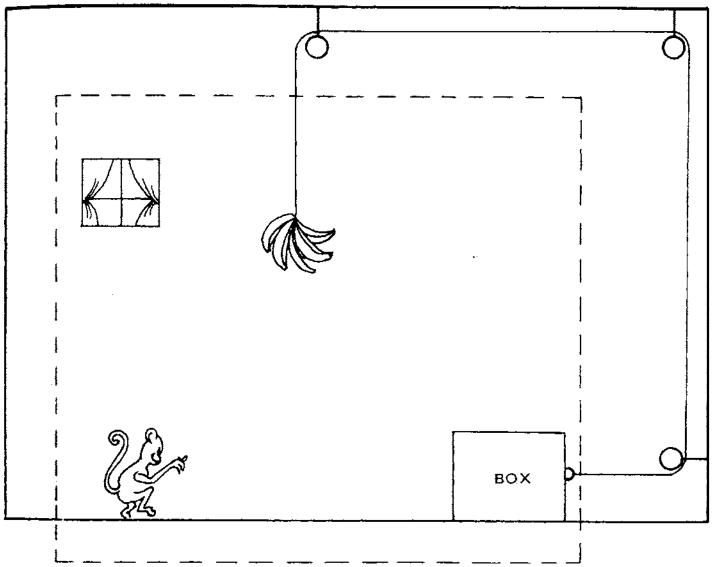

FIG. 10.15. Monkey and bananas problem: how does the monkey get the bananas? (The usual approach to this problem assumes, though doesn't necessarily explicitly state, that the relevant 'world' is that shown inside the dotted-line frame. In other words, nothing exists outside this frame which causes significant changes in it on moving the box.) Reprinted from Boden (1977: 387)

We hereby warn the reader, if it is not already clear to him, that these ideas are very tentative and may prove useless, especially in their present form. However, *the problem they are intended to deal with, namely the impossibility of naming every conceivable thing that may go wrong, is an important one for artificial intelligence, and some formalism has to be developed to deal with it.* (p. 490; italics added)

While they were writing these words, the first of their three escape routes was already being developed by some of McCarthy's Stanford colleagues. On the one hand, by Green (who described it at the same Edinburgh workshop: C. C. Green 1969); on the other, by the programmers of STRIPS, the triangle-table planner used by SHAKEY (Fikes and Nilsson 1971; Fikes *et al.* 1972*a*, *b*). And as soon as the Edinburgh paper was off the press, people started writing about "the frame problem" in AI (Raphael 1971; Sandewall 1972).

Roboticists in particular, who couldn't avoid real-world exigencies even in highly artificial environments, were well aware of "the impossibility of naming every conceivable thing that may go wrong". But common-sense reasoning was threatened too, as McCarthy and Hayes' telephone example had shown. The impossibility of giving cut-and-dried definitions of concepts, or natural-language words, were further sources of this general difficulty.

In fact, their find-the-phone-number example had identified *two* problems, not one. Because both of these were introduced in relation to the same example, they're often conflated—even confused. Both are called "the frame problem", although it's usually clear from the context which one the speaker has in mind.

The first was the problem of knowing just which aspects of a situation would be changed by a particular action, and which would not. For instance, whether it's true that "if a person has a telephone he still has it after looking up a number in the telephone book", or that moving the box doesn't move the bananas. That is "the frame problem" strictly so called, because that is the one addressed by the first of their three escape routes, which is where the word "frame" entered the discussion.

The second was the problem of reasoning with incomplete knowledge—where one doesn't know, for instance, whether the page has been torn out of the phone book, or whether the phone system is out of order. This problem (often called the frame problem, but sometimes the qualification problem: see 13.i.a) is a feature both of our inevitable ignorance about the facts of the real world, and also of the irredeemable vagueness of ordinary-language concepts. It's normally dealt with by some form of default reasoning—their second escape route. But of course the default doesn't always apply.

In general, the first version of the frame problem was relevant for robot planning, and the second for common-sense reasoning. Given the importance of both of these (especially the second) for AI in general, it's hardly surprising that the frame problem (dual sense) has been on the lips of AI researchers, not to mention AI's opponents, ever since it was first named (e.g. Raphael 1976: 146–52; Pylyshyn 1987; Dennett 1984*b*; Ford and Hayes 1991; Ford and Pylyshyn 1996; Sperber and Wilson 1996; Shanahan 1997)—nor that it's mentioned in various other chapters in this book (e.g. 7.iii.d, 8.i.b, 9.d–f).

McCarthy and Hayes themselves were no exception. They spent many years trying to defuse the problem, working respectively on non-monotonic reasoning and naive physics (Chapter 13.i.a–b).

(Today, Hayes feels that they were over-sanguine in the 1960s and 1970s, and that the frame problem is probably unsolvable: see 13.ii.b. Certainly, the claim—see Shanahan 1997—that it has already been solved is over-optimistic for the general case.)

The statement of the frame problem, and the suggestions regarding a situation calculus, were the most influential features of 'Some Philosophical Problems'. But a third was sometimes picked up too. This was McCarthy and Hayes' distinction between three sorts of representational "adequacy", whether in minds or in machines: metaphysical, epistemological, and heuristic. (They might have embarked on a philosophical discussion of reductionism here, but they didn't; Fodor 1968 had just used broadly comparable ideas to do so.)

A representation of a problem is metaphysically adequate "if the world could have that form without contradicting the facts of the aspect of reality that interests us" (p. 469). Such representations were mainly useful, they said, for constructing general theories. For example:

1. The representation of the world as a collection of particles interacting through forces between each pair of particles.
2. Representation of the world as a giant quantum-mechanical wave function.
3. Representation as a system of interacting discrete automata [a system which they went on to explore in their paper]. (p. 469)

A representation is epistemologically adequate "if it can be used *practically* to express the facts that one actually has about the aspect of the world [being considered]" (italics added). The language of particles-and-forces, they said, can't be used to express the facts that "dogs chase cats" or "John's telephone number is 321–7580", but ordinary language can. On the other hand, English can't express the information processing involved in recognizing a particular face. (Nor, one might add, can it express the NLP rules involved in interpreting Chinese—despite John Searle's famous claim to the contrary: see 16.v.c.)

With respect to philosophically problematic concepts such as cause, ability, and knowledge, a main aim of their paper was to find a way of representing/expressing these which would be epistemologically adequate for a computer—or, indeed, for a metaphysician. In that case, they would *no longer be* philosophically problematic.

Finally, a representation is heuristically adequate "if the reasoning processes actually gone through in solving a problem are expressible in the language". Only in very simple cases is the representation which is epistemologically adequate *also* heuristically adequate. They said virtually nothing more about this level of adequacy, but it underlay the already recognized need for high-level programming languages, and would soon aid the development of AI planning.

There may be more than three representational levels, for heuristic adequacy can exist on multiple levels of abstraction. High-level programming languages are needed because people can't think fruitfully in machine code when they're trying to solve relatively large-scale problems—in other words, machine code isn't heuristically adequate for such problems (Section v, below). So solutions found in the PLANNER programming language must be translated into LISP, and then into machine code, before they can actually be executed.

We've seen, for instance, that neither GPS nor early STRIPS could produce an overall strategic plan before starting on the detailed solution. In effect, they made no distinction between heuristic and epistemological adequacy. As problem complexity increased, they were soon scuppered by the combinatorial explosion. But that distinction was recognized in Sacerdoti's ABSTRIPS. This could ignore the low-level details while formulating the strategic plan, and also (during execution) translate that plan into detailed instructions about what needed to be done. Whereas STRIPS couldn't see the wood for the trees, ABSTRIPS could represent a hierarchy of woods, in which copses and trees of decreasing size could be successively specified in heuristically adequate terms, until an epistemologically adequate level was reached.

In sum, the logicist case was argued more explicitly, and (thanks to philosophical logic) more persuasively, in 'Some Philosophical Problems' than in McCarthy's harbinger papers. But the ever-hungry worm nestling at the heart of logicism had been made clearly visible.

10.iv. The Need for Knowledge

Minsky had said (in 'Steps') that work on AI "is concerned with using all we know to build the most powerful system that we can" (1961*b*: 446). But much of the newest NewFAI, as we've seen, was ignoring much of what we know. In other words, it was seeking *general* theories of intelligence. By the 1970s, however, Minsky's remark was being interpreted more seriously. For generality wasn't working as well as had been hoped. Increasingly, the 1970s saw a flight from domain-independent models. (This didn't apply to Minsky himself, who complained about this trend in his high-visibility Turing Award lecture: Minsky 1969.)

As Winograd put it (in March 1974), there had been a growing split between people "making programs do more and more intelligent things" and people studying "general issues of representation and problem-solving". But from now on, things would be different:

Today I see a movement towards a middle ground. The theorem-proving craze is slowing down. People are aware that very general systems are not going to be the basis of practical programs, and people who have been doing specialized programs are asking what these programs have to offer which can be brought to bear on more general problems. (Winograd 1974: 92)

a. A triumph, and a threefold challenge

Winograd was a mere graduate student in September 1970, and a neophyte postdoc in September 1971. Nevertheless, he was invited to give a talk at the second IJCAI Conference in London that autumn. This was no mere parallel session, fighting for attention among half a dozen others. On the contrary, it was the inaugural *Computers and Thought* Lecture, supported by the royalties donated by Feigenbaum and Feldman (ii.b, above). Those of us in the UK who were planning to attend the meeting were enthused by the rumours of his participation, for his work—available as a Technical Report from MIT's AI Lab since February of that year—was already a glowing beacon for the cognitive science community.

Why all the fuss? Well, Winograd's SHRDLU—written as his Ph.D. thesis of 1971 and officially published, to huge acclaim, a year later—was a triumph of NLP (9.xi.b). It was also a triumph of AI programming. But Winograd had done more than write an amazing program: he'd challenged three basic assumptions of the conventional NewFAI approach.

First, he abandoned generality and relied instead on detailed domain knowledge. Indeed, he was one of the strongest voices arguing for this move. Since he wasn't merely arguing but also achieving, and that in a spectacular fashion, his words carried weight. In interpreting the input sentences, SHRDLU relied heavily on its detailed knowledge of syntax. Its unprecedented ability to parse sentences as complex as *How many eggs would you have been going to use in the cake if you hadn't learned your mother's recipe was wrong?* was the result. And Winograd drew a general moral: whatever the problem domain happened to be, successful AI required that the relevant domain knowledge be provided to the program.

He wasn't the only one in the early 1970s to be saying this. Within NLP, HEARSAY combined syntactic, semantic, pragmatic, lexical, phonemic, and phonetic knowledge—all simultaneously available via the blackboard architecture (Reddy *et al.* 1973; Newell *et al.* 1973). Outside NLP, work in vision and expert systems was similarly relying on specific knowledge of the domains concerned (see subsections b–c, below). And Joel Moses (of MIT) had seen the writing on the wall for NewFAI generalism as early as 1967:

The word you look for and you hardly ever see in the early AI literature is the word knowledge. They didn't believe you have to know anything, you could always rework it all . . . In fact 1967

> is the turning point in my mind when there was enough feeling that the old ideas of general principles had to go [which is why, for instance, Danny Bobrow ignored GPS to work on STUDENT] . . . I came up with an argument for what I call the primacy of expertise, and at the time I called the other guys the generalists. I was antigeneralist for many years. (interviewed in McCorduck 1979: 228–30)

But Winograd was especially influential. Indeed, Moses went on to say that "it took some difficult doing" for knowledge-based AI to be recognized as necessary, and "I think what finally broke [the generalists'] position was Winograd" (McCorduck 1979: 229).

The second major challenge to NewFAI posed by Winograd was his criticism of "declarative" programming and his urging of "procedural" programming instead. The logicist dream was that intelligence could be modelled as theorem proving carried out propositions in predicate calculus. Such propositions are declarative: they state *It is the case that* . . . Even those NewFAI workers who favoured non-logical representations (such as semantic networks) thought of programs, in essence, as starting from facts and inferring other facts from them. (For instance, the *isa* network links between *cat/mammal/animal* meant that *A cat is a mammal* . . . etc.) So what AI programmers needed to do was to declare (*sic*) the facts relevant to the domain concerned, and then let some general-purpose inference engine—a theorem-prover, or a network-rambler—take over. In short, providing domain knowledge to a program meant telling it *what is the case* rather than *what should be done*.

Winograd disagreed. His definitions of words weren't 'factual' statements or logical axioms expressing the word's meaning (see 9.xi.b). Nor were they semantic networks, whose pattern of nodes and links defined the meaning. Rather, they were mini-programs ("procedures"), which would be run when the word was encountered. On encountering the definite article *the*, for example, SHRDLU would immediately start looking for one and only one thing which fitted the following description, e.g. *pyramid*. Similarly, SHRDLU's definition of *and* was a mini-program that interrupted the normal parsing sequence to tell the system to "look for another one [i.e. a syntactic category] like the one you just found" (Winograd 1973: 179). This enabled it to cope sensibly—and relatively quickly—with both *The giraffe ate the apples and peaches* and *The giraffe ate the apples and drank the vodka*. Sometimes, the definition of a word would include a program for examining *previous* sentences—as for the word "one" in *Pick up the green one*. (As Winograd pointed out, all this was possible largely because he was using a version of the new PLANNER programming language: v.d, below.)

A wide range of work in AI and computational psychology was profoundly affected by Winograd's recommendation of procedural programming (see 7.ii.d and iv.c). Throughout the 1970s, as we've seen (iii.a, above), knowledge representation was a key focus of GOFAI research. The already familiar question of whether predicate logic could represent all of human knowledge was now joined by the broader question of whether *any* declarative representation could do so. For a while, there were heated discussions between declarative and procedural camps. The former presented the latter as tinkerers, content to cobble programs together without worrying about logical consistency. At the same time, logicist approaches (and logic-based languages) were viewed with suspicion, not to say disdain, by the proceduralists. (Often, they drew an analogy with Gilbert Ryle's distinction between knowing *how* and knowing *that*: pulling such a famous philosopher on board seemed to raise their spirits significantly—see 16.i.c.)

By the late 1970s, however, most people had realized that the divide between the two programming styles wasn't absolute. After all, even LISP instructions (procedures) could be used as data by other instructions: see v.c, below. And Newell and Simon's productions, despite being based on a system of *logic*, were rules which *made things happen*. So whether one chose to regard a particular representation of knowledge as "procedural" or "declarative" was largely a matter of emphasis, or point of view.

Winograd himself eventually admitted that AI work should combine the two types of representation, so as to get the best of both worlds (1975). Indeed, a prime aim of the new programming language (KRL) he developed with Bobrow was to do just this (Bobrow and Winograd 1977). KRL made quite a stir at the time. It was given pride of place as the very first paper to be published in *Cognitive Science*, and was later described as "one of the more ambitious efforts in the history of AI representation frameworks" and "the high point of a certain style of Knowledge Representation" (Brachman and Levesque 1995: 263). (Not everyone was impressed, for it was also described as "a splendid edifice [constituting] a castle in the air": McDermott 1978.)

KRL tried to get "the best of both worlds", because the two approaches had complementary advantages and drawbacks. It's easier to add new knowledge to a declarative representation; for although simply *adding* an instruction may (sometimes) be just as easy, its implicit effects are less clear. In general, declarative languages are easier for people to understand, whereas procedurally embedded knowledge may be highly opaque to the human user. But adding knowledge isn't enough: one must also specify how it can be used. Often, it's easier to embed knowledge implicitly inside a procedure (which will actually get the relevant task done) than to provide it as a theoretical background from which the necessary procedures must be inferred. Imagine trying to give a theoretical justification of all the heuristics used in AI programs, for instance: even deducing *Protect your queen* wouldn't be trivial. For effective action, a set of domain-specific procedures may be more economical than long lists of facts to be manipulated by general deductive procedures. In short, the *advice* "If you know Turing's human, assume that he's fallible" may be more helpful than the *data* "Turing is human, and all humans are fallible".

All of that became evident, however, largely as a result of the discussion prompted by Winograd's unflinching support for procedural programming in his early work. The familiar Popperian point applied: your scientific theory doesn't have to be right, but it should lead to challenges and tests that show whether it may be right, and—if not—just what theory might be better.

The last of Winograd's three challenges was directed against hierarchical programming: "heterarchical" programming was recommended instead. In a hierarchical program, one part—the master program, or central executive—has overall control and the others are subordinate to it, as mere subroutines in the service of its goals. Hierarchy had been crucial to GPS, and even to Pandemonium (whose demons could communicate only upwards, not laterally or downwards: 11.ii.d). Moreover, Simon (1962, 1969) had declared hierarchy to be necessary for both artificial and biological intelligence, despite certain disadvantages pointed out by his colleague Newell (1962). Winograd didn't deny its importance. But he did deny that inflexibly top-down control was the best way of exploiting it. In place of rigid hierarchy, he said, what AI needed was heterarchy.

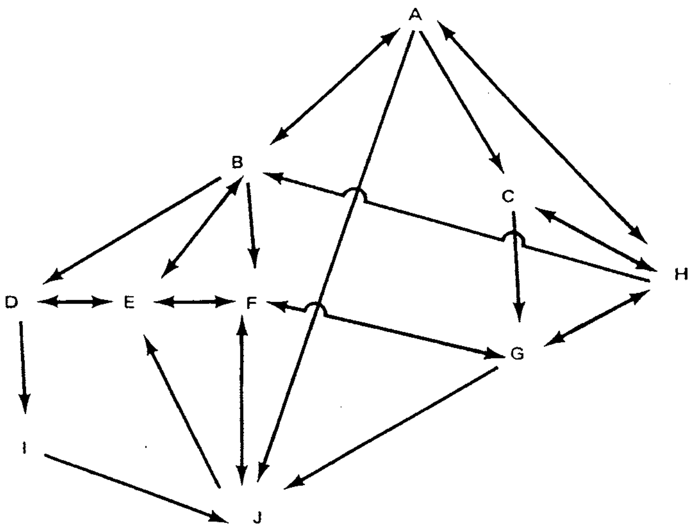

FIG. 10.16. Heterarchy. Reprinted from Boden (1977: 126)

In a heterarchical program, control is more equally distributed throughout the system, and internal communication between the various subroutines is increased. The component programs can call upon each other upwards, downwards, or sideways (see Figure 10.16). Moreover, they can do this at various points in their (potentially independent) functioning. SHRDLU, for example, could do it many times in parsing a single sentence (see 9.xi.b).

The added flexibility which heterarchy provided to AI problem solving was avidly welcomed for work on many domains. Fahlman, for instance, identified heterarchy as the key source of BUILD's ability to plan blocks-world structures. And an example applied to vision, for use by the MIT robot (for which SHRDLU had been written in the first place: see 9.xi.b), is shown in Figure 10.17.

The various parts of a heterarchical program were *thought of* very differently from the subroutines in GPS. Winograd's colleague Winston, for instance, put it like this:

> Communication among these modules should be more colorful than mere flow of data and command. It should include what in human discourse would be called advice, suggestions, remarks, complaints, criticism, questions, answers, lies [better: approximations], and conjectures . . . Note particularly that . . . programs normally thought to be low level may very well employ other programs considered high level . . . [In computer vision, for instance] line-finders that work with intensity points are low level but may certainly on occasion call a stability tester that works with relatively high-level object models. (Winston 1972: 444)

In short, a heterarchical program was conceptualized as a community of autonomous *agents*—although that terminology didn't become widespread in AI until the 1980s (see Chapter 13.iii.d).

The term "heterarchy" wasn't coined by Winograd. It had already been used by neurophysiologists such as McCulloch (1947). And they'd borrowed it from the political philosophers. Today, it's typically used—by sociologists, political scientists,

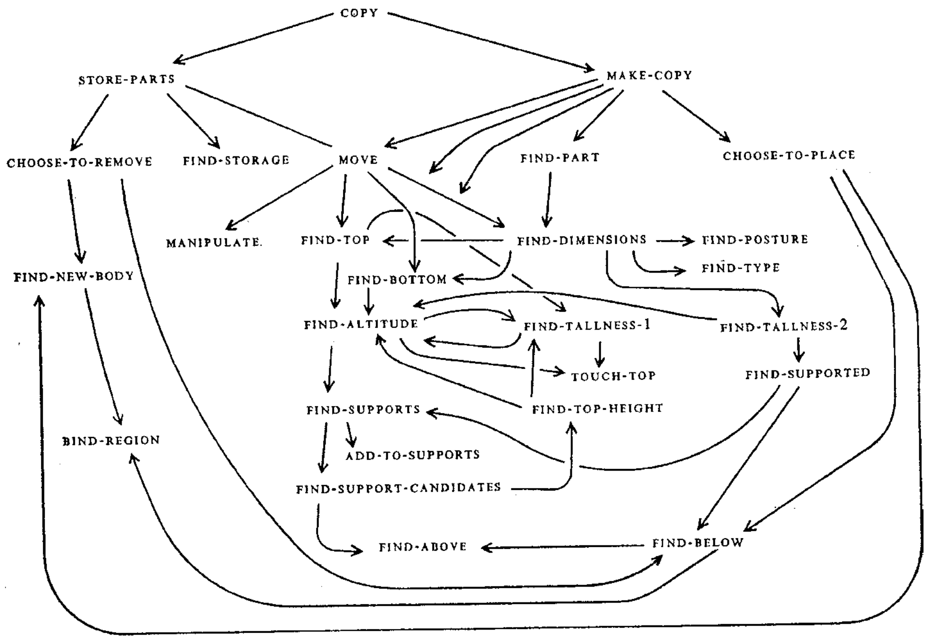

FIG. 10.17. Heterarchical organization of the MIT robot's vision system. Reprinted with permission from Meltzer and Michie (1972: 456)

and management gurus—to describe human organizations (e.g. Stark 1999). Within AI, it has fallen out of use, being replaced by "agents" or "distributed AI".

These terminological points are relevant because they highlight the human and political aspects of the concept—which were never far from the surface, even in technical treatises on computer programming. Autonomous agents deserve respect. Someone who's allowed (see the quotation above) to advise, suggest, criticize, and complain . . . is an equal, not a mere lackey. And so it was with the components in heterarchical programs. Winston, again: "the modules interact not like a master and slaves but more like a community of experts" (1972: 443). The new programming style was repeatedly described in terms of "committees" of "experts", bound by mutual respect and judicious negotiation rather than autocratic power relations.

In other words, socio-political metaphors were commonly used by AI scientists to recommend heterarchy over hierarchy—at the height of the Cold War, with resonant implications (see 1.iii.b–d). (Twenty years later, when "multi-agent systems" became all the rage, their popularity would be partly fuelled by similar political considerations, even though the Cold War had thawed by then: 13.iii.d.)

(As for the wunderkind Winograd, what happened to him? It's an interesting story, and not one which AI people like to hear. For in their view, their hero betrayed them: see Chapter 11.ii.g.)

b. Clearer vision

Vision is the prime example that shows why AI is no longer defined as Minsky originally defined it: "the science of making machines do things that would require intelligence if done by men" (Minsky 1968, p. v). We don't normally think of vision as requiring intelligence: after all, everyone who isn't blind can do it—and so can squirrels. Accordingly, the initial NewFAI attitude to vision was that it must be pretty simple. As late as 1966, Minsky asked a bright first-year undergraduate, namely Sussman, to spend the summer linking a camera to a computer and getting the computer to describe what it saw. This wasn't a joke: both Minsky and Sussman expected the project to succeed (Crevier 1993: 88).

In the very earliest days of NewFAI, "vision" had meant pattern recognition, modelled by highly general techniques (see Uhr and Vossler 1961*b*). This might conceivably have been enough for the bookreader-for-the-blind envisaged by Selfridge and McCulloch. But it wasn't enough to capture vision as described by the "New Look" psychology of Bruner and Richard Gregory, which posited top-down influences from perceptual hypotheses about the real world. Indeed, Gregory (1967) was arguing that visual computers would suffer from illusions just as humans do, and for similar reasons (6.ii.e).

The implication was that pattern recognition should make way for scene analysis, where the program's task was to interpret visual input *as depicting objects in real-world scenes*. (Most of the early scene-analysis programs are detailed in Boden 1977, chs. 8–9.) This, in turn, implied that the image should be articulated into distinct parts—which pattern-recognizers couldn't do. So some NewFAI pioneers started thinking about the *structure* of images. Narasimhan in Bombay, and (following Narasimhan's lead) Max Clowes in Oxford/Canberra, offered hierarchical "picture grammars" inspired by Chomsky's syntax (Narasimhan 1964, 1966; Clowes 1967, 1969). And Clowes, whose earliest work had been in technological character recognition (Clowes and Parks 1961), now drew inspiration also from psychology and neurophysiology: specifically, from Miller's 'Magical Number Seven' and retinal/cortical feature-detectors (Clowes 1967: 181, 195–6; see 6.i.b and 14.iv.a–b).

In particular, pattern recognition wasn't enough for robotics. An AI robot—as opposed to a fixed-routine *Unimate* bolted to a factory bench—needs to know where something is in 3D space; what size and shape it is; what the currently invisible parts of it are like (e.g. the occluded corners of the wedge numbered "11" and "12" in Figure 10.18); what the orientations of the various surfaces are; and how to distinguish one 3D something from another one in the first place. Accordingly, the people associated with the MIT robot, Stanford's SHAKEY, and Edinburgh's FREDDY tried to write programs enabling a computer to interpret 2D images in terms of 3D scenes.

Those last nine words were easy for me to write, and for you to understand: today, the distinction between (retinal) "image" and "scene" is clear. In the 1960s, it wasn't. With the 20:20 vision of hindsight, it's amazing how blind early NewFAI was to it. When AI workers first tried to write 2D-to-3D programs, they often made mistakes precisely because they hadn't taken this distinction properly on board. In other words, they hadn't realized the need to include *knowledge of the image-forming process* in their programs.

The image-forming process held to be most relevant at that time was projective geometry. 2D-to-3D algorithms based on physical optics would be written later, in the mid- to late 1970s (14.v.f and 7.v.b–d). But before then, optics was used only in 2D-to-2D line-finders (Roberts 1965; Shirai 1973) and region-finders (Tenenbaum *et al.* 1974; Tenenbaum and Weyl 1975). Computer vision used hand-drawn line drawings, or line drawings generated from grey-scale camera input by line-finders (Winston 1975).

Because the geometrical knowledge embodied in the first scene-analysis programs wasn't made fully explicit, they succeeded for largely mysterious reasons. Likewise, they suffered apparently inexplicable failures.

The prime example of that type of blindness was due to Adolfo Guzman (1943–), a Mexican graduate student at MIT (today, working at Mexico's National Polytechnic Institute). On one level, Guzman's SEE program (1967, 1968, 1969) was a triumph. For it could interpret a complex image as representing many separate physical objects: eleven, in Figure 10.18.

It did this by first finding the *vertices* (classified into nine basic types), and then using them to guide linkages between line-bounded *regions*. A link between two regions assigned them to one and the same physical thing. Linked regions were usually neighbours, but not always (see Figure 10.19). So seven non-adjacent regions in Figure 10.18 (labelled 3, 21, 22, 23, 24, 28, and 29) were all assigned to "one" object, as were regions 1, 2, and 33.

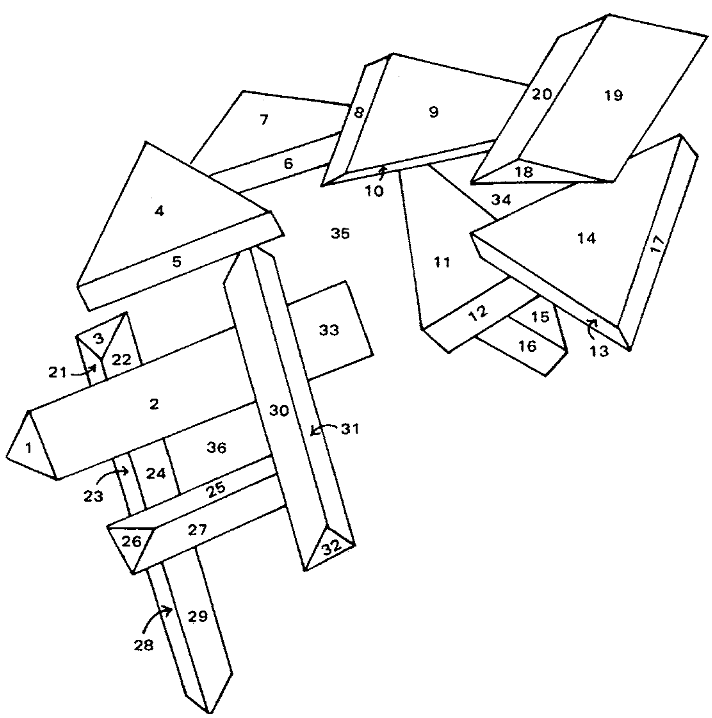

Fig. 10.18. Guzman's "HARD". All bodies were correctly identified by SEE, even though one (regions 6:7) has no "useful" visible vertices. The background (34:35:36) also was correctly found. Reprinted with permission from Guzman (1969: 273)

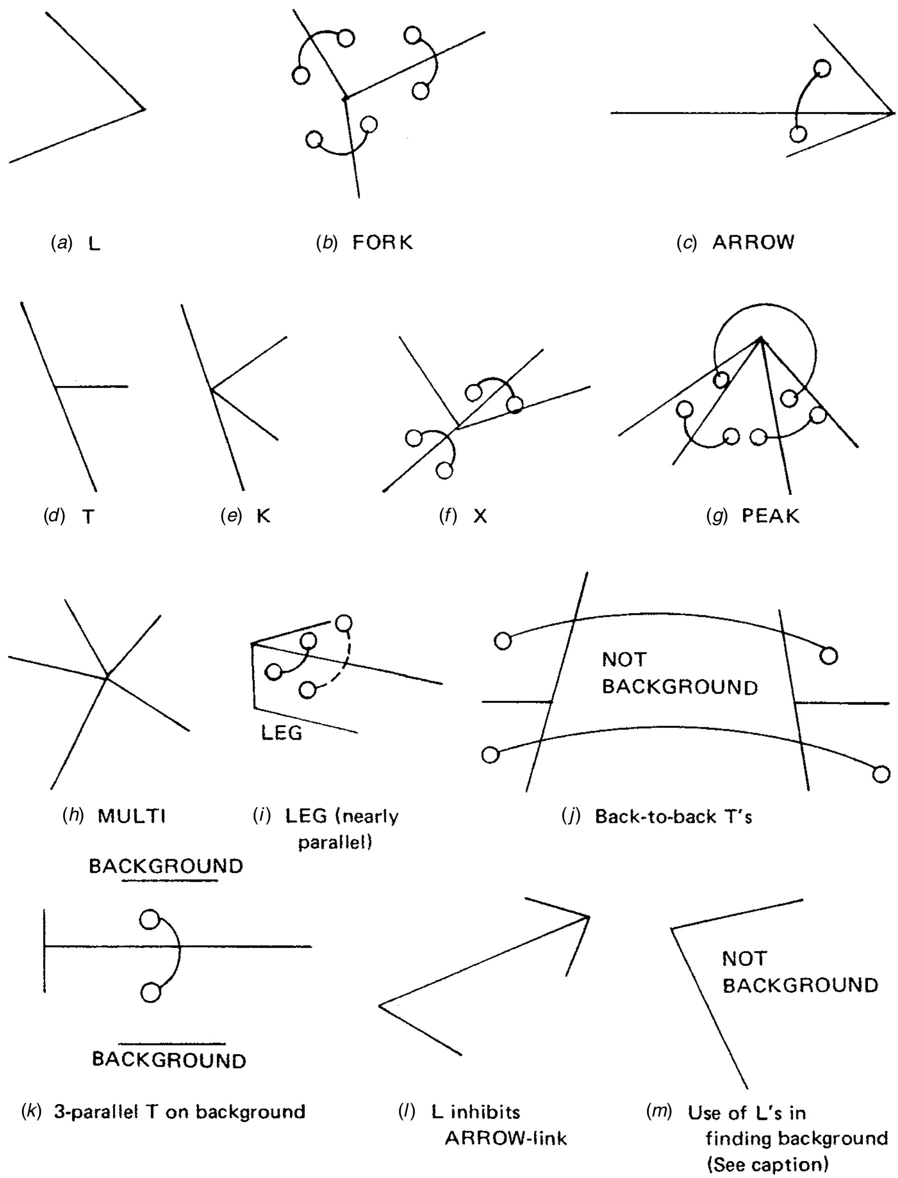

FIG. 10.19. Guzman's vertices and their associated links. Items (*b–c*), (*f–g*), and (*i–k*) show strong region-links. The absence of links in items (*a*), (*d–e*), and (*h*) means that these vertices provide no reliable cues about physicality. Item (*i*) shows a weak link, placed on ARROW by an adjacent LEG. Items (*j–k*) show strong links placed on complex patterns. Item (*l*) shows link-inhibition by an L-vertex (assumes convexity). And (*m*) shows the convexity assumption in the use of Ls to identify the background. Adapted with permission from Guzman (1969: 258; 1968: 87)

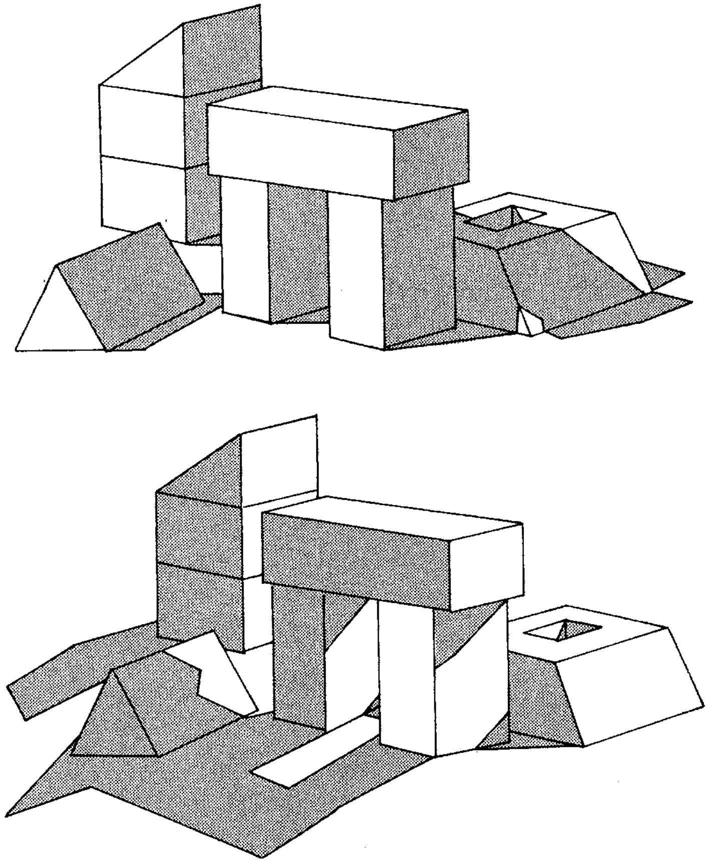

FIG. 10.20. Two differently shadowed images of the same scene. Adapted with permission from Waltz (1975: 20)

It turned out, much to Guzman's puzzlement, that there were some things which SEE *couldn't* see. Holes, for instance. Even without the shadows (which SEE couldn't cope with), Guzman's system wouldn't have recognized the object on the far right of Figure 10.20 as a single thing.

His colleague Winston (1970*b*) was as puzzled by this as Guzman, and tried to extend SEE so as to cope with holes—without success. Nor could SEE have recognized images of impossible objects as impossible (see Figure 10.21). Moreover, even when it did see things correctly Guzman didn't really understand why. He didn't know *why* a fork normally allows one to place region-links across all three lines, nor *why* the few link-inhibition rules were helpful yet not foolproof: see items (*b*) and (*l*) in Figure 10.19. Even more to the point, he didn't ask.

Admittedly, another NewFAI scientist had already produced a program that could articulate an image in terms of distinct 3D objects. Larry Roberts (1937–) had cut his teeth at MIT by trying to speed up the perceptron (J. A. Anderson and Rosenfeld 1998: 100). But he'd turned to scene analysis for his doctoral thesis, written in 1961 but

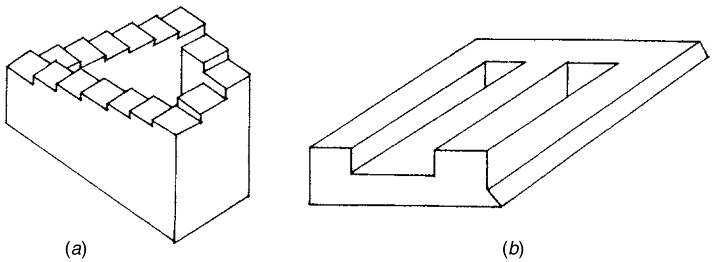

FIG. 10.21. Two impossible objects. Item (*a*) adapted with permission from Meltzer and Michie (1971: 296); item (*b*) reprinted with permission from Clowes (1971: 105)

not officially published until later (Roberts 1963, 1965). Indeed, it was his early 1960s research which initiated the polyhedral blocks world. (He initiated something else, too: appointed head of the information-processing group at ARPA in 1966, he was largely responsible for the creation of the ARPAnet.)

In some ways, Roberts's program was more powerful than SEE. Besides picking out individual objects it could also identify them as cuboids, or wedges, or . . . which SEE couldn't do. In addition, it could discover precise sizes, locations, and surface orientations (by number crunching guided by information about the picture plane). And it could accept camera input. The hope was that some future version, besides being used in robotics, would be able to interpret aerial photographs—like those which had shown the Soviet missiles on Cuba just as Roberts was embarking on his doctorate. But line drawings were what the program was really about, since the grey-scale image was immediately converted into a drawing. (The line-finder looked for edge fragments in four orientations, inspired by David Hubel and Torstein Wiesel's recent discovery of cortical feature-detectors: 14.iv.b.)

However, this system was less general than Guzman's. It relied on internal geometrical models of three types (cuboids, wedges, and hexagonal prisms), each carrying rules about how to interpret specific 2D cues in 3D terms. Anything that couldn't be analysed by applying those rules was, in effect, invisible. In dealing with the line drawing, the program's first move was to find the lines bounding separate *regions*. Using Roberts's list of "approved polygons" (polygons that could depict a face of one of the three basic polyhedra), it then assigned the regions to distinct physical objects. It could also cope with "compound" polyhedra, some of whose faces wouldn't be approved polygons (see Figure 10.22). At base, however, it had to know precisely what it was looking for in order to find it.

Both these scene-analysis programs had a strong affinity with the New Look. For they both went "beyond the information given" (Bruner 1957*a*), by using top-down perceptual hypotheses about the objects they expected to find. But only Roberts identified the theoretical source of those hypotheses, namely projective geometry. Guzman, by contrast, based his interpretative heuristics in intuition. He didn't ask *why* they worked, *why* a corner of a certain type would appear in the drawings as a vertex of a certain type.

Indeed, he didn't distinguish clearly between "corner" and "vertex" in the first place (and sometimes used these terms interchangeably). The former was a denizen of the

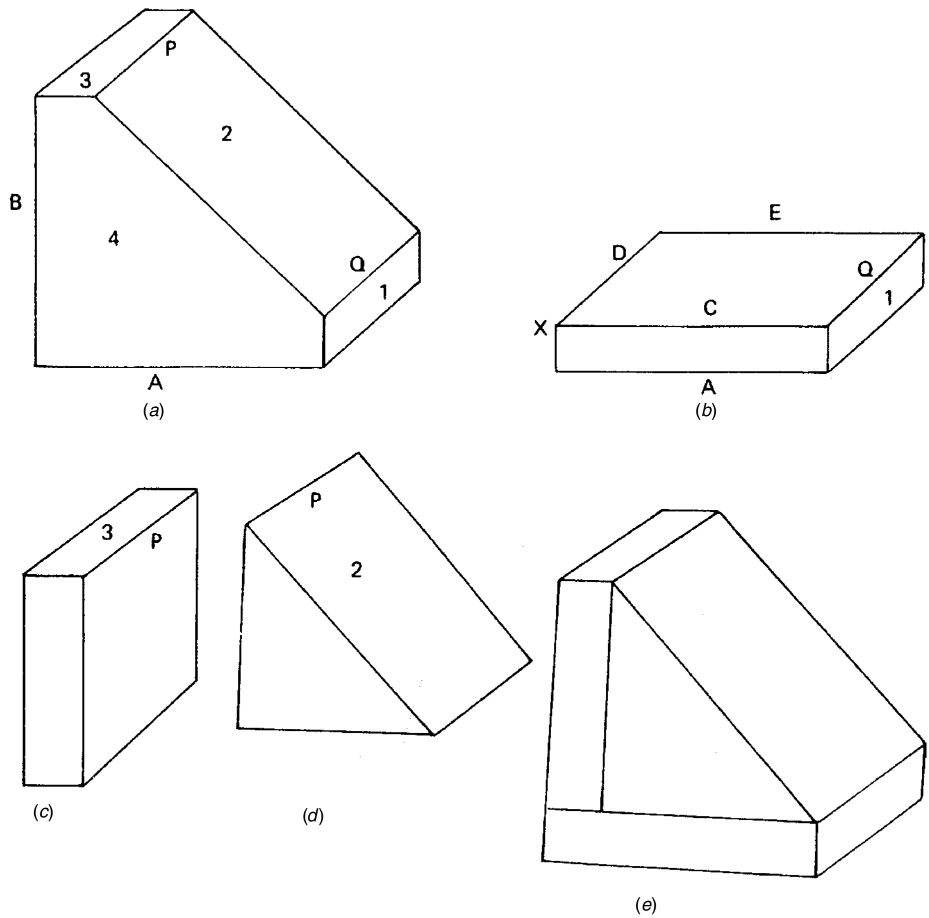

FIG. 10.22. Item (*a*) represents the information passed by Roberts's line finder to his picture interpreter, which searched for significant picture fragments (suggesting "approved polygons"). It found the polygon bounding region 1 with line A connected to it, and constructed and analysed out solid (*b*) accordingly. Similarly, (*c*) and then (*d*) were found. No picture lines remained unaccounted for. The program's final reconstruction of the target compound object is shown in (*e*). Reprinted with permission from Roberts (1965: 182)

scene, the latter of the image. But that was never clearly stated, because Guzman didn't explicitly consider (as Roberts had done) the geometry of the 3D-to-2D projection involved. Instead, he implicitly embedded some of his unorganized spatial intuitions in the region-linking rules. SEE's successes were due to the nuggets of geometrical gold buried inside those intuitions, and to the (atheoretical) improvements that resulted from trial and error with the program.

In the 1960s, it wasn't only Guzman who confused image and scene. Most NewFAI people did. That's why Winston's (1970*b*) treatise on holes added piecemeal procedural patches to SEE, instead of asking systematic questions about 3D/2D representation. It was left to two other people to do that.

One was Clowes (1933–81), by then at the University of Sussex. The other was the mathematician David Huffman (1925–99), who'd recently left MIT to found the Computer Science Department at UC Santa Cruz. Both Clowes (1971) and Huffman (1971), independently, suggested labelling each line according to its *physically possible* interpretations, and then finding the set of *mutually consistent* interpretations across the image as a whole. Clowes recommended breadth-first search to do this, Huffman depth-first search—but their core ideas were so similar that people soon spoke of "Clowes–Huffman labelling". Huffman's labels were the ones most widely borrowed (for his improved version, see Huffman 1977*a*,*b*). However, Clowes's paper was the more interesting for AI, because he reported a scene-analysis program showing how the shared theoretical insights could actually be used.

Clowes and Huffman pointed out that there are four possible interpretations of any line in pictures of polyhedra: either a convex or a concave edge with both associated body surfaces visible, or a "hiding" edge that obscures a surface to one or other side of it. Figure 10.23 shows these four edges, labelled respectively by plus and minus signs and arrows (the visible surface lies to the right of an ant crawling in the direction shown by the arrow). However, no line can be labelled in different ways at either end, because no (non-curved) edge can be convex at one point and concave at another, nor hiding an adjacent surface at one end but not at the other. This allows for tests of mutual consistency between line labels, given that vertices can be sensibly interpreted in only a few ways.

Clowes had originally been puzzled about why SEE worked at all, not only why it sometimes didn't (personal communication). That puzzlement was now solved. He and Huffman had distinguished clearly between image and scene, and analysed the possible relations between them in an orthodox 3D/2D projection. They'd shown why Guzman's "arrow" was so useful: the shaft *must* show an edge, convex or concave, with both adjacent surfaces visible and both belonging to the same object. And they'd shown why his "Ls" were so unhelpful: there are six possible line–label combinations for an L, so Ls have no reliable region-linking rules—see item (*a*) of Figure 10.19. They'd explained why SEE had been defeated by holes, and even by concavities, and they'd offered ways of recognizing these physical features. And both had shown that their methods (for Clowes, a program; for Huffman, a paper-and-pencil algorithm) could find *all possible* picture labellings—which meant that they could also identify *impossible* labellings, and even locate the impossibilities at specific picture points. (Guzman had instructed SEE

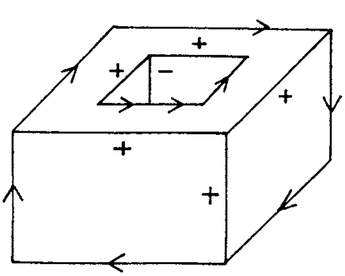

FIG. 10.23. The four physically possible line labels (see text). Reprinted with permission from Huffman (1971: 305)

to reject "illegal" pictures, but his criteria of illegality—e.g. lines not forming part of the boundary of a closed region—weren't properly understood. An illegal picture isn't at all the same thing as an impossible object.)

Two important additions to the domain knowledge used in scene analysis followed in the mid-1970s. One was Mackworth's (1973) gradient space. This was an extension of projective geometry that enabled vision programs to interpret some images that had previously defeated them: namely, drawings of polyhedra with skewed surfaces (see Figure 10.24). Also, by including explicit constraints relating the *relative slopes* of surfaces to their visibility or invisibility, Mackworth explained why Clowes–Huffman labelling worked. This is historically interesting not least because David Marr, despite his scathing criticisms of scene analysis, would later borrow gradient space for use in his own work (Marr 1982: 17, 240–3; see Chapter 7.v.b–d).

The other addition to visual knowledge was David Waltz's (1975) treatment of shadows and cracks. Building on Clowes–Huffman and Mackworth, he allowed lines to represent the boundaries of shadows as well as of objects, and to depict several types of "crack" between adjacent, but separable, objects (e.g. the lines separating the three stacked objects on the left of Figure 10.20). His program could interpret images such as those in Figure 10.20, and could also recognize that they represent one and the same scene.

Even before Waltz's thesis was officially published, further domain knowledge had been added by others. For instance, Kenneth Turner (1974), of the FREDDY team in Edinburgh, extended Waltz's program to include certain classes of curve: see Figure 10.25. (Turner's program started out with a TV image, which it converted to a line drawing, and used hierarchical visual models of the objects that FREDDY might be expected to encounter: see Figure 10.26.)

However, Waltz had done much more than add extra domain knowledge. He'd provided a general method—for coping with multiple constraints—which could be applied in all areas of AI, from resolution theorem proving to connectionist pattern recognition. So today, what people remember best about his early 1970s work isn't the shadows, but the filtering algorithm.

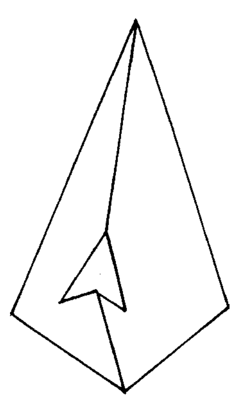

FIG. 10.24. An object with a skewed surface. Reprinted with permission from Mackworth (1973: 134)

Waltz-filtering was a technique developed to overcome the combinatorial explosion when there were many possible interpretations of a single cue (in this case, of a single line). Because Waltz allowed for shadows and cracks, his program had eleven different line labels, as compared with the Clowes–Huffman four. This multiplied the possible vertex interpretations horrendously.

There were 500 sensible interpretations of FORK and T, and 100 each for MULTI, X, and K; ARROW and L both had about 75. Only PEAK was relatively manageable, with merely 10. (Things would have been even worse if Waltz hadn't used his *physical knowledge* about shadows, cracks, and separable edges to exclude impossible interpretations: there were no fewer than 6 million combinations for the "relatively manageable" PEAK.) This meant that provisionally assigning all possible labels to every line (as in the Clowes–Huffman approach), or even to every vertex, wasn't feasible.

Instead, his program chose a pair of neighbouring vertices at random, and provisionally assigned all—and only—the *mutually consistent* line labels to them. Then, it crawled along to the next vertex, and assigned *only those labels which were consistent with the ones already assigned*. To his astonishment, this simple iterative procedure, when applied to simple scenes, found a unique label for every line. That was also true for many complicated scenes. Even when it wasn't, the numbers of "possible" labels remaining were so small that the familiar Clowes–Huffman approach (comparing labels across the whole image) could be used to disambiguate them.

The overall interpretation was speeded up still further when Waltz decided to make the initial choice of vertex only *semi*-random. In doing that, he relied—again—on specific domain knowledge. Given that some vertices have fewer sensible interpretations than others, Waltz ensured that two relatively unprolific vertices were "randomly" chosen. Also, reminding his readers that one usually attacks a jigsaw puzzle by finding the edge-pieces first, he made the program pick vertices that probably contained *object-boundary* lines. (So PEAKS were shunned at this stage, because only two of the ten PEAK interpretations make sense on the scene–background boundary.)

His AI colleagues were quick to get the point:

> Waltz' work on understanding scenes surprised everyone. Previously it was believed that only a program with a complicated control structure and lots of explicit reasoning power could hope to analyze complicated scenes. Now we know that understanding the constraints the real world imposes at junctions is enough to make things much simpler . . . It is just a matter of executing a very simple constraint-dependent iterative process that successively throws away incompatible line arrangement combinations. (Winston 1977: 227)

Waltz-filtering, like gradient space, was another legacy of scene analysis which would be utilized by Marr, despite his harsh words about GOFAI computer vision. It was used by many others too, for it wasn't specific to vision. Any domain involving multiple constraints, and where some local interpretations were mutually inconsistent, could be tackled more efficiently by means of it.

There was a major problem, however. Namely, a single mistake in the Waltz filter's depth-first search might cut off the very branch of the search tree on which the correct solution lay. Geoffrey Hinton (1976, 1977) referred to this as "computational gangrene". As we'll see in Chapter 12.v.h, he formulated an improved constraint-filtering strategy, called "relaxation" (the term was borrowed from other work on scene analysis: Rosenfeld *et al.* 1976). Relaxation found the best overall interpretation *even though* this might contain some minor inconsistencies. In other words, the gangrene was prevented.

Initially, Hinton's ideas were developed in the context of a GOFAI vision system, the Sussex POPEYE project (see below). Soon, however, he (and others) would apply them in PDP models. Today, multiple constraint satisfaction by relaxation is a key pillar of connectionism. But the pillar's base, and even its name, lies in good old-fashioned scene analysis.

Good old-fashioned scene analysis was more varied than I've suggested so far. For instance, the SRI approach differed from MIT's: Jay Tenenbaum's group, which included the young Harry Barrow (1943–), started from photos rather than drawings and from regions rather than lines (Tenenbaum *et al.* 1974; Tenenbaum and Weyl 1975; Tenenbaum and Barrow 1976). Their program, with helpful input from the programmer, wasn't restricted to the blocks world but learnt to recognize real-world objects such as telephones. There were some other (non-interactive) early 1970s programs that started from regions rather than lines (Brice and Fennema 1970; Barrow and Popplestone 1971; Yakimovsky and Feldman 1973). But one of the most interesting examples of 1970s computer vision, albeit not widely noticed at the time, differed even more from MIT's blocks-world paradigm.

This was the POPEYE project, directed by Sloman at the University of Sussex (Sloman 1978, ch. 9). POPEYE modelled the interpretation not of fully connected drawings of perfect polyhedra (or even polyhedra-with-shadows), but of highly ambiguous, noisy, input—with both missing and spurious parts: see Figure 10.27. And it simulated the *complexity* of perception to an extent that was unusual at the time.

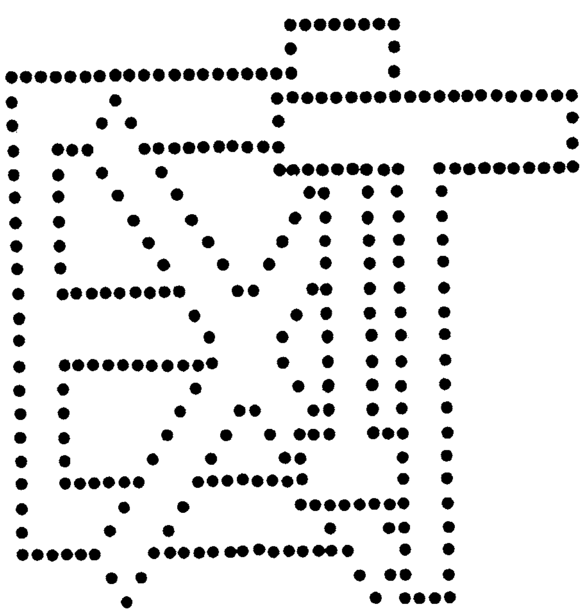

Fig. 10.27. Noisy visual input. Reprinted with permission from Sloman (1978: 219)

POPEYE's complexity had several roots. Many different sorts of background knowledge were combined in the one program. In addition, processing could occur concurrently in different domains, determining which sub-processes would dominate the scarce computational resources. This was different from the heterarchy so popular in the early to mid-1970s. In SHRDLU, for example, there was only one locus of control at any moment; and control was transferred to process X by an explicit call from process Y—as when the syntactic procedure for interpreting the word *the* passed control to a perceptual subroutine, to see whether there was *one and only one* thing fitting the predicate concerned. Each knowledge domain in POPEYE had its own priorities for finding/processing information, and these priorities could change suddenly as a result of new information arriving unexpectedly. Complexity (and flexibility) was increased also by the fact that some of the internal representations constructed by POPEYE were temporary, rather than provisional. (Something provisional may become permanent, but something temporary should not.) At the point when its funding was cut, the POPEYE program was about to be turned into a hybrid system (12.ix.b). A neural net was being designed (by Hinton) to replace the GOFAI spell-checker included in POPEYE. The idea was that the network would be trained on a collection of known words, and would then suggest the most likely word when presented with a "half-baked" letter sequence (A. Sloman, personal communication).

Considered as a practical visual system for a robot, POPEYE wasn't at all impressive. But Sloman wasn't trying to advance robotics, least of all robotics confined to toy polyhedral worlds. Rather, he was trying to advance Immanuel Kant's argument that the mind must provide some prior knowledge for even the "simplest" perceptions to be possible. Kant had talked about the mind's comparing representations, combining and separating them . . . and so on, but "What Kant failed to do was describe such processes in detail" (Sloman 1978: 230).

Whereas for Kant the principles of organization were very general, and innate (see Chapters 2.vi.a and 9.ii.c), for Sloman they also included highly specific examples. Citing recent work on how we avoid word-by-word parsing of commonly heard phrases and on how we learn visual "phrases" too (Becker 1973, 1975), and referring also to Bartlett (see 5.ii.b), he pointed out that visual schemata can aid recognition enormously.

For instance, the familiar upper-case sign "EXIT" helps us—and POPEYE—to recognize the four letters in Figure 10.27. Likewise, a head, or leg, in a photo of a human being not only speeds up our interpretation of that picture-part but also guides our recognition of other parts. In both cases, the computational complexity has a chicken-and-egg aspect: if one recognizes a particular set of dots in Figure 10.27 as colinear, that can help one to recognize an "E"; but if one has already recognized "EXIT", one will be much more likely to recognize *those very dots* as colinear (Sloman 1978: 228–32). POPEYE was an attempt to move towards a realistic degree of visual complexity. To do that, it needed to be fairly complex itself:

> Our program uses knowledge about many different kinds of objects and relationships, and runs several different sorts of processes in parallel, so that "high-level" processes and (relatively) "low-level" processes can help one another resolve ambiguities and reduce the amount of searching for consistent interpretations. It is also possible to suspend processes which are no longer useful, for example low-level analysis processes, looking for evidence of lines, may be terminated prematurely if some higher-level process has decided that enough has been learnt

about the image to generate a useful interpretation. This corresponds to the fact that we may recognize a whole (e.g. a word) without taking in all of its parts. (Sloman 1978: 229)

One reason why POPEYE had relatively little influence on AI vision research is that, in effect, it was killed in about 1978. By that time, Marr's exclusively bottom-up approach to vision had become popular with the referees advising the grant-awarding bodies, and POPEYE was marked down accordingly. Sloman's account of what happened is given in the historical note added to the online version of his 1978 book. (One of the many factors he mentions is the widespread move from AI languages such as LISP or POP-11 to more general, more efficient, languages such as Pascal or C/C++. These make it very difficult to express "complex operations involving structural descriptions, pattern matching and searching", and to permit "task-specific syntactic extensions . . . which allow the features of different problems to be expressed in different formalisms within the same larger program"—see Section v, below.)

However, POPEYE wasn't wholly forgotten. Quite apart from Sloman's own later work, it was cited by the neuroscientists who recently caused a sensation by positing two visual pathways in the brain—one for perception, the other for action (Goodale and Milner 1992; Milner and Goodale 1993: cf. Chapter 14.x.c). The dorsal pathway apparently locates an object in space relative to the viewer, who can then grasp it; the ventral pathway may (this point is contested) locate it relative to other objects, and enables the viewer to recognize it. The evidence lies partly in brain-scanning experiments with normal people, and partly in clinical cases: damage to these brain areas leads to visual ataxia and visual agnosia, respectively. For example, one patient can recognize an envelope but is unable to post it through a slot, whereas another can post it efficiently but can't say what it is.

These 1990s researchers, too, asked a host of questions about how the different pathways can be integrated in various circumstances. In Sloman's view (personal communication), even they didn't really get the point—which was that there are many visual pathways, not just two. Of course, he was talking about computation, not neuroscience: there may or may not be distinct neuranatomical pathways related to distinct types of function. (In low-level vision, it appears that there are: 14.i.c.) But the moral of POPEYE, as of Sloman's more recent visual work (1989), was that *many* types of background knowledge play their parts *concurrently* in perception.

In a sense, POPEYE wasn't really about vision. Rather, it was an exercise in architecture building. For Sloman saw computer vision as a way of keying into the computational architecture of the mind as a whole. (More accurately: as a way of keying into the space of all possible minds—1978, ch. 6.) Over the years, he would focus increasingly on the control structure of the entire mind, and—after a long period of relative neglect—his work on that topic is now attracting significant attention (Chapter 7.i.f).

A final word: GOFAI vision and robotics were typically pursued in terms of the Cartesian sensori-motor sandwich (see 2.iii.a). MIT's early Mars robot was a rare exception—and even there, the sandwich was ignored rather than challenged (13.iv.a). The slices of bread, one white (the sensory input) and the other brown (the motor output), enclosed the meat at the centre: vertices, line labels, models of "EXIT" . . . in other words, mental representations linked by theorem proving, planning, and other forms of inference. Marrian research, which eclipsed scene analysis in the 1980s

(7.v.b–d), fed on the same sandwich, for Marr too treated perception and motor action as separate aspects of intelligence.

This didn't sit well, for instance, with the finding that only *self-activated* locomotion helps kittens to develop visual discrimination (Held and Hein 1963), for that fact suggested a much more intimate relation between sight and movement. And it ran counter to the approach of the two mid-century Williams, namely Ross Ashby and Grey Walter (4.viii). But they were (temporarily) out of fashion. Although computer vision had become increasingly enactive, utilizing the changes in input caused by the movements of the system/camera itself (including 'foveal' focusing and continual 'saccades'), internal representations—and the action–perception split—had endured. Not until the "situated" and "dynamical" roboticists of the late 1980s (13.iii.b–c) would AI seriously question the sensori-motor sandwich.

c. Expert Systems

Expert systems showed the 1970s "need for knowledge" especially clearly. For these AI programs embodied highly specialist knowledge gleaned from human professionals. The first examples were written in the late 1960s, and more appeared in the 1970s (Michie 1979). The target areas were very strictly confined, and were originally drawn from science, medicine, or science-related businesses such as computer manufacture or oil prospecting. (Soon afterwards, law was tackled too: see 13.ii.c.)

Developed for *practical* use, the early expert systems were then the prime example of technological AI. As remarked in Chapter 1.ii.b however, technological AI is often based in psychological insights. Expert systems were intended to capture the knowledge and reasoning processes of human experts. In the 1970s, moreover, the venture capitalists hadn't yet moved in on the field. Lacking strong commercial pressures, expert-system builders still aimed, in part, to investigate intelligence as such. So at the close of the decade the co-directors of MIT's AI Lab wrote that "*most* of the people doing artificial intelligence", besides trying to make computers more useful, hoped to formulate theories applicable to "any intelligent information processor, whether biological or solid state" (Winston and Brady 1979, p. ix; italics added).

Throughout the 1970s, AI scientists developed what Feigenbaum (1977) dubbed knowledge engineering, defined as "The art of designing and building expert systems and other knowledge-based programs". This included the "art" of coaxing the real experts to make their human expertise explicit, so that the programmer could program it. As soon became clear, much of the expert's knowledge wasn't available as facts/theories in the domain textbooks. Rather, it consisted in informal heuristics developed over the years, rarely verbalized and almost never communicated. All agreed that making this knowledge explicit wasn't going to be easy—and some critics doubted whether it's even possible (see 13.ii.b).

In general, knowledge engineering required special methods of questioning (analogous to the "protocol analysis" of the Gestalt psychologists and LT/GPS authors), developed by trial and error over the early years (R. Davis 1976/1982). Sometimes, the questioning would be done by human beings. But sometimes, it was done by a program: an expert system whose expertise lay in knowing *how* another expert system (e.g. MYCIN) represents its domain knowledge, and *how* it reasons about it. Using this "meta-knowledge", the automatic knowledge engineer would be able, for instance, to criticize the format of a new item of knowledge added by the non-specialist user—and might also suggest a way out of the difficulty.

AI was notionally aimed at expert systems right from the start. Licklider (1988) had contributed to AI so generously, both intellectually and (via ARPA) financially, because he hoped for military and civilian applications—many of which would assist human experts, or occasionally replace them (see 11.i.b). NewFAI's search for generality, however, implied that expert systems weren't its prime concern. So even MIT's Project MAC, an ambitious (ARPA-backed) 1960s programme of mathematical research, was generally regarded more as NewFAI's close cousin than as its twin. But as NewFAI matured into GOFAI, AI projects focused increasingly on specific practical domains.

That focus wasn't due merely to people wanting to be useful and/or rich. Some were disillusioned with the failure of generalist programs to progress beyond the first, exhilarating, days. And some felt that the intellectual challenge would be greater as a result.

Feigenbaum, for instance, embarked on AI as blue-sky research:

> At that time, [as a student] in the fifties, I didn't think of practical applications at all. I was intrigued by the vision of a highly intelligent, maybe super-intelligent, artifact. (interviewed in Shasha and Lazere 1995: 213)

Some ten or fifteen years later, when visiting Newell and Simon at CMU in the late 1960s, he still had that vision. But now, he put it like this:

> You people are working on toy problems. Chess and logic are toy problems. If you solve them, you'll have solved toy problems. And that's all you'll have done. Get out into the real world and solve real-world problems. (Feigenbaum and McCorduck 1983: 62)

Naturally, Feigenbaum felt that this finger of scorn couldn't be pointed at himself. For he'd arrived to give his talk at CMU carrying the defensive shield of DENDRAL on his arm.

DENDRAL (the name came from the Greek for *tree*) was the first expert system. It was developed at Stanford by Feigenbaum with Bruce Buchanan (1940–), Georgia Sutherland, and the Nobel geneticist Joshua Lederberg (1925–). Soon after the start, they were joined by the chemist Carl Djerassi, who acted as the domain specialist. It was begun in the mid-1960s, as a result of conversations between Feigenbaum and Lederberg.

Lederberg had been sympathetic to AI for some years (Lederberg 1987: 17–19). He'd been captured by Minsky's infectious enthusiasm, had read his 'Steps Toward Artificial Intelligence' on its official publication in 1961, and had been impressed when Minsky showed him the interactive possibilities in Spacewar. He'd even tried to persuade Minsky to move to Stanford (the Medical School), in McCarthy's wake. He could use a computer, and had done some computer-based medical work—on genetic epidemiology. However, that was merely computerized card shuffling. (Often, using appallingly low-quality data—which implied, for instance, that some mothers give birth at three-month intervals.) He was already convinced that "computers [and especially interactive computers] were going to change the whole style of scientific investigation". Specifically, by 1963 he was hoping to use computers to study chemical structures. But he realized full well that "This was not going to happen with card deck data entry."

In short, when Feigenbaum first met Lederberg—introduced by Karl Pribram in 1963, when *Computers and Thought* was hot off the press (Lederberg treasures his signed copy)—and communicated his youthful hopes to the older man, he was pushing at an open door. The graduate student Feigenbaum wanted a tractable AI problem to work on, dealing with what he called "empirical induction in science" (Feigenbaum and Watson 1965). The Nobel prizewinner Lederberg had a suitable domain already in mind. He'd even sketched a structural taxonomy of organic molecules, and had outlined some problem-solving procedures. But he had "no idea how one would go about translating these structural representations into a computer program" (1987: 22). In 1965, when Feigenbaum arrived at Stanford, they agreed to collaborate on a specific chemical problem chosen by Lederberg—and the result was DENDRAL (so called, because it generated *trees* of candidate structures).

The DENDRAL program was completed by the end of the decade, when it was presented alongside "Some Philosophical Problems" at the fourth Machine Intelligence Workshop (Buchanan *et al.* 1969*a*). More accurately, the *first* completed program was presented there. Increasingly powerful versions soon appeared, and were described at the next three Edinburgh Workshops (Buchanan *et al.* 1969*b*, 1972; Feigenbaum *et al.* 1971; Buchanan and Sridharan 1973). The most interesting improvement was meta-DENDRAL, which was under development from 1970 to 1976 (Buchanan and Mitchell 1978). Besides learning domain-specific rules inductively, this could propose historically new rules itself, which could be included alongside the ones it had been given (so it was one of the few early "creative" programs—see Boden 1977: 327–32). The final version of DENDRAL, and a retrospective view, appeared in 1980 (Lindsay *et al.* 1980; see also Barr and Feigenbaum 1982, chs. VII–VIII).

DENDRAL's expertise lay in a particular corner of organic chemistry, concerning the steroids used in contraceptive pills—at that time, still a novelty. Analytical chemists often discover the structure of an unknown compound by using mass spectroscopy, in which an electron beam breaks the molecules into fragments. Having identified the fragments (by their spectrographs), chemical theory suggests how they could fit together in a whole molecule. DENDRAL was designed to do the same sort of thing, by combining chemical knowledge with AI techniques of heuristic search. A "toy" problem, this was not. Nevertheless, its performance compared well with that of human chemists.

Chemical theory played a large part in DENDRAL's success. The program could formulate probable hypotheses about an unknown compound's molecular structure (on the basis of its spectrograph), and then test these hypotheses by way of further predictions. Besides analysing specific molecules, it came up with inductive hypotheses based on the data (e.g. "IF the graph of the molecule contains the estrogen skeleton, THEN break the intramolecular bonds between nodes 13–17 and 14–15"). It didn't stop there: it selected the most likely hypotheses, by reference partly to chemical considerations (such as the number of bonds assumed broken) and partly to logical features such as simplicity, uniqueness, and evidential strength. Moreover, DENDRAL provided, for the first time, a complete list of the set of possible isomers of a given empirical formula within several families, including amines and thioethers.

As for meta-DENDRAL, this discovered mass spectrum fragmentation rules for several types of compound (such as aromatic acids) which hadn't previously been recognized by expert chemists. It did this by first seeking regular patterns in the experimental data, and then applying known concepts to see whether it could find any explanation of them. So it would ask, in effect, "What's so special about nodes 13–17 and 14–15? Why do the intramolecular bonds break there, rather than elsewhere?" Its answer would be couched in terms of some smaller, more general (sub-molecular) structure in the immediate environment of the broken bonds. The latest version could even accept mixed data drawn from several different molecular structures, and separate out the different sub-groups while finding a characteristic explanation for each.

A final advantage, for chemistry, of the DENDRAL research was that the process of extracting the human expert's knowledge led to some new insights. For example, one of the non-chemists involved remarked that it seemed to him that amines are something like ethers. That analogy hadn't ever occurred to the chemists themselves, but they agreed that there was an interesting similarity. This was a special case of the general point—which was becoming more evident with every NewFAI year that passed—that trying to express a theory (in chemistry, or psychology . . . whatever) clearly enough for it to be programmed can lead to new insights, both before and after the computer is plugged into the wall. That general point was illustrated also by the new psychological insights about expert reasoning *as such* which sprang from these exceptionally intensive interviews.

In short, DENDRAL was fulfilling Lovelace's prophesy that some future Analytical Engine might help scientists to "adequately express the great facts of the natural world" (3.iv.b). It was doing this, at the level of the virtual machine, not by what she'd called "mathematical" (algebraic) computation, but by logical-symbolic inference. However, Ada's mentor Babbage had believed that logic and algebra were essentially one. So one can see NewFAI research on KR as an attempt to justify his hunch *in practice.* DENDRAL had apparently done that—and had inched chemical science forward in the process.

Close on the heels of DENDRAL came MYCIN, also from the Stanford stable (Shortliffe *et al.* 1973, 1975; Buchanan and Shortliffe 1984; Cendrowska and Bramer 1984). The core programmers were Buchanan and Edward Shortliffe, who soon qualified in medicine. (One co-author, Stanley Cohen, later developed the basic technology for recombinant DNA.) A production system of 450 rules, MYCIN simulated a medical consultant specializing in the diagnosis and treatment of infectious diseases. Clinicians reported that it performed much better than junior doctors, and as well as some experts—a report that was later confirmed by blind testing (Yu *et al.* 1979).

MYCIN was much more than a table of bugs-and-drugs, for it employed then advanced AI techniques. It engaged in question-and-answer conversations, lasting twenty minutes on average, with doctors needing specialist help. The NLP was of little interest, but it was backed by complex domain reasoning. The physician would ask MYCIN for advice on the identification of micro-organisms, and on the prescription and dosage of antibiotic drugs. That advice would be based on blood tests and histology, and on the patient's symptoms and past medical history. If the relevant evidence hadn't been provided, MYCIN could ask the doctor for it. In addition, MYCIN could explain its advice, at the appropriate level of detail.

Whereas DENDRAL had had a scientific theory (as well as experts' reported intuitions) to go on, MYCIN didn't. Why? Because chemistry does, and this area of medicine doesn't. MYCIN was wholly dependent on rules (heuristics) gleaned from clinical textbooks and from the experts consulted by the knowledge engineers. Also, and again unlike DENDRAL, it had to express various degrees of uncertainty—in a way that reflected how doctors assess the impact of evidence on their diagnosis. So it could present *several* hypotheses to the user, prioritizing them according to the various confidence levels—which, in turn, could be explained.

In brief, this was a user-friendly interface designed for people knowing nothing about computers (cf. 13.v). It conversed in English. It asked questions when it needed to, and in so doing it often reminded the user about things as yet undone. It offered helpful advice, and explanations too (so it could be used as a tool for teaching, as well as clinical practice). It gave estimates of how reliable its advice was likely to be. And it even explained just why it couldn't be sure. Indeed, if providing incomplete medical data counts as "putting the question in wrong", then MYCIN (after requesting the missing data) could do what Babbage's lady visitor had required of the tiny Engine in his salon: have "the answer come out right" nevertheless (3.i.a).

Both DENDRAL and MYCIN were production systems (v.e, below). Feigenbaum and Buchanan had been inspired to use that methodology by their ex-colleague Newell, who'd visited Stanford to lecture about it in 1967. One of the advantages, for expert-system builders, was that each production rule was stated independently. So one didn't need to rewrite the whole program in order to add an *extra* item of knowledge gleaned from the human expert, including his/her explanation of the program's past failures. (This didn't mean, of course, that its interactions with existing rules could be foreseen: the combinatorial explosion was always lying in wait.)

Feigenbaum and Buchanan tried to extract the logical skeleton of the production systems they'd pioneered, so that others could use it to write expert systems in indefinitely many domains. In doing that, they developed EMYCIN: the first expert-systems "shell".

The "E" stood for Empty, for a shell was a content-free inference engine. (The term "inference engine" was coined by Randall Davis, in homage to Babbage—interview in Crevier 1993: 157.) It specified, for example, the basic blackboard architecture, and the method of conflict resolution to be used when more than one production was satisfied. Also, it provided methods for "forward-chaining" and "backward-chaining" inference. The former was used bottom-up to generate conclusions from data, the latter top-down to find evidence for a supposition (and to explain an item of advice by recapitulating the previously fired rules). Several expert-systems shells were being marketed by the close of the 1970s, for use in building new systems for commercial clients.

By the early 1980s, then, expert systems had become a recognized field within AI. At that point, the field was given an added boost by Japan's Fifth Generation project (Chapter 11.v). This prompted several popular publications from AI leaders, such as Feigenbaum's *The Fifth Generation* (1983) and Winston's *The AI Business* (1984). There was a burst of technical discussion, too (e.g. Stefik *et al.* 1982; R. Davis and Lenat 1982; F. Hayes-Roth *et al.* 1983; Merry 1985; Waterman 1985). Optimism reigned.

But there were problems lurking in the undergrowth. Some expert knowledge was highly elusive. And some of that tacit knowledge might elude capture for ever. By 1990, various insightful critiques had highlighted the difficulties, and the need to keep human beings somewhere inside the loop (see Chapter 13.ii.b–c).

10.v. Talking to the Computer

Abstract proofs about universal Turing machines (4.i.c) and universal programming languages are all very well. But in practice, as George Orwell might have put it, some languages are more universal than others. Indeed, a list of epigrams on programming, written by CMU's Alan Perlis (who led the team that designed ALGOL in the late 1950s), includes this salutary warning: "*Beware the Turing tar-pit in which everything is possible but nothing of interest is easy*" (Perlis 1982).

When the first computers were built, it was difficult even for experts to tell them to do anything interesting. For one had to use the machine code (or some very closely associated assembly language). That involved long sequences of 0s and 1s, which human beings find almost unintelligible. So J. Clifford Shaw, the person primarily responsible (aided by Newell) for the *programming* of the Logic Theorist and GPS, remembers:

> It was very painful [in 1954] to try to program anything, to make progress towards a chess-learning machine, because we didn't have an adequate language for communicating. [Newell and I] had done a number of programs in what was essentially machine language . . . but it was far too low-level a language to begin to specify the chess-playing program. *As programmers, we had a creative task each time with trying to invent a representation in the machine corresponding to what we were communicating fairly loosely in English.* (Shaw, interviewed in McCorduck 1979: 141; italics added)

For NewFAI to be practicable, then, it would have to escape the shackles of the binary code. To do that, it relied on three Ls: List processing, Logic, and LOGO. Each of these enabled people to avoid thinking of computers only as shufflers of 0 and 1, even though that's what they are at base.

List processing was the first of the three to rule the NewFAI roost, in the mid-1950s. Logic programming became prominent twenty years later. As for LOGO, this was less widely used by AI researchers. But it was much more interesting to other people. It wasn't merely a programming language, but embodied a specific psychology of thinking, learning, and teaching.

a. Psychology outlaws binary

There's a reason why binary code is near-unintelligible: namely, the "magical number seven" (Chapter 6.i.b). It's because of that limitation on human memory that computer science as we know it, NewFAI included, couldn't have got off the ground without programming languages.

When the psychologist Miller first identified the "magical number" he pointed out that it can be cheated by chunking. He also pointed out that since there can be no more than about seven chunks, we regularly compose larger chunks out of smaller chunks . . . on indefinitely many levels. Programming languages are chunkers: one term in the high-level language is defined by many in the machine code. That's why programmers can write complex software using these languages which they couldn't have hoped to write without them.

The need for programming languages had already become clear in practice even as Miller was writing his paper (published in 1956). And his colleague Licklider was well aware of this. In his famous call to arms on enabling "Man–Machine Symbiosis"

(11.i.b), he listed them as an essential prerequisite for that happy state of affairs (1960: 4). The lack of powerful programming languages, he said, was "the most serious obstacle to true symbiosis".

Why was Licklider so concerned? After all, by the mid- to late 1950s a few such languages were already available. The most widely used were IBM's FORTRAN (the acronym came from FORmula TRANslation); the algebra-like ALGOL, designed in Germany with some input from Zuse; and COBOL, created by Grace Hopper (who'd also written the first compiler, in 1952).

However, these weren't much use to NewFAI. Programming languages are like traps, designed to catch different animals in different ways: they store and process information differently, and are best suited to different computational tasks. FORTRAN and ALGOL had been custom-made (for scientists and engineers) to represent mathematical formulae or number arrays, not to model hierarchical problem solving or associative thought. (Weizenbaum used FORTRAN to program ELIZA, as we've seen: but he didn't try to *do* anything with it, besides superficial template matching.) Similarly, COBOL was designed largely to help businessmen and accountants to do their sums. But AI was focused on symbol processing *in general*, not just numbers. (Zuse's Plankalkul was non-numerical, but was still unknown: see subsection f.)

Since AI required new types of task to be accomplished, the AI community had to create new ways of telling computers what to do. That explains Licklider's concern, for he'd been closely involved with the NewFAI pioneers right from the start. It also explains why Minsky could justify the "slow" rate of progress in 1950s AI by saying that "Much of [our] time has been spent on the development of programming languages and systems suitable for the symbol-manipulation processes involved" (1961*c*: 215).

The design of such languages depended on three things: (1) how people find it easiest to think; (2) what NewFAI folk wanted to think about; and (3) how the new language could be implemented.

The last question was crucial. Someone can define a formal language and then use it 'intuitively'. That's what Bertrand Russell did when he proved theorems in his propositional and predicate calculi (Chapter 4.iii.c), and what Chomsky did when he applied his transformational grammar to English sentences (Chapter 9.vi). But to enable a machine to use the language, someone has to show how to represent the newly defined chunks in the computer's memory, and how to translate them into machine code so that the program can actually be run.

The same applies to the development of user-friendly computer interfaces (Section i.h above and Chapter 13.v). As Engelbart put it, in discussing the desirability of word-processing:

> [The] internal structure [of symbols in the computer for words, phrases, sentences, paragraphs, cutting, pasting, copying, etc.] may have a form that is nearly incomprehensible to the direct inspection of a human (except in minute chunks).
>
> But let the human specify to the instrument his particular conceptual need of the moment, relative to this internal image. Without disrupting its own internal reference structure in the slightest, the computer will effectively stretch, bend, fold, extract, and cut as it may need in order to assemble an internal structure that is its response, structured in its own internal way . . . [It] portrays to the human via its display [i.e. interface] a symbol structure designed for *his* quick

and accurate perception and comprehension of the conceptual matter pertinent to his internally composed substructure. (Engelbart 1962: 87)

These psychological facts of life affected the development of NewFAI very deeply. It required special programming languages right from the start, and couldn't have matured into GOFAI without continual (and still continuing) improvements in *how* to tell a computer what to do. Deciding *what* to tell it to do, which is what people normally focus on when they think about AI, was therefore just one side of the coin. NewFAI researchers had to originate both the head and the tail.

b. Entering the lists

When Newell died in 1992, the *AI Magazine* printed three full-page pictures of him, including one on the front cover. In addition, they ran a twenty-six-page obituary, a memoir by Simon, and a previously unpublished speech of Newell's—championing AI as a "fairy-story" full of "enchantment"—that he'd given nearly twenty years before his death (Laird and Rosenbloom 1992; Simon 1992; Newell 1976/1992). Fully one-third of the Winter number was given over to him.—Why?

For the obituarists, his long-time SOAR collaborators John Laird and Paul Rosenbloom, his research as a cognitive scientist was paramount (see Chapters 6.iii.b–c and 7.iv.b). The nature of mind, they said, was "the ultimate question", which they hoped wouldn't be lost in AI's rush to money-spinning commercial applications (p. 41).

Newell's own theory of mind was the paradigm of GOFAI, even including the claim of strong AI (Chapter 16.v.c and ix.b). His SOAR colleagues made that very clear. They didn't mention the fact that he'd encouraged other cognitive science approaches, too. The connectionist Hinton, recalling Newell's offering him a job at CMU, has said:

[Newell] was very eclectic. He was very broadminded. He realized that sooner or later there was going to be a connection between what went on in the mind and what went on in the brain . . . [He] was in favor of having people do all sorts of things [at CMU], so he was basically in favor of having someone who worked on neural nets there. He could see it coming back into fashion . . .

I was very impressed by the fact that Newell was open to getting somebody in an area that he didn't believe in. It's very rare to see that in academics. (J. A. Anderson and Rosenfeld 1998: 375)

But if the obituarists didn't praise Newell's eclecticism, they did laud his work on programming languages—which enabled him, and many others, to ask that "ultimate question" in computational terms. By inventing new programming languages, Newell—with Simon—revolutionized the potential of AI. One might even say that they *made AI possible*. For in the mid-1950s, they implemented the first list-processing language.

I say "they", but the younger man was the senior in terms of computing expertise. Most of the technical details were worked out by Newell, although the overall rationale was developed jointly. (The same was true of their second revolution in programming, namely, production systems: subsection e, below.) Presumably that's why Newell, not Simon, was elected as AAAI's first President. (His vision for AAAI was recently reprinted in their twenty-fifth anniversary number, and extensively quoted in the opening paper: Newell 1980/2005; Reddy 2005: 9.)

List processing enabled computers to handle problems of greater hierarchical complexity than had been possible before. And it enabled them to be more than mere number-crunchers. That is, it supported what Minsky (1968) termed "semantic" information processing, concerning matters normally expressed not in numerals but in logical symbols or even natural language.

In principle, of course, list-processing languages weren't necessary. Any universal programming language, in theory, can support any computation (Chapter 4.i.d). Indeed, Colby later switched from a Newell–Simon list processor to ALGOL (designed to represent numerical arrays) when writing the later versions of his neurotic program (7.i.a). What's possible in principle, however (the Turing tar-pit), may be very different from what's feasible in practice. And in practice, list processing was a huge advance.

Its ability to represent hierarchy, a prime feature of human thought and action, made it both easier to work with during the programming process and more apt for modelling thought. The second point was especially important to Newell and Simon, who were psychologists before they were computer scientists (Chapter 6.iii). When they first designed new languages for AI, they weren't doing an abstract exercise in computer science. Rather, they were trying to get the Logic Theorist off the ground (Newell and Simon 1956*b*; Newell and Shaw 1957).

Their initial attempt at going beyond machine code was the "Logic Language", which they used for paper-and-pencil simulations (Newell and Simon 1956*a*). They soon buckled down to implementation, however, with the help of a RAND colleague: the professional computer scientist Shaw. Through the late 1950s, they pioneered a six-sibling family of Information Processing Languages, or IPLs (Newell and Shaw 1957; Shaw *et al.* 1958; Newell 1960; Newell *et al.* 1964).

The first sibling wasn't actually implemented. For IPL-I was none other than the Logic Language, its name being "a label we put on retroactively" (Shaw, in McCorduck 1979: 142).

IPL-II, however, was implemented—and was powerful enough to be used for the Logic Theorist. It had no compiler, and had to be translated into machine code by hand. (This was a labour-intensive exercise: Newell and Simon worked out the relevant binary numbers simultaneously, saying them out loud to ensure that they agreed.) IPL-III, Newell said many years later, was "the best one of the bunch", because it had "no syntactic structure at all" (Laird and Rosenbloom 1992: 23). But it had to be abandoned, because it "was so space intensive that you simply couldn't run it on the machines"—which, in those days, were still tiny. IPL-V was more tractable, and was used for writing GPS.

In these IPL programs, each component ("statement") was a list structure. In general, a list needn't be a list of single items: it may be a list *of lists*. Just as a shopping list can be hierarchically organized (Grocer: sugar, tea, biscuits; Greengrocer: lettuce, carrots, courgettes; Draper: ribbons . . .), so could an IPL routine. So an IPL program wasn't best thought of as a sequence of instructions all conceptualized at the same level. Some instructions were simple (compare: "Get money from bank machine"), others more complex (compare: "Go to the grocer—and while you're there, buy sugar, tea, and biscuits and order some coffee beans").

Since *everything* was a list, statements could be treated either as data (information, facts . . .) to be noted, copied, or even changed, or as routines to be executed. So routines could be altered during execution, by the same processes that altered lists of data. These processes included substituting one symbol for another, adding an item to the end of a list, and inserting one list into another.

The last facility was necessary for solving problems whose goal/sub-goal complexity wasn't known beforehand. Think of going downstairs to fetch some milk from the fridge: it may turn out that you first have to search for the key of the kitchen door. Even in theorem proving, which was Newell and Simon's concern at this time, one doesn't usually know how many levels of means–end analysis will be necessary.

This required creative thinking about basic aspects of computer science. I implied, above, that if one could implement lists then hierarchy (lists of lists) would come for free. But this wasn't going to happen by magic: AI wasn't such a "fairy-tale" as that. How, then, were lists to be implemented?

For instance, how could a lower-level list be contained within a higher-level one? To do this (which was needed for means–end analysis, as we've just seen), memory access and allocation had to be handled in a new way. Specific sections of the memory couldn't be pre-assigned to this or that function, as was usual, because the programmer couldn't foresee how much memory would be needed when the program was run, nor just which items would need to be associated with (or included within) each other.

Newell and Simon's solution was to label each item with the memory address of the next item on the list—where 'adjacent' items needn't be close together in the physical memory store. The listed items could then be accessed in the right order *despite* being scattered across the memory as a whole. Functional ordering was liberated from physical ordering. Similarly, list insertion could be effected not by 'pushing other items aside' (compare making room in the crockery cupboard for a new set of bowls) but by changing a couple of memory addresses. As Simon put it later:

> [The] entire memory could be organized like a long string of beads, but with the individual beads of the string stored in arbitrary locations. "Nextness" was not determined by physical propinquity but by an address, or pointer, stored with each item, showing where the associated item was located. Then a bead [or a sub-string of beads] could be added to a string or omitted from a string *simply by changing a pair of addresses*, without disturbing the rest of the memory. (Simon 1991: 212; italics added)

Another fundamental contribution was the 'push-down stack'. The IPLs were recursive languages, meaning that one procedure could be nested inside another. To achieve that, Newell and Simon implemented the push-down stack. (An earlier form of push-down stack had been suggested, but not implemented, by Turing in the ACE report: Chapter 3.v.c.) This is analogous to a stack of unpaid bills placed on a spike, to be dealt with one by one and removed accordingly. If instruction A includes the instruction to do B, then A is temporarily stored ('pushed down') in such a way that it can be refound ('popped up'), and control passed back to it, as soon as B has been completed. This is possible even if instruction A is nested inside *itself*: the push-down stack ensures that the computer won't 'lose its way' by forgetting which level should be in control at any given stage.

That's how GPS was able to represent, and be efficiently controlled by, means–end hierarchies with goals and sub-goals on various levels. And it's how computers were able to accept self-reflexive procedures such as this (expressed here in English):

```
CLIMBSTAIRS:
  push right toe forwards
  IF toe meets obstacle
     THEN raise right foot onto next step
        AND raise left foot onto same step
     CLIMBSTAIRS
  ELSE stop.
```

In such cases, *repetition* (of reaching the next step) was implemented as *recursion* (of CLIMBSTAIRS).

A third innovation concerned memory loss. Earlier computer programming had followed the principle that when one routine hands over control to another it instantly forgets everything it had needed to know about the local context while it was working. After all, why waste memory space? However, instant memory loss on the relinquishing of control would make recursive routines impossible. One clever feature of IPL-V was that the programmer didn't need to state explicitly, every time a different goal took over the control, that the relevant context should be remembered (for push-down) or recalled (for pop-up). Nor did he/she need to state that when a given routine had been completed its contextual information could be deleted to save space, or that if it was abandoned then *everything* currently in the push-down stack could be removed simultaneously. The programming language took care of all that automatically.

As it turned out, IPL-V was soon dropped like a hot potato (see below). So why did Newell's obituarists make such a song and dance about it? The reason was that Newell and Simon hadn't merely invented a new type of programming language. They'd also developed a new approach to programming *in general*—and here, Simon was at least as important as the more technically skilled Newell.

Simon summarized his general ideas about hierarchical complexity soon after the birth of IPL-V (Simon 1962). He expanded them as the Karl Compton Lectures on 'The Sciences of the Artificial' in 1968—since when, they were revised and reprinted many times (Simon 1969). But the seeds had been evident in the first IPL-V manual, Newell's (1960) RAND memo on the language.

That memo was widely read within the NewFAI community—indeed, it helped to *create* that community. After circulating within the core of insiders, it was put out by a trade publisher in 1961; and a second edition appeared a few years later (Newell *et al.* 1964). By that time, IPL-V had been well-nigh abandoned. So the interest wasn't primarily in that particular language. Rather, it was in the manual's general advice on programming: e.g. recommending top-down design, short subroutines, and the avoidance of GOTO instructions. This was valuable to all NewFAIers, irrespective of their choice of programming language. As Newell's obituarists put it, he and Simon had introduced "*a design philosophy for programming* that years later would be reinvented independently as structured programming" (Laird and Rosenbloom 1992: 24; italics added).

In short, IPL-V was an important contribution to computer science, to software engineering, and (via GPS) to cognitive science too. That's partly why the *AI Magazine* honoured Newell so generously (see also subsection e, below).

c. LISPing in 'English'

Newell and Simon weren't the only ones to program in IPL-V. Colby, for instance, did so too, when writing the first version of his neurotic program (7.i.a). Nevertheless, it wasn't easy to use.

It was slow, because it had no compiler to translate instructions *directly* into machine code (it depended on an interpreter). It forced the programmer to keep track of some boring 'housekeeping' details, such as declaring whenever an unwanted list could be deleted to make room for a new one. And it was defined at a very low level, more like an assembly language (which is just one step up from the machine code) than what people think of today as a programming language. It therefore looked more like algebra than English—and not pretty algebra, at that. Indeed, Sloman (personal communication) describes it as "a horrible inelegant mess, [which] had no hope of surviving".

It didn't follow that the IPL-V *manual* was destined for the dustbin, as we've seen. But despite their respect for the programming strategy spelt out there, most computer scientists were loath to use IPL-V as their programming medium. Several other list-processing languages were soon designed accordingly.

MIT's Bobrow and Raphael compared some of them (Bobrow and Raphael 1964), as J. Michael Foster of Aberdeen University did a few years later (1967, ch. 7). Their differing advantages and disadvantages included speed, computational potential, and ease of use. For example, were the instructions interpreted or compiled, or both? Did the user have to oversee the 'garbage collection' (tidying up the used/unused memory locations)? Could lists be represented in only one fixed way? Was sharing of sub-lists allowed? And what about circular lists? These questions guided the very early AI researchers' choice of language, given that some form of list processing was desired.

So IPL-V soon had rivals. Gelernter, for instance, developed FLPL to write his geometry program (Gelernter *et al.* 1960*a*; see Chapter 6.iv.b). And Victor Yngve's (1958) COMIT was designed to deal with words, for the purposes of machine translation. COMIT was more easily intelligible than either IPL-V or FLPL—indeed, even beginners (such as myself: see Preface, ii) could use it. This was due not least to its relatively user-friendly programming manual, which stood out from the crowd in those days of aggressively 'macho' technicality (Yngve 1962*a*,*b*). (In fact, COMIT remained in use outside AI well into the 1970s: Yngve 1972.)

Within AI, the rival which won out was LISP—an acronym for LISt-Processing language. This was developed by McCarthy, and was one of his most important contributions to the field.

He'd already declared the need for a new, and English-like, language in his funding application for the 1956 Dartmouth Project (see i.h, above). Following discussions there with Newell and Simon, he started work on LISP that autumn (Chapter 6.iv.b). (He recalls: "I wasn't much influenced by Dartmouth—unless, perhaps, Newell and Simon pushed me into logic as a way of expressing information": personal communication.)

McCarthy was then teaching at Dartmouth, which didn't yet have an IBM 704 machine, so he was confined to using pencil and paper (Gabriel 1987: 520). When he went to MIT, he "concentrated on doing LISP" (J. McCarthy, personal communication). He wrote his first LISP program, for differentiating algebraic expressions, while visiting

IBM in summer 1958: it had if–then conditionals, and recursive use of conditionals (personal communication).

He outlined his ideas for the language publicly two years later, both in the very first MIT AI Lab memo and at Albert Uttley's November 1958 NPL meeting in London (McCarthy 1958, 1959). More detailed descriptions soon followed (McCarthy 1960; McCarthy *et al.* 1962). (The implementation details, and many subsequent improvements made by McCarthy and others, are described in Gabriel 1987.)

Introducing the famous CONS and CDR, McCarthy described a new way of implementing lists. This owed something to IPL-V and its recent cousins, but went far beyond them too. LISP quickly became the natural language of choice for AI (Bobrow 1972). Three decades later, when NewFAI had long given way to GOFAI, it was still being described as "the most widely used language in AI programming" (Gabriel 1987: 527).

The first version of LISP had several technical strengths. It was up to two orders of magnitude faster than IPL-V (and less demanding of memory space), because it had a compiler as well as an interpreter. And it provided automatic garbage collection. Besides tidying the memory store, this kept track of the partial results of various computations without any need for human monitoring.

LISP made the activity of programming easier, too. Because it offered built-in arithmetical functions, the programmer who happened to need them didn't have to define them anew. And it enabled one to write conditional (*if–then . . .*) instructions easily, as well as straightforward imperatives (*do this*). This was due to its intellectual origins in logic: specifically, Alonzo Church's lambda calculus (Chapter 4.i.c) and Gottlob Frege's higher-order functions (2.ix.b). (The first of these was later commemorated in the name of the hugely popular VR environment LambdaMOO: see 13.vi.d.)

Since functions could be arguments in other functions, recursion could be made explicit in the program, instead of being handled purely behind the scenes by the push-down stack. (Strictly, a LISP program wasn't a sequence of *instructions* but a set of *function calls*: one function call could include arguments returned as values from other function calls, and so on.) Like the IPLs, then, LISP allowed the definition of a term to include that term, so that processes could invoke themselves: CLIMBSTAIRS, all over again.

With respect to *what one could talk about* when talking to the computer, however, the most important innovation was its syntax. Recursion was represented more 'naturally' in LISP than in IPL-V, by nesting one bracketed expression inside another. Compare: *(The cat (I saw on Saturday night (when I came to supper)) sat on the mat)*. And there were no arcane symbols. The simplest LISP expressions consisted of up to thirty capital letters and digits, with commas and brackets as well: e.g. ((ABCDEF,239),(MNO,835)) or ((FATHER,MAGGIE),(HUSBAND,DOROTHY)). This syntax carried a liberating—but potentially deceptive—advantage, and an annoying disadvantage too.

The disadvantage was that the more complex LISP expressions could have many, many nested brackets. This meant that structures of significant hierarchical complexity could be represented. So far, so good. But typing errors were common. One of SHRDLU's sentence parsings, written in a LISP-based language, ends with a sequence of eleven brackets, thus:))))))))))) (Winograd 1972: 176). These are difficult to count accurately, even if one uses a pencil tip to do so. (Try it!) Today, the computer editor could count the brackets for you. But in those days, the brackets had to be matched by hand. As a result, bracket bugs were common in LISP programs. (And the name was sometimes glossed as "Lots of Inane Stupid Parentheses".)

The advantage was that LISP allowed the user to employ symbols visually identical with English words—as in the (FATHER,MAGGIE) example, above. Indeed, McCarthy's (1959) introductory paper had stressed this fact. LISP's origins were in logic, as we've seen. But McCarthy wanted to have his cake and eat it, by combining the deductive power of logic with the representational power of natural language. So in his talk at Uttley's meeting, he'd proposed the Advice Taker: a (notional) program that would accept statements in English and draw inferences from them (Section i.f, above).

The option of using English terms made it much easier to program complicated procedures in LISP than in IPL-V. For each step or sub-procedure could be named and/or expressed by symbols that looked like semantically appropriate, and therefore easily remembered, English words. In terms of ease of use, then, LISP was a liberation.

For this reason (plus the speed, arithmetic, garbage collection, and conditionals), AI professionals in the USA overwhelmingly opted for McCarthy's language. IPL-V was dropped, as were its other rivals. LISP ruled supreme.

(UK researchers used LISP too, in the early days. By the late 1960s, however, the Edinburgh-based POP2 was widely preferred, and remained dominant there—spreading to other European centres—for many years: Burstall and Popplestone 1966. Indeed, its successor POP-11 is still used by some AI researchers east of the Atlantic. Unlike LISP, which was designed for offline use, POP2 was a pioneering online computer language. That is, it was intended for use "by a person communicating directly with a computer *via* a typewriter"—Popplestone 1966: 185. It combined facilities offered by ALGOL and LISP: arrays, as well as lists. And its syntax avoided the plethora of brackets that plagued LISP programmers, making bugs due to typing mistakes less likely.)

However, there was a sting in the tail. LISP's major advantage—that it appeared to be using English words—was a mixed blessing. Too often, programmers unthinkingly assumed that the wordlike symbols in the program meant much the same as the corresponding words in natural language. As a result, they deceived themselves and others about the power and psychological relevance of their research.

They'd be rapped sharply over the knuckles for this by an AI colleague in 1974 (11.iii.a). But despite the knuckle rapping, the temptation to over-interpret procedure names and data labels persisted. Twenty years later, leading AI researchers were still being accused of believing that their programs were doing something (e.g. finding/recognizing analogies) in a 'human' way largely because this was implied by the mnemonic labels they'd chosen (Hofstadter and FARG 1995: 275–91).

Another way of putting this is to say that LISP made it easy for AI workers to fall into the trap described by Searle (16.v.c). Even though (*pace* Searle) a program *is not* all syntax and no semantics (see 16.ix), it can be so regarded for certain purposes. That is, it can be seen as an uninterpreted formal system. Purely formal systems can sometimes be mapped onto structural relations between meaningful concepts. For instance, a simple letter-shuffling or necklace-building game may map onto the rules of arithmetic—something one realizes spontaneously, as one plays the game (Hofstadter 1979: 46–54; Boden 1990*a*: 42–6). Where AI programs are concerned, there will always be *some* degree of match to the domain being modelled. The more insightful and/or competent the programmer, the closer the mapping will be. So people, programmers included, will be tempted to understand LISP's 'English' symbols as though they were the equivalent English words.

In general, this will be a mistake. Setting aside the philosophical question of whether there can be any real understanding there (Chapter 16), a program's quasi-understanding will inevitably be less rich than the human's. For in practice, not all of the relevant semantic associations will have been provided. Even arithmetical calculations by a computer can fail to map onto the human equivalent (13.ii.b). And natural-language words are interpreted by us in terms of types of relevance undreamt of by NewFAI (7.iii.d and 9.x).

This wasn't clear to AI workers in 1960, despite Bar-Hillel's recent critiques of MT (9.x.e) and Ludwig Wittgenstein's just-published *Philosophical Investigations* (9.x.d). Nor was it clear to 1960s cognitive scientists in general. Their common assumption, which guided Bruner's work on concept formation for instance, was that words could be defined by necessary and sufficient conditions. Indeed, the programme of logical atomism was still close to many people's hearts, from McCulloch (4.iii.c) to McCarthy himself. Small wonder, then, that 'English' was commonly assumed to be English.

In sum, what looks like gobbledygook isn't likely to be misread as good plain sense, but what *looks like* good plain sense is easier to write than gobbledygook is. If IPL-V hadn't given way to LISP, there'd have been less misunderstanding of AI. On the other hand, there'd have been much less AI to be misunderstood.

d. Virtual cascades

Even LISP had its weaknesses. There were certain things that late 1960s AI programmers would have liked to be able to do which simply couldn't be done, or which could be done only with great difficulty. So several people at MIT started asking themselves whether they could design better languages.

They might have started from scratch: *Forget LISP! Let's invent a fundamentally new language!* After all, that's what Robin Popplestone (1938–2004) had done when he designed POP. And it's what Kay at Xerox PARC did in 1971–2 when he designed SMALLTALK, the first object-oriented programming language (A. C. Kay 1993).

Object-oriented languages are 'natural' in the sense that they allow the programmer to think in terms of objects, or hierarchical concepts (think *frames*), without always having to worry about *just how* those objects can/will interact. In effect, the object (as defined in the programming language) already 'knows' how it behaves, and/or how it relates to other objects. Often, it can 'tell' the user what it can do, and ask just which feature the user wants to focus on. (That's partly why object-oriented languages are useful for designing computerized *agents*: see 13.iii.d.) The reason is that object-oriented languages have an "inheritance" mechanism, whereby properties already defined with respect to one concept are automatically inherited by any concept defined as a subclass of it. (Compare: if I tell one of my grandsons that a lynx is a type of cat, he immediately knows a great deal about lynxes because he already knows a great deal about cats.) Java is a well-known modern example, but there are others besides. (SMALLTALK itself is still used occasionally: Shasha and Lazere 1995: 49.) Licklider had remarked the need for object-oriented languages in his 1960 paper, pointing out that computers at that time had only two elementary symbols (0 and 1), and "no inherent appreciation either of unitary objects or of coherent actions".

But although Kay was using SMALLTALK for his own research (see 13.v.d), it was too far ahead of its time to be effectively implementable. (Today's Java is partly inspired by SMALLTALK.) At MIT, moreover, LISP ruled the roost. It was so well established there that the natural option was to use it as the basis for designing more powerful languages.

It was already known that one programming language could be defined in terms of another. (Gelernter's FLPL, for instance, had been a list-processing language embedded in FORTRAN—hence the "F" in the acronym.) In other words, there could be a *cascade* of computational environments.

Just as computer scientists weren't restricted to working in machine code, so they weren't restricted to working in a 'base-level' programming language such as IPL-V or LISP. The facilities made available by a programming language on level n could be used to define new facilities in language $n + 1$, which in turn could support the computational environment of language $n + 2$ and so on. In the terminology used in Chapters 7.i.f and 16.ix.a, each language provides a particular *virtual machine*, and one virtual machine may be implemented in another . . . until we reach the machine code—which alone can make something happen in the electronic entrails.

In such cases, successive levels of internal translation have to be done by the computer. Because this costs time and memory space, multilevel languages are inefficient. Eventually, new languages and/or hardware would be developed in which functions previously considered as high-level (needing one or more layers of compilation/interpretation) were directly implemented in the hardware. For instance, in the late 1970s MIT developed the LISP Machine, in which basic LISP functions were embodied in the machine code (Bawden *et al.* 1977), and also the Connection Machine (Hillis 1985), in which parallelism—instead of being simulated by a von Neumann computer, as is still usual today—was built in. (Neither was a commercial success: 11.v.a.) But that was for the future. Meanwhile, NewFAI was still struggling to find better ways of telling computers what to do.

At MIT, several virtual cascades were defined, of which the two best known were PLANNER and CONNIVER. Indeed, the former became world-famous as a result of Winograd's thesis, which electrified the AI community—and cognitive scientists in general—early in the 1970s.

Recall, for instance, Winograd's opening remark to SHRDLU: "Pick up a big red block" (iv.a, above). This wasn't a straightforward task, because the green block had to be cleared away first—which involved noticing it, picking it up, finding empty space for it on the table, and putting it down. But Winograd didn't have to say any of that: he left SHRDLU to work it out for itself. If he'd been using LISP, he couldn't have written such a vaguely specified instruction. He'd have had to say not only what he wanted done, but precisely how it was to be achieved.

Instead of LISP, Winograd had used (a cut-down version of) Carl Hewitt's new language, PLANNER (Hewitt 1969, 1972; Sussman *et al.* 1970). PLANNER was the first "goal-directed" language, in which one could specify a goal in general terms without having to identify all the particular objects and operations involved in attaining it.

This was possible because procedures were indexed not by some individual descriptor or name, but by general patterns specifying the type of data on which (or towards which) they were supposed to work. So procedures could be called indirectly, using (unbound) "open variables" instead of (bound) "closed variables".

To see the difference, compare asking a friend to bring you a copy of today's newspaper with asking them to walk to the third counter on the right in the newsagent's shop on Middle Street with the purple awning, riffle through the newspapers until they find *The Independent*, and then buy it, handing over the money to the shop assistant and bringing back the change. The first version of your request is much easier to give. But you have to assume that your friend has enough nous to be able to execute it. They need to know already, for example, that if one wants to buy a newspaper the best place to do so is a newsagent's, that there's a newsagent nearby (on Middle Street or elsewhere), and that all the newspapers will be laid out together.

So it was with PLANNER. Winograd's instruction "Pick up a big red block" activated the PICKUP function by name. But the PLANNER procedure defining this function included within itself the general information: "If you wish to pick up X (whatever it is), and there is (any) Y on top of that X, then you should call CLEARTOP to get rid of Y before you try to move X". In this example, the first occurrence of X is open, as is the first occurrence of Y, but the subsequent occurrences of both are closed. When PICKUP was called, *the program itself* could be relied on to fill in the requisite values of the variables. In LISP, by contrast, every procedure call had to include only closed variables (otherwise, the LISP compiler would spit it out, with an error message asking the programmer to bind the open variable).

As this simple example illustrates, a 'single' PLANNER procedure could include calls to other procedures within it (these calls might be recursive, hierarchical, or heterarchical: Section iv.a, above). More complex PLANNER procedures could include heuristic advice about which other procedures *might* be relevant, and which of these should be tried first. When no heuristic advice was specifically included, the PLANNER procedure would search the database for *any* item whose goal matched the desired pattern, trying each one in turn.

All of this involved hidden processing. A PLANNER program would *automatically* remember what was the last decision, and which alternatives had remained at the time. If the current attempt failed, it would backtrack to the last decision point and try another alternative—or, if none remained, it would back up to the next-highest level in the search tree and try any alternative remaining there. This processing strategy was implicit in the programming language, whereas a LISP programmer (or in the case of GPS, an IPL-V programmer) would have had to specify it explicitly. Since such details were hidden, PLANNER programs were relatively 'chunky' and so relatively easy to understand. The "magical number seven" had been cheated, again.

By the same token, however, the hidden details could include unsuspected inefficiencies and dead ends. Consider the housekeeping involved in the automatic backtracking. PLANNER handled its push-down stacks in such a way that the details of the local environment at each previous decision point were saved, to be reinstated when failure caused the program to pop up to some higher level. However (as in the earlier list-processing languages), abandonment of a goal on level n would automatically delete the contextual information at level n. Human thinking isn't like that: when someone decides to return to a previous decision point so as to restart the search from there, they'll usually want to remember *why* the previous attempt failed. For if they don't, they might try a second alternative (and a third, and . . .) that's doomed to failure for precisely the same reason. Also, they might want to remember *how the world changed* while they were making the unsuccessful attempt. For if they can do that, they may even be able try the same alternative again—this time, making sure that a specific troublesome change is either prevented or immediately remedied.

To avoid PLANNER's stupidity in situations of failure, Hewitt's MIT colleagues Sussman and McDermott designed yet another LISP-based language, called CONNIVER (Sussman and McDermott 1972*a*,*b*). A failed CONNIVER procedure could not only tell its higher-level module why it failed, but also pass on information about the sequence of world changes it encountered on the way. This was a prime reason why HACKER (written in CONNIVER) could learn from its mistakes, whereas SHRDLU couldn't (see iii.d, above).

A prime reason why CONNIVER programs could do things which no PLANNER program could do was the language's economical (and automatic) storage of contextual information. A series (or tree) of local contexts was stored in such a way that the *shared* information didn't have to be repeated. After the first context frame, any information that was explicitly coded represented only environmental *change*. So a robot wouldn't have to reiterate the fact that a square box *stays square* no matter how many times it's moved. Or rather, it wouldn't have to do so if the programmer had had the foresight to build that proviso in. (This was one way of trying to avoid, or anyway lessen, the notorious frame problem.)

Another strength automatically provided by CONNIVER was the ability to choose *the best* of a set of alternative procedures, instead of (as in PLANNER) making an unordered list of candidates and trying them out one by one. To be sure, some PLANNER programs could make such choices too—but that ability had to be specifically written in by the programmer. In CONNIVER, it was tacitly provided by the language itself.

PLANNER and CONNIVER were, in effect, LISP with knobs on. Other AI languages were developed later which weren't based on LISP. But the point of general importance here is that a new programming language, even if it's defined in terms of a previous one, can hugely increase the ease of programming—and the power of the ensuing computation.

e. NewFAI in parallel

Having pioneered list processing, Newell and Simon could have been forgiven for resting on their laurels—at least so far as the technological aspects of AI were concerned. But they didn't.

In the mid-1960s, they (again, mostly Newell) developed yet another way of talking to computers: by using production systems, or PSs. Strictly, these were a type of computational architecture rather than a specific programming language. Like semantic networks, or ATNs (9.xi.b), they could be defined in many different languages (see below). In other words, they were a new class of virtual machine for AI's armoury—providing a form of *parallel* processing, of a richness far surpassing Pandemonium (Chapter 11.ii.d).

Thanks to the ever-present grapevine, NewFAI's inner circle knew about this development from the start. In 1967 Newell's lectures on PSs at Stanford had inspired Buchanan and Feigenbaum (who'd collaborated with Newell on IPL-V at RAND, ten years earlier) to use them as the basis of DENDRAL, officially reported in 1969. But it wasn't until the early 1970s that Newell and Simon themselves published on their new approach (Newell 1972, 1973*a*; Newell and Simon 1972).

Through the rest of the 1970s, that approach was widely adopted within both technological and psychological AI. Encouraged by DENDRAL and its cousin MYCIN, PS-based expert systems burgeoned. And psychological modelling flourished too, following Newell and Simon's massive tome on *Human Problem Solving* (Chapter 7.iv).

Like LISP, PSs grew out of logic. In 1947 the Polish-born logician Emil Post (1897–1954) had defined "rewrite production systems" as a way of representing recursion. As formally defined by Post (1943), a production system was a set of logically independent condition–action rules, or "productions". As implemented by Newell and Simon, a production system was a set of *if–then* pairs: *if* the condition is satisfied, *then* the action is executed. In effect, then, the whole system consisted of demons (or of ants: 7.iv.a–b). This was a huge liberation from the recursive programming languages, in which each procedure had to be explicitly invoked by some other procedure. Productions, by contrast, were triggered by the current state of affairs.

Post's logic had already entered cognitive science before Newell and Simon took an interest in it, for Chomsky (1957) had based the rewrite rules of his phrase-structure grammar on it (Chapter 9.vi.c). It had also affected *computer* science, where it was being used in the early 1960s to design compilers. Indeed, Simon first heard about production systems from a young computer scientist called Bob Floyd, who was working in a Boston software company before Simon gave him a job at CMU (Crevier 1993: 150). But it hadn't yet spread to AI. Although Chomsky had done important theoretical work in computer science (including a proof that push-down stacks can handle context-free languages: 9.vi.a), he wasn't interested in AI—not even computational linguistics. His only venture into this area was in collaboration with a psychologist colleague (G. A. Miller and Chomsky 1963: 464–82). Newell and Simon, by contrast, had been committed to computer modelling since the mid-1950s (6.iii.b). When they discovered Post's logic, they showed how it could be implemented for AI purposes—and how it could be *put to work*.

Since sets of IF–THEN rules can in principle be used to represent any computation, PSs were in effect a universal (very high-level) programming language. Indeed, Newell's student Michael Rychener (1976) reimplemented many classic NewFAI systems as PSs. However, they're usually thought of not as a programming language but as a general type of program. For PSs are a *class* of control architectures, which have been implemented in a variety of (lower-level) programming languages.

Some of these languages were designed with PSs specifically in mind. One of the first widely used examples was PSG. This was the final version of a series of possible languages outlined by Newell (1973*a*) to implement different control systems for PSs—"different", for instance, in the ways in which conflict resolution and/or memory matching and/or backtracking were handled.

PSG, in turn, gave rise to successive versions of OPS, or Official Production-System language (Forgy and McDermott 1977; Forgy 1981, 1984). These were all developed at Newell and Simon's home base in Pittsburgh, and partly by Newell himself. One of the first commercially successful expert systems, John McDermott's VAX configurer (11.v.b), was written in OPS4 and OPS5.

The main aims behind OPS were to support Newell and Simon's claims that PSs could function in complex environments (which provide many interruptions), and could learn general lessons from experience while so doing (Forgy and McDermott 1977: 933). In other words, OPS was a departure from the early expert-systems approach, in which a PS would be tailored for a single task: specialized, uninterrupted, and fixed. (Likewise, Newell and Simon's PS models had been a departure from GPS—which also was specialized, uninterrupted, and fixed.)

In general, PSs used a "blackboard" architecture. Although production systems, like GPS, were sequential (only one rule could be executed at a time), they weren't pre-ordered instruction lists: first do *this*, then do *that* . . . Instead, all the currently active conditions were made simultaneously visible to the whole system, by being placed on a central blackboard. The PS progenitors, Newell and Simon, allowed no more than nine symbols on the blackboard, so as to match the "magical number seven" of human psychology (Chapter 7.iv.b). But not all PS designers limited their systems in that way. Blackboard architectures were pioneered in the early 1970s HEARSAY speech system, a project led by Newell himself. The blackboard was helpful here because it enabled the program to integrate evidence drawn from widely different areas—namely, phonetics, syntax, and semantics (Chapter 9.xi.g). (Eventually, blackboard PSs were used as the basis of most expert systems.)

In essence, if a production found its condition on the blackboard, then it would fire automatically. Because that was so, and because (as Post had specified) the individual productions were logically independent, a PS was in effect a parallel-processing system. Like Selfridge's (1959) Pandemonium (11.ii.d), the virtual machine was parallelist even though the basic implementation wasn't. And since hundreds, or even thousands, of productions could be involved, most PSs were immeasurably richer than Pandemonium.

In practice, however, this richness presented a problem. For two (or perhaps many more) productions might find their conditions satisfied simultaneously. So some way—preferably sensible, not random—had to be found of enabling the system to choose *just one* of these for execution. Various conflict-resolution methods were used. For instance, the unfired productions might remain visible, as in SOAR, or they might be repressed—as in the earlier PSs (see Chapter 7.iii.b).

In other words, one of the major architectural dimensions on which PSs could differ was their method of dealing with simultaneously satisfied productions. Another was their method of backtracking, and yet another was memory matching (Newell 1973*a*). Memory matching was problematic, for instance, because there might be tens of thousands of individual rules in a single system: how can the blackboard be efficiently inspected, given this fact? Partly because of differences in memory matching, forward and backward chaining (iv.c, above) could be done in various ways.

In sum, production systems offered a rich store of virtual machines implemented in other virtual machines (including languages specially designed for PSs) . . . and differing among themselves not only in low-level detail but also on several broadly defined computational dimensions. The potential for both psychological and technological AI had been hugely increased. Those twenty-six pages of obituary were well deserved.

f. It's only logical!

LISP was designed so that the programmer could tell the computer what to do, when. So the general form of a programmed procedure was *do this, then do that, followed by the other*... Even the 'knobby' LISPs, such as PLANNER and CONNIVER, required the programmer to lay down a sequence of goal-oriented actions, although the details would be decided by the program itself at run time.

Given the sequential architecture of the von Neumann machine, this made sense. But AI workers sometimes wanted to shrug off the sequential straitjacket. This was so, for example, if their programs had to deal with situations arising at unexpected times. Indeed, it would in general be nice—so they thought—not to have to trouble themselves with issues of temporal order. How much simpler if the machine could be given the facts and then left to do what it had to do, in whatever order it pleased.

As we've seen, one way of avoiding specifications of task order was to provide anticipatory demons, which would lie in wait until aroused by their input cue. Another was to use a 'parallelist' PS. And a third was logic programming.

(A word of clarification: programming *in* logic—i.e. logic programming—must be distinguished from programming *inspired by* logic, and from programming a computer to *do* logic. Moreover, one logic must be distinguished from another. Three have given rise to hugely influential AI languages: Russell's predicate logic, Post's production systems, and Church's lambda calculus. However, when people mention "logic" in the context of programming languages, or "logicism" in cognitive science, they usually mean predicate logic—perhaps supplemented by modal logics of various kinds: see 13.i.a–b.)

Logic programming was PROgramming in LOGic—hence the acronym of the best-known language of this type, PROLOG. But PROLOG wasn't the only example, nor even the first. Zuse had designed a logic-based programming language, the Plankalkul, as early as 1946. However, this wasn't published until 1972 (and translated in 1976). It didn't catch on: despite being better than its rivals in some ways, they were already well established (Bauer and Wossner 1972). Adopting a new programming language is almost as difficult as abandoning the QWERTY keyboard. It does happen, but only if the advantages are significant.

In Anglo-American computing, theoretical work on 'declarative' programming languages had started in the early 1960s (e.g. Laski and Buxton 1962), and the turn of the decade saw the first fully implemented example. This was ABSET (with its compiler ABSYS), named after ABerdeen and SET theory (Foster and Elcock 1969; Elcock *et al.* 1971).

The authors' motivation was clear. In a preliminary paper tellingly subtitled 'Programs Written Without Specifying Unnecessary Order', Foster had said:

> The basic elements in this system are not instructions to do something, as are the statements of ALGOL, but assertions about the data, such as $a = b$ or $a + b = c$. The evaluation of a program of assertions *is not* the obeying in specified sequence of a set of instructions, but *an attempt to find data which satisfies the assertions*. (Foster 1968: 387; italics added)

At that time, his "Assertions" language (like Ted Elcock's work on 'Descriptions': 1968) was only partly implemented. But within a year or so the ABSET/ABSYS version had been completed. Again, the aim was to avoid the sequential straitjacket:

The overall design aim of ABSET was to devise an interactive programming language in which it is possible, at will, to take or defer decisions about a program: we therefore require that *decisions which are logically separable can indeed be taken separately and in any order*. (Elcock *et al*. 1971: 467; italics added)

We have concentrated on more primitive ideas [including notions taken from set theory], *the distinction between an ordering of decisions and an order of evaluation*, and the manipulation of partly-evaluated program. (pp. 467–8; italics added)

Two themes run through [our work]: that it should be clear what a program says, and that *the language should not force the programmer to commit himself to decisions he would prefer to postpone*. (p. 469; italics added)

Like set theory in mathematics, ABSET/ABSYS was focused on the primitive logical concepts underlying more familiar notions—here, not *numbers* but *list processing, matrix multiplication, text processing,* and so on. That is, it was intended as a general programming language. By 1980, however, it—and respected logic-based rivals such as SYNICS, named for SYNtax and semantICS (Edmonds and Guest 1977*a*,*b*; Edmonds 1981: 406–17)—had been overtaken by PROLOG.

In a retrospective review, two of the Aberdeen authors showed that "anything expressible in PROLOG was capable of straightforward translation into a subset of ABSYS" (Elcock and Gray 1988: 1; see also Elcock 1988). Indeed, they quoted Robert Kowalski's (1988) admission that "ABSYS, a declarative programming language . . . anticipated a number of PROLOG features"—including resolution, unification, backtracking, and the notorious 'negation by failure' (see iii.b, above).

Kowalski's word, here, was significant. For it was he who'd made PROLOG work. Or rather, it was he who'd made PROLOG work best. PROLOG was a language based on Russell's predicate calculus, and using an efficient form of resolution defined by Kowalski in 1971 (Kowalski and Kuehner 1971). It was first conceived—also in 1971—by Alain Colmerauer (1941–) and Philippe Roussel at the University of Aix–Marseille, for use in NLP. It was implemented by them in ALGOL a year later (Colmerauer and Roussel 1993). Kowalski's more efficient implementation was done at Edinburgh (until 1975) and then at London's Imperial College (Kowalski 1979).

One of the advantages of PROLOG was that it provided "for free" much of the inference machinery which had to be specifically programmed in LISP. By the mid-1980s, it was being widely employed in Europe (van Caneghem and Warren 1986), and introductory accounts had been written for AI students (Clocksin and Mellish 1981; Clocksin 1984). Not the least spur to its success was its use by the Japanese in their Fifth Generation project (11.v.a).

Like PSs, a PROLOG program—according to the blurb—would provide the machine with a set of items, and leave it to cope with them in whatever order it pleased. Unlike PSs, the items in question weren't expressed as conditionals (*if–then* rules) but as declaratives (assertions). The program would use general methods, such as logical *unification* and *resolution* (J. A. Robinson 1965), to draw whatever inferences it could from the items available.

PROLOG attracted a lot of attention in its early days partly because it was seen as a protagonist in the then raging 'procedural/declarative' controversy (iv.a, above). Logic, as such, says nothing about the *order* in which assertions are to be tested (or, in a Post production system, the order in which rewrite rules are to be applied). That's decided by the human logician. Indeed, logically independent assertions (such as the various conjuncts within one long conjunction) could in principle be considered simultaneously. That's why many PROLOG programmers insisted that PROLOG, as an implementation of logic, provided declarative program specifications—not procedural programs. (Hence my reference to "the blurb".)

It gradually became clear, however, that it had to be thought of in both these ways. In trivially simple cases, to be sure, a PROLOG program could be seen as purely declarative. When there are only a few assertions to be tested, the order of testing won't matter. But a large PROLOG program (like a large PS) will include many individual items—and may require long chains of inference too. Random testing could take for ever and a day. Some ordering preferences must be followed—which is to say that some *procedural* information must be provided in the program. Eventually, as people realized the futility of this dispute, the language was judged more by a 'horses for courses' criterion. (Logic programming was *combined* with list processing in POPLOG, a programming environment widely used in the UK and Europe which integrated PROLOG with POP2: Hardy 1984.)

With respect to horses for courses, there was an embarrassment lurking in the undergrowth. PROLOG was logically elegant—indeed, logically reliable. But whether it was *practically* reliable was less clear. For as we saw in Section iii.b, resolution theorem-provers can't distinguish between *proving that X is false* (i.e. genuine negation), and *failing to prove that X is true* (i.e. negation by failure). The same applied, then, to any program written in PROLOG. However, there's a huge difference between these two types of negation (if you doubt this, read X as *my partner is having an affair*). If the program is doing theorem proving in a closed logical system, this may not matter. But the case is different for reasoning in 'open' systems, where one can't assume that all the relevant information is present. The use of PROLOG for real-world expert systems was therefore problematic.

This was pointed out very early on (K. L. Clark 1978). Even so, the Japanese adopted PROLOG enthusiastically in their Fifth Generation programme a few years later. Their assumption, apparently, was that every essential feature of the relevant specialist domain could be adequately represented in a PROLOG-based expert system—"adequately" for technological purposes, if not for Marcel Proust or for jealous lovers. (The adequacy of PROLOG for various *legal* purposes was discussed at length by Kowalski himself: Chapter 13.ii.c.) Soon, various people tried to provide 'real' negation, combining goal-directed user questioning with an underlying three-valued logic: *true*, *false*, and *don't know* (Aida *et al.* 1983; Edmonds 1986).

When Kowalski first implemented PROLOG, he used von Neumann machines. But the virtual parallelism of PROLOG—i.e. the logical independence of individual assertions—was in principle well suited to hardware parallelism. So when the Japanese committed themselves to PROLOG, they committed themselves also to developing a PROLOG machine, where the inferential methods of unification and resolution weren't programmed in, but implemented in the hardware. (In effect, logic was the *machine code* of the computer.) Today, PROLOG is still used—with or without PROLOG machines—by many people in AI.

10.vi. Child's Play

LOGO wasn't just yet-another-programming-language: it was more like a philosophy of life. And it had a fascinating life story of its own. It started in the 1960s, in a form so simple that it was easy for AI researchers to ignore. Around 1990 it metamorphosed into something radically different, and very exciting.

From the start, it brought Piagetian psychology into the world of programming, and (soon afterwards) programming into the world of child education. Eventually, it even helped to bring computing to Everyman, in personal computers like the one you may have sitting on your desk at home.

a. The power of bugs

In 1967, while his MIT colleague Hewitt was struggling to sophisticate LISP as PLANNER, Papert (1928–) was defining a new language, LOGO. This was specifically intended for use by children as young as 4 or 5 (Papert 1972, 1973). As such, LOGO needed to be both simple and intuitively accessible.

Accordingly, the virtual world it defined contained a "turtle" moving about on a CDU screen, according to the child's instructions. These were expressed in familiar terms such as FORWARD, BACK, STOP, TURN, RIGHT, LEFT, 5, 10, PEN UP, and PEN DOWN. And the human–computer interface had to be designed anew: instructions weren't given by typing, but by button pressing (how would a 4-year-old manage to type "FORWARD"?).

Very soon, Papert took a leaf out of W. Grey Walter's book (Chapter 4.viii.a–b) and implemented LOGO as a language for controlling robot turtles moving around the floor. (The first turtles were made in the AI Lab's workshop, but they were commercially manufactured from 1977, by Terrapin Software.)

Whether in the virtual (CDU) or the real world, LOGO turtles carried a "pen" which they could lower so as to leave a trace on the screen/paper as they moved. The possibility arose, then, of the child's defining routines and subroutines for drawing a SQUARE, a ROOF, a HOUSE, a MAN, a FACE, and so on.

Usually, the first attempts wouldn't work (see Figure 10.28). Perhaps the child, trying to draw a square, would tell the turtle to TURN. But should it turn LEFT or RIGHT? Often, the child wouldn't say, assuming that this was obvious (especially if the first turn had already been made). And how far should it turn? In a program for drawing a square, "TURN 90" was needed; for starting to add a roof, some other angle would be required. And PEN-UP would be needed if, having drawn the house walls, the child now wanted to add a door or a window. Otherwise, an unwanted line would mar the drawing.

All pretty trivial . . . ? For Papert, absolutely not. The object of this playful exercise was education, not meaningless play—and education not in drawing houses but in self-critical, creative thinking *in general*. As he put it, he was concerned less with mathematics than with *mathetics*: "the set of guiding principles that govern learning" (Papert 1980: 52). In other words, he was doing cognitive science, not technological AI.

His five years with Jean Piaget in Geneva had convinced him that learning comes about by *construction*, not *instruction*. That is, the child's interactions with objects in

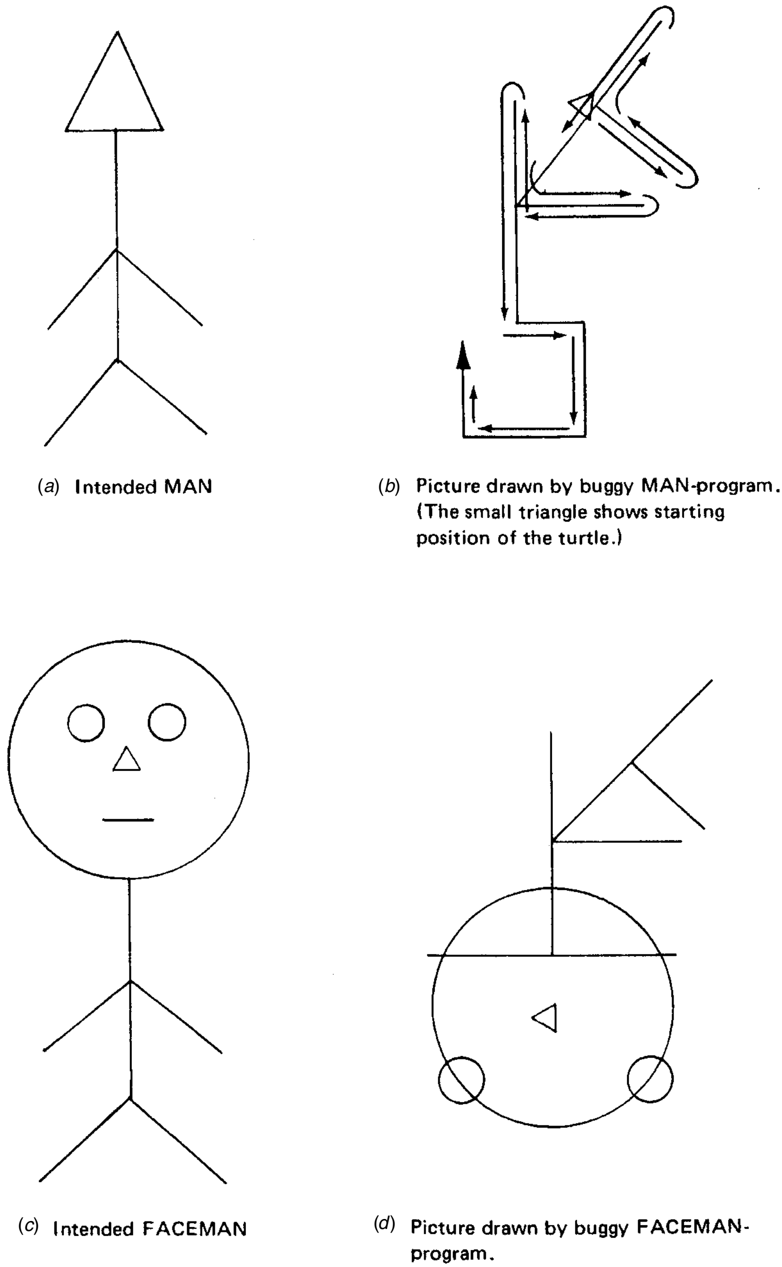

Fig. 10.28. Drawings done by children's LOGO programs. Reprinted with permission from Goldstein (1975: 250)

the world (and virtual worlds) enable him/her to construct problem-solving schemata, which become increasingly well adapted to the task as a result of active reconstruction prompted by errors (Chapter 5.ii.c). So Papert relied on the child's own exploratory activities to foster progress through constructive (*sic*) self-criticism, perhaps aided by a sensitive teacher.

A key idea was "powerful ideas": concepts that would help the child (and his/her teacher) to understand what's involved in thinking. Perhaps the most powerful idea of all was *bugs*.

Bugs are errors. But they're errors of a very special kind. Because they occur in programs, they're in principle both recognizable (as Lovelace had realized: see 3.iii.b) and correctable. In addition, they're displayed by the (non-judgemental) computer, rather than being pointed out by a (possibly scornful) human teacher. As illustrated in Figure 10.28, Papert enabled children to use their own buggy programs to gain insight into their thinking processes, and thereby to improve them.

One mid-1970s MIT project aimed to devise a computer program to play the role of the teacher. So Ira Goldstein's MYCROFT used general ideas about debugging, like those already being used in HACKER, to evaluate and correct *drawings done by computers programmed to draw by children* (Goldstein 1975). Given a mismatch between the intended and actual drawings, MYCROFT would inspect the child's program to locate the bugs. But it wouldn't merely spit out a corrected program. (The child probably wouldn't learn much if it did.) Rather, it would analyse the faults in relation to specific bugs, which the child might learn how to correct—and how to avoid—in future. For instance, if one starts to draw a man (as in Figure 10.28*b*) by drawing the two legs splayed out from the starting point, one will have to insert an extra orienting step before starting on the body. Otherwise, as in this buggy picture, the body will be aligned with the second leg instead of being at an angle to it.

Reorientation bugs *in general* involve the failure to restore some previous state of affairs so as to continue with the next main step of the procedure. They occur in all sorts of contexts, not just in drawing. Papert's hope was that LOGO-based experience, whether with MYCROFT or with a human teacher, would help children to recognize—and avoid—common bugs in many different domains, as well as increasing their self-confidence by 're-educating' their attitude to error.

His own writings, and those of his adherents, abounded with anecdotal evidence that this was so (e.g. Papert 1980; Howe *et al.* 1980; Weir 1987). As a result, LOGO in some form (including LEGO/Logo: see below) was being used "in about one-third of the elementary schools in the United States" by the mid-1990s (Resnick 1994: 26).

However, some careful 1980s attempts to assess the educational value of LOGO programming were ambiguous. The effects were there, to be sure—but they were neither so strong nor so generalizable as Papert had hoped (Pea and Kurland 1984; Kurland *et al.* 1986; Pea *et al.* 1987).

Today's verdict, after many empirical studies (focused on other programming languages as well as on LOGO), is that positive effects depend on the extent to which the instructions, and the teachers' comments, stress *metacognition*, or thinking about thinking. Merely teaching children to program, without such metacognitive encouragement, doesn't necessarily help them to develop transferable thinking skills.

The Harvard educational psychologist David Perkins, who'd been familiar with Papert's work from the start, reviewed the literature and concluded:

> Originally, one might [like Papert, and others too] have thought of programming as a kind of cognitive playground; mere engagement in the activity of itself would exercise the mind as real playgrounds exercise young bodies, without any need for *instruction finely tuned* to provoke such consequences. Unfortunately, the research argues against such a vision.
>
> Instead . . . certain inconvenient conditions must be met. [These include huge time commitments for practice, and significant programming expertise on the part of the teacher.] Taken together, these points suggest that the *straightforward* teaching of elementary programming is not a very good way to foster cognitive skills. (Salomon and Perkins 1987: 163–4; italics added)

Some twenty years later, his judgement remains unchanged (D. N. Perkins, personal communication).

b. Complication and distribution

Even in the 1970s, LOGO wasn't restricted to drawing-with-turtles. For instance, Harold Abelson and Andrea diSessa (1980) showed how LOGO could be used to teach children about other types of mathematics, such as spherical geometry and algebraic vectors—and the laws of physics, too. Part of the interest here was that a law of physics could be deliberately varied, or omitted, and the result would be visible on the CDU screen.

In today's terminology, the children were constructing a virtual reality whose behaviour one could actually *see*. But because the computer graphics used by Abelson and diSessa were so minimalist, these imaginary physical worlds couldn't begin to compare with what we now think of as VR (13.vi).

The 1980s saw the addition of list processing to LOGO. This suited it, for instance, for helping children to learn writing skills (Friendly 1988). Also in the 1980s, Papert added *real* bells and whistles. In other words, he helped the LEGO toy company to design special sensors and actuators to be connected to LEGO components (Resnick 1994: 24–31). The sensors could respond to touch, infra-red, and light; and the actuators included gears, pulleys, wheels, motors, and light switches. Using this LEGO/Logo construction kit, children could build/program their own machines. These ranged from toy cars through ovens to robots—with Valentino Braitenberg's lifelike "vehicles" in between (15.vii.a).

Still more was to come. In the 1990s, LOGO was hugely improved/expanded so as to be suitable for 'real' AI programming (B. Harvey 1997). In addition, a parallelist version called StarLogo was developed towards the end of the century (Resnick 1994: 31–47; Colella *et al.* 2001).

StarLogo provided a high-level language whereby *thousands* of turtles (agents) could be simulated simultaneously. Each one had its own "program", in the form of a set of rules about what to do in various situations. These rule-sets could be identical in every agent, or there might be several different rule-sets distributed (equally or unequally) across the population. Think of a beehive: there's only one queen, but there are many workers and drones. Queen, worker, and drone follow very different rules, live very different lives. And the entomologist can study the overall organization within the beehive, as well as studying the behaviour of individual bees.

In a StarLogo program, each little local environment ("patch"), too, could execute StarLogo commands. So it could grow more 'food' in certain circumstances, for instance, or release 'chemicals' towards neighbour patches at various rates. As a result, the user could model *interactions with and within* the environment, as opposed to *agents' actions on* a passive environment.

In short, StarLogo gave people a way of studying *distributed* systems. These are made up of many autonomous agents—which may be very simple, or relatively mindlike (see 13.iii.d–e and 15.viii–ix). They're all around us: not just beehives, but traffic jams too. But being ubiquitous doesn't make them easy to understand.

StarLogo might even be called the first postmodernist programming language. It's not that postmodernists are enamoured of traffic jams, or less anxious than the rest of us when near a beehive. But, as we saw in Chapter 1.iii.d, they eventually progressed beyond their counter-cultural predecessors of the 1960s–1970s (whose rejection of computer-grounded psychologies was total) by warming to certain types of computational psychology and AI/A-Life: namely, those focused on distributed systems. Much as heterarchy was more politically congenial than hierarchy (see iv.a, above), so cooperation between autonomous individuals was more acceptable—and also more veridical—than rigidly other-directed behaviour.

c. Pointers to the future

The children hadn't dropped out of the picture. Far from it.

On the one hand, they could use StarLogo too. And in playing (*sic*) with it, they could, for the first time, get an intuitive sense of the behaviour of distributed systems.

On the other hand, Papert's passion for child-friendly computing had helped lead to technologies without which many children's lives today—and probably yours, too—would be very different. Namely, user-friendly interfaces and virtual reality. In other words, Papert's work was crucial in turning the futuristic visions of Bush and Engelbart into everyday realities.

But that's a story for a later chapter (13.v–vi).

11 OF BOMBS AND BOMBSHELLS

NewFAI didn't excite only its practitioners: it electrified plenty of other people as well.

Some were cognitive scientists: psychologists, linguists, and philosophers enthused by NewFAI's promise of turning *mind-as-machine* from a metaphysical slogan into a scientific research programme. Their excitement was raised almost to fever pitch by the consciousness-raising meetings of the late 1950s (see Chapter 6.iv). But some were vociferous opponents, fiercely scornful of any such idea—and worried about AI's technological potential, to boot.

This wasn't a private fight: virtually everyone could join in. In other words, the critiques came largely from journalists, social commentators, and the general public. As we'll see, their passionately held views had important (and usually damaging) effects on the intellectual advancement of AI and related disciplines.

Early connectionism, too, met opposition—but this came only from AI insiders. It sometimes aroused passions, to be sure. Indeed, a major scandal ensued within the field when Marvin Minsky's mid-1950s criticisms in 'Steps . . .' were brought to a head in 1968 (Chapters 10.i.g and 12.iii). But outsiders knew little or nothing of that. Their sights were set on the symbolic footpath, not the cybernetic one (1.ii.a). In essence, that was because it was symbolic AI which claimed to represent specific propositional content, and rational thought (4.v.d and 10.iii.a).

(In the 1980s, when connectionist AI became more widely known, some of the public opposition to NewFAI was generalized to cover that as well. Only "some": many members of the public were seduced by the connectionist propaganda machine—see Chapter 12.vi–x.)

The opposition to AI, and to cognitive science in general, was both theoretical and political—sometimes, closely interrelated. Mostly, it came from critics proud to be outsiders, and anxious to distance themselves from computational ideas in any way possible. But basic criticism occasionally came from insiders as well—arousing no little glee in the outsiders, of course.

Between the mid-1960s and the mid-1980s, a number of fundamental challenges arose which affected symbolic AI's practices and public relations—and which spilled over to some extent onto cognitive science as a whole. Each of them, to a greater or lesser degree, illustrates the claim made in Chapter 1.iii.a, that the Legend of wholly disinterested science is a myth. We can think of these challenges in terms of (literal) bombs and (metaphorical) bombshells.

"Bombs", because the US military's view of the psychology of decision making and rationality (Chapter 6.iii.a–b), and especially its sponsorship of AI technology for weapons and strategic planning, troubled many people. As the bombs got nastier, the opposition got more pointed. In the 1980s, when the bombs had become very nasty indeed, and the governmental decisions about their use increasingly irrational (by common-sense standards), the AI researchers themselves made concerted efforts to counter these lunacies. The bombs are discussed in Section i.

As for "bombshells", by my count there have been nine of those. For a criticism to qualify as a bombshell, it didn't have to be correct: some were, some weren't. But it did have to be so widely accepted by the general public and/or those holding the purse-strings for research funding that the field was undermined, or at best temporarily held back. The one exception to this was the early 1980s bombshell from Japan, a challenge which invigorated AI instead of damaging it (Section v, below).

The earliest bombshell of all has been described already: a US government committee report of 1960 that paralysed the funding of machine translation (MT) in the West, recovery coming only years later (see 9.x.f). (AI *as a whole* wasn't severely damaged by that particular blast, because the pioneering AI labs at MIT, Stanford, and Carnegie Mellon weren't doing MT: it's no accident that none of the "harbingers" of Chapter 10.i discussed it.) The latest, namely "situationism" AI, will be discussed in Chapters 13.iii.b–e and 15.vii–viii and xi. (The dust from that one is still settling.) So that leaves seven to be covered here.

Three philosophical bombshells, only one of which was detonated by a philosopher, are highlighted in Section ii, below. They were aimed at symbolic AI and cognitive science. Their original target was NewFAI-based work, but each was—and still is—directed also at later research.

Next, in Section iii, we'll consider an admonishment demanding better intellectual hygiene in AI—again, initially aimed at NewFAI but still sometimes needed today. Sections iv and v outline the effects, for both GOFAI and connectionist work, of an explosive charge from 1970s England, and of another (ten years later) from Japan: namely, the Lighthill Report and the Fifth Generation project.

Finally, Section vi identifies the early 1980s development that devastated some parts of the field (at least in the public eye) while clearing obstacles from others. That ultra-brief section heralds Chapter 12, in which this parcel of connectionist dynamite (whose fuse had been smouldering since mid-century) is described at length.

11.i. Military Matters

Mathematical research has long been exploited for military purposes. Even Archimedes was persuaded by King Hieron of Syracuse to put his beloved geometry to practical use (Chapter 2.i.a). That's why he designed the ship-destroying crane, and other weapons aimed against the besieging Romans in 212 BC. Nearly 2,000 years later, much the same thing was happening. But now, as well as geometry, there was AI.

AI's precursor, cybernetics, had already been used for urgent military purposes in the Second World War (4.vii.a). The techniques made available by AI as such could serve an even wider range of military purposes, involving reasoning as well as missile tracking.

This section outlines how the military helped give rise to NewFAI, and how the ups and downs of defence spending were reflected in changes in support for AI in general. Connectionism wasn't immune: as we'll see in Chapter 12.vii.b, DARPA's mid-1980s decision to fund it was driven by their hope for "next-generation, fire-and-forget, autonomous weapons" (DARPA 1988, p. xxv).

(Now, in the post-9/11 world, the military are expecting even more from AI. Reporting a significant rise in technical papers submitted to the 2005 'Innovative Applications of AI' (IAAI) conference, a journalist noted that "Various strains of AI are viewed as critical to homeland security, antiterrorism, and emergency response. Governments are allocating huge amounts of funding for AI research"—Hedberg 2005: 12. And in Europe the journal *IEEE Intelligent Systems* devoted a special issue to 'Artificial Intelligence and Homeland Security' in autumn 2005. One ludicrous result of this situation was a widely cast military request for predictive models of the emotions of terrorists: see Chapter 7.i.f.)

Cognitive science was often affected too. By the early to mid-1960s, for instance, even 'straight' linguistics and cognitive psychology were being generously funded in the USA for defence-related reasons, including the national loss of face caused by the 184 pound Sputnik in 1957, and the Soviets' space dog Laika, sent into orbit in Sputnik-II a few months later (6.iv.f; see also Koerner 1989). Of course, Sputnik didn't represent only loss of face. Potentially, it presented a military threat (so prompting the formation of ARPA, as we'll see): spies, and worse, in the sky.

As we saw in Chapter 2.ii.c, science depends on wealthy philanthropists of some kind. Today, AI is supported by many different institutions. These include academic grant-givers such as the USA's National Science Foundation and the UK's various research councils, and major charities like the Rockefeller and Nuffield foundations. But such is the wide range of AI applications that funds are available also from many governmental departments, and from private businesses—some of which have in-house AI teams.

Military and space-related sources (such as RAND, NASA, and Lockheed) are of course included. But war-related funding was even more important half a century ago. Indeed, *all* post-war scientific research was heavily in debt to the military. In 1947–50 the USA's Office of Naval Research alone was funding half of all the sponsored science being done at MIT (Mirowski 2002: 200). Ten years later, NASA too was a prime sponsor. Formed by President Eisenhower in July 1958 as the Aeronautics *and Space* Administration (replacing NACA: the National Advisory Committee on Aviation), this was a speedy—not to say panicked—response to the two Soviet Sputniks of a few months earlier. Where NACA's budget had been a mere $117 million, for 8,000 people, NASA soon received $6,000 million (for a staff of 34,000). Inevitably, some of that munificence would reach the universities—perhaps not for research in medieval poetry, but certainly for engineering and computing, and for cognitive psychology too.

This fact not only made AI possible, but to some extent affected the topics it chose to study. Only *to some extent*: even Noam Chomsky, no friend of the military, has allowed that "When MIT was funded maybe 90 per cent by the military it had no constraints on what it should do. As it has moved from the Pentagon to corporate funding there are more and more constraints" (quoted in Swain 1999: 28–9). (After 1973, this liberal attitude on the uses of military funding was tightened up: see below.)

In addition, AI's dependence on military funding, and the military support for computational psychology too, influenced public attitudes towards both fields.—Rarely, of course, for the better.

a. Nurtured in war

Warfare was part of the context even when NewFAI was merely a twinkle in Alan Turing's eye. Computer technology as such, and cybernetic control-systems too, were first developed for military ends (Chapters 3.v and 4.vii.a).

The Harvard Mark 1, for example, was largely funded by the US Navy. Howard Aiken was a commander in the US Naval Reserve, and Grace Hopper a lieutenant—later, an admiral. And the ENIAC was built for the US Army, via their Ballistic Research Lab in Maryland. (Unusually, the military resources were limited, for resistors were very hard to find; the ENIAC was ready on time only because someone discovered that one of the manufacturers had bins full of rejected samples, rejected not because they were physically faulty but because the colour markings were wrong—M. V. Wilkes 1982: 54.)

(Today, things haven't changed as much as one might think. "The most powerful publicly admitted [*sic*] computer in the world" in 1997 was mainly used for "*in silico* nuclear weapons testing"—J. M. Taylor 2001: 168. As for software, a single project was said by DARPA's director to have paid back "the entire investment that ARPA had made in artificial intelligence since the beginning"—namely, the conversion of an ARPA-sponsored program written for factory scheduling into a logistics aid for moving soldiers, tanks, etc. in the first Gulf War—Shasha and Lazere 1995: 220. And one doesn't have to be employed by the military to join in. In 2003–4 DARPA announced a cash award of $1 million for the first team whose autonomous vehicle could cross Death Valley, from Los Angeles to Las Vegas, within a specified time—DTI 2004: 34. If the prize is won by a gaggle of pacifist garage tinkerers, so be it: DARPA's intent is to use whatever ingenuity they can find, to accelerate a technology that could be used for military purposes.)

The one exception to the military dominance in early computing was the series of computers designed in pre-war Germany by Konrad Zuse (Chapter 3.v.a). By 1941, these included an operational version of the Z3: in effect, a stored-program von Neumann machine, capable of floating-point arithmetic—and potentially of 'semantic' computing too.

Fortunately, the German military (although it had partly funded Zuse's research) turned out to be interested in neither. Soon after being conscripted into the army in 1941, Zuse asked for leave to work on his machine (which could be used to calculate matrices predicting wing flutter in aircraft flying at different speeds). His application was supported by a letter from a respected professor. In his autobiography, he recalled the result:

> The Battalion commander, a major, summoned me, first informed me that as a completely new soldier I had no right to take leave anyway, and continued "What does it mean here [in the letter] when it says that your machine has applications in aircraft construction? The German *Luftwaffe* is top-notch, what needs to be calculated there?"—What was I to say to this? How could I have responded to this? Permission denied. (Zuse 1993: 56–7)

Zuse's cryptographic skills went to waste too: his work on coding wasn't needed, he was informed, because the Germans had the Enigma machine. (If he'd been told that Turing was already breaking the Enigma code, he'd have been as surprised as the major—not least, because he hadn't yet heard of Turing.) Instead, he was put to work on weapons development: the successors to the flying bombs that ravaged London in the last years of the war.

It was said later that when Adolf Hitler was told of Zuse's invention "he replied that he didn't need any computing machine, he had the courage of his soldiers" (Zuse 1993: 81). Zuse never learnt the truth about that titbit: "Fact or fiction?—It was a time of rumors." But it's clear that computing wasn't high on the German military's agenda.

Things were very different across the Channel, and across the Atlantic too. After the Second World War ended, the urgency had gone. And so had much of the money—but by no means all.

Whereas US defence spending after 1918 dropped to a minimum, in the post-1945 period it dropped only to just under half (see the graph in Molina 1989: 11). Money was still needed, the powers-that-be decided, to deal with the military challenges posed by the Cold War: e.g. the Berlin blockade of 1948, the Chinese revolution of 1949, the first Soviet A-bomb test (also 1949), and the Korean war in 1950–1. That war caused defence spending to peak again, and although it did sometimes decrease it never returned to the low post-1945 level.

During the 1950s, AI was getting off the ground. War-related funding was crucial (Edwards 1996, chs. 2 and 8; Mirowski 2002: 161–90). Some of the money was spent on obviously military applications. As early as 1953, for example, the US military asked a budding NewFAI scientist (Alex Bernstein) to try to simulate Washington DC's missile air defence system (McCorduck 1979: 154). But much of it was spread more widely.

For instance, mid-1950s MT research in the UK, USA, and Soviet Union was being funded by military bodies. The US Navy, as we've seen (Chapter 9.x.a), was supporting British MT work focused on such blamelessly pacific sentences as *agricola incurvo terram dimovit aratro*. That may seem odd—but if one could translate sentences about farmers and ploughs, one could probably translate sentences about admirals and battleships as well. And while the Navy was sponsoring descriptions of the ploughing farmer, and Frank Rosenblatt's perceptrons too (12.ii.f), one of its sister services was developing "techniques of air warfare" at the RAND Corporation.

RAND—the acronym stands for Research ANd Defence—had been founded in 1946 by the US Air Force (with Douglas Aircraft, who dropped out two years later). The aim was to apply game theory and systems analysis (developed during the Second World War) to weapons design and to nuclear strategy. Throughout the 1950s, its computation and software development centre was one of the largest in the world. For computers were *essential* to RAND's purposes: planning for nuclear warfare could be done only by simulation. In addition, RAND employed psychologists and other social scientists to improve the efficiency of the human beings in warfare's technological loops. So Allen Newell and Herbert Simon were (separately) hired to focus on air defence simulations and game-theoretic/bounded-rationality models of warfare, respectively (Chapter 6.iii).

At the end of the 1950s Paul Armer, then heading RAND's Computer Science Division, wrote an influential survey-cum-prospectus of AI (Armer 1960/1963). This was published not by an academic journal, but by the Wright Air Development Center

(Wright, as in Wilbur and Orville). That wasn't surprising, given RAND's Air Force roots. A full third of the paper was devoted to Russian attitudes to AI (these were divided, as they were in the West), and to the Russian research that was going on in the area.

Clearly, and unsurprisingly (given the global reach of the Cold War mentality), there was a good deal of that. One Soviet scientist had remarked (speaking in English) that simulating the brain with a computer was "*the* number one problem"—and, said Armer, the emphasis was clear in his intonation (p. 402). The Russians were already discussing "chess playing by machines, and the deciphering of ancient Mayan manuscripts" (p. 404). Trivialities, perhaps, like the ploughing farmer. But Armer made it very clear that he agreed with the President of General Dynamics Corporation that "if the area has real military or psychological value to them, they'll put massive concentration on it" (p. 404).

In that, of course, the Soviets weren't alone. Defence spending in the USA tracked the national politicians' view of military threat. After Korea there were several more peaks:

* one in the post-Sputnik and Cuban missile era,
* one linked to Vietnam (where US involvement lasted from 1965 to 1973),
* and one—in 1992, still rising—in connection with President Reagan's military programme of the early 1980s (see Figure 11.1).

Some of this money went on building more bombs. But much of the R & D tranche was spent on the development of information technology—primarily hardware (including $3 million from DARPA for the ill-fated Connection Machine: Hillis 1985), but also

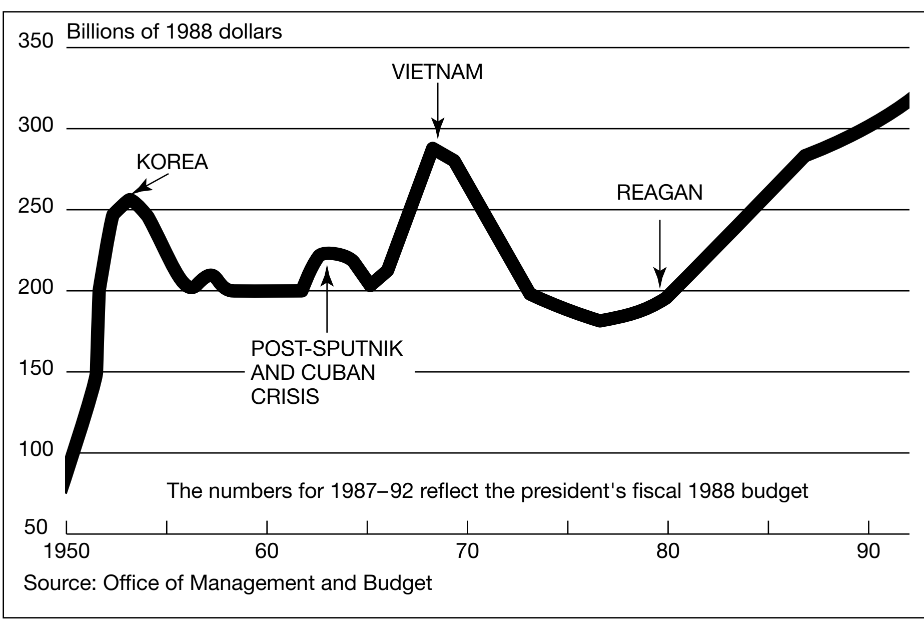

FIG. 11.1. Total volume of defence outlays in the USA (1950–early 1990s). Constant 1988 dollars. Redrawn with permission from Molina (1989: 17)

software. Indeed, creating new sorts of bomb required a huge investment in new computers, and in new ways of using them. (For some fascinating, if frightening, details, see MacKenzie 1991*a*,*b*.) In effect, the microelectronics industry we take for granted now was developed by the military. It was RAND's 1950s efforts in computer building, for instance, which led IBM—despite Thomas Watson's early scepticism (2.iv.c)—to decide to manufacture digital computers (Edwards 1996: 122).

The vicissitudes of the Department of Defense's (DOD's) budget, and especially the early 1980s funding rise (subsection c, below), also influenced the development of AI. One change—not in the amount of money, but in its favoured recipients—was due to the Mansfield Amendment of 1970: ARPA's annual budget of $26 million for information-processing research was now directed only to *military* applications (Chapter 6.iv.f). But various other changes affected the *amount* of money available. The course of US government funding for mathematics and computer science (i.e. excluding the bombs, as such) is shown in Figure 11.2.

b. Licklider as a military man

In the 1950s and early 1960s, military aims—and therefore funding—were already suspect to some people. Probably most, however, considered them respectable—after all, military efforts had recently saved the world from Nazi/Imperial-Japanese domination.

AI benefited hugely from that fact, not least because Joseph Licklider was in the second group:

I had this little picture in my mind of how we were going to get people and computers really thinking together. [And I thought that] "command and control essentially depends on interactive

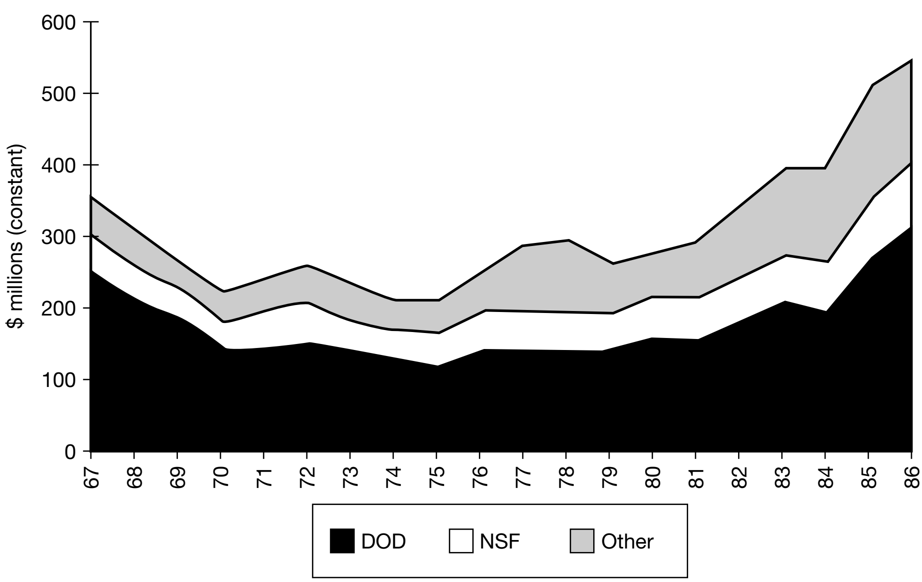

Fig. 11.2. Federal funding for mathematics and computer science, 1967–86. Data: Flamm (1987: 46). Redrawn with permission from Edwards (1996: 283)

computing [i.e. time-sharing] and there isn't any interactive computing so the military really needs this". *I was one of the few people who, I think, had this positive feeling toward the military.* It wasn't just to fund our stuff, but they really needed it and *they were the good guys.* (Edwards 1996: 267; italics added)

Today, Licklider is widely remembered as the prime sponsor of the technological advances in computer communication that led from the pioneering ARPAnet (first suggested in 1967) to the Internet (Waldrop 2001). Besides providing the money, he'd also provided the vision—in his influential essay on 'The Computer as a Communications Device' (Licklider and Taylor 1968). But what's more relevant here is that he had a crucial formative influence on AI in its earliest days. So his attitude to the military mattered.

ARPA had appointed him the first director of their information-processing section in 1962 (see Chapter 5.iv.f) largely because of his visionary 'Man–Computer Symbiosis'—which cited several early AI programs, both symbolic and connectionist (Licklider 1960). One historian has said that this paper "rapidly achieved the kind of status as a unifying reference point in computer science (and especially in AI) that *Plans and the Structure of Behavior* [see 6.iv.c], published in the same year, would attain in psychology" (Edwards 1996: 266). It wasn't a detailed review, orienting future AI research. That place was held by Minsky's 'Steps'. Rather, it was a vision of some potential *applications* of AI.

The 'Symbiosis' paper forecast the use of interactive (time-sharing) AI systems as assistants to human beings in many situations—explicitly including military command and control, where real-time functioning is often crucial. The idea of time-sharing had come from John McCarthy. Indeed, Licklider confessed to having undergone "a religious conversion to interactive computing" as a result of McCarthy's lectures at MIT (Edwards 1996: 264).

He'd been influenced also by McCarthy's harbinger paper of 1959 (see 10.i.f). Although the computers would provide speed and accuracy and the humans flexibility and common sense, he insisted that the contributions of the two sides couldn't easily be teased apart (hence, "symbiosis"). For instance, he said, theorem-proving programs could learn from experience (as McCarthy had suggested), and the SAGE program could suggest courses of action which the human being may not have considered.

SAGE was an ambitious *military* program, whose interface had been designed by Licklider himself (Edwards 1996, ch. 3). The interface was almost the first in which information was shown on a VDU; and different graphic displays could be brought onto the screen by touching it with a lightpen. Licklider's experience as a psychologist of perception was being put to good practical use.

SAGE was the first large computerized system for "C3": command, control, and communications. The "SA" in the acronym stood for Semi-Automatic, marking the man–machine symbiosis he'd recommended. (The "GE" stood for Ground Environment.) The machines, in this case, included a line of radar stations in Canada—and used as much power as a small city (J. McCarthy, personal communication). In other words, SAGE was the 1950s predecessor of the fully automatic "Star Wars" of the 1980s (see subsection c, below).

When Licklider joined ARPA, it was only 4 years old. President Eisenhower had set it up early in 1958, in a near-panic response to the Soviet Union's Sputnik (launched just a few months earlier, in October 1957). Some scientists feared that this political panic would sideline non-military research, or even squeeze it out of consideration—and funding—altogether. For instance, the Stanford biologist Joshua Lederberg recalls:

> Starting with the observation of Sputnik . . . I had set out [in late 1957–early 1958] to assure that fundamental biological science was properly represented in the programs of space research that were just emerging. *The danger was that scientific interests would be totally submerged by the international military and propaganda competition.* They have never gained first priority; they might have been totally excluded. (Lederberg 1987: 17; italics added)

Given Licklider's background (not to mention the benefit of hindsight), it's not too surprising that he also appreciated "fundamental" scientific interests. And where Licklider led, ARPA (and ARPA's money) followed.

ARPA's newness was one reason why Licklider was able to have such a seminal effect on the organization's policy. Another is that, as a member of MIT and as one of the Macy participants, he was already close to many other cyberneticists and budding cognitive scientists. Besides Donald Hebb, whose *magnum opus* he'd commented on in draft (Chapter 5.iv.f), these included Norbert Wiener, Jerome Lettvin, Warren McCulloch, George Miller, McCarthy, and Minsky (and many others too—Edwards 1996: 263–4). Indeed, his long-standing links to Minsky would be wryly remarked by many people when DARPA funds for connectionism dried up in the late 1960s (Chapter 12.iii.e).

On his appointment to ARPA, Licklider funded not only time-sharing (which he'd helped design: 10.i.h) but also AI—including psychological AI (Licklider 1988). He'd started out as a psychologist himself, working alongside Miller on speech and psychoacoustics; and he helped to design the HEARSAY speech-processing project (Newell *et al.* 1973). Indeed, he'd set up MIT's first Psychology programme in the late 1940s. If that hadn't been so, early AI would probably have been very much more "technological" in aim than in fact it was.

He soon sponsored MIT's ambitious Project MAC, launched in 1963. The acronym was spelt out sometimes as Man And Computer, sometimes as Machine-Aided Cognition, and sometimes as Multi-Access Computing—i.e. time-sharing. Project MAC's funding was exceptionally generous: $2 million as the start-up sum, and $3 million for each of the following years. The young AI Lab at MIT benefited to the tune of nearly $1 million. (All in early 1960s values.)

In addition, Licklider funded the first four US graduate programmes in AI—at MIT, CMU, Stanford, and SRI. For the next fifteen years, he continued to provide large amounts of money to these four groups, his attitude being that ARPA money should go to the people he knew to be excellent scientists (see 10.ii.a). Unlike the more 'academic' National Science Foundation (NSF), ARPA didn't have to function via peer review. In effect, this was an old-boy network from his days at MIT and Bolt, Beranek & Newman: the favoured few—notably, Minsky and McCarthy (and Newell and Simon)—were given the money and left to get on with it.

If Licklider retained his faith in the military as "the good guys", many members of the general public didn't. The military's respectability was soon undermined, in their eyes. This was one aspect of the counter-culture that emerged in the late 1960s, and which was strengthened by the psychological aftermath of warfare and US defeat in Vietnam (1.iii.c).

Although the US politicians stopped well short of wearing flowers in their hair, they did listen. In the mid- to late 1970s, there was less money available for R & D in America. MIT, for example, suffered financial difficulties across the whole institution as a result (see 14.vi.a).

To be sure, this situation was largely due to OPEC's sudden tripling of the oil price in 1973. Further price-hikes followed: in a ten-month period in 1974, the price of a barrel of oil rose 228 per cent (Boal *et al.* 2005: 14). But in addition, a greater proportion of the R & D tranche was socially directed. For a "new set of demands and values" was in play, in reaction against those which had previously driven technological development (Molina 1989: 24). An important part of the counter-cultural movement was:

> [a] critique of the social consequences of unfettered technological development, ranging from the environmental damage caused by the side-effects of modern science-based production processes to the use of sophisticated electronics in the war in Vietnam. (Dickson 1984: 30)

As a result, defence expenditure declined (as a percentage of GNP, it dropped from 2.9 to 2.3—Molina 1989: 24). This meant, among other things, that there was less money available for AI research. A very cold wind was blowing: ARPA's cutbacks to AI funding in 1974 had several "two-million-dollar-a-year contracts cut to almost nothing" (Hans Moravec, interviewed in Crevier 1993: 117). And ARPA cut back its support of *basic* research still further, accordingly (*THES* 1975).

But that state of affairs didn't last. By the late 1970s, the "new set of values and demands" had been sidelined by the economic crisis that followed the recent oil shocks. One historian of technology says:

> *[The counter-cultural] demands for greater social responsibility and accountability in the development of science and technology were superseded.* Such demands could not provide an impetus similar to war or international competition—either politico-military or economic. This period of socially-aware demands was a time of little growth for the R&D system. As soon as the spectre of the Vietnam defeat began to fade, replaced by alarm at the economic crisis, war and international competition began to reassert themselves and, with them, the same dominant social interests [namely, those of the scientific, corporate, and military elites]. (Molina 1989: 26; italics added)

By the early 1980s, then, American R & D in computing was rising steeply again, largely due to increased defence spending (see subsection c).

The AI community benefited, not least because part of the DOD's agenda was to advance US information technology *in general* so as to meet the Fifth Generation challenge (Molina 1989: 76–7; see v.a–b, below). The politicians were persuaded to authorize the vast sums involved partly because of fears that the USA's economy would be outstripped by Japan in the coming information age (Roland and Shiman 2002). The $4 million provided to NASA in 1985 for space-related AI (which they'd been supporting at a lower scale since 1982) was justified not only by national pride with respect to the space race, but also by the expectation of technological spin-offs. The law passed by Congress to authorize this stated that "the development of [advanced automation and robotics] shall be estimated to cost *no less than 10 per centum of the total space station cost*" (Montemerlo 1992: 51; italics added).

By the late 1980s, the annual budget for NASA's AI research programme had risen to $13 million, and it stayed at this level until at least 1992. But not all of this new money had come in response to the Fifth Generation. Nor was it attributable to Licklider's efforts. Rather, it was the result of a highly controversial political decision.

As such, it wasn't welcomed by the AI community as a whole—as we'll now see.

c. Star Wars and AI qualms

Some members of the AI community had been wary of accepting military money from the start. Wiener had stopped all his military work in 1946, at the end of the Second World War (so Theodore Roszak's impassioned attacks on him had been partly misguided: see 1.iii.c–d). Unlike Licklider, they didn't see the military in uncomplicated terms as "the good guys".

Vietnam provided further ethical complications. And the burgeoning cruise-missile technology added yet more. Benjamin Kuipers (1949–), for instance, had been funded as a graduate student by NSF and "didn't think much about military funding and AI research at that time" (Kuipers 2004). On graduating in 1974, he accepted one year's funding from DARPA before changing from AI vision to AI in medicine: for DARPA, the only agency willing to fund his vision work, wanted to use it for developing better-targeted cruise missiles.

Kuipers (a conscientious objector during the Vietnam war: see ii.e, below) may have been more scrupulous than most. But ten years later, the ambivalence had spread—and deepened. The AI profession of the mid-1980s was highly uneasy about the project then gobbling up most of the generous AI funding. This was the "Star Wars" programme, or Strategic Defense Initiative.

Star Wars was announced on national TV by President Reagan himself, in March 1983. Immediately, DARPA was allocated $600 million—later rising to $1 billion—over five years to develop the computing required (Roland and Shiman 2002). (The similarly named Strategic *Computing* Initiative had already been planned by DARPA, as its response to Japan's Fifth Generation project. In the event, SCI was swallowed up by SDI: Edwards 1996: 298–9.)

Most of this huge sum of money, DARPA decided, would be devoted to five specific aims, each involving AI at its core (Edwards 1996: 296). These were an intelligent image-processing system, for battlefield reconnaissance; two AI battlefield management systems; an autonomous land vehicle for use by the US Army; and an intelligent fighter pilot's assistant, which would possess 10,000 words of English and be able to understand the pilot's speech even in a noisy jet cockpit.

You may smile, realizing the many impracticalities being blithely ignored. But in the geopolitical circumstances of that time, it wasn't funny. The least funny aspect of all was that man–computer *symbiosis* had virtually disappeared. The goal of Star Wars (or so people were told: see below) was to provide an AI shield to defend the USA—if necessary, by triggering machine-made attacks. So Star Wars computers would not only detect an imminent Soviet attack but would also deploy an *automatic* nuclear response. (Hence the DARPA director's assurance to a US Senator that "we might have the technology so he couldn't make a mistake", where "he" was the President of the United States, faced with the awesome decisions required in a nuclear confrontation—Edwards 1996: 71.)

This removal of the human being from the loop caused explicit opposition from AI scientists around the world. And from many others too—including Hollywood directors, literary theorists, sociologists, and philosophers. For instance, the hugely successful 1984 film *The Terminator* played on people's fears of failures in early-warning systems, as well as their distrust of AI technology in general (Edwards 1996: 22–6). And Donna Haraway's monitory *Cyborg Manifesto* was written at much the same time (Chapter 1.i.b).

But one didn't have to be a counter-culturalist to be sceptical. The historian Paul Edwards states that Reagan "did not bother to consult Pentagon analysts before announcing the plan", but that "had he done so, *most would have refused to support it*" (1996: 289; italics added).

Computer scientists, of course, were in a special position to understand the technical problems. They knew only too well that a program consisting of 10 million lines of code (which was what the Star Wars directorate was proposing) couldn't, in practice, be bug-free.

What's more, they knew that even a bug-free program won't always do *precisely* what it was intended/expected to do. All the standard programming languages were ambiguous. This applied even to the supposedly mission-critical Ada (named after Ada Lovelace), which the DOD in 1975 had insisted be used for any real-world military application. That is, a given instruction in Ada (or any other source code) could be translated in different ways by different compilers when it was run. And *concurrent* execution was often ambiguous too, in that the programming language left it open for the compiler to choose which instruction should be followed first (E. Robinson, personal communication). In time-critical real-world applications, this might matter.

Later, a very carefully defined subset of Ada, called SPARK, would avoid ambiguity entirely (Chapman *et al.* 1994*a*,*b*; Chapman 2001). In the 1980s, however, it was rife. Admittedly, this rarely (if ever) caused problems in practice. But many felt that launching nuclear weapons wasn't a context in which to take that for granted.

Over and above those highly general points, AI professionals had by then learnt some lessons. The days of the "ten years" hype were (mostly) over. They knew that many of the AI problems assumed by Star Wars protagonists to be solvable were intractable in practice, and perhaps even in principle. These included real-world examples subject to the frame problem, and the (proposed) automatic programming of complex and bug-free code. Moreover, they'd learnt that AI successes could often be derived only by heuristic programming, not by success-guaranteed algorithms. Where an inappropriate decision could have such dire effects, the essentially fallible nature of heuristics was more than a little troubling.

As if all that weren't enough, several failures in early-warning systems *had already happened*. In one case, an unusual (so hard-to-spot) fault in a 46 cent computer chip had caused the North Atlantic Defence (NORAD) computer to report a Soviet attack, and 100 B-52 bombers had been readied for take-off (Edwards 1996: 285). In another, a major alert had been caused by someone's forgetting about leap years when programming the calendar, needed for predicting when and where the rising moon would appear in the sky (H. Thompson 1984). If even something so straightforward as the calendar could be misprogrammed, how much greater was the potential for mistake lurking in the arcane science and mathematics built into nuclear warning devices. In one eighteen-month period (after NORAD installed new computers), there'd been no fewer than 147 false alerts—four of which had moved the US defensive forces one step closer to a nuclear response.

The public concern was so great that the US House of Representatives held two days of hearings in May 1981 on "Failures of the NORAD Attack Warning System". These hearings "revealed a long and mostly secret history of spectacular failures in the computerized . . . Ballistic Missile Early Warning System" (Edwards 1996: 284).

All this explains why, when US Vice-President George Bush (senior) visited England in 1985, he was greeted by a media campaign criticizing the technical assumptions implicit in the Star Wars project. That campaign included a letter signed by seventy British computer professionals, including some mentioned elsewhere in this book. At the same time, the British Computer Society organized several meetings to look into the military implications of computing.

Bush didn't have to go abroad to encounter such resistance. There was plenty of it at home:

> A pledge not to take SDIO [Star Wars] funding, in order not to support *the impossible fantasy* of effective nuclear defense, circulated widely on [US] university campuses. Thousands of scientists signed. (Edwards 1996: 289; italics added)

On both sides of the Atlantic, the recently founded CPSR (Computer Professionals for Social Responsibility) was one of many sources of professional criticism. CPSR gave strong backing, and publicity, to the computer scientist David Parnas (1941–). Besides running several pieces by/about him in their own newsletter, they sponsored a volume on *Computers in Battle: Will They Work?* (Bellin and Chapman 1987), in which one chapter was written by Parnas.

Parnas had been invited to give evidence on this question to the US Senate. In December 1985 he assured the senators that Star Wars *couldn't* be made to work. Moreover, he said, since mistakes were so likely and their effects so horrendous, it shouldn't even be attempted.

His evidence was especially weighty because he'd been deeply involved in defence-sponsored projects. He'd done eight years' study of real-time software to be used in military aircraft, and from 1979 to 1982 he was head of software engineering research for the US Navy. So far was he from having any *political* axe to grind in these matters, that in June 1985 he'd accepted the US government's invitation to join their top advisory group on the computing aspects of Star Wars (the SDI Committee on Computing in Support of Battle Management).

Soon after the committee's first meeting, however, he'd resigned. He published his letter of resignation (with eight brief explanatory appendices), which later formed the basis of his Senate testimony (Parnas 1985*a*,*b*, 1986, 1987; cf. D. B. Davis 1985). So Parnas's protest wasn't a principled anti-militaristic, or even anti-nuclear, one. Rather, it was pragmatic: war is sometimes necessary, and so are nuclear weapons—but *this* military strategy was just too dangerous to use.

(This all seems so obvious. So why didn't Reagan listen? Why didn't he halt Star Wars forthwith? Indeed, why had he suggested it in the first place?—One common answer is that its being "an impossible fantasy" didn't matter, because the primary aims weren't military at all. Rather, they were political and ideological: Reagan intended to bankrupt the Soviet Union, which would be bound to try to respond in kind even though it couldn't afford to do so. Whether it was his original intention or not, that's what happened. With the fall of the Berlin Wall in 1989, and the break-up of the USSR soon afterwards, the political "need" for Star Wars disappeared. The fear lessened—and, as one might expect, the Federal money available for AI lessened too.)

d. *Les mains sales?*

Given the insuperable technical difficulties detailed by Parnas and others, and the huge risks to humanity implied by the nuclear dimension, it was easy for AI scientists to disapprove of Star Wars. As in the case of Parnas himself, one didn't have to hold an especially subtle and/or left-wing moral–political position to want to have nothing to do with the project. And it was relatively easy—at least for those employed by universities, and/or those outside the USA—to refuse to accept grants for work that was directly, explicitly, related to Star Wars. But deciding on one's position with respect to military work *in general* was more tricky (Ladd 1987).

Some individuals accepted money only for military research that was relatively benign in intent. After all, autonomous vehicles could prevent human soldiers from getting killed, as bomb-disposal robots do. (Several decades later, the title chosen for the 2006 International Conference on Automation and Robotics, which dealt with "demining, search/rescue missions, homeland security . . . etc.", was 'Humanitarian Robotics'.) Some, such as Kuipers (a Quaker), refused to work on any military projects. However, others objected that for non-pacifists to do that was as squeamishly hypocritical as for meat-eaters to refuse to work in abattoirs. The British AI scientist Yorick Wilks declared that if our soldiers had to risk their lives on our behalf then he, safe at home in his laboratory, was glad to support them. And to refuse *any* military funding was to be cut off from the most lucrative grants (so one could employ only graduate-student assistants, not research fellows: Kuipers 2004). In short, AI people faced dilemmas like those facing the hero of Jean-Paul Sartre's *Les Mains Sales*.

One could be ambivalent about this, even in the midst of a terrible war. Zuse, for instance, had had mixed feelings about his work on flying bombs:

> Technically speaking, our assignments were very interesting. The fact that the sophisticated weapons we were working on in the final analysis served war and death, was easily forgotten. And yet we all would have preferred working on civilian projects. (Zuse 1993: 60)

(Tom Lehrer might have taken that claim with a pinch of salt, for when Zuse's workplace was bombed in 1945 he spent a few weeks working with the Lehrer-immortalized rocket scientist Werner von Braun.)

AI researchers varied widely in their preparedness to accept/seek military funding. In Edinburgh, for instance, Bernard Meltzer was wholly against accepting grants from military sources whereas Donald Michie baulked only at doing *classified* research. MIT in the 1960s adopted a policy of doing no classified research on campus, although its special laboratories, such as the Draper and Lincoln labs, did do military work. (It wouldn't need a cynic to say that that's why they were founded in the first place: the Lincoln lab was set up in 1953–4 to design SAGE—Rheingold 2000: 142–3.) McCarthy and Edward Feigenbaum, by contrast, had no problem with accepting money for classified purposes (Fleck 1982: 206).

Feigenbaum even argued—both in a best-selling book and in evidence to a Congressional hearing—that the Fifth Generation project threatened the USA's military superiority, which the government should take urgent steps to preserve (Feigenbaum and McCorduck 1983: 215–20). He became a national leader in this area of applied AI (and today, specifically mentions it on his web site). He was also more up front than most in acknowledging the military's role in getting AI off the ground:

> When no corporation or foundation chose to take AI seriously, or could afford to, the Advance [*sic*] Research Projects Agency (ARPA) of the Department of Defense supported it through two decades of absolutely vital but highly risky research. Since the Pentagon is often perceived as the national villain, especially by intellectuals, it's a pleasure to report that in one enlightened corner of it, human beings were betting taxpayers' money on projects that would have major benefits for the whole human race. (Feigenbaum and McCorduck 1983: 215)

And in urging an immediate US response to the Fifth Generation project, he said, "It is essential that the newest technological developments be made available to the Defense Department . . . [which] needs the ability to shape technology to conform to its needs in military systems" (p. 217). Perhaps it's not too surprising, then, that he eventually became chief scientist for the US Air Force.

His Stanford colleague Terry Winograd (who'd founded CPSR with Brian Cantwell Smith) had a very different attitude—and avoided military funding as a result. He couldn't deny that military research may have beneficial spin-offs. (In applying for government funds, DARPA had made a point of stressing the likely commercial benefits from Star Wars research.) But he was very uneasy at the extent to which *everyone* receiving DARPA money—including about 85 per cent of the AI research done at the four major centres (MIT, CMU, SRI, and Stanford)—was now fairly directly implicated in military research (Winograd 1991). For DARPA had announced in 1983 that even basic research now had to be related to one of the five military aims specified above. (The mid-1970s policy shift mentioned below had merely required that it be relevant to military use in general.)

AI researchers' consciences were troubled also by the fact that even seemingly innocent AI work could be used for military purposes. That's why ARPA, which wasn't engaged in the disinterested pursuit of truth, had been prepared to fund it in the first place. Their mandate had specified the responsibility to fund research which the DOD wouldn't otherwise have supported "because the feasibility or military values of the new capabilities were not apparent at the beginning" (Edwards 1996: 260).

Consider, for instance, NLP research on anaphora, such as the little—but decidedly tricky—word *it*. MIT's Eugene Charniak (1972, 1973, 1974) wrote a program to analyse stories about children's birthday parties. One sentence was *He will make you take it back*. How could this be interpreted? Suppose the gift-giver had just said *I put the toy train on the table*: for sure, the table (mentioned nearer to *it* than the train was) would not be what the birthday boy would want his guest to take back. But how was the program to know that? When ARPA turned more mission-oriented in the relatively cash-strapped mid-1970s, eschewing basic research in favour of projects with military relevance (*THES* 1975), some NLP researchers encountered funding difficulties for the first time. A friend told me that he'd solved the problem by resubmitting his proposal, now using examples like *The battleship was spotted North-East of the rock. The gunner aimed at it*. This man was no more concerned with battleships than Charniak had been with toy trains: both were interested only in *it*. However, anyone writing an NLP-based battle management system would need to be able to cope with *it*.—Morally, then, there were no easy answers.

Specifically military research proceeded, regardless. By the mid-1980s, an impressive—or depressing, depending on your point of view—roster of (non-secret) applications had been developed. Some of these had advanced AI *as such*. That's not surprising, for real-world problems in general provide a useful discipline to the programmer. And military applications had some specially challenging features:

> Military operations . . . possess significant characteristics that have not always been prominent in other AI application domains. One such characteristic is the time-critical nature of tactical decision making—the need for appropriate, real-time response to dynamic situations. (J. Franklin *et al*. 1987: 605)

Typically, the "dynamic situations" weren't merely rapid (like the movement of a guided missile), but also highly complex. That is, they involved battles, not just single weapons. As a result, much military AI focused on increasing the efficiency of search and pruning techniques, and of *distributed* reasoning under uncertainty (see 13.iii.d)—where the data were not only uncertain, but also vast in quantity, multi-sourced, and used for different purposes by different types of personnel (J. Franklin *et al*. 1987: 606).

Among the many programs developed in this general area were one (called BATTLE) for deciding what weapons to send where, before and during a battle, and another (ANALYST) for integrating sensory information betraying the current location of enemy units (Slagle and Hamburger 1985; Bonasso 1984). Others were aimed at building (for example) "smart" bombs, mine-laying robots, and (non-intelligent) radio sensors. The latter were disguised as twigs, jungle plants, and animal droppings; and they were used for detecting movement, body warmth, the noise of truck engines, or even the scent of human urine (Edwards 1996: 3).

Clearly, then, the computer scientists of the 1980s weren't short of ingenuity. But political critics already saw them as morally compromised. Some of Chomsky's fiercest polemic, for instance, had been directed against the use of high-tech weapons on an undeveloped country halfway across the world (Chapter 9.vii.a). In his eyes, indeed, DARPA/RAND were doubly guilty. Not only had they invented these fearsome devices, but their game-theoretic strategists had advised that it was "rational" to use them (cf. 6.iii.a).

Today, twenty years later, robot planes and tanks are only too familiar. Indeed, the US Congress has approved a programme to make fully one-third of all US ground attack vehicles and deep-strike aircraft unmanned by 2010 (Almond 2005).

As for robot soldiers (i.e. robots used instead of soldiers), they're normally justified in terms of lessening the mortality rate of human soldiers—which, no doubt, they do. But one especially cynical (or especially honest?) military expert, the Director of America's "Global Security" research body, was recently quoted as saying this:

[Robots] will kill without pity or remorse. Historically, only about 1% of soldiers in real war are like that. They are sociopaths who these days are used as snipers. Half of the rest just spray bullets around and the other half never fire at all. (John Pike, quoted in Almond 2005: 21)

Given the cold bellicosity behind those words, it would be comforting to think that this newspaper quotation was as inaccurate as many of them are. But I wouldn't bet on it.

In sum, Archimedes and King Hieron live on: the link between AI and the military is as strong as ever. And still, expectations of AI are sometimes so unrealistic as to be risible. A US Army general in 1970, on being shown SHAKEY, asked whether a bayonet could be mounted on it—apparently assuming that it could skip across grassy meadows and crawl through ditches and tunnels . . . whereas in fact it could barely stand up (B. Raphael, personal communication). Three decades later, a US-government employee asked an AI researcher whether he could model the emotions of terrorists—something that's way beyond the state of the art (although the other AI workers he'd approached hadn't admitted this: see Chapter 7.i.f). Any opportunity to put AI to martial use, however fanciful, is eagerly explored. *Plus ça change, plus c'est la même chose.*

11.ii. Critics and Calumnies

Alongside the bombs, there were the bombshells. Between the mid-1960s and mid-1970s three waves of intellectual criticism washed over NewFAI, and the cognitive science projects associated with it. These were wide-ranging and widely disseminated critiques, whose influence is still strong today (see Chapters 13.ii and 16.vii).

The first, and most famous, came from an outsider: the phenomenological philosopher Hubert Dreyfus (1965, 1972). The next best known came from a neighbour: the computer scientist Joseph Weizenbaum (1976). And the third came from a highly respected AI insider (see Section iii, below).

Dreyfus's charge was twofold: that GOFAI wasn't succeeding, and that it never could. Weizenbaum's was that even if it could appear to succeed (which he, too, doubted), it shouldn't be used—at least, not in 'human' contexts.

Criticism, and the debate it engenders, isn't always good-tempered. These two critics repeatedly hurled calumnies at their opponents, who were tempted to answer in kind. The more passionate the writing, the less effective it was in changing the minds of the enemy, i.e. NewFAI-influenced cognitive scientists. Points of criticism that were both just and important received less attention than they deserved.

Since many supporters of Dreyfus and/or Weizenbaum were members of the general public already disposed to dismiss AI, these heartfelt criticisms spread like wildfire. The 1970s critique of GOFAI was no mere intellectual exercise, confined to the academy: it was a passion-ridden cultural phenomenon too.

a. The outsider

Hubert Dreyfus's first extended critique of AI bore the RAND Corporation imprimatur, and he was employed by MIT at the time, a formative point in his career (he was born in 1929). Nevertheless, he was an outsider.

He was a professional philosopher (with a first degree in physics), not an AI researcher. In the mid-1960s he was teaching the subject at MIT, but he soon moved to Berkeley's Philosophy Department (alongside John Searle). Even more to the point, his philosophy—a form of phenomenology taken from Martin Heidegger, Maurice Merleau-Ponty, the later Ludwig Wittgenstein, and Michael Polanyi (see 16.vi–vii)—was deeply antipathetic to GOFAI.

The RAND connection was due to his brother Stuart, a mathematician working there (and at MIT) at the time. He'd persuaded Armer, then head of RAND's Computer Science research, to invite Hubert to visit their Santa Monica centre for two weeks in the summer of 1964 (S. E. Dreyfus, personal communication). This sojourn on the Pacific coast would enable him to observe the AI work being done there by Newell, with a regular visitor from the other side of the continent—namely, Simon (Chapter 6.iii.b–c). So far as the siblings were concerned, he was going there to meet the enemy at close range.

It wasn't a friendly meeting, and it didn't lead to a truce. On the contrary, after his fortnight sojourn at RAND Hubert wrote a stinging ninety-page critique of GOFAI, based on a talk he'd given there in August 1964. Provocatively, he called it *Alchemy and Artificial Intelligence* (H. L. Dreyfus 1965).

Alchemy argued two different, though closely related, points. On the one hand, it declared the overall project to be in principle impossible for philosophical reasons—in essence, because the "higher" forms of intelligence are *necessarily* derived from "lower" forms concerned with bodily action (this claim is discussed in Chapter 16.vii.a). On the other hand, it mocked the performance of the programs that had actually appeared thus far.

Dreyfus accused NewFAI of four general performance failings, each missing out some "essential" aspect of human intelligence. These were reliance on the fringe of consciousness; discrimination between the essential and the accidental; tolerance of ambiguity; and perspicuous grouping. The lack of those aspects, he said, resulted in the two glaring weaknesses of NewFAI: crudity and brittleness.

Some types of intelligence, he allowed, were in principle programmable: "associationist" and "simple formal" thinking. But "complex formal" and "non-formal" intelligence weren't. The latter types included chess and "intuitive" theorem proving, and riddles and translation. Whatever successes NewFAI had achieved so far, and might achieve in future, lay within the first two classes of problem. These could be tackled by formalized "counting out" and "trial and error". Heuristic search wasn't a general answer, because AI heuristics were derived by human insight—and (in people) heuristics often need to be applied insightfully, too.

Moreover, he said, intelligence *did not* constitute a "continuum", as assumed by Armer and by Feigenbaum and his co-editor Julian Feldman (see the quotes given in 10.ii.b). On the contrary, there were fundamental qualitative differences between the four classes. In any event, it was likely that "the body plays a crucial role in making possible intelligent behavior" (H. L. Dreyfus 1965: 59). If so, then computers simply couldn't qualify.

One of the specific criticisms he made was that GPS relied crucially on its programmers' human ability to distinguish between the essential and the accidental, in choosing how to represent the problem. Another pointed out that pattern recognition programs belied the fact that human concepts are networks of Wittgensteinian family resemblances, not definable by necessary and sufficient conditions. Yet another rejected Rosenblatt's vision of a mechanical secretary: no one knew how to begin making such a device, Dreyfus said, because acoustically identical speech signals are heard as different phonemes depending on the "global" factor of expected meaning (but see 9.xi.g). Some others were directed at MT in general, Yehoshua Bar-Hillel being repeatedly quoted.

In essence, these criticisms weren't new. Quite apart from the by-then-familiar complaints about MT (9.x.d–f), the relevant features of human thinking had been stressed also by the Gestalt psychologists. Merleau-Ponty (one of Dreyfus's three major influences) had borrowed extensively from the Gestaltists, and had also highlighted the importance of having a *body* (16.vii.a; cf. H. L. Dreyfus 1967).

These aspects of thought had even been noted by the AI researchers themselves. Newell and Simon owed much to the Gestaltists (6.iii.c). As for the frame problem, which exemplified the 'essential/accidental' difficulty, this had been pointed out by NewFAI people in the 1950s and named by them in the 1960s. Moreover, ambiguity was being confronted (in as yet unpublished work) by Yorick Wilks (9.x.d), and perspicuous grouping by Adolfo Guzman (10.iv.b).

But although Dreyfus failed to acknowledge the extent to which NewFAI had already *recognized* such issues, his main claim was correct: attempts to *deal with* them, when they weren't simply ignored, had been crude. This, he said, wasn't a question of AI's being a very young science. Rather, the crudity was inevitable, because the last two of his four "classes" of intelligence were immune to AI methods. Famously, he compared NewFAI claims about progress to a man climbing a tree in order to reach the moon (1965: 17, 86). The climber would move a tad nearer to his goal, to be sure. But clambering up even the Californian redwoods wouldn't ever get him there.

Besides criticizing specific programs, Dreyfus scornfully quoted various wildly optimistic predictions made by NewFAI enthusiasts. Chief among these was Simon's forecast, in a talk given in 1957, that a computer would beat the world champion at chess within ten years (Simon and Newell 1958: 7). The prospects of that happening were already dim when he wrote *Alchemy*:

> As described in their classic paper, [Newell, Shaw, and Simon (1958*b*) admitted that] their program was "not yet fully debugged" . . .
>
> In fact, in its few recorded games, the NSS program played poor but legal chess, and in its last official bout (October 1960) was beaten in 35 moves by a ten-year-old novice (xxxi). Fact, however, had ceased to be relevant. [Their] claims concerning their still bugged program had launched the chess machine into the realm of scientific mythology. (H. L. Dreyfus 1965: 6)

The notorious chess forecast was one of many examples of hype in AI (both symbolic and connectionist) that were used by opponents to damage the field. Simon himself produced another gem a few years later: the hubristic "ten years" had been doubled to a more modest twenty, but the substance of the prediction had multiplied a thousandfold—"machines will be capable, within twenty years, of doing any work that a man can do" (Simon 1965: 96). Even if "any work" actually meant only office work (he was writing about his old love, management), this was optimism gone wild.

Dreyfus wasn't the first opponent to mock such claims made by AI researchers. Bar-Hillel, for instance, had preceded him (9.x.b. and e). Nor was he the last: Sir James Lighthill (iv.a, below) would target several of them.

There were plenty of less highly publicized criticisms over the years, of course. There's some evidence, for instance, that DARPA killed their programme on speech understanding in the mid-1970s not simply because the allotted five years had ended, but because they felt let down—even deceived—by the fact that the grammar used when speaking to the system had to be very highly constrained. I'm tempted to say that this should have been obvious to them right from the start (although SHRLDU may have led them to expect better), except that the research director himself has protested,

> But nobody had ever said anything about not constraining the grammar! Nobody even understood that that was a parameter that could be adjusted at the beginning of the project! (Raj Reddy, interviewed in Crevier 1993: 116)

That example reminds us that there are two types of hype. In honest hype, the optimists themselves are misled. In irresponsible or dishonest hype, they know that they're exaggerating (see iii.b, below). Dreyfus's arrows of contempt were aimed primarily at the first.

b. Scandal

Alchemy was no dry intellectual critique, but a passionate attack on a project perceived as the enemy. And it engendered responses in kind.

Dreyfus's mockery of the 1957 chess hype soon came back to plague him. In 1966, only a year after *Alchemy*, he himself was beaten by Richard Greenblatt's MacHack program in a match organized by Seymour Papert. (Greenblatt was still an MIT undergraduate when he wrote the program—in response to Dreyfus's earlier remarks.) The match was reported in the *New Yorker*, and in less exalted publications too.

Dreyfus's defence—that he hadn't claimed that no program would ever play a competent game, and that he was a "rank amateur" anyway—was true enough (1972, pp. xxxii–xxiii, 223 n. 45). (Legends are long-lived: he's still falsely accused of making "the blunt assertion that no computer program would be able to play a good enough game of chess to beat a ten-year-old"—Levy 1994: 89.) But he *had* said that any program play would be inhuman and mechanical. And Simon—not a disinterested observer, of course—described the 1966 game as "wonderful" and "a cliffhanger" (McCorduck 1979: 199).

So, in the eyes of the NewFAI community, Dreyfus had egg on his face. The incident delighted them, and prompted gleeful comments and witticisms in several issues of the SIGART newsletter.

Their satisfaction wasn't drily professional/technical, but all too human. Most of SIGART's readers loathed Dreyfus. That's hardly surprising, for the feeling was mutual. His contempt for their activities was unplumbed. Even his choice of title was insulting, intended (as his text made clear) as *Alchemy alias Artificial Intelligence*. Significantly, he had nothing good to say about alchemy. Years later, he'd mellowed enough to agree with Winograd's (1977) remark that "it was the practical experience and curiosity of the alchemists which provided the wealth of data from which a scientific theory of chemistry could be developed" (H. L. Dreyfus 1979: 2). His RAND fireball, however, *didn't* allow this. According to what he said there, chemistry had been substituted for alchemy—not developed from it.

The way in which Dreyfus had presented his arguments was at least as important in triggering the ensuing scandal (not too strong a word) as were the arguments themselves. This cat wasn't merely stalking the pigeons, but teasing and sneering at them unmercifully. The sharpness of his tongue is illustrated by this remark:

> This output of confusion [i.e. various NewFAI predictions about chess machines] makes one think of the French mythical beast which is supposed to secrete the fog necessary for its own respiration. (1965: 8)

NewFAI researchers, and people doing "cognitive simulation", were described (in Dreyfus's words) as credulous, smug, unscientific, casual, dogmatic, and naive. They were accused (again, Dreyfus's words) of self-delusion, methodological confusion, and absurdity; of spreading intellectual smog; and of preferring adventure to patience.

Newell and Simon (especially Simon) got the worst of it. Besides the epithets just quoted, they were said to show "either a will to obscure the issues or a total misunderstanding" of the Gestaltists' position, and to have "surreptitiously" introduced their own insight into their programs. And Simon's hugely over-optimistic chess prediction of 1957 was mocked over and over again. There were only two people for whom Dreyfus had a good word to say: "Only Shannon", he declared, "seems to be aware of the true dimensions of the problem" of ambiguity in language and perception (p. 75). And only Donald MacKay, he said, had seen that *analogue* processing, and/or "wet" engineering, might be needed for successful AI (cf. 4.v.b and 12.ix.b).

The mockery—and the philosophy too—alienated Armer, already an influential champion of AI (see 10.i.f). (Years later, he said that if he'd known about the brothers' 1962 attack on AI he wouldn't have invited Hubert to RAND in the first place—McCorduck 1979: 194.)

He wanted to suppress Dreyfus's paper, and had "a big squabble" with some RAND colleagues who liked it (interview in McCorduck 1979: 195). It's pretty certain that they weren't paid-up phenomenologists. So perhaps they liked it largely because they were 'pure' computer scientists, who saw AI as a betrayal of the proper standards of theoretical rigour (see iii.a, below). Or perhaps they were merely speaking out for academic freedom: let a hundred flowers bloom, and so on. (Unlikely: academic freedom wasn't high on RAND's agenda, and many of its reports were classified.) In any event, Armer faced a mini-rebellion in the RAND ranks.

After about nine months of this—while rumours about the draft spread from the Pacific to the East Coast, and across the Atlantic too (I remember being all agog to see it)—Armer allowed it to come out as a RAND memo in December 1965. This mimeographed paper was eventually followed by a properly printed version, in 1967. A few changes had been made, and some abusive remarks removed.

But by that time, of course, the first—venomous—version had been widely circulated. Indeed, it had already achieved a mention in the *New Yorker's* Talk of the Town column of 11 June 1966, which repeated Dreyfus's scornful remarks on the weakness of computer chess. Naturally, the AI community weren't pleased. Simon, the chief target of attack, was even more incensed by Armer's decision to publish than by the journalist's high-profile follow-up. RAND's imprimatur, he said, gave Dreyfus a credibility which was "really false pretences" (McCorduck 1979: 194).

Alchemy is usually thought of as Dreyfus's first public assault on the field. In fact, the earliest was an attack—co-authored with his brother—prompted by a 1961 meeting convened by MIT's School of Industrial Management to celebrate the Institute's Centennial Year. Among the interdisciplinary delights in that conference were an opening speech on scientists and policy making by C. P. Snow, and a paper on digital libraries that would have made Gabriel Naudé's hair stand on end (Kemeny *et al.* 1962). But NewFAI was featured too.

Besides a paper on EPAM by Simon and Feigenbaum, there was a general talk on AI given by John Pierce (of ALPAC fame: 9.x.e). This was followed by invited comments from Claude Shannon and Walter Rosenblith (introduced by Vannevar Bush), and then a General Discussion. Not liking what they heard, the two brothers wrote a note that was eventually published as part of the official record (H. L. Dreyfus and Dreyfus 1962). Ink was already being mixed with pepper: AI wasn't merely opposed, but scorned. (What later became the tree-to-moon argument appeared there as mountain-to-moon.)

However, an editor's footnote (on p. 321) admitted that their remarks "were not made at the Pierce session itself, but were submitted in writing a short time thereafter". Simon was enraged by that too, as he admitted later to Pamela McCorduck:

> It was not a discussion that took place during the meeting, it was an afterthought they had. And it was a nasty little diatribe about this preposterous stuff that was being peddled. (interview in McCorduck 1979: 193)

His rage would increase on publication of *Alchemy*, wherein the pepper had grown even hotter.

The brothers Dreyfus weren't the first to attack NewFAI, and the nascent cognitive science associated with it, in strongly emotional terms. As we saw in Chapter 9.x.f, Mortimer Taube (1910–65) had done this a few years before, in his book *Computers and Common Sense: The Myth of Thinking Machines* (1961). And the ratio of abuse to factual/analytic discussion had been even higher there. The psychologist Walter Reitman had commented:

> This book is the work of an angry man.... [Taube] concludes that an uninformed, science-worshipping public is being deceived, hoodwinked, and bilked of millions of dollars by electrical engineers and computer enthusiasts. (Reitman 1962: 718)

Reitman wasn't imagining things, for Taube's disdain near-scorched the pages. His remark that Turing himself displayed "the tendency of computer experts to be pontifical about subjects in which they have no competence" was a relatively mild example (Taube 1961: 51). He'd accused MT researchers of "writing science-fiction to titillate the public and to make an easy dollar or a synthetic reputation". And he'd specifically said that "the nation's monetary resources" were being wasted when used to support AI research.

Armer had bridled then, too—not least, because Taube's book led to a "[negative] climate of research in the field" (Armer 1960/1963: 389). Nor was he the only one. Besides the hostile review penned by Reitman, another attack was mounted by Richard Laing (1962), then a member of Arthur Burks's team at the University of Michigan and doing work on neural networks and automata theory (1961*a*,*b*). (Like several others in

Burks's group, he was later recognized as an early worker in A-Life: see Chapter 15.v.b, and Richard Laing 1975, 1977, 1989.)

Stuart Dreyfus (1962), by contrast, had approved of the book. (Simon "blew up at me in his office" at RAND, as a result: S. Dreyfus, personal communication.) In a review written for a friend's literary magazine, he did distance himself from it in some degree, saying that "not all of Dr. Taube's arguments are convincing" and allowing that "some innocent researchers are doubtless encompassed by some of Taube's sweeping condemnations". However, he described chess-playing machines as "a haven for frauds for centuries". (True, but hardly tactful.) And he continued:

> [The] state of the artificial intelligence art has been grossly exaggerated. It is further clear that the natural desire of the bored public for believable science fiction, of the newspapers for sales, of computer companies for publicity, and of hard-working scientists for adulation contribute to this systematic delusion. (S. E. Dreyfus 1962: 54)

He poured scorn on the "multitudinous, disorganized, helter-skelter projects" of AI, and on LT/GPS (and Simon's chess prediction) in particular. And he described Taube's volume as the first book on AI childcare, remarking: "Taube may not be a wise or sympathetic parent, but at least he is willing to stand up to the pampered child."

One sentence was prophetic. He didn't have a "non-existence proof" of intelligent machines, but: "Conceivably, someday, a philosophic study of positive attributes of intelligence might [provide one]." In short, his and (still more) his brother's major intellectual project was already being flagged.

If even Stuart Dreyfus remarked on Taube's sweeping condemnations, and his lack of wisdom and sympathy, it's not surprising that the book cut little ice with the AI community. Despite his international eminence, Taube's over-the-top rhetoric led most of them to overlook his criticisms. The brothers Dreyfus each had a quiverful of insults too, as we've seen. Naturally, these were resented by NewFAI folk:

> [Dreyfus's attack on AI contains] a set of almost defamatory personal allegations. (Papert 1968: 0–8)

> Dreyfus' mission does not end with showing that people associated with Artificial Intelligence are wrong or even foolish. He is called to expose them as obscurantists and liars. (III–1)

The infamous RAND memo, then, expressed—and aroused—so much antagonism that it wasn't taken as seriously by NewFAI people as it might have been. (And, at that time, its author had no international eminence to command respect.) AI-leaning philosophers, too, were largely unimpressed. That's evident in Daniel Dennett's "little scalpel job" (personal communication) of 1968 (his first publication), and in my own critiques as well (Boden 1972: 146–50, 222–3; 1977: 435–41).

The situation wasn't helped by the fact that Dreyfus had made many mistakes, and even some disingenuous remarks—and omissions. The errors were ruefully acknowledged even by Weizenbaum, who shared many of Dreyfus's worries about the AI project: "It was terribly incompetent. [Dreyfus] knew so little about computers, and made so many mistakes!" (interview in Crevier 1993: 123). But the disingenuousness was even worse than the errors, and both were noted by Papert (1968), in a paper mischievously called 'The Artificial Intelligence of Hubert L. Dreyfus: A Budget of Fallacies'.

Papert being the AI star that he was, and Dreyfus already a notorious intellectual gadfly, this was a high-visibility contest. And likely to be a fierce one, too. Papert's flair for combativeness was evident from the tone of the already well-known draft of *Perceptrons* (see 12.iii.b). He would pull no punches.

And so it turned out. Papert accused Dreyfus of "questionable honesty". He showed, for example, that Dreyfus had deliberately omitted a brief sentence from a passage by W. Ross Ashby (about Herbert Gelernter's program: 10.i.c) which would have made nonsense of his ill-informed criticism (Papert 1968: III-8–9). Similarly, he'd stopped short of quoting a sentence from Wiener which confessed to a huge weakness of chess programs (III-4). And he'd claimed that Simon said in 1962 that his 1957 chess prediction was "almost realized", whereas Simon had said no such thing.

As well as bad faith, there was a failure to do his homework:

> The most astonishing feature of Dreyfus' texts [the two versions of *Alchemy*] is their bibliography. His references to experiments on Artificial Intelligence are almost entirely confined to early work that has filtered into anthologies of "classical papers" [i.e. *Computers and Thought*]. (Papert 1968: 0–11)

One of the missing items was Guzman's work, which though still unpublished was in the air, and being done by "people who live within ten miles of him" (II-9). Dreyfus's ignorance of the literature was compounded by his ignorance of what the literature was trying to achieve. On that topic, *A Budget of Fallacies* outdid even *Alchemy* in its level of calumny. For instance:

> [His] discussion is irresponsible. His facts are almost always wrong; his insight into programming is so poor that he classifies as impossible programs a beginner could write . . . (Papert 1968: 0–2)
>
> [His] comments on actual projects [show] that he systematically misunderstands their purpose, their methods, and their difficulties. The reason is simple. He knows nothing about the technical issues and barely understands the language used. In addition he is sufficiently suggestible to take people as meaning what he thinks they must. (0–7–8)
>
> [He ludicrously alleges that Ashby misled people.] That "naive" readers might be misled is undeniable. But scientific writing is not addressed to the ignorant and the naive (even if they are professors of philosophy). (III-9)

(*Ouch!*)

If *Alchemy* was as bad as this, why bother with it? Surely Papert, as one of the half-dozen top people in AI at the time, had better things to do? He answered:

> I have been told that it is a waste of time [to rebut *Alchemy* in detail]. I have been told that only a pedant would object to the technical nonsense that pervades every paragraph of Dreyfus' papers about Artificial Intelligence since his real purpose is to provide insight into the rich subtlety of human intelligence. I have been told that his arguments must be read as literary conceits with rich "humanistic" content.
>
> I think it does matter. I sympathize with "humanists" who fear that technical developments threaten our social structure, our traditional image of ourselves and our cultural values. But there is a vastly greater danger in abandoning the tradition of intellectually responsible and informed enquiry . . . The steady encroachment of the computer must be *faced*. It is cowardice to respond by filling "humanities" departments with "phenomenologists" who assure us that the computer [cannot encroach further] into areas of activity they regard as "uniquely human".

Our culture is indeed in a desperately critical condition if its values must be defended by allowing muddled thinking to depose academic integrity. (Papert 1968: 0–2–3)

The protest about "filling" humanities departments with phenomenologists was aimed at the postmodern turn in Western society: *les événements* were already spreading far beyond Paris (cf. 1.iii.c–d, 6.i.d, and 8.ii.b–c). As we'll see below (subsection e), had Dreyfus written his RAND squib a decade earlier Papert might not have been so concerned to demolish it.

Papert could have given a more literal answer to the question "Why bother?" He could have said, "I wrote it because Armer asked me to." As it turned out, Armer was disappointed: RAND's lawyers forbade publication for fear of slander suits (McCorduck 1979: 196). MIT's lawyers were less nervous, or perhaps they weren't consulted. Papert's paper, after circulating widely in draft, eventually appeared (still unfinished) as a Project-MAC Report.

c. After Alchemy

RAND Corporation memos aren't found in airport bookstores—although *Alchemy*, despite Armer's attempt at censorship, was the most widely read RAND memo of all time. But Dreyfus soon started work on a book-length statement. On its publication in 1972, it became a best-seller overnight. Many members of the general public got their first extended vision of AI from Dreyfus's book.

What Computers Can't Do (1972) contained much more philosophical discussion than *Alchemy*, and was graced by a Preface written by Harvard's Anthony Oettinger (1929–), a well-known critic of MT. But the technical aspects were virtually unchanged. Indeed, most of the text of *Alchemy* was reproduced verbatim. (This explains why Dreyfus remarked that "the funny thing is, there was practically no additional response when the book was published"—McCorduck 1979: 195.) Some extra examples were added, to be sure; for instance, he pointed out (contra McCarthy) that being "at home" isn't simply a matter of being in a particular physical location but of owning (or renting . . .) the real estate in question—which can't be defined in logicist terms (1972: 150). But McCarthy's logicism wasn't new.

In the book's discussion of 'Ten Years of Research in Artificial Intelligence (1957–1967) [*sic*]', the AI programs that had been written since the original RAND squib were almost all ignored—even those trying to address the very problems which Dreyfus had highlighted in the mid-1960s. Apart from McCarthy and Newell–Simon, Dreyfus focused only on MIT. (Even so, Winograd, whose work had electrified the AI grapevine and was about to electrify the wider world, wasn't mentioned. This may have been because SHRDLU wasn't featured in Minsky's *Semantic Information Processing*, from which Dreyfus drew heavily.) AI work had been going on elsewhere too—but from his new pages, you'd never think so. As Bruce Buchanan put it:

One can only speculate why the author fails to acknowledge recent AI work. To this reviewer, and other persons doing AI research, programs developed in the last five years seem to outperform programs written in the tool-building period of 1957–1967 . . . One would hope that a criticism of a growing discipline would mention work in the most recent one-third of the years of work. (Buchanan 1972/1973)

The anti-GOFAI rhetoric, too, was as virulent as before. The ever-courteous Buchanan chided Dreyfus gently, but firmly:

> It is lamentable that the critique of AI in this book has taken the form of a popular-press attack on AI work. The author's phrases are damning but his arguments are not convincing. As the author mentions, the popular press has often given over-enthusiastic impressions of AI work; this book is written in the same vein, but with a negative sign. (Buchanan 1973)

A few leading GOFAI workers admitted that he'd said some things worth saying, and the GOFAI psychologist Zenon Pylyshyn (1974), while rebutting him at length, did so too. For example, Wilks (1976) allowed that "the naive, and from this distance in time, absurd over-optimism of many in early AI is now sad reading", and that—as Dreyfus had insisted—what Wittgenstein called the human "form of life" must underlie/inform natural language. He did say: "Dreyfus's empirical arguments are not sound, they disprove nothing." But he added:

> Whether or not its survey of research is fair, or its arguments are sound, the book has done a great deal of good in a field whose lack of self-generated criticism is scandalous. Dreyfus should review the field every five years and change his empirical arguments each time—AI workers should then be grateful and ask no more of him, for he would be doing them a considerable service. (Wilks 1976: 184)

In effect, Wilks got his wish. For Dreyfus's critique would run and run. Quite apart from other books and papers attacking AI (e.g. H. L. Dreyfus and Dreyfus 1986, 1988), *the* book turned out to have many lives. (It's still being reprinted roughly once a year.)

Dreyfus's book lived on in other outsiders' writings, too. Most of these authors were in his home discipline, philosophy (Chapter 16.vii). But a few had studied the psychology of human skills, and/or had experience—if only as observers—of GOFAI in practice.

One person inspired by him was Harry Collins, whose late-century critique of expert systems will be outlined in Chapter 13.ii.b. Another, who was initially inspired by Heidegger but who later took Dreyfus's work willingly on board, was David Sudnow (1978/2001). His subtle descriptions of the phenomenology of learning a motor skill, namely piano playing, were mentioned in Chapter 7.vi.h. In general, the descriptions of skills offered by the Dreyfus brothers and their followers often provided interesting data. What was missing, and what's required by cognitive science, was an *explanation* of those data. (In the last quarter-century, some such explanations were attempted: see 14.viii.b, 15.vii–viii, and 16.vii.)

An unrepentant second edition of *What Computers Can't Do* appeared in 1979, consisting of the first version unchanged but with an added Introduction, in which some post-1967 AI work featured. Winograd—who hadn't yet come out as a lapsed GOFAIer (see subsection g, below)—was now discussed, with respect to both SHRDLU and KRL (pp. 5–15, 48–55). Scene analysis and robotics made an appearance (pp. 15–25). And frames, conceptual-dependency theory, and KRL were explored in relation to early to mid-1970s research on knowledge representation (pp. 27–55)—see Chapters 9.xi.d and 10.iii. But the verdict was unchanged: all were declared valueless.

(Dreyfus, like Licklider and Bar-Hillel, had predicted from the beginning that a "symbiosis" of man and computer might achieve more than unaided human intelligence can—1965: 83. Now, he admitted that specialist applications such as DENDRAL were useful, but insisted that these had nothing to do with general intelligence—1979: 5.)

Dreyfus's ink was still peppery. Citing an MIT report that had described research on flexible motor action by robots as "somewhat dormant", he tartly remarked, "[We] can only take 'dormant' as a polite synonym for stagnant or even comatose" (1979: 25). And having praised Winograd for being "admirably cautious" in his claims about modelling language as a whole, he commented drily:

> [Everyone] interested in *the philosophical project of cognitive science* will be watching to see if Winograd and company can produce a moodless, disembodied, concernless, already adult surrogate for our slowly acquired situated understanding. (1979: 55; italics added)

In brief, cognitive science was chasing a philosophical mirage. GOFAI programs were "not at all promising as contributions to psychology" (p. 18).

This new edition opened with a mini-history of the field, which boiled down to *I told you so!* During the previous decade, he said, his critique "has been more or less acknowledged", and "the wishful rhetoric characteristic of the field has been recognized and ridiculed by AI workers themselves [specifically, McDermott: see Section iii below]" (Dreyfus 1979: 1). In sum:

> Almost everyone now agrees that representing and organizing commonsense knowledge is incredibly difficult, and that facing up to this problem constitutes the moment of truth for AI. (1979: 3)

d. Dreyfus and connectionism

If 1979 was "the moment of truth" for GOFAI, it was also the moment for the first multidisciplinary meeting on distributed connectionism (Chapter 12.v.b). If Dreyfus knew anything of the work reported there, he didn't mention it in his new edition.

Indeed, in a Panel Discussion held in New York five years later, he declared:

> The ability that people have . . . to have the right thing pop into their head . . . requires having images and having memories since it involves seeing the current situation as resembling earlier situations, where resembling is a tricky notion because resembling doesn't mean identical with respect to any particular features, *which is the way machines always have to analyze resemblance*, but simply overall similarity. (Pagels *et al.* 1984: 341; italics added)

He was right about the "trickiness" of the notion of resemblance. But if he'd known anything about PDP connectionism at that time (which in all conscience he should have done), he would never have said that machines "always" have to analyse it as sharing identical features.

Two years after that, it became abundantly clear, even to outside observers, that GOFAI was no longer the only AI game in town (12.vi.a–c). The American Academy of Arts and Sciences therefore organized a wide-ranging debate on AI. The brothers Dreyfus contributed a paper giving guarded approval to connectionism, and saying of GOFAI: "The rationalist tradition [in philosophy] had finally been put to an empirical test, and it had failed" (H. L. Dreyfus and Dreyfus 1988: 34; cf. Dreyfus 1972: 215). The editor of the trade book that carried this debate evidently agreed with them, for it bore the tendentious subtitle *False Starts, Real Foundations* (Graubard 1988).

Accordingly, Dreyfus started work on another 'revision' of his book, defiantly called *What Computers STILL Can't Do* (1992). Like the earlier editions, this attracted a great deal of attention. The journal *Artificial Intelligence* devoted almost an entire number to it, including reviews by McCarthy, John Haugeland, and Collins (among others), and Dreyfus's reply (Stefik and Smoliar 1996).

Dreyfus's new Introduction provided some predictable mockery of Douglas Lenat's CYC project (1992, pp. xvi–xxx; see Chapter 13.i.iii), and an equally predictable salutation to the now reconstructed Winograd and to Philip Agre and Lucy Chapman (pp. xxxi–xxxiii: see 9.xi.b and 13.iii.b). Mainly, however, it focused on PDP connectionism. Again, there came the *I told you so*:

> In retrospect, the stages of my critique of attempts to use computers as physical symbol systems [which a connectionist system is not] to simulate intelligence now fell into place. My early appeal to holism, my concern with commonsense understanding as know-how, Stuart's phenomenology of everyday skills, and the capacities of simulated neural networks all added up to a coherent position—one that predicted and explained why GOFAI research should degenerate [*sic*] just as it had. (1992, p. xv)

("Degenerate", because GOFAI was said to be "a paradigm case of what philosophers of science call a degenerating research program": p. ix.)

But Dreyfus's new essay was less a matter of *Three cheers for connectionism!* than of *So much the worse for AI!* AI of some (non-GOFAI) sort, he said, might not be impossible: "no one has been able to come up with such a negative proof" (p. ix). But the prospects didn't look rosy.

Dreyfus admitted that neural networks were superior to GOFAI in some ways (1992, pp. xiv–xxxvi; cf. H. L. Dreyfus and Dreyfus 1988). For instance, they allowed for family resemblances in concepts (12.x.b). They showed that skilled behaviour needn't involve abstraction of a *theory* of the domain (12.vi.e). And they demonstrated that learning could take place without all the relevant 'beliefs' being explicitly represented beforehand (12.vi.c).

But, he continued, "The commonsense-knowledge problem resurfaces in this work and threatens its progress just as it did work in GOFAI" (1992, p. xxxvi). So neural networks can make inappropriate generalizations, such as learning to recognize the presence/absence of shadows instead of tanks; and they'd probably "stupidly" fail to learn *our* generalizations, or to adopt our priorities, such as symmetry (cf. Chapter 8.iv.b). Perhaps only a neural net with cell numbers, architecture, and initial connectivities identical to the human brain could ever model our intelligence.

As for learning, supervised PDP learning is dependent on the human trainer. Even unsupervised (reinforcement) learning, if the network were to be intelligent like us, would require—he said—that it have needs and perspectives like ours, and a comparable sense of relevance. And, of course, artificial neural networks lack bodies, just as GOFAI programs (and robots) do.

In short, he wasn't hopeful: "it looks likely that the neglected and then revived connectionist approach is merely getting its deserved chance to fail" (p. xxxviii). Even technological AI, if aimed at implementing *general* intelligence, was futile. As for psychological AI, this was a waste of time.

e. The neighbour

Weizenbaum (1923–) was a neighbour not only in the sense that he was located in MIT's Computer Science Department, but also in the sense that his ELIZA program was regarded by the public as an example of NewFAI. That was a mistake, for ELIZA hadn't been an effort in AI (see 10.iii.a). However, this wasn't widely known. The publicity afforded to his mid-1970s attack on AI was therefore all the greater.

Weizenbaum's book *Computer Power and Human Reason: From Judgment to Calculation* (1976) was memorable for three things. It provided perhaps the best introductory account of a Turing machine (cited in Chapter 4.i.b). It gave a superbly funny description of the priorities and social (or antisocial) habits of a new subspecies of *Homo sapiens*, the dedicated "hacker" (pp. 115–24). (The hacker lifestyle had already been described in *Rolling Stone*, but with more appreciation and less humour: Brand 1972.) And it argued at length that GOFAI could never replace human judgement—and that even if it could, it shouldn't.

Weizenbaum didn't discuss actual AI programs in any detail, wanting "to avoid the unnecessary, interminable, and ultimately sterile exercise of making a catalogue of what computers will and will not be able to do, either here and now or ever". He complained that Dreyfus was too concerned with "the technical question of what computers can and cannot do" (1976: 12). This, he said, wasn't the key issue:

> [If] computers could imitate man in every respect—which in fact they cannot—even then it would be appropriate, nay, urgent, to examine the computer in the light of man's perennial need to find his place in the world. (Weizenbaum 1976: 12)

As for that "which in fact they cannot", this was a matter of principle. Man-as-machine was an absurdity:

> Whether or not [the programme of AI] can be realized depends on whether man really is merely a species of the genus "information-processing system" or whether he is more than that. I shall argue that an entirely too simplistic notion of intelligence has dominated both popular and scientific thought, and that this notion is, in part, responsible for permitting artificial intelligence's perverse grand fantasy to grow. I shall argue that an organism is defined, in large part, by the problems it faces. Man faces problems no machine could possibly be made to face. Man is not a machine. (p. 203)

His insistence that AI systems, even if they could be hugely improved, should not be substituted for human judgement was especially fierce with respect to contexts involving interpersonal respect or emotions. In such cases, the very idea of replacing human judgement with computer calculation was "obscene": merely contemplating such projects "ought to give rise to feelings of disgust in every civilized person" (1976: 268). So Weizenbaum denounced his rival Kenneth Colby's plans to use ELIZA-like programs for interviewing mental patients (see 7.i.a).

In part, he was (understandably) worried by the crudity of the NLP involved in Colby's programs, and the consequent crudity of the computer's performance. In part, however, he was concerned that the patients' naivety would lead them to believe that Colby's computer was really intelligent. As evidence for this concern, he reported that his secretary had once asked him to leave the room when she was interacting with ELIZA. In truth, this was no cause for alarm: if *you* were playing around with ELIZA and had decided to answer its quasi-questions honestly, would you want your boss reading over your shoulder? Nevertheless, it was possible that some programs might fool some people into attributing genuine intelligence to them.

Weizenbaum also poured scorn on the idea that AI programs might be used in the law courts, to aid the judges in their deliberations. He'd already crossed swords about this with McCarthy, for his views were already familiar to "the artificial intelligentsia"—both from face-to-face meetings and from the pages of *Science* (Weizenbaum 1972). McCarthy hadn't shared his horror at the prospect of AI-in-the-law-courts. Weizenbaum recalled:

As Professor John McCarthy once put it to me during a debate [IJCAI-1973, at Stanford: Kuipers *et al.* 1976: 13], "What do judges know that we cannot tell a computer?" His answer to the question . . . is, of course, "Nothing." And it is, as he then argued, perfectly appropriate for artificial intelligence to strive to build machines for making judicial decisions. (Weizenbaum 1976: 207)

Weizenbaum gave an answer to McCarthy's question, but was horrified that it should have been asked at all:

What could be more obvious than the fact that, whatever intelligence a computer can muster . . . it must always and necessarily be absolutely alien to any and all authentic human concerns? *The very asking of the question, "What does a judge (or a psychiatrist [see 7.i.a]) know that we cannot tell a computer?" is a monstrous obscenity.* That it has to be put into print at all, even for the purpose of exposing its morbidity, is a sign of the madness of our times. (pp. 226–7; italics added)

(No one, then, was seriously suggesting that AI programs might be seated on the bench: McCarthy had merely been responding to a rhetorical question from Weizenbaum—see below. But people were already working on expert systems representing relatively clear-cut laws, as we'll see in Chapter 13.ii.c–d. And it was the philosophically sophisticated Buchanan who'd first suggested that this be done: Buchanan and Headrick 1970.)

In short, expert systems were (potentially) all very well for dealing with geology for oil prospecting, or medical diagnosis of bodily diseases. At a pinch, they might even be used as aids, though not as substitutes, in searching legal databases for precedents. But where decisions about human lives were concerned, AI programs should be forever eschewed.

Various NewFAI leaders would make fierce ripostes. That's not to say that they rejected every one of Weizenbaum's warnings. But not all were willing to spend time in planning how to pre-empt them. Take McCarthy, for instance. His answers to *What worries about computers are warranted?* showed that he thought there were some (Kuipers *et al.* 1976: 10). But he hadn't lost much sleep in worrying. He hadn't thought seriously, for example, about *What do judges know that we cannot tell a computer?* He didn't even remember saying it, although he was happy to reply to it (in one brief sentence) as a "rhetorical" question. His reply was typically recalcitrant: "I'll stand on that if we make it 'eventually tell' and especially if we require that it be something that one human can reliably teach another" (p. 9). In other words, he didn't take Weizenbaum's question about AI judges as a *practical* issue, but as an attack on the philosophical principle (which he'd been among the first to adopt) that all human knowledge can be formally represented by AI.

Nor had McCarthy thought seriously about any other social implications of the widespread use of AI. Indeed, he'd said in the early 1970s that it wasn't worth speculating about these ahead of time. Once the technology was actually being used in society, it would be clearer what the real problems were. On those grounds, he'd opposed Donald Michie's setting up a meeting of a few carefully selected participants to discuss these issues (The Serbelloni File 1972, letter from J.M. to D.M.M.).

Michie's meeting did eventually take place, at the Rockefeller Foundation's Villa Serbelloni in Italy. That fact alone indicated that some NewFAI people disagreed with McCarthy on this matter. (My own view was that it was irresponsible *not* to consider the possible social implications, despite the unavoidable uncertainties at that early stage: Boden 1977, ch. 16.) They felt that Weizenbaum had been right to raise these concerns, even if he'd done so in an unnecessarily emotive, near-hysterical, fashion. One didn't have to go all the way with him to be worried about such things.

In particular, one didn't have to share his socio-political views. But as we'll now see, many did. Some of the feeling in his favour, on the part of professionals and public alike, was grounded in the cultural context of the time.

f. A sign of the times

Both Dreyfus and Weizenbaum were important voices in the counter-culture (Chapter 1.iii.c–d). But the counter-culture itself had already prepared the general public to pay attention to them.

Let's consider Dreyfus first. His book sold well, in all three versions, not only because he had some important things to say, nor only because many people agreed with him. In addition, they *wanted* to agree with him, and empathized with the virulence of his attack. Indeed, that's largely why Papert had taken such pains to rebut *Alchemy*. Had the RAND memo been published only ten years earlier, when the most powerful McCarthy in the land was Senator Joseph, he'd probably have agreed with his friends that to criticize it in detail was "a waste of time" (see above). In the late 1960s, however, it wasn't.

The first edition of Dreyfus's book fitted well with the emerging counter-culture. One aspect of that cultural emergence was that Dreyfus's background position, namely neo-Kantian phenomenology, was enjoying a renaissance in the Anglophone world. By the time that *What Computers Can't Do* appeared, even Hilary Putnam, the founder of functionalism, was already starting across the philosophical divide (Chapter 16.vi).

The philosophical movement gained strength—or anyway, numbers. By 1990, several prominent cognitive scientists (including Agre and Chapman, and Brian Cantwell Smith) were regularly quoting Merleau-Ponty and, especially, Heidegger. The MIT roboticist Rodney Brooks even felt the need to say of his own seminal paper in the technical journal *Artificial Intelligence* that "It isn't German Philosophy," though he did admit to "certain similarities" (1991*a*, sect. 7.5; cf. M. W. Wheeler 2005, ch. 1). According to that stream of philosophy, as we saw in Chapter 2.vi, *no* naturalistic account of human thought is possible, not even a neuroscientific one: AI is just the worst of a bad bunch.

Another counter-cultural aspect was that AI was closely associated with military-industrial concerns. Dreyfus himself didn't stress this. Nevertheless, most young readers in the 1970s were very happy to see AI denounced.

Unreconstructed aficionados of the old philosophical/political order, of course, weren't. Feigenbaum, for instance, had little patience for Dreyfus:

> What artificial intelligence needs is a *good* Dreyfus. The conceptual problems in AI are really rough, and a guy like that could be an enormous help . . . We do have problems, and they could be illuminated by a first-class philosopher. But Dreyfus bludgeons us over the head with stuff he's misunderstood and is obsolete anyway [see above] . . . And what does he offer us instead? Phenomenology! That ball of fluff! That cotton candy! (interview in McCorduck 1979: 197; italics added)

(Buchanan, whose Ph.D. had been in philosophy, was less dismissive of phenomenology: "If there is any reason to read the book at all, it is to become acquainted with this current view of man and the world which is different from the traditional scientific view"—1973: 21.)

The "cotton candy" is considered at length in Chapter 16.vi–viii and ix.d–e, together with attempts, even on the part of the Dreyfus brothers (1990), to reconcile phenomenology and cognitive science—but not GOFAI. Here, what's relevant is that outsiders in general were readier to consume it in the 1970s than they would have been at any previous time.

That's largely why the young Dreyfus, who didn't have international (or even national) eminence when he wrote *Alchemy*, very soon achieved it.

Similar remarks apply to the historical context of Weizenbaum's book, published just four years after Dreyfus's. Indeed, he himself saw it in this light (1976: 10 ff.). So he thanked the counter-cultural figures Lewis Mumford, Steven Marcus, and Chomsky: not just for their constructive advice on the drafts, but for their encouragement when he "despaired" at others' having said what he had to say more eloquently:

> [As] Lewis Mumford often remarked, it sometimes matters that a member of the scientific establishment say some things that humanists have been shouting for ages. (Weizenbaum 1976, p. x)

Specifically, he was firing a salvo in the "science wars" that caused havoc in social psychology and, especially, anthropology (Chapters 1.iii.b–d, 6.i.d, and 8.ii.b–c). Having said that "This book is only nominally about computers" (p. ix), he declared "scientism" to be the true enemy—of which psychological AI was a special case (pp. 222–3).

It's hardly surprising, then, that his views were widely welcomed by the general public. Many of them were already highly sceptical about (and frightened by) AI, so were delighted to receive support from someone in the know. Dreyfus, after all, had been a mere philosopher: Weizenbaum, by contrast, knew which side of a computer was which. Many also cheered his bitter critique of the use of computer programs—often incomprehensible to the user—for destructive military purposes in Vietnam and elsewhere (1976: 236–43).

A proviso: with respect to Weizenbaum's strictures on computer judges, the "general public" didn't include young black males in inner-city USA (Turkle 1995: 292). Their view of judges was very different from that of white middle-class students. Whereas the latter usually agreed with Weizenbaum (saying, for instance: "Judges weigh precedents and the specifics of the case. A computer could never boil this down to an algorithm"), their black contemporaries said things like:

> This is a pretty good idea. He [the computer judge] is not going to see a black face and assume guilt. He is not going to see a black face and give a harsher sentence.
>
> [From another young man:] I know that if I ever had to go before some judge, there is a good chance that he is going to see my face and he is going to think "nigger".
>
> The computer judge would have a set of rules. He would apply the rules. It might be safer. (both speakers quoted in Turkle 1995: 292–3)

Those interviews were done in 1983. By 1990, PDP had come on the scene. An MIT student (race unspecified, but the context suggests that he was black) now pointed out:

> If you were training a [neural net] computer to be a judge and it looked at who had been found guilty and how they were sentenced, it would "learn" that minority people commit more crimes and get harsher sentences. The computer would build a model that minorities were more likely to be guilty, and it would, like the human judges, start to be harder on them. The computer judge would carry all of the terrible prejudices of the real ones . . . Of course, you would never be able to find a "rule" within the system that said you should discriminate against minorities. The computer would just do it because in the past, people had done it. (quoted in Turkle 1995: 293)

In short, a PDP judge would have racist flaws similar to those of the NewFAI expert system designed to select candidates for a London medical school (see 13.ii.c).

Weizenbaum hadn't simply attacked specific applications of AI, such as military or legal programs. AI in general, he said, depended on a "corruption" of language whereby intentional terms such as *problem*, *understanding*, and *knowledge* were tacitly redefined to fit the mechanistic mould. Minsky, Newell, and Simon were specifically named. But this wasn't a matter restricted to the laboratory:

> [The] computer, as presently used by the technological elite, is . . . an instrument pressed into the service of rationalizing, supporting, and sustaining the most conservative, indeed, reactionary, ideological components of the current *Zeitgeist*. (p. 250)

Such remarks went down well on campuses across the world, and with sensation-hungry journalists. Within the profession, however, they were to some extent counter-productive. They antagonized the AI cognoscenti, many of whom were themselves out of sympathy with US policy, above all in Vietnam. His MIT colleague Kuipers, for instance, complained:

> I had some strong reactions to Joe Weizenbaum's book *Computer Power and Human Reason*. The book mentions some important concerns which are obscured by harsh and sometimes shrill accusations against the Artificial Intelligence research community. On the whole, it seems to me that the personal attacks distract and mislead the reader from more valuable abstract points . . . *I see [many of his ideas] as being quite current in the AI community, so I was quite puzzled by Weizenbaum's vehement attacks on us for not sharing them*. (Kuipers *et al.* 1976: 4; italics added)

Kuipers may have been more annoyed than most, being a conscientious objector who did alternative service (before going to graduate school) instead of submitting to the

Vietnam draft. But he certainly wasn't the only NewFAI researcher to be offended by Weizenbaum's accusations of lack of moral/political integrity.

Nevertheless, the book couldn't be ignored by the NewFAI community. It was the subject of many debates, both formal and informal. McCarthy, for one, saw it as a threat to AI research in general, being all of a piece with the counter-culture of the time:

> This moralistic and incoherent book uses computer science and technology as an illustration to support the view promoted by Lewis Mumford, Theodore Roszak, and Jacques Ellul, that science has led to an immoral view of man and the world. I am frightened by its arguments that certain research should not be done if it is based on or might result in an "obscene" picture of the world and man. Worse yet, the book's notion of "obscenity" is vague enough to admit arbitrary interpretations by activist bureaucrats. (Kuipers *et al.* 1976: 5; cf. p. 9)

McCarthy wasn't one of those who, like Kuipers, sympathized with Weizenbaum's politics. He complained that "Certain political and social views are taken for granted," accused Weizenbaum of "political malice" and "new left sloganeering", and—by implication—objected to his description of US policy in Vietnam as "murderous" (Kuipers *et al.* 1976: 6, 7, 9).

But a significant number of his colleagues did share Weizenbaum's concerns. Partly due to the efforts of Winograd, a new society and newsletter were founded in Palo Alto in 1981: Computer Professionals for Social Responsibility, or CPSR (see <http:www.cpsr.org>). Offshoots soon sprang up at other US locations, at the universities of Edinburgh and Sussex, and in France, Germany, and Italy.

Within a few years, CPSR was lobbying against the technical inanities of the USA's Star Wars programme (see i.c, above). One prime concern was the issue already mentioned by Weizenbaum: programs so complex that they're incomprehensible to the layman (including military personnel) and sometimes even to computer professionals. A new journal, *Computing and Society*, was founded in 1988 by CPSR's executive director, Gary Chapman, to draw attention to these matters. Across the ocean, several attempts were made in the 1980s to warn the public *and AI professionals themselves* about the risks of using certain types of AI system (H. Thompson 1984, 1985; Whitby 1988; Council for Science and Society 1989). Sometimes, these warnings were placed in the context of a specific, though unorthodox, philosophy of science—as we'll now see.

g. The unkindest cut of all

Another bombshell of this general type was due, believe it or not, to Winograd. In the mid-1980s, he publicly accepted the arguments already put forward by Dreyfus and Weizenbaum, and added those of the Chilean biologist Humberto Maturana.

All three of these men were seen as highly maverick by GOFAI folk, and were mostly ignored by them accordingly. (Maturana was rarely even read, partly because he wrote in such an opaque manner; his work became popular only much later: see 15.viii.b.) Winograd, by contrast, couldn't be ignored.

What caused most consternation in GOFAI circles wasn't the force of his newly borrowed arguments. Rather, it was his offering the enemy the glamour and authority of his hugely famous name. For this was the man who, only a couple of months after getting his Ph.D., had been invited to give the inaugural *Computers and Thought* Lecture at IJCAI-1971. His youthful achievement in NLP, and his influence on 1970s symbolic AI in general (and on cognitive science too), had been nothing short of phenomenal (see 9.xi.b and 10.iv.a).

A person of lesser intellectual honesty could have rested comfortably on those early laurels for a lifetime. Through the 1970s, however, he'd become increasingly sensitive to the difficulties inherent in NLP—already emphasized by Bar-Hillel and Dreyfus. And he said as much in print, writing alongside Minsky and Papert (and others) in an official national report:

> The AI programs of the late sixties and early seventies are much too literal. . . . This gives them a "brittle" character, able to deal well with tightly specified areas of meaning in an artificially formal conversation. They are correspondingly weak in dealing with natural utterances, full of bits and fragments, continual (unnoticed) metaphor, and reference to much less easily formalizable areas of knowledge. (Winograd 1976: 17)

By the early 1980s, he'd long abandoned SHRDLU, and put his major efforts into founding CPSR instead. He was disenchanted also with his programming language KRL, which was "collapsing perhaps under the weight of its own features" (Brachman and Levesque 1995: 263). His long-heralded treatise on *Language as a Cognitive Process* had a promising title, from the point of view of orthodox cognitive science. But it never progressed beyond the first instalment, on syntax (Winograd 1983).

Semantics, he now felt, was very much more difficult. He'd hinted as much in a talk he gave at IJCAI-1973 in Los Angeles. But there, he was saying in effect, "When I wrote SHRDLU, I hadn't really thought much about semantics. I'll have to do so"—and he praised Roger Schank, as someone who was already attempting the taxing task of bringing the communication of meanings into AI (see 9.xi.d). At that point, he hoped to emulate, even surpass, Schank's efforts. But by the mid-1980s, when his *Syntax* book appeared, he'd given up. He'd decided that the task wasn't just taxing, but impossible. And he soon said so, at length, in a book co-authored with Fernando Flores (Winograd and Flores 1986).

Flores had been the key player in leading Winograd to change tack. It was he who'd introduced Winograd to his compatriot Maturana's writings—and to Maturana himself, who later gave them feedback on the draft of their book (Winograd and Flores 1986, p. xiv). Flores didn't go in for nitty-gritty linguistic theory, still less the highly abstract semantics of Richard Montague, then gaining popularity on another part of the Stanford campus (9.ix.c). Indeed, he was less interested in language as such (i.e. sentences) than in the forms of human communication it made possible.

Winograd was drawn to him by political sympathies as well as intellectual ones. Deeply influenced (as a student of engineering) by Stafford Beer's cybernetic work in the 1960s, Flores had been largely responsible for inviting Beer to design the Cybersyn network for the newly elected Allende government in Chile (Chapter 4.v.e). He'd been the minister responsible for nationalizing Chile's industry, and after Colonel Pinochet's CIA-led coup in 1973 he spent three years in prison. He was released in 1976, thanks to the good offices of the San Francisco chapter of Amnesty International—which brought him to Stanford, three years after Winograd's arrival there.

The two men's shared intellectual sympathies eventually went much further than a dissatisfaction with formalist NLP. For, to his previous colleagues' bewilderment, Winograd followed Flores (and Dreyfus) and turned to hermeneutics and phenomenology (9.xi.b and 16.vii), and to autopoietic biology (15.viii.b and 16.x.c). The co-authored book of 1986 bitterly disappointed most of his long-time admirers as a result.

Even Winograd himself hadn't foreseen this volte-face. When he went to Stanford in 1973, he'd known of Dreyfus only through the scandal described in Section ii.a–c above. He says now that he "wasn't pre-inclined" to him (personal communication). I take this remark to be code for something very much stronger: benignly non-competitive though he was, Winograd could hardly have escaped infection by the virulent hostility to Dreyfus then current at MIT. But his inclinations changed. For Dreyfus turned out to be one of a small group, also including Searle and Daniel Bobrow, attending "a very interesting series of informal private lunch seminars". (If Winograd had adopted the macho 1980s motto "Lunch is for wimps", maybe things might have turned out differently!)

One person whose life was changed by the Winograd–Flores book, which he read while it was still in preprint form, was Randall Beer. Then, he was a graduate student in GOFAI, happily writing expert systems in LISP. Now, he's a renowned A-Life roboticist and dynamical systems theorist (15.vii.c and viii.d).

For Beer, Winograd's new book was an epiphany. This wasn't because of its views on language as such, but because it introduced him to the biological ideas of Maturana and Francisco Varela (M&V). Their theory of autopoiesis (15.viii.b and 16.x.c) had persuaded Winograd and Flores to think of 'Language as a Biological Phenomenon' (pp. 38–53). On reading their book, and then M&V's (Maturana and Varela 1972/1980), Beer was convinced that cognition couldn't be understood except as a property of life, and that both these concepts had to be theorized in dynamical, embodied, terms. He now sees his own work as "an attempt to concretely express, illustrate and apply some of the insights that [M&V's ideas on autopoiesis] bring to understanding biological behavior and cognition" (R. D. Beer 2004: 310).

But if the new publication was a welcome wake-up call for this young AI student, for most of its older AI readers it was a very nasty shock. Like M&V themselves, who avoided all talk of "representations" and even of "feature detectors" (15.vii.b), Winograd was rejecting the computational approach wholesale. Considered as a philosophical position, functionalism and "strong AI" were being declared intellectually bankrupt (16.iii–iv, v.c, and ix.b). Considered as a practical proposition, GOFAI-based NLP was being dismissed as a waste of time.

In the eyes of the GOFAI community, this was betrayal. Winograd had started as a heretic and rapidly became a high priest of the orthodoxy. Now, he was an apostate. That in itself was enough to qualify as a bombshell. And GOFAI's philosophical enemies, naturally, made the most of the ammunition.

11.iii. A Plea for Intellectual Hygiene

Neither Dreyfus nor Weizenbaum, nor even the newly reconstructed Winograd, had been asking for AI to be done better. They didn't really want it to be done at all.

Admittedly, they were happy for AI to be applied for highly limited technological purposes. But they didn't want it to be used as the intellectual core of cognitive science.

Indeed, they didn't want cognitive science: *mind as machine* (they believed) was absurd, and *mind as formalist/symbolic machine* was anathema.

Our next bombshell, by contrast, was specifically asking for AI to be done better (McDermott 1976). The person who dropped it in the mid-1970s believed that human intelligence could be explained by symbolic AI in principle, and that logicist programs might model much of it in practice. (He later changed his mind about logicism: see 13.ii.a.) But there was no chance of that, he said, if AI research carried on in the way it had started.

He accused the early AI programmers of being scientifically ill-disciplined and often self-deluding. To turn over-excitable NewFAI into respectable GOFAI, they'd need to mend their ways.

a. The insider

Drew McDermott (1949–) was a well-respected AI researcher at Yale (previously at MIT) when he first threw a cat among the AI pigeons. He was also an accomplished philosophical logician, with a good grasp of work in epistemology and metaphysics. He'd won his GOFAI spurs by helping develop CONNIVER (Chapter 10.v.c), and by modelling some of the automatic inferences made when we hear familiar words (10.iii.d). So he was 'one of the boys'.

However, while the AI community was still basking in the reflected glory of SHRDLU, he wrote a squib about the field for SIGART, provocatively called 'Artificial Intelligence Meets Natural Stupidity' (1976). This was a critique (even, as he put it, "self-ridicule"), not an attack. But it was so cutting, and so well aimed, that when Haugeland later included it in his collection *Mind Design* (1981) it was sandwiched between David Marr's (1977) strongly anti-GOFAI 'Personal View' and Dreyfus's (1981) characteristically dismissive 'AI at an Impasse'.

McDermott charged his NewFAI colleagues—and, disarmingly, himself—with systematic self-deception and obfuscation, various types of sloppy thinking, and lack of persistence in improving first-effort programs. In short: he diagnosed an overall lack of scientific self-discipline, which compared unfavourably with common practice in other areas of computer science.

It was no accident, he said, that many professional computer scientists looked down their noses at AI. It wasn't simply that, as *mathematicians*, they preferred proven theorems to unreliable heuristics. In addition, they deplored the lack of intellectual discipline that was all too common in the NewFAI days. (Resentment at the glamour and media publicity attending AI probably played a part too: I certainly got that impression in several conversations with computer scientists in the 1970s.) "If we are to retain any credibility", he declared, "this should stop" (1976: 143).

Today, 'pure' computer scientists still look down their noses at AI (see 13.vii). But, partly because AI now is technically so much deeper and more rigorous than it was then, McDermott sees this as a primarily methodological difference:

> AI people [today] are willing to try an algorithm and test it empirically even though theorists have proven it won't work. I've had more than one theorist tell me that the value of AI is in its practitioners' willingness to try things. When they work better than expected, often lots of interesting theoretical issues are created as a byproduct, and the theorists move in.

> I'm not saying that AI shows the theory was *wrong*. [We know, for a problem that's NP-complete, that] there's no hope of finding an algorithm that solves every instance of the problem. The question is whether there are interesting clusters of instances where better algorithms can be found, and there's no way to know without empirical exploration. (McDermott, personal communication, 2004)

NewFAI workers, said McDermott in his bombshell paper, weren't being irresponsible at random. A systematic source of self-deception was their common habit (made possible by LISP: see 10.v.c) of using natural-language words to name various aspects of programs.

These "wishful mnemonics", he said, included the widespread use of "UNDERSTAND" or "GOAL" to refer to procedures and data structures. In more traditional computer science, there was no misunderstanding; indeed, "structured programming" used terms such as GOAL in a liberating way. In AI, however, these apparently harmless words often seduced the programmer (and third parties) into thinking that *real* goals, if only of a very simple kind, were being modelled. If the GOAL procedure had been called "G0034" instead, any such thought would have to be proven, not airily assumed.

The self-deception arose even during the process of programming: "When you [i.e. the programmer] say (GOAL . . .), you can just feel the enormous power at your fingertips. It is, of course, an illusion" (p. 145). Indeed, he said, one of the advantages of CONNIVER over PLANNER was that it was *harder* to program in CONNIVER, because FETCH & TRY NEXT was used instead of GOAL, METHOD instead of THEOREM, and ADD instead of ASSERT (144–5). (But he too, he confessed, had been guilty of obfuscation: CONNIVER's so-called "CONTEXTS" were no such thing.) The rot had also affected AI thinking about *deduction*. The meaning of this familiar, and apparently unambiguous, word had been unwittingly changed (by AI work on resolution theorem proving: 10.iii.b) to become "something narrow, technical, and not a little sordid" (p. 145).

Self-deception was rampant in the names given to subroutines. Among the countless examples McDermott could have cited were Colby's FINDANALOG (7.i.a), and Robert Abelson's REINTERPRET FINAL GOAL, ACCIDENTAL BY-PRODUCT, and FIND THE PRIME MOVER (all procedures for "rationalization": 7.i.c). As for the names of entire programs, the famed GPS, with its spurious promise of being a *general problem-solver*, would have been better called LFGNS—"Local-Feature-Guided Network Searcher". And Ross Quillian's (1969) 'Teachable Language Comprehender' would have caused less excitement had it been—honestly—named 'The Teachable Language Node Net Intersection Finder'.

Indeed, whole sub-fields had been optimistically misnamed, with unfortunate effects:

> And think about this: if "mechanical translation" had been called "word-by-word text manipulation", the people doing it might still be getting government money. (p. 148)

Here, McDermott was referring to the disastrous effects of the ALPAC bombshell of 1964 (Chapter 9.x.e), and to the general disenchantment with machine translation seeded in 1960 by another insider, Bar-Hillel (9.x.b and e). He might have added that a similar reproof could have been made—and, already, often was—against McCarthy's name for the field as a whole: artificial *intelligence*. Some AI sympathizers had foreseen this from the start, and had recommended other names accordingly (6.iv.b).

Quillian (1961, 1968) had pioneered another near-ubiquitous example of self-deception, namely, work on semantic networks (10.iii.a). These, said McDermott, were neither semantic nor networks (p. 160). For instance, the apparently simple IS-A link (aka *isa*) was fraught with misinterpretation—usually, over-interpretation. McDermott's worries about IS-A (146 ff.), and about the handling of "a" and "the" (152–3), were broadly similar to those of William Woods (see 9.xi.e). In a nutshell, highly limited—though precisely defined—program procedures were being *interpreted* in a much vaguer, and richer, way.

The sloppy thinking connected with the IS-A link was largely due, McDermott argued, to the lazy assumption that natural language provided both problems and solutions. In other words, language-like internal representations in the computer were felt to be intrinsically superior to more abstract ones. (This was implicit in Quillian's little note of 1961, for example.) To the contrary, any really illuminating (and workable) representation of a familiar concept or an English sentence would be "a directly useful internal representation, probably as remote as possible from being 'English-like' " (p. 150).

Moreover, natural language was being underestimated. Not only is it often/usually used for purposes other than transmitting information, but its meaning can't be easily corralled. For instance, the common NewFAI assumption that words such as *the*, *a*, *all*, *or*, and *and* are expressible in something like predicate calculus terms was an illusion. Russell and the logical atomists had believed it, to be sure (Chapter 4.iii.c). But their philosophical critics had been legion. Even the exercise of "examining two pages of a book for ten-year olds, translating the story as you go into an internal [programmed] representation" (p. 153), said McDermott, would show the task to be horrendously difficult. (Here, he was thinking of Eugene Charniak's work: Charniak 1972, 1973, 1974.)

In general, he added, people should distinguish clearly between what their program actually did and what some other version of it might do in the future. As it was, "Performance and promise run together like the colors of a sunset" (p. 157). What the program *didn't* do should also be made clear:

> AI as a field is starving for a few carefully documented failures. Anyone can think of several theses [including some highly publicized ones] that could be improved stylistically and substantively by being rephrased as reports on failures. I can learn more by just being told why a technique won't work than by being made to read between the lines. (p. 159)

(It's worth remarking, by the way, that one of the many commendable—and often commended—aspects of Winograd's Ph.D./book had been his unusual honesty in pointing out the *limitations* of his program.)

Last but not least, McDermott identified a "common idiocy" in AI research: the abandoned-program syndrome. Far too often, people supposed "that having identified the shortcomings of Version I of a program is equivalent to having written Version II" (p. 156). (Again, he identified himself as one of the culprits: McDermott 1974.) There was some sociological excuse for this, in that the culture of awarding Ph.D.s in AI prioritized theoretical comment over effective programming, and sought new work on new problems rather than improvements on research already done (whether by Self or Other). But scientific excuse, there was none. What true scientist would happily report only his initial, half-baked, ideas, without carrying them forward in later work?

Colleagues, too, should be able to carry them forward. But if AI was to benefit from normal scientific cooperation (Chapter 2.ii.b–c), programs should be properly debugged so that other people could run them, test them, and develop them. Although McDermott didn't say so (because he didn't know it at the time: personal communication), Winograd was at fault here. The man–machine conversation he'd reported was the only one of that length ever produced (even so, it may have been 'cobbled together' rather than being one continuous interchange), and it turned out that SHRDLU couldn't be effectively run by walk-up users because of the bugs remaining in it (Winograd, personal communication—see 9.xi.b). McDermott admitted, however, that a first-effort program may be very useful—and surprising—in showing what can be done, and what with persistence *might* be achieved.

This was strong stuff: McDermott didn't mince his words ("stupidity", "idiocy" . . .). But he didn't suffer the calumnies that the AI profession was directing against Dreyfus and Weizenbaum. Not only was he an insider, and a self-confessed culprit to boot, but he was undeniably right. His arrows had hit the mark. Moreover, he wasn't saying (as they were) that AI was a worthless enterprise. Even logicist AI was a respectable project (so he believed at that time: but see 13.ii.a).

b. Natural Stupidity survives

Some others, too, were complaining that AI's "lack of self-generated criticism is scandalous" (Wilks 1976: 184). Their remarks, and McDermott's, shamed some of their colleagues into being more self-critical. Even so, complaints about "natural stupidity" still had to be made in the 1980s . . . and occasionally have to be made now.

(To be fair, natural stupidity wasn't monopolized by GOFAI. It was a feature of some *connectionist* AI as well. "Why think when you can simulate?", as James Anderson put it—see Chapter 12.ii.a.)

A decade after McDermott's squib, two similar complaints were made on either side of the Atlantic. One came from McCarthy, then President of the AAAI (McCarthy 1984).

His brief President's Message (constantly threatening, he said, to turn into a paper) argued that we need better standards for AI work. Not that AI people were any less motivated than other scientists to do good work: they weren't "fooling" the funders, or the public. But in any science evaluative standards have to develop, and this takes time. In AI, he said, they "are not in very good shape" (p. 7). He identified seven principles that should help AI to progress faster, some of which (such as repeatability) had been anticipated by McDermott. And, by the way, he pointed out that although the Turing Test can be an interesting "challenge" for AI research, it *isn't* a "scientific criterion" of AI value (8)—see Chapter 16.ii.

The other complaint published in that year came from Edinburgh's Alan Bundy (1947–). He criticized GOFAI work as—still—insufficiently analytical and (therefore) non-cumulative (Bundy 1984; Bundy *et al.* 1985). Although learning was the particular domain he considered, his conclusion was directed at AI in general. A more scientific, not to say mathematical, approach was required if the field was to progress.

With respect to learning, Bundy showed that a powerful "focusing" algorithm defined by some of his Edinburgh colleagues in the year following McDermott's 'Natural Stupidity' tirade subsumes many AI programs modelling superficially different types of learning in apparently different ways (discrimination, generalization, version-spaces . . .). That is, the principled core of these seemingly diverse programs was the same. Moreover, it helped explain the differences in the ways in which they modify their rules on the basis of positive or negative information, and in learning conjunctive or disjunctive concepts.

The explanation of *why* these programs worked, as opposed to mere reports *that* they worked, lay in such theoretical analysis. In Chomsky's language (which Bundy borrowed), AI research shouldn't merely describe a program's performance, but should identify its competence as well (Chapter 7.iii.a).

By that time, Marr too had asked for more systematic theoretical analysis in AI (D. C. Marr 1977). Indeed, he'd gone further than either Bundy or McDermott, claiming that AI programming is a waste of time if the abstractly definable task underlying the domain concerned hasn't been identified (7.iii.b).

Minsky and Papert, of course, had provided an abstract computational analysis of one type of AI—namely, simple perceptrons—twenty years earlier (12.iii.a–c). Indeed, ten years earlier still Minsky had shown (in 'Steps': 10.i.g) that analytical questions and comparisons were crucial. But the point hadn't sunk in. For far too long, the Minsky–Papert exercise remained the Lone Ranger of *theoretical* AI, or what McCarthy called meta-epistemology. If McDermott's advice had been truly taken to heart when he wrote his paper, companions might have turned up sooner.

As it is, most of McDermott's complaints still ring true of much AI work. That's clear from these two late-century remarks—one astringent, the other defensive:

> We need to discipline ourselves so that our tests are both proper in themselves and connectible, through common data or strategies, with those done by others. Because if we do not seek the standards [that] doing information science should imply we will be open, correctly, to the claim that we're just inventing copy for the salesmen. (Sparck Jones 1988: 26)

> Computer science is really like physics in 1740. People are so happy for any results, that more than haphazard repeatability and duplication of other people's results are too much to ask. It's still at the stage where people are discovering rather than colonizing. (D. B. Lenat, interviewed in Shasha and Lazere 1995: 229)

It's clear, too, from the fact that AI hype still occurs.

For instance, the official web site for RoboCup, the ongoing competition in robot soccer, opens by declaring this as the aim:

> By the year 2050, [to] develop a team of fully autonomous humanoid robots that can win against the human world soccer champion team. (<http://www.robocup.org>, accessed 9 Apr. 2004)

In 1999, soon after RoboCup was launched—at the IJCAI-1997 meeting in Nagoya, Japan—with ninety AI teams competing (Asada *et al.* 1999, 2000), one of its initiators quoted those words and commented:

> The current technology is nowhere near the accomplishment of that goal, as most robots use wheels instead of legs, and have serious difficulties seeing a ball and other robots. Nevertheless, we believe that the goal can be accomplished by 2050. (Kitano 1999: 189)

One of the main issues, he said (p. 190), was collaboration: How can robots learn to collaborate? How could teamwork emerge? How can we program it? Do we even need to program it? (One of the papers representing the then state of the art described an entirely behavior-based approach: Werger 1999, and cf. 13.iii.d–e.)

The competition's spokesman Mats Wiklund apparently hadn't read the first sentence of that last quotation. For he was reported by Reuters in 1999 as predicting man-sized soccer automata by 2002, "although we don't expect the robots to stand a chance against humans at that stage". If Reuter's quotation was accurate, Wiklund's words "at that stage" were more lunatic than cautious.

A few years later, more than 300 research groups around the world were involved with RoboCup; and the 2003 competition in Padua registered 243 teams and 1,244 participants. By that time, much of the more successful (i.e. least embarrassingly unsuccessful) efforts were going into small puppy robots, not large two-legged ones. (Most of these were AIBO robots bought off the shelf from Sony: see <http://www.eu.aibo.com>. The challenge was in the programming, not the engineering.) And the dreaded offside rule was still nowhere to be seen. But the overall aim hadn't changed.

There's no doubt that something of interest will ensue (has already ensued) from this exercise, which involves real-time world-modelling and real-time decisions about cooperation and strategy. That's argued persuasively in a recent paper co-authored by the eminently sane Alan Mackworth (Sahota and Mackworth 1994). It was he who first recommended soccer as a fruitful domain for AI. Although he's now given up on soccer (because it doesn't allow for long-term planning), he's still working with ball-kicking robots relying on recognition and guidance—i.e. not on lasers or sonar (13.iii.c). Indeed, he suggests replacing "GOFAI" with "GOFAIR", where the "R" stands for *situated* or constraint-based Robotics (Mackworth 1993, 2003). (Unlike the more radical situated roboticists described in Chapter 13.iii.b, however, he doesn't deny representations or planning: GOFAI is part of GOFAIR.) But he bemoans the lack of scientific discipline in most of the RoboCup work:

> Our original robot soccer-players were the world's first . . . We did enter the simulation track [of RoboCup] three times. We were focussed more on the science than performance (at least, that was our excuse)—we won the odd game, but never a competition. I tried as a member of the Board to get people to accept a standard hardware platform but failed. So much of the effort went into hacking a better kicker etc., not into smart controllers and planners. Although it has had a tremendous stimulating effect on students and good PR, not a lot of great new science has come out of it. That disappointed me since I started it all. But in retrospect soccer has lots of great features as a test bed but it lacks longer term time horizons and hence planning and the like. (A. K. Mackworth, personal communication, 2004)

Most RoboCup competitors are less judicious than Mackworth. There are occasional signs of caution in the PR material: the report on the latest bout of the competition, for instance, opens by saying, "We do not promise that this [officially stated] goal will be reached by 2050" (Pagello *et al.* 2004: 81). Nevertheless, the mind boggles. The defence given to me in 2004 by one of RoboCup's winning team leaders (tact forbids . . .) that "It's not a prediction, it's a challenge. No one takes it seriously!" was disingenuous. For this admission came only after repeated needling from me. At first (and second, and third . . .), this person had insisted that the declared goal was achievable. I was repeatedly given the PR party line, obviously compiled for communication to journalists, with no attempt to engage with the scientific questions I'd raised.

In short, RoboCup isn't unambiguously "good PR". It may well have brought more students into AI, as Mackworth says. It's even been named by Paul Cohen (also an eminently sane individual) as one of the "new challenges" to replace the Turing Test as a measure of advance in AI (P. R. Cohen 2005: 63–4, 67). And it undoubtedly gets AI onto our TV screens. But as *the very first item* on the RoboCup web site, the ludicrous prediction cited above is potentially damaging. For such attention-seeking irresponsibility can lead people to devalue AI as a whole—as McDermott pointed out over thirty years ago.

McDermott, here, should have the last word. In a recent interview (in the ACM's first electronic publication), he was asked how he feels about being an AI researcher today:

> I'm thrilled with my station in life now. I think AI has matured a lot and has developed into a much more hard-edged discipline. I'm glad just to be a part of that. (McDermott 2001*a*)

Even so, he said in the same interview that youngsters entering AI should beware of the superficially "exciting" projects, and question their supposedly technical vocabulary so as not to fall into "fantasy":

> If somebody starts talking about meta-rules and you're thinking "Wow, this is really neat, this is like something that is self-conscious, it's able to think about its own structure, etc.", think again. I cringe when I hear people talking about meta-knowledge representation of something. It seems to me there are still a lot of people in AI who are living in a fantasy world, and it ultimately hurts the field. (2001*a*)

In sum, his rules of intellectual hygiene for AI are still valid—and sometimes still needed.

11.iv. Lighthill's Report

As René Descartes foresaw long ago, progress in scientific research requires not only intellectual creativity but also financial support (2.ii.b–c; cf. 6.iv.f). So the historian must sometimes consider money: where it came from, why it occasionally dried up, and what—sometimes—made it start flowing again.

GOFAI suffered four funding bombshells. These were especially damaging, not least to overall morale, when they were grounded not in fiscal/military policy in general (as recounted in Section i) but in the funders' disaffection with AI in particular. That applied to the first and second financial bombshells: two government-initiated reports which, in essence, declared AI to be a waste of time—and money.

The first was the ALPAC Report of 1960 (9.x.f), the second the Lighthill Report some ten years later. The former was launched in the USA, and virtually stopped MT funding on both sides of the Atlantic. The latter originated in the UK, and caused significant damage there—with shock waves spreading across the Pond.

It's worth remarking that the explosive force of the second of these bombshells was largely due to the personality of one man. His personality, you'll notice: not his research. As such, it's a telling objection to the Legend of wholly disinterested science (Chapter 1.iii.b).

a. A badly guided missile

The Lighthill Report was twenty-one pages of dynamite, sent from on high to wreak havoc on the ground. It caused a recurring nightmare for AI in Britain, a bad dream that was eventually ended by dawn trumpets from Japan. It even engendered a few restless nights in the USA. This extraordinary episode wouldn't have happened but for the personal characteristics of a single individual: namely, Michie.

Michie was the founder of symbolic AI in Britain (see 6.iv.e). He was clever, literate, charming, self-confident, persistent, energetic, entrepreneurial . . . and each of these, in spades. In a word, charismatic. But he was also, for such a suave man, surprisingly brash in his claims about his own, and AI's, achievements and potential.

Before turning to AI, he was already well known—and, significantly, well connected—as a geneticist (a protégé of Conrad Waddington at Edinburgh: see 15.iii.b). In the 1950s, with his first wife, Anne McLaren (now Dame Anne, FRS), he'd published research that helped lay the groundwork for today's reproductive technology—and later earned him a Pioneer Award from the International Embryo Transfer Society. So although AI became his passion, it wasn't his first scientific success.

As for his achievement in AI, this was significant. Indeed, he was recognized by IJCAI's Reward for Research Excellence in 2001. For example:

* His pole-balancer, written on his MENACE-inspired visit to Stanford in 1961 (see 6.iv.e), was the first reinforcement-learning program (Michie and Chambers 1968). It wasn't a simulation, but controlled a real pole on a real cart.
* The pioneering Graph Traverser (Doran and Michie 1966; Doran 1968*b*; Michie and Ross 1969) provided ideas that are now standard in heuristic search, and it still lives on as the core of a widely used planning program developed by Austin Tate (Michie 2002: 4).
* His later work (with Ivan Bratko) on chess endgames was an important contribution to chess programming—and to our knowledge of chess (e.g. Bratko *et al.* 1978; Bratko and Michie 1980).
* And his recent StatLog project, which ranges from statistics through tree building to dynamical systems, has been described as "by far the most exhaustive investigation into the comparative performance of learning algorithms" (Russell and Norvig 2003: 675; cf. Michie *et al.* 1994).

For present purposes, however, what's most relevant is his sociological influence as a research leader and highly visible AI guru. In those roles, he was hugely constructive, on the world scene as well as nationally. But he also sowed some destructive seeds.

His Department of Machine Intelligence and Perception was the first in the world to be dedicated to AI. (For the story of how it came to be founded, see Chapter 6.iv.e.) Among the AI leaders who came from that stable were Patrick Hayes, Robert Kowalski, Aaron Sloman, Michael Brady, Rod Burstall, Robin Popplestone, James Doran, Bundy, and Tate. In addition, many US scientists spent brief visits there—and some recorded their gratitude for Michie's guidance and suggestions (e.g. Quinlan 1983: 481). His Edinburgh colleague Meltzer was the first editor of the *Artificial Intelligence* journal (founded in 1970). And Michie's international Machine Intelligence meetings and publications, initiated in the mid-1960s, were the first regular series in the field.

All that was highly commendable—and hugely influential. So much so, that when Donald Broadbent and others in 1970 lobbied to get some much-needed government funding to support the maverick AI being done by Gordon Pask's team in Richmond, they lost out to Michie's team in Edinburgh (Mallen 2005: 87). But there was trouble in the offing.

By the time of the break-up of the Edinburgh triumvirate in 1970 (Chapter 6.iv.e), two of Michie's colleagues, Meltzer and Christopher Longuet-Higgins, had become his bitter enemies (P. J. Hayes 1973: 36–7, 43–4; Howe 1994). Indeed, Meltzer (1971) had recently regaled their international peer group, the readers of the *SIGART Newsletter*, with a squib containing some caustic remarks about the Edinburgh robot FREDDY. (His subtitle, 'Bury the Old War-Horse!', referred to the Turing Test, wrongly seen by the public as a criterion of success in AI—but one might have been forgiven for interpreting the title in another way!) Since he was the first Editor of the *Artificial Intelligence* journal, Meltzer's criticism of his colleague's pet project carried weight as well as venom.

The discord had spread way beyond Edinburgh. Michie's tireless lobbying for and publicizing of AI had offended many people. In part, they were annoyed by (even jealous of?) the huge public attention his department attracted: so many TV crews and other visitors made their way there that such visits eventually had to be restricted. In part, too, they were upset by his unrealistic optimism. Domestic robots, according to him, were just around the corner. (That's not quite fair: sometimes, he was more realistic—e.g. Michie 1968*b*.)

Worse, some doubted his reports of the present almost as much as his hubristic hopes for the future. They suspected that his glowing descriptions of FREDDY were, to put it delicately, inaccurate (see below).

The squabbling in his department was the most important of three factors which prompted the Science Research Council (SRC) to commission Sir James Lighthill (1924–98) to write a "dispassionate" report on AI research in the UK. They could hardly have chosen anyone more high-profile. For Lighthill, a world leader in hydrodynamics, was the holder of the Lucasian Chair of Applied Mathematics at Cambridge—previously held by Isaac Newton and Charles Babbage (and today by Stephen Hawking).

The second factor behind the decision was a recent SRC review of computer science. This had found a troubling division in professionals' attitudes towards the centrality/marginality of AI (SRC 1972: 19). And the third was Michie's recent (failed) application for a seven-year grant, which had included a request for a PDP-10, a machine larger than any the SRC had ever provided for research in any discipline (Michie 1972).

The Report, submitted in September 1972, had been intended as an internal document for the SRC's eyes only. But it was so controversial that the Council decided (uniquely, so far as I can discover) to publish it—and with four commentaries alongside it (SRC 1973).

The original version had contained corrosive personal comments about Michie, who'd been *very* generously funded by SRC. One member of the relevant SRC committee (who prefers to remain anonymous) recalls, for instance, that they were shocked to discover that Michie's widely shown film of FREDDY was speeded up by sixteen times, and that the assembly being filmed wasn't fully autonomous but was being controlled by someone at a keyboard. The defence, he tells me, was (1) that the measurements being used by the human controller were correct, so they *would* work in an autonomous robot; and (2) that the slowness was due to the human's being unable to tell the arm/gripper to move *up 7*, *left 21*, *down 3*, but having to type in each step incrementally: *UUUUUUULLLLLLLLLLLLLLLLLLLLLDDD*. That defence might have been grudgingly accepted if these shortcomings had been mentioned up front, but they weren't.

In short, Michie hadn't delivered what he'd promised, nor even what he'd announced. To be fair, he wasn't the only person playing this sort of game. Hans Moravec, a graduate student at Stanford when grant reports/applications were being prepared for the SHAKEY robot, remembers a similar deception:

> An entire run of SHAKEY could involve the robot going into a room, finding a block, being asked to move the block over to the top of a platform, pushing a wedge against the platform, rolling up the ramp [formed by the wedge], and pushing the block up. SHAKEY never did that as one complete sequence. It did it in several independent attempts, which each had a high probability of failure. *You were able to put together a movie that had all the pieces in it*, but it was really flaky. (interviewed in Crevier 1993: 115; italics added)

Moravec added: "Not that it fooled anybody: the DARPA people who were reading those reports had been students in AI a few years before!" So perhaps Michie's 16-accelerated film might have been viewed more indulgently had it not been for the composition of the committee. My informant tells me that the panel included highly influential theoretical computer scientists who would have had scant time for AI, which is largely experimental, even if it had been done by the Angel Gabriel.

The Lighthill Report fizzed with bubbles of contempt. The fiercest criticisms were excised before publication, although they'd already spread on the grapevine to some extent. However, everyone in the AI community was able to decode the expurgated text, considered as a *roman-á-clef*.

What caused the major scandal (as opposed to the insider gossip) was Lighthill's dismissive judgement of AI in general. Or rather, *what he took to be* AI in general (see subsection b).

He divided AI into three categories. Category A was Advanced Automation for specific purposes—including expert systems, speech recognition, and MT. Category C was Computer-based CNS research—including models of cerebellar function, associative memory, language, and vision. These two categories, he said, had only "a minor degree of overlap of interest" (Lighthill 1973: 6). They were closer to already established (code: respectable) disciplines—computer science and control engineering for A, neurophysiology and psychology for C—than to each other. The third was category B: the Bridge Activity of Building Robots, where "aims and objectives are much harder to discern but which leans heavily on ideas from both A and C and conversely seeks to influence them" (pp. 2, 17). It sought to "mimic" hand–eye coordination, visual scene analysis, use of natural language, and common-sense problem solving (p. 7).

Although the Report started by including all three categories within AI, it went on to treat category B alone as "AI" properly so-called. Broadly speaking, Lighthill approved of work in categories A and C. Indeed, in 1973 he told MIT that Stephen Grossberg was doing, as Grossberg has put it, "exactly what AI should have done" (Chapter 14.vi.a). "Bridging" projects, however, were lambasted.

The only AI person for whom Lighthill had a good word to say was Winograd—who'd clearly charmed him, as he charmed everyone else, with his refreshing modesty. But even Winograd's work, which he classified as C, was used (because of its reliance on detailed world knowledge) as a stick to beat category B (pp. 16–17).

Lighthill's tendentious definition of category B could be decoded even by outsiders as *What's valuable in B has almost all been pinched from A or C, neither of which have benefited from B—and they never will.* Insiders could just as effortlessly decode it as *The work done at Edinburgh that was directed by Michie, rather than by his colleagues Longuet-Higgins, Meltzer, and Richard Gregory*. And just in case someone hadn't already worked it out, there came a passage which—in the British context—pointed the finger straight at Michie:

> [Disappointments about category B arose because] claims and predictions regarding the potential results of AI research had been publicized which went even farther than the expectations of the majority of workers in the field, whose embarrassments [*sic*] have been added to by the lamentable failure of such inflated predictions. (p. 8)

So Lighthill said, for instance:

> There is . . . a widespread feeling that progress in this bridge category B has been even more disappointing [than in A and C], *both as regards the work actually done and as regards the establishment of good reasons for doing such work* and thus for creating any unified discipline spanning categories A and C. (p. 3; italics added)

> *[The] whole case* for the existence of a continuous, coherent field of Artificial Intelligence research (AI) depends critically on whether between categories A and C *there exists* a significant category of research that may be described as a "Bridge" category, B, as well as on the strength of the case for *any* researches in that category. (p. 6; italics added)

And again, there came a remark that pointed straight to Michie:

> Here, letter B stands not only for "Bridge activity", but also for *the basic component* of that activity: Building Robots. [This is] seen as an *essential* Bridge Activity justified primarily by what it can feed into the work of categories A and C, and by the links that it creates between them. (p. 7; italics added)

The motivations of Robot Builders were sneered at, being said to include "to minister to the public's general *penchant* for robots [from medieval fantasy to science fiction]", and perhaps "to compensate for the lack of female capability of giving birth to children" (p. 7). (One of Edinburgh's small team of roboticists, Pat Ambler, was a woman: perhaps, to this very Establishment male, she was invisible?)

He listed the "past disappointments" in all three categories, and especially in B, with some relish. The vast amounts of money spent on MT and general speech recognition had been "wholly wasted". (This, remember, was advice to a funder.)

Lighthill allowed that B-research on high-level programming languages had been useful. (These included Edinburgh's POP, used for most AI work in Britain for many years: 10.v.c.) He also allowed that computational modelling had encouraged "a new set of attitudes to psychological problems", by distinguishing "possible candidates for consideration and theories that simply cannot be made to work" (p. 12). But he classified this research (including SHRDLU, and early connectionist AI in general) as category C—i.e. not AI at all.

And his diagnosis? Here he pulled rank, using masterly understatement. "As a mathematician", he said blandly—his readers would know that he held Sir Isaac Newton's Chair—he was inclined "to single out one rather general cause" (p. 9). Namely, "failure to recognize the implications of the 'combinatorial explosion' ". (That was unfair: as we saw in Chapter 10.iii, the combinatorial explosion had been recognized since the late 1950s. Waltz-filtering, for instance, was developed to avoid it.)

The rubble created by this missile was widespread. Summaries and titbits from the Report appeared in the media: *Sun* readers might not be assailed by it, to be sure, but opinion-formers taking *The Times* or other broadsheets were. Moreover, Lighthill's eminence (besides holding Newton's Chair, he'd amassed twenty-four honorary doctorates by the time he died—Mialet 2003: 443) ensured that his judgements would be taken as authoritative by the general public, and by the scientific community at large. They'd even be *welcomed*, since—as explained in Section ii.f, above—most people were suspicious and/or fearful of AI in the first place. (A close parallel was Sir Roger Penrose's ill-informed but widely popular attack on AI, around 1990: Chapter 14.x.d.)

In short, the picture looked grim.

b. Clearing up the rubble

Such was the concern at Lighthill's conclusions that, besides publishing the Report (largely at Michie's insistence, I'm told), the SRC Chairman Brian Flowers announced in the Preface that "The Council would welcome readers' comments on the importance of artificial intelligence research, and the extent of the support the Council should plan to give to it." As a start, the SRC publication itself included four sections of commentary written by people with differing views.

The most important objection, which was made by many people, was that Lighthill's (regrettably vague) A–B–C classification, and his tendentious definition of category B, betrayed fundamental misunderstanding of the field. As the psychologist Stuart Sutherland put it:

> Area B [best interpreted not as Building Robots but as "Basic" research] has clearly defined objectives of its own. Its aim is to investigate the *possible* mechanisms that can give rise to intelligent behaviour, to characterize these mechanisms formally, and to elucidate general principles underlying intelligent behaviour. These seem to be valid scientific aims and are clearly different from those of work of types A and C. (N. S. Sutherland 1973: 22)

Similarly McCarthy:

> If we take [his] categorization seriously, then most AI researchers lose intellectual contact with Lighthill immediately, because his three categories have no place for what is or should be our main scientific activity—*studying the structure of information and the structure of problem solving processes independently of applications and independently of its realization in animals or humans.* (McCarthy 1974: 317)

Sutherland, Michie, McCarthy, and Hayes all pointed out that many examples of AI work couldn't be readily fitted into *only one* of Lighthill's three categories. All agreed that B-research didn't cover only robotics. (Lighthill's use of "Robot" was unclear in any case, for he sometimes included chess-playing programs—P. J. Hayes 1973: 39–40.) And Hayes remarked that the A–B–C classes "fit altogether too neatly" with the "idiosyncratic" views of three mutually hostile personalities at Edinburgh: Meltzer, Michie, and Longuet-Higgins (P. J. Hayes 1973: 43). Their interests, as well as their personalities, differed. (Meltzer was a theoretical computer scientist, and the first Editor of *Artificial Intelligence*; Longuet-Higgins, who'd won his FRS as a chemist, had already done seminal research on associative memories, language, and the perception of music: see Chapter 12.v.c and Longuet-Higgins 1962, 1972, 1976, 1979; Longuet-Higgins and Steedman 1971.) (An intriguing snippet: Lighthill and Longuet-Higgins had been separated by only one year at Winchester public school, where they used to work on maths conundrums together—H.C.L.-H., personal communication.)

Definitions can always be nit-picked, of course. But as Sutherland said (1973: 23), definitions *matter* when what's being discussed is which areas should be supported by a funding council, and which should not.

Lighthill's misunderstanding wasn't too surprising, for his "independence" was close to ignorance. He'd spent only two months investigating AI, and hadn't contacted some whom one would have expected to be approached. His fifty-one names included many non-AI people, and were mostly British—although McCarthy, Minsky, Winograd, David Hubel, Bertram Raphael, and Ira Pohl were also listed. Indeed, it appeared that he'd spent most of his time talking to people at Edinburgh (Hayes 1973: 37). That was too bad. Even Lucasian professors need to do their homework.

The main set of Comments published alongside the Report was written by Sutherland, Professor of Experimental Psychology at Sussex. This was a masterly demolition of Lighthill's paper, explaining why psychological AI is the intellectual core of cognitive science.

The other comments came from Longuet-Higgins (by then, also at Sussex), Roger Needham, and Michie. Longuet-Higgins (1973) praised Lighthill's paper as "shrewd", "penetrating", and "comprehensive", and (predictably) endorsed his positive valuation of category C. But, he said, Lighthill had been too concerned with the brain's hardware, as opposed to its software. Even Marr's abstract models of the neocortex (14.v.c–e) would "for some time to come" be less valuable for the cognitive sciences (*sic*: see 1.ii.a) than non-neurological AI theories of cognition would be.

The most like-minded response came from Needham, a leading computer scientist at Cambridge (see Preface, ii). But even he admitted that the A–B–C classification was "contentious" (SRC 1973: 32).

The commentary didn't stop there. The UK's/Europe's AI Society ran two reviews in their newsletter. One was a delicious two-page spoof supposedly written by "Sir Grogram Darkvale FRS" (the ogre's name having been turned upside down), but actually authored by Sussex's Max Clowes (Anon. 1973). The other was a more serious piece, by McCarthy's collaborator Hayes—who defined AI as "the development of a systematic theory of intellectual processes, wherever they may be found" (1973: 40).

Meanwhile, across the seas, McCarthy (1974) reviewed Lighthill for the *Artificial Intelligence* journal. He allowed that AI faced great difficulties, and had been "only moderately successful" (p. 322). Nevertheless, he concluded that "Lighthill has had his shot at AI and missed" (p. 321). This was hardly surprising, since the missile's goal had been so badly defined.

(In private, of course, the sparks flew even higher. Hayes was heard to remark that accusing roboticists of having repressed maternal instincts was like accusing hydrodynamicists of suffering from premature ejaculation.—Lighthill, you'll remember, was a hydrodynamicist.)

Certainly, Sutherland, Hayes, and McCarthy were all *partis pris*. Even so, their reviews would astonish the innocent reader. Rarely can such an important piece of advice on scientific funding, and by such a hugely eminent author, have been so shoddy. (An Edinburgh friend, who shall be nameless, told me that someone he knew phoned Flowers to say: "You idiot! If you wanted to bury Michie, why didn't you pick someone who'd do the job properly?")

Michie, of course, was the *parti* most *pris* of all. He didn't lie down quietly. Indeed, it was largely due to him that the Report had been made public in the first place. His official reply filled eight pages in the SRC's Lighthill booklet. This concentrated on the substantive issues, and on the implications for funding needs in the UK (for a PDP-10, for instance, and an interface to the ARPAnet). To reach a much wider readership, he also wrote four papers timed to coincide, more or less, with the publication of the Report. One was for the popular *Computer Weekly*, for whom he was soon writing a regular column ("Michie's Privateview") in which AI was often lauded (Michie 1973*a*). Another, comparing the vast sums spent on largely irrelevant nuclear physics with the much smaller amounts needed for practically useful AI, appeared in the equally popular *New Scientist* (1973*d*). A third, specifically defending Edinburgh's AI work, graced the pages of the business-oriented *Management Informatics* (1973*b*). And the last, aimed at his scientific peers, was for *Nature* (1973*c*).

He didn't stop there. Within a twelvemonth, he republished some of his less technical articles (written from 1961 onwards), aimed not at AI specialists but at administrators and scientists in general (Michie 1974). Other trade books on AI would eventually follow (Michie 1982; J. E. Hayes and Michie 1983; Michie and Johnston 1984). True to form, these pulled no punches: the question of the potential of AI "is believed by some to be the most consequential ever posed" (J. E. Hayes and Michie 1983, p. ix).

But the damage was done: journalists, businessmen, and even scientists were more aware of Lighthill's scandalous conclusions than of the detailed rebuttals. The Lighthill Report thus undermined the morale of AI researchers in the UK. Not only did they fear the SRC funding stop which Lighthill had recommended, but their scientific reputation in the eyes of outsiders (including alternative funders) had been lowered.

Among those who left for the USA as a result were Hayes and Brady, both then at Essex. (After helping to run the MIT AI Lab for some years, Brady eventually returned; he's now "Sir Michael" and Professor of Information Engineering at Oxford.) They didn't escape entirely, however, for the psychological shock waves were felt across the seas.

This is evident from contemporary issues of the *SIGART Newsletter*. Indeed, one of the best-attended sessions at IJCAI-1973, held in August at Stanford, was a hot-off-the-press video of the Royal Institution's (July) debate between Lighthill, Michie, Gregory, and McCarthy. (I remember the atmosphere's being more like a pantomime than an academic occasion: the dramatis personae drew repeated hisses and cheers from the Stanford audience.) And although various US colleagues tell me that they can't recall research funding being affected, there was a cutback in US money for robotics (Fleck

1982: 192). In addition, as noted above, ARPA started favouring mission-directed research. The historian Fleck grants that this happened in a social context of *general* cutbacks for 'irrelevant' scientific research (see i.b and c, above), but he believes that Lighthill was an additional factor (ibid.).

Whether the Report hugely delayed the advance of AI in the UK is controversial. The administrative leader of the Alvey Programme (see v.c, below) stated that Lighthill "dealt a heavy blow to AI research in Britain from which, in 1981, it had yet to recover" (B. Oakley and Owen 1989: 15). So did the post-Alvey evaluation commissioned by the government:

> Prior to Alvey [i.e. in the early 1980s] the UK AI community was small and fragmented. Government support for AI was minimal. The Lighthill Report of 1973 *had resulted in a significant reduction in AI funding and led to a brain drain of many key figures from the UK*. By 1980 skilled personnel were concentrated in a handful of academic centres. (Guy *et al*. 1991: 16; italics added)

The SRC itself had said much the same, in 1979:

> The Panel [on Proposed New Initiatives in Computing and Computer Applications] *has no doubt* that the reluctance of the present community to take up the challenge (of industrial robots research) is due at least in part to *the general discouragement of Artificial Intelligence* which took place in this country several years ago and that it is now up to SRC to take steps to remedy the situation. (quoted in Fleck 1982: 215 n. 87; italics added)

But Sloman disagrees:

> In the UK, it certainly did not nearly (even temporarily) kill off AI, as some people often say. The main effect was to facilitate the spread of funds for AI to other parts of the UK, so that it became less heavily concentrated in Edinburgh. (personal communication)

Although the funding for Edinburgh became less generous, they did get the PDP-10 and ARPAnet access that Michie had asked for. And other centres, Sussex included, were given access to it for SRC-funded AI research. So work didn't grind to a halt.

It's true that AI funding in 1973–83 didn't reach the level that had been recommended in the earlier SRC review (SRC 1972). But science funding in general during that period, in the UK as in the USA, fell as a result of the OPEC-initiated oil crisis. Much of the UK's 1970s AI was funded not as "Computer Science" but via the new SRC Panel on Cognitive Science. This, as it happens, was set up largely as a result of the anti-Lighthill arguments from Longuet-Higgins and Sutherland.

As for Michie, he was officially sidelined. A new Department of Artificial Intelligence (headed by Meltzer) was formed in 1974, which took over most of the resources, including the robotics equipment, built up under his leadership. He was shunted off into an independent Machine Intelligence Research Unit, and forbidden to work on robotics (Fleck 1982: 189).

But he was irrepressible. Through the rest of the 1970s he accepted many visiting appointments abroad—mostly in Virginia (with his ex-Bletchley colleague Jack Good) and Illinois, but also Canada and the USSR. At home, he spent much of his time in publicizing expert systems. Besides his contributions to the media, he set up a British Computer Society special interest group on expert systems, which ran its own conferences and newsletter.

By the early 1980s, he'd even achieved some distance from the crisis. He now explained the Lighthill incident as a "mishap of scientific politics" due to all-too-human frailties:

> Officialdom has subsequently indicated eagerness to repair the damage. Bodies such as the Science Research Council may find it hard to accept some of the remedies required—notably *the return from abroad and re-habilitation of some of those whose work was pilloried*.
>
> At the time, I felt amazement. Ecclesiastes, that incomparable analyst of the dark side, has warned about this feeling: "If you see in a province . . . justice and right violently taken away, do not be amazed at the matter; for the high official is watched by a higher, and there are higher ones over them . . .".
>
> A number of officials attempted at the time to palliate my wrath by explaining in just such terms some of the actions which their jobs had obliged them to take. I concluded that nothing but ignorance at the top could be the cause of the abuses, and that no good could be accomplished until the minds of men were better informed [and so I wrote many "popular" articles about the achievements and promise of AI]. (Michie 1982: 247; italics added)

How had he regained his urbanity? The "re-habilitation" had been made possible when the UK's AI nightmare was abruptly ended by loud noises from Japan. As we'll now see, this clarion call was shamelessly economic/political, not Legend-arily scientific.

11.v. The Fifth Generation

The third funding bombshell was constructive rather than destructive, rescuing non-military AI from the doldrums—and, to some extent, from other scientists' scepticism. It can be called a "bombshell" nevertheless, because its advent was unexpected and its immediate results explosive. For it came in the form of a challenge from Japan, one so frightening that it reinvigorated official sponsorship of GOFAI (and relevant aspects of cognitive psychology) on both sides of the Atlantic.

a. A warning shot from Japan

In October 1981 the Japanese used AI to fire a warning shot over the bows of the Western economies. It had huge repercussions, for it led to an injection of governmental and industrial funds on a huge scale. It was this which revivified the field in the UK, and which took it up to a new level of public interest in the USA and elsewhere. AI was suddenly ubiquitous: it was featured at length in *Fortune*, *Forbes*, and *Time* magazine (where a computer was chosen as "man of the year"), and even made the front cover of *Newsweek*. By 1985, the biennial IJCAI was attracting some 6,000 participants (twelve years earlier, there'd been only about 250).

Had the Japanese made some great intellectual advance? An AI equivalent of the genetic code, perhaps? No. What caused the excitement, and the frissons of fear, was Japan's announcement in October 1981 of a ten-year national plan for developing "Fifth Generation" computers.

This came to most people, including journalists, as a bolt from the blue. The worldwide AI grapevine, however, had had fair warning. The project's overall director, Tohru Moto-Oka (1929–85), later recalled:

[Before the conference] there had been workshops and so forth to hear the opinions of international scholars; through [Japan's IT association] there were discussions with research institutions of the principal countries of Europe and America, and some information was obtained from a survey visit to America.

In addition, there were invitations to participate from [Japan] to American and European governments, and because the project had already become well known abroad, more than eighty overseas participants attended the Fifth Generation Computer Conference.

Before this conference I spent a month . . . touring America, Germany, France, and Great Britain, in preliminary discussions with participants [including Colmerauer and Feigenbaum]. (Moto-Oka and Kitsuregawa 1985: 6)

What caused the huge public—and political—excitement was less the ambitious technological project than Japan's economic motivation for launching it. They weren't seeking to appropriate just another market, to be added to cameras and video equipment. Their aim, baldly stated to the Western politicians and industrialists they invited to the "Announcement" meeting in Tokyo, was world domination in information technology (Moto-Oka 1982). Pre-eminence here, they argued, meant economic pre-eminence *tout court*.

Indeed, as the opening speech from Moto-Oka made clear, for Japan it meant economic survival:

Japan . . . cannot attain self-sufficiency in food [or energy]. On the other hand, we have one precious asset, that is, our human resources. Japan's plentiful labor force is characterized by a high degree of education, diligence, and high quality. It is desirable to utilize this advantage *to cultivate information itself as a new resource comparable to food and energy*, and to emphasize the development of information-related, knowledge-intensive industries which will make possible the processing and managing of information at will. (quoted in Feigenbaum and McCorduck 1983: 12; italics added)

Similarly, an official of the Ministry of International Trade and Industry, the body overseeing the Fifth Generation programme in Japan, told an American journalist:

Until recently we chased foreign technology, but this time we'll pioneer a second computer revolution. If we don't, we won't survive. (Feigenbaum and McCorduck 1983: 135)

In other words, industrial economies needed AI—and Japan, lacking rich agricultural or oil/mineral resources, needed it most of all.

Fifth Generation computers were thus defined not (like the first four generations) by their hardware components, but as computers designed to be suitable for supporting AI applications (Moto-Oka and Kitsuregawa 1985). This included not only parallel computers but also powerful machines dedicated to a specific AI language, such as LISP or—especially—the recently developed PROLOG. (For several years, PROLOG's implementer Kowalski virtually lived on the plane from England to Japan.)

As it turned out, LISP machines didn't catch on widely—not even as exotic workstations for the laboratory bench. Designed at MIT's AI Lab in the mid- to late 1970s (Greenblatt 1974; Bawden *et al.* 1977; Greenblatt *et al.* 1984), they were eventually launched—amid much excitement, fanned by the goings-on in Japan—by two companies set up by MIT personnel (Symbolics and LMI). But they were very expensive, and—one Symbolics employee believes—suffered guilt by association when the over-inflated early 1980s expectations for AI failed to be satisfied (Withington 1991). The same was true of the massively parallel, and massively expensive, Connection Machine—also designed at the MIT AI Lab (Hillis 1985).

But that was for the future. Meanwhile, there was the breathtaking announcement in Tokyo. This was astonishing in terms of both the scale and the nature of the Japanese commitment.

The Fifth Generation plan was to be jointly funded by the country's government and electronics industry, to a minimum of $810 million—some observers were already speaking of billions. (As it turned out, the Japanese government provided less money than any of the eight companies was devoting to its own R & D programme, and vastly less than the $1 billion per year that IBM was spending on its research—Newquist 1994: 212.)

What's more, the project had been allowed to overturn the traditional Japanese attitude to seniority. The director of Tokyo's newly formed AI institute (ICOT) was a surprisingly young man, in his early middle age. He insisted that ICOT be staffed only by *very* young computer scientists, under 30 years old, whose training was up to date and whose creativity was still comparatively high. Each of the Japanese companies involved would be expected to provide four or five of their best young researchers, free of charge to ICOT.

Not the least surprising aspect of the Fifth Generation project was that it was officially announced to an *international* audience. The declared reason for this was that, in this very expensive R & D area, competitors in the capitalist marketplace needed to *cooperate*.

Such cooperation would soon be initiated in Texas. August 1982 saw the foundation of MCC (the Microelectronics and Computer Technology Corporation) in Austin. The AI section was headed by W. W. (Woody) Bledsoe (1921–95), and the overall director was Vice-Admiral Inman—previously Deputy Director of the CIA, but described by Douglas Lenat as "the most charismatic person I'd ever met" (Shasha and Lazere 1995: 234). (In 1993 Inman would be nominated as Secretary of Defense by President Clinton; a few weeks later, however, he decided against accepting the post, which was given to William J. Perry instead.) The good impression was evidently mutual: MCC would soon provide the tens of millions of dollars required for Lenat's CYC project (see 13.i.c).

b. Self-defence in the USA

Capitalist cooperation—and in Texas, of all places!—was just one example of the huge effect this announcement had on AI research funding in the USA, and in the UK and Europe too. The 6,000 participants of IJCAI-1985 included venture capitalists as well as ordinary businessmen, all prepared to provide money for AI research.

The money reached both 'pure' and 'applied' AI workers. Quite apart from the funds coming directly or indirectly from the US government, the newly founded AAAI benefited hugely. Feigenbaum, having been a core AI researcher for many years and having also got wind of the incipient challenge from Japan, was a leader in establishing AAAI in 1980 (Feigenbaum 2005; Reddy 2005). Unlike its long-time UK/European predecessor, AISB (see 6.v.c), it found itself showered with money. Hayes, a refugee from the Lighthill debacle across the Atlantic (who'd be elected President of AAAI a few years later), was impressed—and not a little envious:

> I remember having a kind of distant amazement that the USA could find so much money in such a short time. AI societies in Europe were run on shoestrings, almost entirely by volunteer academics, but AAAI had piles of cash from day one (well, actually maybe something like day three) thanks to the AI explosion and the trade fair at the early meetings. Nothing like that had happened outside the USA. (Hayes, interviewed in 2005—Reddy 2005: 11)

Even inside the USA, however, nothing like that would have happened if it hadn't been for the Fifth Generation. In short, AAAI blossomed not just because the USA was rich, but because it was frightened.

Two AI pioneers, Feigenbaum and Buchanan, founded Teknowledge, the first commercial expert-systems company in the USA. (A much smaller enterprise had been started by Michie in the UK, but Teknowledge was on an altogether more ambitious scale.) They had no trouble finding eager recruits:

> [We] hired as many smart people as we could afford. At one point, I had taken a leave from Stanford to manage the company and a friend at IBM Watson labs complained to me that IBM couldn't hire enough talented AI scientists because Teknowledge was hiring them all. (Buchanan 2003: 3)

The task of this new company was to write expert systems to commission and/or to develop off-the-shelf shells for an indefinitely wide range of clients. At much the same time, Feigenbaum also co-founded a specialist medical company called IntelliGenetics. This was based on Stanford's MOLGEN expert system, which advised biochemical researchers on how to clone specific DNA sequences. Other software, and hardware, AI companies soon followed them.

(Few of these companies prospered to the expected degree. The author of one history of these events puts this down to a number of reasons, not least the "egos, frailties, and foibles" of scientific researchers with no head for business—Newquist 1994, p. xiii.)

Some commentators compared the Fifth Generation's influence in stimulating scientific research in the USA to that of the Soviet Sputnik in 1956. (In part, this was because the USA—unlike Japan—saw the Fifth Generation largely in terms of its military significance.)

Hard-headed businessmen and ambitious politicians, naturally, had scant interest in psychological AI: technological AI was what they cared about. Nevertheless, AI in general shared the benefits: not only would more young people need to be trained in this new technology, but basic AI research would be needed too.

Moreover, Japan's stated goals—which included MT, speech processing, intelligent assistants, advanced problem solving, and robotics—would require advances in psychological AI, even if the human example was to be dropped as soon as it became inconvenient. By the same token, they'd require advances in other areas of cognitive science, especially psychology.

AI, at last, had been shown to be *useful*. And it was being widely *said* to be useful. Feigenbaum wrote a trade book, which sold over 200,000 copies in the English-language edition (plus several translations), outlining 'Japan's Computer Challenge to the World' and arguing that hugely increased funding for AI was needed if the USA were to retain its economic success (Feigenbaum and McCorduck 1983).

His AI colleagues weren't greatly impressed, although they'd be among the beneficiaries if his wake-up call succeeded. For even if one ignored the vulgarity of the tone (which wasn't easy to do), many of the judgements were questionable. However, that didn't worry most of the readers, who didn't know what questions were relevant.

The book was hugely influential—if not within the field, then outside it. It swiftly propelled AI onto the TV screens, and Feigenbaum onto the chat shows. Quite apart from his (well-deserved) status as a pioneer of expert systems, he had special access to the Japanese developments. For his wife, the computer scientist Penny Nii, was Japanese herself. Five years later, they'd cooperate in a book brashly proclaiming the business successes recently achieved by AI technology (Feigenbaum *et al*. 1988).

One can't say that the hype had ceased: far from it. (McDermott's lessons hadn't been fully taken on board.) Both of Feigenbaum's volumes, not to mention the journalists' offshoots, needed to be taken with a pinch of salt.

So did Winston's *The AI Business*, which appeared hot on the heels of Feigenbaum's *The Fifth Generation* (Wilson and Prendergast 1984). The book's nicely ambiguous title should have warned readers that it was a piece of advertising, not a mere report of scientific advance. Besides straightforward accounts of existing expert systems (including one for configuring VAX machines uniquely to suit clients' needs, which had already saved its parent company DEC a fortune: Kraft 1984), this collection contained its fair share of shaky predictions. It even offered a tendentious editorial defence of past NewFAI claims, such as Simon's notorious vision of a chess program beating the world champion by the mid-1960s (see Section vii.a–b). The people making those predictions, said Winston, were conscientious scientists "simply trying to fulfill their public duty" by preparing people for something that seemed quite plausible at the time (Wilson and Prendergast 1984: 3).

Even NASA, whom one might have expected to be more hard-headed, fell foul of the demon of hype. The manager of NASA's AI research admitted as much, a few years later:

> [We held] a week-long workshop in April 1985 in which each NASA center got to describe the AI and robotics projects that it had under way. By the end of the second day, the total number of expert systems *that had been described as having been developed* was about 100. However, *none of these expert systems ever became operational*.
>
> NASA's AI research program *was not immune to overselling and overpredicting*. The objectives stated [in an official "white paper" of 1986] for the program during its inception [were hugely ambitious]. These goals were to be achieved by 1995! (Montemerlo 1992: 51–2; italics added)

The hype of the early 1980s (especially at NASA) was largely due to inexperience. As work on automation and expert systems progressed, people's expectations matured and their predictions became more realistic. By the mid- to late 1980s, NASA was turning "from revolution to evolution", and devising many useful systems—partly by picking the "easy" problems first, and partly by including in-the-loop human control (Montemerlo 1992: 53–7). (An insightful defence of the need for humans to remain in the loop was published in 1990 by Dreyfus's disciple Collins: 13.ii.b.)

NASA wasn't alone. The VAX configurer (XCON) and its successor XSEL (J. P. McDermott 1980, 1982) was providing a crucial service to DEC's clients *and* saving the company over $40 million a year (Russell and Norvig 2003: 24). From 300 rules (and very low accuracy) in 1979, it had grown to more than 3,000—and could now reliably configure ten different DEC computers, not just one (Bachant and McDermott 1984).

XCON/XSEL was the top success story. But there were now many other proven money-savers. At last, AI was successful enough, and visible enough, to attract huge financial support from both government and industry. The AI industry in the USA burgeoned from a few million dollars in 1980 to billions of dollars in 1988.

It wasn't all good news: as usual, the hype became counter-productive. The boomerang effect peaked around 1990. Misled by the optimism, not to say disingenuousness, of AI's vociferous champions, the industrialists expected too much—and met with inevitable disappointments. The period of 1980s largesse was followed by a brief "AI Winter", in which "many [AI] companies suffered as they failed to deliver on extravagant promises" (Russell and Norvig 2003: 24). Eventually, the promises grew less extravagant—and were very often delivered.

(Today, AI is—in practical terms—even more successful. But it's much less visible. Both GOFAI programs and neural networks are hidden inside a myriad of everyday products and services, from cars to refrigerators, call centres to credit checks. That's partly why, when people mistakenly say that GOFAI has "failed" as a technology, they're often believed: see 13.vii.b.)

For all the obvious cultural reasons, the main effect in the West of the ICOT initiative was seen in the USA. Indeed, Feigenbaum's first book relentlessly exploited American fears that US economic and political interests, and ascendancy, were threatened.

Describing the Fifth Generation as "comparable in human intellectual history to the invention of the printing press, with the certainty of making even greater changes in the life of the mind than books did", he chided counter-cultural American intellectuals for seeing the computerization of university campuses not as an opportunity but as "the new barbarism" (p. 210). "Most self-styled intellectuals", he complained in disgust, "don't even recognize what's happening" (p. 211). As for more explicitly political comments, he said:

> The Japanese plan [for AI applications] is bold and dramatically forward-looking. It is unlikely to be completely successful in the ten-year period. But to view it therefore as "a lot of smoke", as some American industry leaders have done, is a serious mistake . . .
>
> We now regret our complacency in other technologies [small cars, videos, computer chips]. Are we about to blow it again? The consequences of complacency . . . will be devastating to the economic health of our most important industry. The Japanese could thereby become the dominant industrial power in the world. (p. 2)

> *We believe that Americans should mount a large-scale concentrated project of our own; that not only is it in the national interest to do so, but it is essential to the national [military] defense.* (p. 216)

> A superiority in knowledge technology provides whoever holds it with . . . an unequivocal advantage—whether we are speaking of personal power, national economics, or warfare.
>
> The Japanese understand this perfectly . . . Other nations recognize the soundness of the Japanese strategy—and, of course, its inevitability. In response to the farsighted Japanese, ambitious national plans are being drawn up in many places. But the United States, which ought to lead in such plans, trails along in disarrayed and diffuse indecision. (p. 239)

He got his wish. The US government, via ARPA in the Department of Defense, committed $1,000 million over five years—twice as much as ARPA's total expenditure on computing over the previous twenty years.

c. Lighthill laid to rest

In the UK, the response to the Japanese initiative was less up front in tone. But it happened. However, it couldn't happen as quickly as it did across the Atlantic. Quite apart from cultural differences in attitudes to innovation and entrepreneurship, the UK was still carrying the baggage of the Lighthill Report.

If this had been an embarrassment before, it was doubly so now. Perhaps triply. For Michie, as he often said (e.g. Michie and Johnston 1984: 38), had written the very first commercially marketed expert-system shell, back in the 1960s. (Called AL/X, Ray Reiter wrote his Illinois MS thesis on it in 1981—and see Harmon and King 1985: 109.) The prospect of hearing "I told you so!" from him was not one his former detractors found agreeable.

Accordingly, yet another report was commissioned by the SERC—the new name for the SRC (Alvey Committee 1982). This one, too, was entrusted to an eminent mathematician: Sir Peter Swinnerton-Dyer—although the criteria he was given ignored scientific importance, being based only on how information technology could aid UK industry in general (Alvey Committee 1982: 5–6; cf. Cornwall-Jones 1990). And this time, the intended verdict was delivered: a green light for AI.

Given the hangover from Lighthill, however, the term "artificial intelligence" was declared inadmissible (a further reason why, in the UK at least, AI has low visibility today). The powers-that-be insisted on "Knowledge-Based Systems" instead. (So when Sussex received new money for "technology transfer", in the form of thirty guaranteed M.Sc. studentships a year, we had to change the name of the already existing course: AI became IKBS.)

The key strategy group involved, which included Michie, had no illusions about this. A couple of months before the Japanese announcement, they'd met to discuss the future of AI in Britain:

> "A bunch of us had felt for quite a time that we really ought to try to do something about rehabilitating AI in the U.K. after Lighthill." . . . [The aim was to set up a special SERC programme in AI.] "We were all sitting around a table wondering what to call this new area", says John Taylor [a big wheel in the Admiralty's Weapons Establishment, and in the computing section of SERC]. "Should we call it artificial intelligence? *We didn't want to call it artificial intelligence because of all the Lighthill connotations*, and we didn't want to call it expert systems, and we came up with this awful phrase 'intelligent knowledge-based systems' or IKBS." (B. Oakley and Owen 1989: 15; italics added)

For public consumption, Lighthill discreetly wasn't mentioned. (The official evaluation of the Alvey project would be less coy—Guy *et al*. 1991: 15–16.) The explanation given for the change in terminology was that "AI" was overambitious and unnecessarily provocative, whereas "IKBS" was not.

As a psychological observation about people's prejudices and mental associations, this was doubtless correct. But a moment's clear thought would have shown that the term "knowledge" was no less philosophically problematic than "intelligence"—which anyway hadn't been dropped, but merely transformed into an adjective. Some people, accordingly, preferred the term "inference computing" (B. Oakley and Owen 1989: 270). But it didn't catch on. (Feigenbaum now favoured KIPS: knowledge information processing systems, of which expert systems were a special case.)

After the Japanese fired their public warning shot two months later, this budding SERC activity was merged into the national Alvey Programme, which spent £350 million over five years on advanced information technology (B. Oakley and Owen 1989: 294). Business and war were both represented: besides the SERC, the money came from the Department of Trade and Industry and the Ministry of Defence.

Of the four main areas of IT involved, one was AI (the others were man–machine interfaces, VLSI, and software engineering). It was agreed at governmental level that £21 million should go via the SERC to universities for AI and computer science (half each)—plus more money to work done, and 50 per cent funded, by industry (Alvey Committee 1982: 2). This would be partly for immediate/short-term demonstrations of IKBS systems with clearly commercial uses, and partly for longer-term, including highly general, AI research (Alvey Committee 1982: 17). (This was the first time that the SERC, supposedly an autonomous body, had been instructed by government to set aside a certain sum of money for university research in a particular area.)

In addition, the UK was a contributor to the European ESPRIT Programme, which had a budget of $650 million from governments and another $650 million from industry. Other European countries, too, supported their own AI research more generously—in some cases ensuring that most of the increase went on basic, not applied, research (Dickson 1986).

Looking back on the five-year Alvey Programme, its director, Brian Oakley, asked 'Was It All Worthwhile?' (B. Oakley and Owen 1989: 265–94). His answer wasn't an unqualified "Yes". For the hoped-for cooperation between industry and academia, always a problematic area in Britain, had been less fruitful than expected. In some cases—the work on speech technology, for example (a dozen projects, the largest of which was at Edinburgh)—the major industrial funder had pulled out after deciding that progress wasn't fast enough (p. 291).

Nevertheless, AI applications—in connectionist pattern recognition as well as GOFAI-based data handling and expert systems—had burgeoned. So had work on human–computer interfaces (13.v): "for many years to come human intervention, and so the significance of the human interface, will remain essential for most applications of AI" (B. Oakley and Owen 1989: 271). Hardware issues had progressed, and software engineering had benefited too. Market awareness had been hugely raised, which had been one of the aims of Alvey from the start. "It remains only a matter of time", said Oakley, "before inference-computing applications far exceed today's so-called conventional uses of computers" (p. 284).

Finally, the need for interdisciplinarity had been underlined. The Alvey directorate, Oakley reported, had exerted "a bit of pressure" to foster cooperation in the face of "the rigid departmental structure of universities" (p. 292).

Despite the call for interdisciplinarity, Oakley—and Alvey—was primarily concerned with AI as an economic force, not as basic and/or psychologically oriented research. The same was true of the effort in Japan, and of the responses in Europe and the USA.

Indeed, Minsky complained that the success of the current expert systems "bodes ill for making further progress", because commercial companies weren't prepared to look ahead—to incorporate learning, for instance. In particular, he said:

> There is no significant increase in the number of people working on the ideas that we will want to use in ten years. The number of people doing *basic* research in Artificial Intelligence is probably under one hundred people and maybe under fifty. (Minsky 1984*a*: 245; italics added)
>
> [Large companies who boast about their AI groups are loath to provide small amounts of money to support a few students.] They do not seem to understand where the ideas came from and where the new ones will come from in another decade. (p. 251)

For all that, the effects on AI in general had been broadly beneficial, especially in the UK where (thanks to Lighthill) Establishment scepticism had reigned. By the late 1980s, Oakley saw a change in the "fashion" for public support of research in the West, with "a renewed emphasis on basic research in academia and a weakening of academic/industry ties" (B. Oakley and Owen 1989: 292–3). Lighthill had been laid to rest at last.

11.vi. The Kraken Wakes

John Wyndham's sci-fi novel *The Kraken Wakes* narrates the havoc caused when a sea-monster, asleep in the depths of the ocean for many years, suddenly becomes active again. From GOFAI's point of view, the Kraken was connectionism. This (eighth) bombshell comprised an intellectual watershed for AI, as well as a financial one.

a. Small fry and sleeping draughts

Connectionist AI was spawned in the 1940s (Chapter 12.i). And some of the small fry had swiftly grown appreciably larger. So in 1958 Rosenblatt published his seminal paper on "Perceptrons"—in the very same volume of *Psychological Review* which, a few months earlier, had carried the GPS authors' 'Elements of a Theory of Human Problem-Solving' (Newell *et al.* 1958*a*).

Minsky and Papert, however, were (at that time) less eclectic than the editor of *Psychological Review*. From 1956 (i.e. 'Steps') onwards, they expressed fundamental doubts about the value of perceptrons. The small fry swam on, regardless—until the MIT duo administered a powerful sleeping draught in the late 1960s (12.iii).

But the ensuing slumber was a doze, not a coma: important connectionist research was still going on beneath the waves. In 1979 connectionism raised its nose above the waters, at an interdisciplinary meeting in La Jolla (12.v.b), and the whole of the Kraken's head became visible soon afterwards (12.vii.a).

b. Competition

Worse was to come. The monster leapt high out of the ocean in 1986, on publication of the two-volume connectionist 'bible' (12.vi).

Almost immediately, the USA's main research sponsor had second thoughts about its generous funding of GOFAI. Late in 1987, DARPA sponsored a detailed two-month study to reconsider their policy (12.vii.b). The result was a shift in their priorities. To be sure, symbolic AI wasn't put in the dire position that connectionist AI had been in before. (Since the late 1960s, ARPA/DARPA had favoured the former almost to the exclusion of the latter—not least, because of Licklider's closeness to Minsky.) But the limited research money now had to be shared.

Perhaps even more to the point, the flow of research students into GOFAI slowed. That was no accident. The connectionist bible had been written, priced, and marketed as a deliberate attempt to induce youngsters onto the connectionist pathway through the AI field (12.vi.a).

Outsider interest shifted as well. Many psychologists and (especially) philosophers transferred their concern from GOFAI to connectionism, which promised a more plausible account of concepts (12.x). Symbolic AI was commonly said to have failed. As remarked above (i.d), one high-status collection on the symbolic/connectionist AI debate was subtitled *False Starts, Real Foundations* (Graubard 1988)—hardly a neutral way of putting it.

Coincidentally, Haugeland's patronizing definition of GOFAI dates from this general period. His critique was driven by phenomenology, not connectionism—which wasn't even discussed (the bible was still in press when his book appeared). But his readers would be even more ready to accept his criticisms in the pro-connectionist climate.

The journalists, too, swam with this tide. They saw only the connectionist Kraken, dismissing the still-advancing GOFAI as a wounded minnow floundering in the shallows. Symbolic AI was no longer glamorous, no longer sexy. And cognitive science in general, if it was to retain respect and gain new adherents, had to follow in the Kraken's wake.

The history of this intellectual watershed, and of GOFAI philosophers' attempts to meet it in a principled fashion (12.x.d), is detailed next, in Chapter 12. Then, in Chapter 13, we'll see how symbolic AI fared in the aftermath.

12

CONNECTIONISM: ITS BIRTH AND RENAISSANCE

"Only connect", said E. M. Forster as the motto of *Howards End*. Connectionists say this too. But whereas the novelist was talking about people, they're talking about neurones—or, more accurately, abstract computational units inspired by neurones. This chapter explains the "connect", and casts doubt on the "only".

If connectionism reminds one of *Howards End*, it also reminds one of *The Sleeping Beauty*. For the infant field, spawned in the 1940s by cybernetics, went into hibernation in the late 1960s. Ironically, the sleeping draught had been forced down the Beauty's throat in a no-holds-barred attack by one of her earliest suitors—an extraordinary story, told in Section iii.

Her heart was still ticking over during dormancy, however, and some important thinking was done during the twenty-year sleep. She stirred visibly in 1979, aroused by an interdisciplinary get-together on the Californian coast. The return to full activity happened, amid a blaze of publicity, in the mid-1980s. She rose from her bed and danced around the world, posing for the newspapers and entrancing almost all who met her.

The awakening of connectionism invigorated many philosophers and psychologists, but it constituted a bombshell from the point of view of symbolic AI (see 11.vi). Indeed, the few who remained unentranced by the merrily dancing Beauty were long-time devotees of GOFAI (x.d, below). But a bombshell, despite delivering a very nasty shock, need not end one's life. It may leave certain strengths unharmed—and even unsurpassed. The sections below (viii–ix) which cast doubt on the "only" show why GOFAI didn't leave the floor. It would continue steadily on its way during the next quarter-century (a story told in Chapter 13), achieving results which connectionism couldn't—and still can't—match.

That human minds *do have* rich associative powers had been obvious for centuries. And two early twentieth-century writers had provided a host of intriguing examples illustrating the subtleties involved. One was Sigmund Freud, whose work on dreams and slips of the tongue suggested countless strings of surprising, but psychologically possible, associations of ideas (see Chapter 5.ii.a). The other was the literary scholar John Livingston Lowes (1930), a specialist on Samuel Taylor Coleridge's poetry. In a masterly detective story hunting out the sources of the imagery in *The Ancient Mariner* and

Kubla Khan, he gave highly detailed, and intuitively convincing, hypotheses about just where Coleridge's ideas had come from. But in answer to the question *How?*, all he could say was to repeat Coleridge's own metaphor of "the hooks and eyes of memory" (cf. Boden 1990*a*, ch. 6).

In other words, by 1940 *the fact that* our memory is richly associative was clear, but *how it manages* to associate wasn't. Indeed, things had been made worse by Karl Lashley's recent failure to find localized memories (5.iv.a). As he put it, "I sometimes feel, on reviewing the evidence . . . that learning just is not possible. *It is difficult to conceive of a mechanism* which can satisfy the conditions set for it" (Lashley 1950: 477–8; italics added).

The connectionists tried to answer that *How?* question, in scientific rather than merely intuitive terms. They hoped to explain not only the maverick associations found in poetry or dreams, but also everyday perception, language, learning, and rational thought. And they showed how, in principle, a memory could be distributed over a whole network of cells, rather than being stored in one place.

Connectionists thought of the hooks and eyes of memory in two different, but closely related, ways. On the one hand, they wanted to define idealized computational networks, made up of many simple interconnected units, which could in principle underlie this or that psychological phenomenon. On the other, they wanted to identify the computations actually carried out in the brain, and to understand how the relevant brain mechanisms implement them.

The first is the aim of connectionist AI/psychology, the second of computational neuroscience. The two disciplines are discussed here and in Chapter 14, respectively. Some people's research was guided by both aims, so is mentioned in both chapters. Walter Pitts and Warren McCulloch in 1947, for example, defined two novel types of information processing *and* related them to specific neural structures. And Albert Uttley, in the early 1950s, focused on real neurones as well as artificial ones—and turned towards neuroscience even more strongly in his mature work.

Connectionism seeks to explain (and to model) psychological capacities that intrigue almost everyone: perception, memory, analogy, creativity, language, learning, and development. It puts computational flesh onto the associative bones sketched by Freud and Livingstone Lowes, suggesting how haunting images can arise—whether neurotic or poetic. And it carries a strong whiff of the brain. So far, so good.

At base, however, it's the study of two highly abstract topics: the configuration (anatomy) of neural nets and the functioning (physiology) of learning rules. Inevitably, then, much of this chapter concerns the mathematics of various learning rules and nets. I'll spare you (and myself) the equations, for this isn't a practitioners' manual. Even so, some paragraphs may be tough going for some readers. The overall story, however, should be readily intelligible—and exciting, too. For connectionism has aroused heady hopes, passionate controversies, huge media interest, and intense philosophical debate.

The first two sections below focus on the opening quarter-century of connectionism: first, the initial ideas, whose implementation—if any—could only be highly schematic; second, some pioneering computer models. Section iii deals with a notorious 1960s critique of some of that early work, which is widely (though perhaps unjustly) accused of having set the field back for almost twenty years. What was actually going on in those years of hibernation is described in Sections iv and v.

The heyday of parallel distributed processing (PDP)—which is what most people today take "connectionism" to mean—is discussed in Sections vi and vii, as is the explosion of the "bombshell". Sections viii and ix consider how PDP research later tried (and failed) to recover some of the lost strengths of GOFAI. Finally, Section x explains why many philosophers were excited by PDP, and how some contributed to its development.

12.i. Lighting the Fuse

Connectionism's fuse was laid down in the mid-eighteenth century, and patted into the ground more firmly several times over the next 200 years. It wasn't until the 1940s, however, that it began to smoulder. That happened when McCulloch and Pitts (1943) defined idealized neural nets based on logic (see 4.iii–iv).

During the 1930s, neural feedback loops, or reverberating circuits, had often been posited to explain psychopathology of various kinds (4.iii and v). But by the early 1940s, McCulloch was thinking of them mostly as the brain's *normal* activity. As for how they might be acquired, he and Pitts suggested in their 'Logical Calculus' paper (1943) that learning could—in principle—be modelled by cyclic nets.

Even then, there was no intellectual explosion—only a dull glow. Initially (as we saw in Chapter 4.iii.f), their paper faced hostility or indifference from most psychologists. One reason was its neurological implausibility. Another was its rebarbative abstractness. And a third was its blue-sky character: at that time, its ideas could be implemented only in a very primitive fashion (with soldering irons to the fore). The dull glow wouldn't brighten until computers came on the scene.

a. A long gestation

Connectionism was conceived almost three centuries ago (in the 1740s), but had a long gestation. In its embryonic form, it was merely biologized introspection: David Hartley's view that thinking is grounded in associative mechanisms in the brain (2.x.a). These, he said presciently, make two things possible. First, they link different concepts so that the one comes to mind when one thinks of the other. Second, they enable a mere fragment to recall a whole stimulus. (Hum the first three chords of Beethoven's Fifth Symphony, or of Three Blind Mice—and see whether your neighbours can stop themselves from thinking of the fourth.)

Hartley was unusual in thinking about brain mechanisms at all. His contemporary David Hume, an immeasurably greater philosopher, theorized about mental associations but not about any detailed goings-on in the brain (2.x.a). His supposed Newtonian "attractions" were even more mysterious than Hartley's hypothetical "vibrations".

A hundred years later, Hartley's hints were echoed by the father-and-son philosophers James and John Stuart Mill (2.x.a). They, too, supported their mentalistic focus on the association of ideas with speculations about the brain. They argued that learning could be due to an increased likelihood of brain activity at certain points, as a result of simultaneous activity earlier. But *just what* this activity was, and *just how* its probability could be modified, remained mysterious.

In the late nineteenth century, some then unorthodox biologists ventured that the mechanism might involve links between separate units, or brain cells—as opposed to a continuous network, or reticulum (2.viii.c). And in 1890, thanks to William James's widely read *Principles of Psychology*, that general idea became familiar in the new discipline of psychology.

Yet familiarity didn't bring clarity, still less proof. For nearly 200 years, Hartley's hunch remained no more than intriguing.

By the 1940s, however, it had begun to look highly plausible. The neurone theory had been vindicated. "Animal spirits" and "vibrations" had given way to action potentials. And various synaptic properties—facilitation, inhibition, thresholds, and refractory periods—had recently been established (see Chapter 2.viii).

These ideas led McCulloch and Pitts to describe psychology as the study of precisely defined neural nets (4.iii.e). Lashley and Donald Hebb proposed that psychologists should also think about the activity of less precisely defined *populations* of neurones (5.iv). And in 1949, Hebb put the central idea into a more tractable form, suggesting that a "connectionist" (his word) learning rule for modifying synapses is the neural mechanism underlying memory and conceptual thought (5.iv.b–e).

By that time, too, ideas about computation, and about "self-organization" (as cybernetic control) in animals *and* machines, had arisen (Chapter 4). Since it was now conceivable that some artefacts might work in a way somehow similar to the brain, connectionism was often expressed in computational terms—drawing sometimes on logic, sometimes on statistics.

Some of these early systems managed to show how a whole group of (artificial) units could store a 'single' representation—and access it, as Hartley had guessed, when given only a partial cue. And the 1950s saw the development of models that could learn concepts as well as associating them. Typically, these used some version of Hebb's 'ft/wt' (fire together, wire together) rule.

Connectionism was no longer just a twinkle in Hartley's eye. The baby was now well and truly born.

b. Turing and connectionism

The prototype of the first modern computer, MADM, wasn't completed until five years after the 'Logical Calculus' paper. And the von Neumann computer, whose design rested in part on McCulloch and Pitts' 1943 theory, became available later still, in the early 1950s (Chapter 3.v.e). Only then could functioning models of the mind—whether symbolic or connectionist—be based on their ideas.

Before that time, various people had predicted that the advent of digital computers would make exploratory modelling possible. They were mostly engineers, or psychologists with a background in physics or engineering.

Belmont Farley and Wesley Clark, engineers at MIT's Lincoln Laboratory, had even sketched potential simulations of trial and error learning (Farley and Clark 1954). Describing "self-organizing networks" based on Turing machines, they distinguished "conditioning" and "serial learning" in terms of short-performance and long-performance units, respectively. But these were merely suggestions: in the early 1950s, functioning models were still thin on the ground.

One of the very first was due to Alan Turing. He'd already implemented a learning network by 1947, on an embryonic version of MADM. He reported observing "the sequence of externally visible actions for some thousands of moments" (Turing 1947*b*: 20). Most of his connectionist experiments, however, had been pencil-and-paper simulations.

It may seem strange to refer to Turing and connectionism in the same breath. For he's usually thought of as the guru of symbolic AI, thanks to the Turing machine (4.i) and the Turing Test (16.ii.c)—not to mention his early efforts in programming (3.v.b). It's widely assumed (by non-specialists) that he said nothing about connectionism. But that's not so. His oft-repeated aim "to build a brain", which dated at least from 1944 (Hodges 1983: 290), *isn't* relevant here, for it didn't necessarily imply a brainlike (micro-)anatomy. But in a speculative report written in September 1947, he discussed a range of computational networks consisting of standard binary units, each one linked to (zero or more) others (Turing 1947*b*).

Such networks could be specifically designed to perform a pre-set task, as McCulloch and Pitts had remarked. Alternatively, they could be "unorganized". In the latter case, their links were randomly assigned. This, said Turing, is "about the simplest model of a nervous system with an arrangement of neurons [such as the cortex] whose function is largely indeterminate" (1947*b*: 10, 16).

For learning to occur in an initially unorganized network sounded, on first hearing, like magic. But he suggested that some training procedure, analogous to the education of a child, might be imposed which would gradually alter the linkages. A random network could be converted into one that behaves in systematically adaptive ways, he said, if the positive and negative influences on the links ("pleasure and pain") were set appropriately. His observations of "thousands of moments" of computer activity were focused on a pioneering model of this type.

Turing's remarks here were, as ever, intriguing. But they had no influence on the field. The paper was an internal report for NPL (the UK's National Physical Laboratory), and remained unpublished until 1969.

Certainly, he sometimes mentioned these ideas to compatriots and foreign visitors. For instance, at a seminar held by the Manchester philosophers in 1949, at which luminaries from various disciplines were present (see 16.ii.a), he speculated about "a machine using neuron-models" (Manchester Philosophy Seminar 1949). But just how this might be achieved wasn't spelled out. Even when lecturing to the London Mathematical Society in the year of the NPL report, he spoke only about ACE (3.v.b), without mentioning the possibility of more brainlike machines (Turing 1947*a*).

He himself failed to develop these ideas further because, by the late 1940s, his own interests were turning from learning to embryology. He was still concerned with the gradual organization of an initially unorganized substrate. But he was now asking how it might happen *without* the "external interference" of a teacher (A. M. Turing 1952: see 15.iv.a). In other words, he'd turned to self-organization.

c. 'How We Know Universals'

While Turing was still writing his NPL report, a very different suggestion about brainlike machines was being published on the other side of the Atlantic. This was contained in an essay on ‘How We Know Universals: The Perception of Auditory and Visual Forms’ (Pitts and McCulloch 1947), and it did make connectionism’s fuse glow brighter.

The new paper by Pitts and McCulloch was rooted in cybernetics. One of its sources was a statistical theory of heart fibrillation, in terms of the spread of impulses within a network of excitable elements. This had been developed in the mid-1940s by Norbert Wiener and Arturo Rosenblueth, and Pitts had recently worked on it.

Pitts and McCulloch had now switched from logic to statistics, from single units to collectivities, and from purity to noise. Although they didn’t use the modern vocabulary, it’s clear that their 1947 paper was describing the brain in terms of what’s now called distributed, cooperative, computing (Chapter 14.ii.b and iii.a).

Whereas their 1943 networks hadn’t been intended as a biologically plausible theory, their 1947 networks were. For they now proposed neurological hypotheses to match specific neural nets (see 14.ii.b). One of the three reasons (mentioned above) for the former indifference to their work had therefore vanished—and indeed, their second paper got a warmer welcome than the first (Bishop 1946). Another obstacle would soon vanish too, when computer technology became available.

The two authors didn’t disclaim their earlier, logic-based, work. On the contrary, they saw the new approach as an “extension” of it, and as “a systematic development of the conception of reverberating neuronal chains”. They still insisted that “any theoretically conceivable net” based on neuronal properties demonstrates that the computation concerned could be physically effected. But they were now ready to be more realistic about what those (anatomical and physiological) properties are.

They allowed that one can’t assume that the brain is made up of such neat and tidy connections as they had previously discussed. Nor can one assume that actual neurones have such constant, reliable, thresholds. Plausible neural nets therefore have to be error-tolerant:

> It is wise to construct . . . these nets so that their principal function is little perturbed by small perturbations in excitation, threshold, or details of connection within the same neighborhood. Genes can only predetermine statistical order, and original chaos must reign over nets that learn, for learning builds new order according to a law of use. (Pitts and McCulloch 1947: 46)

Moreover, perception itself is error-tolerant, in the sense that it involves the recognition of categories—what philosophers call “universals”—whose particular instances may differ in many details. Each cat is somehow unlike every other, but they’re all recognized as cats. A theory of perception should therefore explain how a physical mechanism such as the brain (or, by implication, a computer) could do this.

What they sought, then, was “general methods for designing nervous nets which recognize figures in such a way as to produce the same output for every input belonging to the figure” (p. 47). And “output”, here, covered both *classification* (*recognition*) and *action* (*movement*). For instance, we’ll see below that Pitts and McCulloch asked how the eye muscles can be instructed to lock one’s gaze on the centre of attention.

Instead of strings of precisely positioned logic gates, they now considered parallel-processing, statistical, devices. These were first defined as abstract mathematical systems, and then related to possible implementations in the brain.

“Parallel”, here, meant logical independence rather than precise temporal simultaneity. Time (all but ignored in the 1943 paper) was assumed to be an important factor.

But the real-time details were deliberately ignored. For instance, their system might compute a moving average over the preceding five synaptic delays, but these were unrealistically assumed to be equal and constant (p. 47). As for "statistical", this meant not probability theory but some sort of averaging, or assimilation to a norm.

In general, they argued, a universal is recognized by identifying an invariant under some group of mathematical transformations. They defined two types of mechanism capable, in principle, of doing this.

In the first, an input organ (such as the retina or cochlea) made up of many individual receptor units is "scanned" to find the average of all the independent measurements, or mini-decisions. This could enable the system to recognize (for example) shapes of any size, or chords of any pitch. Their mathematical analysis highlighted a general principle they called *the exchangeability of time and space*. This said that the delay in scanning any stimulus dimension corresponds to the number of distinct places on that dimension. In other words, the fewer discriminable points, the less time needed for discrimination—and vice versa.

In the second, a group of distinct perceptual inputs is "reduced" to a standard form. The "uniform principle of design" here is to select some *one* of the many appearances (transformations) of the category as the norm, and then to define parameters enabling one to locate all the others with reference to it. If any of the transformational equivalents is perceived, then the category will be recognized as such. All triangles, for instance, are topologically equivalent and have straight sides. (Compare John Locke's puzzlement over how a triangle can be thought of as "neither oblique nor rectangle, neither equilateral, equicrural, nor scalenon; but all and none of these at once"—see 2.x.a.)

The example they gave was the gaze reflex, in which the eye centres on some stimulus in the visual field. The norm, here, was defined as the "center of gravity of the distribution of brightness". They showed how a neural mechanism could compute this centre of gravity, move the eyes towards it, and then—through negative feedback—keep them there. The mechanism they suggested, based partly on work done on cats by the neuro-anatomist Julia Apter (1946), involved two point-to-point mappings: one from retinal cells to the superior colliculus, and one from the colliculus to the eye muscles.

This paper aimed for a high standard of theoretical rigour. Its approach was "basically simple and completely general, because any object, or universal, is an invariant under some groups of transformations" (W. S. McCulloch 1961*b*: 10). (Identifying all the relevant transformations was, of course, the $64,000 question.) It even included proofs that a certain net was *the simplest one possible* for effecting a certain computation. But it tried not to substitute abstraction for practicality. Some conceivable systems (designs for brains or computers) were defined only to be rejected, because of the combinatorial explosion.

However, it dealt with neither learning nor randomness. Its topic was how we know (recognize, represent) universals, not how we learn them. The "small perturbations" in thresholds and connectivities weren't supposed to result from the processing history of the system, but were taken as given. (They corresponded to the spontaneous neural firings discovered in the 1930s, and caused by chemical changes at the synapse: see 2.viii.f.) Moreover, they had to be small if the mathematics was to fit: massive changes or randomness would significantly alter the computed average and/or distance from the norm.

Randomness was widely recognized by cyberneticians as an important challenge, given the behaviourist anti-nativism prevailing at the time (see 5.i.a and 7.vi). If there was little or no prior structure to the newborn's cerebral cortex, how did interaction with the environment manage to produce it? Or if there *was* significant prior structure at birth, could this be ascribed to universal mechanisms of self-organization working in the womb, rather than to individual heredity? (see Chapter 14.viii.a). The encephalographer William Ross Ashby, for example, was working on self-organization in random systems, and would soon unveil his adaptive Homeostat (4.vii.c–d).

Likewise, McCulloch and (especially) Pitts were already trying to generalize their ideas to random nets. But they'd achieved suggestive analogies rather than definitive theorems.

So in a lecture given in the previous year (but not published until 1952), McCulloch had summarized their approach in terms of each neurone's being surrounded by "a nest of surfaces such that the chance of connection with our neuron is the same for all neurons on one and the same surface" (W. S. McCulloch 1946: 270). If only the connections are important, the nest will be spherical. If the directions and/or positions also matter, it will be egg-shaped or somehow lopsided.

In the same lecture, he'd compared learning to the physics of magnetizing a bar of steel. The myriad tiny magnets, initially positioned at random, end up (because of many local interactions) all pointing in the same direction—and, having reached equilibrium, they stay there. After spelling out the analogy between the various stages of magnetization and the formation of synapses, he said:

> It is not too much to hope that with these things in common the mathematics for one may be shaped to fit the other. If it will serve, then we may someday state how random nets may learn by taking on this or that local structure . . . *This may be done in some few years.* (W. S. McCulloch 1946: 273; italics added)

Those years turned out to be many, not few. Pitts had done some work on the mathematics of the three-dimensional "nests" mentioned by McCulloch. But he didn't persist, and never published his results. McCulloch (1961*b*: 110) later said this was "because we could not make the necessary measurements". But part of the problem was the dreadful mental decline that struck Pitts in 1952 (see Chapters 4.iii.d and 14.v.b). He burnt his manuscript on 3D nets, and no trace was ever found—despite major efforts by his friend Jerome Lettvin in searching for it.

Pitts described his new ideas in public only once, at the second Macy conference on cybernetics (see 4.v.b). That lecture wasn't published, either. However, as McCulloch remarked later, "[It] was enough to start John von Neumann on a new tack" (1961*b*: 110).

d. From logic to thermodynamics

This new tack—on which McCulloch, too, was working—was a search for a probabilistic logic (von Neumann 1956). That's one in which the functions, not just the arguments, are more or less probable.

Von Neumann did sketch a probabilistic network of formal neurones. But he wasn't satisfied with it, because the units were far more reliable, and far simpler, than real neurones. So instead of focusing on that network, he generalized his research to cover a diversity of "complicated automata"—now called cellular automata (15.v).

The result, in effect, was invisibility. These highly abstract ideas reached few mathematicians or computer scientists, and even fewer neurophysiologists. Von Neumann did publish a lecture he gave at the Hixon Symposium in 1948 (von Neumann 1951). But otherwise, his work—including five lectures given at the University of Illinois in 1949—remained unavailable until the mid-1960s, well after his death (15.v.b). Again, light was being hidden under bushels.

If von Neumann's work on cellular automata didn't influence the nascent connectionist community, his Silliman Lectures did (von Neumann 1958). These were intended for delivery at Yale, but were still unfinished at his death. They'd grown, at McCulloch's instigation, out of a talk von Neumann gave to the American Psychiatric Association in 1955.

There, he'd stressed the computational complexity of individual neurones as well as of collectivities, and argued that mere redundancy (large numbers of units) couldn't account for the brain's power and reliability. In the Silliman Lectures, too, he argued that brains ("natural automata") are so different from digital computers that computational neuroscience can't be grounded in logic.

The differences he mentioned included:

* the statistical (imprecise, yet reliable) character of the nervous message;
* its implementation as periodic pulse-trains;
* its anatomical restriction (often) to only a few synaptic steps;
* the continuous (analogue) properties of the synapse;
* the rich connections of individual neurones;
* the huge numbers of neurones;
* their functioning largely in parallel;
* and the possibility that neural thresholds and/or connections may change over time.

All these, he said, implied a need for a very different approach:

> [Whatever] language the central nervous system is using, it is characterized by less logical and arithmetical depth than what we are normally used to . . . [The] language here involved may well correspond to a short code [i.e. a basic machine language], rather than to a complete code [i.e. an assembly code or programming language]; when we talk mathematics, we may be discussing a *secondary* language, built on the *primary* language truly used by the central nervous system . . . [Whatever] the system is, it cannot fail to differ considerably from what we consciously and explicitly consider as mathematics. (von Neumann 1958: 81–2)

As for what the new approach should be, however, this unfinished text didn't say.

To be sure, there'd been a hint already. For in the 1948 lecture, von Neumann had suggested that "thermodynamics, primarily in the form it was received from Boltzmann" might be a good analogy for cerebral processing. (Compare McCulloch's earlier remarks on "magnetization", above.) But this idea couldn't yet be explored by computer modelling. The special-purpose differential analysers he'd used since 1940 weren't suitable, and the infant von Neumann machine wasn't sufficiently powerful.

It wasn't even obvious that a more powerful version could fit the bill, until McCulloch proved (in 1959) that a digital computer could implement a probabilistic logic (W. S. McCulloch 1961*b*: 16). But this was a point of principle, not practice. Only very much later would "thermodynamic" connectionism be feasible (see Sections v.e–f and vi.b, below). Meanwhile, von Neumann's fellow Hungarian Andras Pellionisz was inspired by his book to develop a "geometrical" form of connectionism (see 14.viii.b). Tucked away in Budapest, however, his ideas weren't taken up.

Von Neumann's scepticism about logic-based approaches had some influence, nevertheless—not least, because it was seen as a recantation by the master, the man whose eponymous machine had made GOFAI possible. Right from the start, a close friend recalled later, "one of [von Neumann's] motives for pressing for the development of electronic computers was his fascination with the working of the nervous system and the organization of the brain itself" (Ulam 1989: 19). Indeed, he'd altered his own computer design to incorporate the McCulloch–Pitts neurone (see Chapter 4.iv). The fact that he now went to such pains to stress the differences between brains and computers attracted attention accordingly.

Many readers of his posthumous book inferred that GOFAI (still NewFAI at the time) was doomed to failure. They assumed that *brainlike* computer models were needed instead. But just what might that mean?

12.ii. Infant Implementations

Several early cyberneticians had already tried to build brainlike models, some of which were theoretically interesting (see Chapter 4.vi–vii). But they'd had to rely on their own engineering skills, working with the proverbial biscuit tins and string to build special-purpose connectionist *hardware*.

This might involve a monstrous apparatus, like the analogue associative-memory machine constructed at University College London in the early 1950s by Wilfred Taylor (1956, 1959). This machine could recognize patterns, such as alphabetic letters, written in varying tones of black and white, and presented in varying orientations. In effect, it learnt its own feature detectors (see 14.iii). And it worked fast: it could find the pattern edges (high-intensity gradients) in less than a microsecond.

The apparatus had a nine-cell artificial retina. This involved lateral inhibition between neighbouring input units, and a "maximum amplitude filter" that passed on—to the sixteen-cell associative layer—*only* the strongest signal within a given area, provided that it was larger than the others by some minimal amount. (Later, Taylor applied these ideas to the brain, suggesting that specific cortical neurones and connections act as maximum-amplitude filters: W. K. Taylor 1964.) The light intensities were measured discontinuously, as ten distinct levels. Patterns were coded in terms of the most useful sensory input features, such as vertical, horizontal, and oblique lines. These features weren't built in, but were identified (from around 500 possibilities) by means of lateral inhibition.

By the mid-1950s, however, general-purpose computers were becoming available in the leading research centres. These were huge monsters too, of course. But each one could be used for many *different* purposes. This meant that (small) connectionist models could now be implemented more conveniently, by being simulated in digital computers—as Turing (1947*b*) had foreseen.

Not everyone switched from analogue to digital. Taylor, for instance, continued to develop his hardware model through the early 1960s, because the data couldn't be fed into it quickly enough in simulated form. But many others did take advantage of the new technology. The scene was now set for an explosion of work in both symbolic *and* connectionist AI.

a. B24 bricolage

While MADM and EDSAC (see 3.v.b) were still being put through their pioneering paces, Marvin Minsky, then an undergraduate at MIT, was puzzling about trial-and-error learning. He was largely inspired by McCulloch's ideas and by Hebb's then recent book, both of which he'd learnt about from his teacher George Miller.

On graduating in 1951, and before starting work on his Ph.D., he turned his puzzling into practice. With a $2,000 grant from the US Navy (officially, for Miller), he built a machine that simulated four rats in a maze learning to avoid each other:

> In the summer of 1951 Dean Edmonds [a physicist] and I went up to Harvard and built our machine. It had three hundred tubes and a lot of motors. It needed some automatic electric clutches, which we machined ourselves. The memory of the machine was stored in the positions of its control knobs, 40 of them, and when the machine was learning, it used the clutches to adjust its own knobs. We used a surplus gyropilot from a B24 bomber to move the clutches. (J. Bernstein 1981*a*: 69)

Each of the forty "neurons" had a probability of firing, implemented by the machine's potentiometer. The reward/punishment clutch was fired by a gas tube. And when the reward/punishment button was pushed, the shaft would turn clockwise or anti-clockwise, thus increasing/decreasing the probability of passing a signal next time.

(Where is this swords-to-ploughshares machine now? Well, after the 1956 meeting McCarthy's mentor at Dartmouth, John Kemeny, said that he wanted to have it there. Minsky and McCarthy got it up to Hanover, in full working order. However, it was never used for anything else. "Maybe it's still there, in some basement": J. McCarthy, personal communication.)

The contraption's success—up to a point, it worked—had much the same effect on Minsky that NewFAI was to have on many people a few years later:

> *We sort of quit science for a while to watch the machine.* We were amazed that it could have several activities going on at once in this little nervous system. Because of the random wiring it had a sort of fail safe characteristic. If one of the neurons wasn't working, it wouldn't make much difference and with nearly three hundred tubes, and the thousands of connections we had soldered there would usually be something wrong somewhere . . . I don't think we ever debugged our machine completely, but that didn't matter. By having this crazy random design it was almost sure to work no matter how you built it. (J. Bernstein 1981*a*: 69; italics added)

However, he soon abandoned this happy-go-lucky approach. Not only was he unable to interest his friend Burrhus Skinner in the project (he'd been trying to implement Skinner's ideas—Crevier 1993: 35), but his mathematical instincts overpowered his engineering ones.

The switch away from gizmo-gazing was triggered by his meeting someone else who'd worked on learning. Specifically, someone studying the induction of Miller's artificial grammars (Chapter 9.v.d and x.b):

> [In around 1955] I met a young man named Ray Solomonoff who was working on an abstract theory of deductive inference . . . He had worked on a learning machine . . . that was pretty formal. I was so impressed I decided this was much more productive than the neural net system, in which you built a piece of hardware and hoped it would do the right thing. With [this new] approach, *you tried to make theories of what kind of inferences you wanted to make, and then asked "How would I make a machine do exactly that?"* (Minsky, interview in Crevier 1993: 37; italics added)

In other words, bricolage was no longer enough. Nor were intriguing but ill-understood 'successes'.

Nor, significantly, was it enough to try "to understand how the brain works" as opposed to "understanding what it does" (interview in McCorduck 1979: 84). Ray Solomonoff, in short, had made him realize that McCulloch-and-Pitts wasn't sufficient. He also needed *a better theory of the task*.

A few years later, in his seminal 'Steps' paper (Chapter 10.i.g), Minsky would apply this insight right across the AI board. But in this early case, it was being applied to learning. To be sure, his Ph.D. of 1954, part-supervised by von Neumann, described similarly tinkered machines—constructed from "SNARCs": Stochastic Neural-Analog Reinforcement Calculators. But it discussed some of their limitations, as well as their potential (cf. also Minsky 1956*a*). For example, he speculated about how one network could be enabled to control another (a prime focus of research today: Section ix.a, below).

Paul Werbos's diagnosis, years later, was that Minsky—like many others "in the learning-business"—simply "didn't understand numerical analysis [or] the concept of numerical efficiency" (J. A. Anderson and Rosenfeld 1998: 344). However that may be, by the mid-1960s Minsky favoured careful mathematical analysis of the computational power of AI models in general. He dropped connectionist research for a while, disappointed by his own pioneering machine. Indeed, his abstract analysis of early connectionism's limitations would lead to a major scandal in the field (see Section iii).

It wasn't only Minsky who'd matured by the 1960s. Throughout the previous decade, some other connectionists had progressed from isolated tinkering towards systematic analytical research. (Some, but not all: "Why think when you can simulate?" was still a common attitude—J. A. Anderson and Rosenfeld 1998: 245.)

These influential early modellers included the cyberneticians and psychophysiologists mentioned in Chapters 4.v–vi and 14.i–ii. Others, discussed below, were Uttley, Raymond Beurle, Oliver Selfridge, Frank Rosenblatt, and Bernard Widrow.

b. Self-organizing networks

One swallow doesn't make a summer, and half a dozen neurones don't make a network. It was accepted in the 1950s that McCulloch–Pitts neurones could implement logic gates, and many strings and simple loops for performing and/or learning specific tasks were modelled accordingly. But other questions concerned the properties of *whole groups* of neurones, as involved in the reverberating circuits posited by neurophysiologists—and by Hebb (1949).

Turing had recently described embryogenesis in terms of interacting waves (Chapter 15.iv.a), and others now used similar ideas to explain *neuropsychological* self-organization. One such approach was pioneered in 1954 by Beurle at Imperial College, London, and developed by Clark and Farley at MIT (Beurle 1956, 1959; Clark and Farley 1955). They studied the dynamical properties of two-dimensional arrays of randomly connected cells, or neurones. Those properties were conceptualized as waves of activation: building, spreading, persisting, dying—and sometimes meeting and interacting.

The randomness was important not just as a mathematical challenge but as an attempt to match the biological facts. The increasingly common comparisons between computers and organisms, said Beurle, were "interesting when made in relation to abstract fundamental concepts, but less productive when details are considered" (Beurle 1956: 83). For whereas the components of computers are "connected to some exact specification", many parts of the cortex show a "very large random factor in the interconnexions between neurons". In short:

> The aim of this paper [is] to show that some of the basic forms of behaviour of living organisms can be simulated by a mass of simple units *without the necessity of postulating a large degree of specific organization* of these units. (Beurle 1956: 83; italics added)

Among those "basic forms of behaviour", said Beurle, were chains of conditioned responses and memory in general (1956: 81–3).

Beurle made constant references to "servo-control", but his 1956 paper was a theoretical one. In the implementations of his wave-interaction theories, B24 bombers were left far behind. In some of Farley and Clark's later work, a model network was built out of 1,296 analogue units, with as many as thirty connections each (Farley and Clark 1961).

By that time, even larger networks were being *simulated*, not built with soldering irons, by Richard Laing at Michigan—up to 10,000 neurones, with up to 200 synapses per neurone (Laing 1961*a*). But Beurle and Clark-and-Farley were earlier. Moreover, MIT—Clark and Farley's home base—had much more visibility in the AI community than Michigan did (see Chapter 15.v.b). Light under bushels, yet again.

That's not to say, however, that the Imperial and MIT hardware implementations were so primitive as to be a waste of time. Far from it. This work remained influential long after it was done, as we'll see.

The Beurle-inspired networks were guided, to some extent, by mid-century neurophysiology (2.viii.d–e). For instance, although the connections were random, the probability of two units' being connected decreased with their distance from each other. This was based on (admittedly shaky) evidence about the distribution of cell bodies and axons in the cat's visual cortex.

One physiologically unrealistic assumption made by Beurle was that there was a fixed synaptic delay, and a fixed refractory period—after which a cell would suddenly recover its excitability. These timings were important, because the behaviour of the whole network would depend on the proportion of currently excitable cells. Some of his followers, such as Farley and Clark, tried to keep closer to the biology. That is, they allowed for exponential recovery, and for variations in the thresholds and connectivities involved. Their waves could be visually displayed, and even 'frozen' for inspection (Farley and Clark 1961).

Beurle claimed that if several cells at the centre were simultaneously stimulated, the activation would spread out over a proportion of the net. If the stimulus was weak, the wave would eventually extinguish. But a strong stimulus would generate a wave that spreads out over the whole sheet: "[The wave] will increase in amplitude until it 'saturates,' when it uses all the cells in the medium through which it passes, and the amplitude cannot increase further" (Beurle 1956: 63). By contrast, stimulation of a single cell wouldn't spread.

In certain circumstances, a wave of excitation could leave a process of self-excitation behind it:

> Fully saturated waves may follow each other at intervals equal to the period taken by the cells to recover sensitivity completely, and unsaturated waves may follow even closer. This makes it possible for a wave to pass through a region, and return again to the same region some time later when the majority of the cells has recovered. This would allow a relatively local circulation of activity which might be of some importance. (Beurle 1956: 65)

If two waves of excitation were generated independently, specific types of interference pattern would result when they met.

In some of Beurle's computational experiments, neighbouring units mutually inhibited one another. In others, a unit's sensitivity was slightly increased with each activation, so that the collectivity learned to respond differently as time passed. These results were used to ground hypotheses about the difference, and the interaction, between short-term and long-term memory.

Beurle's hypotheses were not merely qualitative, but quantitative too: he offered a mathematical theory describing the origin of wave-interference patterns. It turned out later that some of his mathematics was mistaken. But many of his ideas remained interesting, especially his demonstration that a *part* of a wave could regenerate the rest.

The neurophysiologist Jack Cowan (1933–) came across Beurle when he was at Imperial College in 1956. He now says that "a lot of the basic ideas about the dynamical properties of networks of neurons are sitting in Raymond Beurle's work", and "I found what Beurle had done was really interesting mathematically," despite the mistakes (J. A. Anderson and Rosenfeld 1998: 105).

In the early 1960s, this part-to-whole result would be cited in developing holographic theories of associative memory (see Section v.c). And when Cowan took over Nicholas Rashevsky's then flagging group at that time, he started by trying to develop Beurle's work—hiring the young chemist Hugh Wilson to help him (alongside Stuart Kauffman, "right out of medical school": see Chapter 15.viii.b).

In the early 1970s, Cowan and Wilson formulated an influential theory of neural dynamics that included Beurle's system as a special case. Later still, Cowan realized that they'd created the neural analogue of Turing's (1952) work on morphogenesis, which was a *universal* model of pattern development (J. A. Anderson and Rosenfeld 1998: 111, 118). Small wonder, then, that he regards Beurle's research as mathematically interesting.

c. Connections with the Ratio Club

Uttley (christened Albert, but nearly always called Pete) had outlined an associative memory even before Beurle did. Indeed, Beurle explicitly acknowledged Uttley's help, in the 1956 paper. Uttley grounded his pioneering models in current ideas about the brain—and in McCulloch and Pitts' neuronal logic (Sholl and Uttley 1953). And he tried very much harder than Beurle to match the biological details (see Chapter 14.ii.b).

Uttley was one of the seventeen founder members of the Ratio Club (see Chapter 4.viii). Indeed, it was he who'd chosen the name—because its etymology covered reasoning, relations, and numbers. Among his fellow founders were Ashby, Horace Barlow, Patrick Merton, William Grey Walter, and Donald MacKay. Other members included the visual psychologist William Rushton, the neurophysiologist John Pringle, and the AI pioneer Jack Good (Husbands forthcoming). (At least two of these men are widely regarded as being unlucky not to have won a Nobel Prize: namely, Barlow and Rushton.)

The Ratio members had got used to cross-disciplinary research during the Second World War, but Uttley was even more interdisciplinary than most. Originally a mathematician, he was involved in some early developments of computer technology. During the war, and afterwards at the Royal Radar Establishment, he developed analogue devices for target-tracking. He designed an early digital computer called TREAC (short for Telecommunications Research Establishment Automatic Computer) in the 1950s. This was the UK's first parallel processor. He also designed a dynamic computer memory, using feedback implemented by mercury delay lines—an idea anticipated by Turing (see 3.v.c). His prime interest (and graduate training), however, was in psychology. He left RRE for NPL in the mid-1950s, where he founded the "Autonomics" division to work on learning in brains *and* machines.

Combining mathematical expertise with a healthy respect for experimental data (on both brain and behaviour), his early ideas attracted various people's attention. Computer modellers were interested of course, but so were psychologists and, especially, neurophysiologists. His Ratio colleagues Barlow and Merton, for instance, were strongly influenced by him: the former for his application of information theory to neurones; the latter for his work on the automatic aiming of gun turrets in aircraft, which informed Merton's servo-theory of muscle control (H. B. Barlow, personal communication).

Uttley's reputation was international, too. He was hailed as the founder of "a revolutionary mechanical logic" by a French cybernetician (de Latil 1953: 280). And one of his papers was included by Claude Shannon and John McCarthy in their seminal collection on *Automata Studies* (1956).

In addition, Uttley co-organized the select London (NPL) seminar at which Selfridge and Rosenblatt first presented Pandemonium and perceptrons, respectively (see below), and Barlow first announced his coding theory of perception (14.ii.a). This NPL meeting, like the Dartmouth Project just before it, was an important event in the history of cognitive science (see 6.iv.b). Its participants included many people mentioned in this book.

For all the respect in which he was held, Uttley's ideas weren't always explained clearly. Barlow (personal communication) recalls that "he was not a great communicator", and remembers him "trying, and failing, to get across the idea of what he called 'unitary coding' at the Ratio Club". (Barlow now thinks this may have been a form of "sparse" coding: see 14.x.e.) Nevertheless, Uttley undoubtedly helped foster the nascent interest in cognitive science.

In his early days at NPL, Uttley developed a range of "conditional probability machines" (Uttley 1956, 1959*a*,*b*). These were intended to simulate various neural mechanisms underlying the conditioned reflex (see Chapter 2.viii.b) and innate releasing mechanisms (see Chapter 5.ii.c). One design, implemented by hydraulics as well as electronics, enabled a computer to count coincidences, and then to estimate the probabilities that two distinct inputs would occur together. He saw such probability estimations as the essential ground of all learning (14.ii.b).

Other models were focused on positive and negative conditioning, neural inhibition, memory decay, and time of onset. Uttley showed that if the temporal order of two inputs of equal strength were recorded, twelve different patterns could result—and could be detected automatically. In general, he explained how a single neural circuit used for inductive learning could distinguish several classes and subclasses, depending on the connectivities and thresholds involved.

These mid-century models are still recognized as important early studies of "reward-modified learning" (Minsky and Papert 1988: 282), and of the role of redundancy and probability estimations (Barlow 2001*b*, acknowledgements). Uttley's mature work, by contrast, is rarely cited today (see Section iv.a, below).

Quite apart from his specific models, his general approach—and his hugely exciting 1956 meeting—inspired a number of people in the 1950s to take computer models of intelligence seriously. As Richard Gregory (personal communication) has put it: "The idea that mind is due to physical mechanisms was still quite alien to almost everyone. Uttley saw very clearly that this was the way to go, so he shone out as a pioneer."

d. Pandemonium

One of Uttley's near-contemporaries on the other side of the Atlantic was Selfridge. (Yes, it was his family—his grandfather—who had founded the famous Oxford Street store.)

In today's publication-obsessed research evaluations, he would hardly figure. (His eight first-author entries in this book's bibliography span forty-seven years.) So much the worse for bibliometrics as a measure of intellectual value. For Selfridge was a hugely important figure in the history of cognitive science. His ideas, in conversation as much as publication (and in the circulation of unpublished drafts), would influence not only connectionism but several other areas besides (see Chapters 6.ii.c and iii.b, 10.i.b, 13.iii.d, and 14.ii.a).

As a young man at MIT, Selfridge was at the heart of the cybernetic community. He was close to both McCulloch and Wiener (who acknowledged his help in the second edition of *Cybernetics*). And his near friends included his contemporaries Jerome Lettvin and Pitts, who were his room-mates for a while. By 1947, he was revising Wiener's mathematical theory of heart flutter (with Pitts working alongside, on fibrillation), and already knew of the ideas on stimulus generalization in Pitts and McCulloch's universals paper.

Ten years later, he was publishing on pattern recognition and learning (Selfridge 1955, 1956)—and enthusing Allen Newell and Herbert Simon to embark on simulating thought (see 6.iii.b and 10.i.b). In addition, he was acting as the patron for Minsky's SNARC machine.

But above all, he was implementing his own "paradigm for learning": a program called Pandemonium, named after John Milton's vision of a demon-packed hell (Selfridge 1959). As remarked in Chapter 10.i.b, this could well have been included in the list of AI harbingers there. Its influence was incalculable.

McCulloch described the Pandemonium paper (written in July 1958) as "the outstanding American contribution" to Uttley's seminal NPL symposium on 'The Mechanization of Thought Processes' (W. S. McCulloch 1961*b*: 224). But that's not to say that he was surprised by it.

The fundamental idea—that perception involves a hierarchy of specialized feature-detectors, or "demons"—had been much discussed between himself, Wiener, and Selfridge, and he'd already applied it in designing a tonal 'reading machine' for the blind. It was familiar also to Minsky, Lettvin, and Ulrich Neisser (all acknowledged in an endnote). Indeed, Selfridge had outlined the core ideas several years earlier, at a meeting on learning attended also by Clark, Farley, Newell, McCulloch, Miller, and Selfridge's Lincoln colleague Gerald Dinneen (Selfridge 1955, 1956; cf. Dinneen 1955).

Pandemonium was part-program, part-programmatic. Selfridge had implemented a simple version on an IBM computer, and would describe its progress in the pages of *Scientific American* a few years later (Selfridge and Neisser 1960). The main excitement, however, lay in his vision of its *potential*. This vision included speculative glimpses of mindlike software "agents", capable of cooperation and communication not only with each other but with a human user too (13.iii.d–e).

The program was a NewFAI achievement. (That's why it could have been listed as a NewFAI harbinger.) However, it was conceptualized as a multilevel parallel-processing network (see Figure 12.1). In spirit, then, it was a connectionist system. It used a *localist* representation, in which one unit corresponded to one feature, or concept. From the bottom up, Selfridge distinguished four levels: "data" demons (cf. a cochlea or retina), "computational" demons, "cognitive" demons, and one or more "decision" demons. In effect, the higher-level demons were grandmother cells (14.x.e), each one looking out for a particular feature, or set of features, in the level below.

If a demon found what it was looking for, it "shrieked" (as Selfridge put it) to the demon/demons on the level above. When the input demons responded to specific sensory data, such as sound or light, the computational demons measured their activity—and some computed *compound* features (such as equality, greater than, less than, maximum, and average). The cognitive demons looked out for more complex patterns, such as the letters A or B. Their decisions were continuously graded: the more confident the demon was, the louder it shrieked. Since the image was simultaneously on view to all the cognitive demons, they all shrieked in parallel—hence, pandemonium. The top-level demon identified which one of these was the loudest, and its output represented the network's final decision about what the input pattern was.

Pandemonium could have been programmed to discriminate clearly defined patterns, or classes. But the aim was for it to *learn* to recognize new ones, and to do so even if they *could not* be precisely defined beforehand. Selfridge assumed—as Jerome Bruner

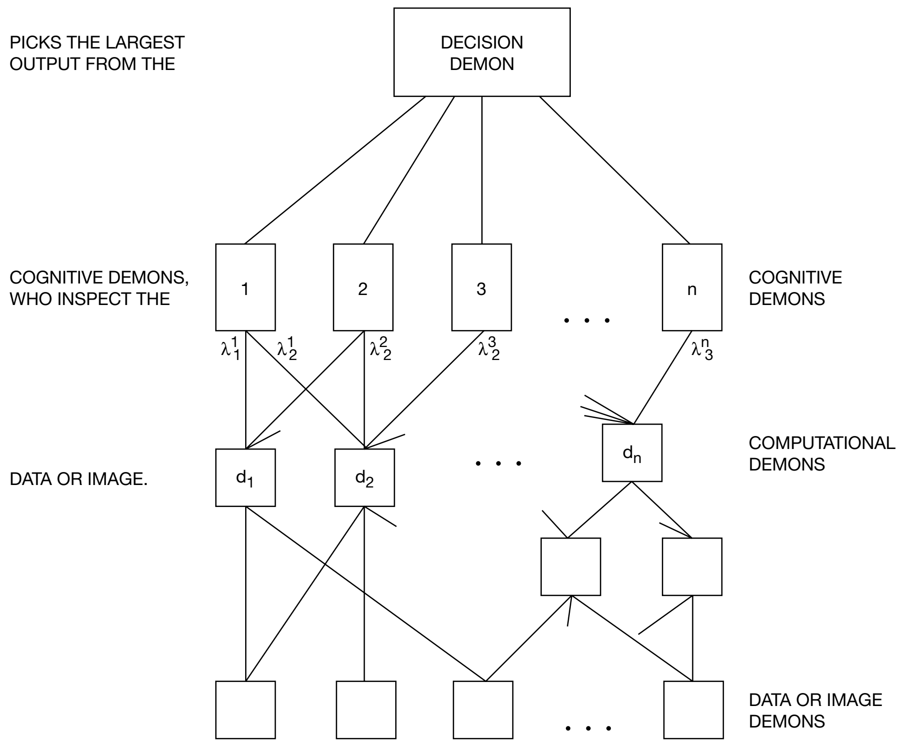

FIG. 12.1. Schematic Pandemonium. Redrawn with permission from Selfridge (1959: 514)

was doing, too (6.ii.b)—that people's classifications (concepts) approximate logical functions of the features concerned. He designed the data demons and computational demons accordingly, and Pandemonium's task was to learn (via the cognitive demons) just which features are involved in this or that class.

It started out with a set of cognitive demons already defined in plausible terms:

For the [cognitive level], we collect a large number of possibly useful functions, eliminating a priori only those which could not conceivably be relevant, and make a *reasonable* selection of the others, being bound by economy and space. We then guess *reasonable* weights for them. *The behavior at this point may even be acceptably good*, but usually it must be improved by means of [several kinds of adaptive changes]. (Selfridge 1959: 516; italics added)

In other words, each cognitive demon computed a weighted sum of the outputs of all the computational demons, but the weights for individual features differed. In recognizing an A or an H, for instance, slanted and vertical lines were weighted differently.

The system was shown examples of various patterns, labelled as such, and had to guess the label for a newly presented example. It was then told whether its guess was right or wrong.

It learnt by hill climbing, a technique introduced in Arthur Samuel's checkers-player (10.i.e). So it continually computed the "score" of its overall performance. On each trial, the weights of some relatively highly weighted feature were slightly altered, in random directions, and the new score was compared with the previous one. This process was repeated until the overall score was maximized—or rather, until every such change reduced it. Selfridge realized that the system might get trapped on a local maximum, or "false peak", but could suggest no way of avoiding this. He did point out, however, that different learning rules would suit statistically different problem landscapes.

The network's method for learning was similar to what Selfridge saw as the basic principle of adaptive movement (see Section iv.b). But there was a crucial difference, which made him distinguish "supervised" and "unsupervised" learning. In these two types of learning the success is monitored, respectively, by the human trainer or by the system itself.

This was an important distinction, and (with the caveat mentioned below) a lasting one.

Today, the three major computational paradigms for learning are *supervised, unsupervised*, and *reinforcement* learning. (And there's some evidence that different brain structures and neurochemicals, such as dopamine, may be involved in the different types: e.g. Schultz *et al.* 1997; Kitazawa *et al.* 1998; Doya 2000.) Each type may result in sequences of input–output pairs (compare chains of conditioned reflexes: 5.iii.a). But this is achieved in different ways:

* In the clearest cases of supervised learning, the human programmer "trains" the system by defining a set of desired outcomes for a range of inputs, and providing continual feedback to the system about whether it has achieved them. When it fails to do so, it has made an "error"—and error messages of various sorts are crucial in the learning rules concerned. In other cases, the target is specified by the system itself, based on sensory signals and higher-level goals (Wolpert *et al.* 2001: 489). Examples include the "emulator systems" discussed in Chapter 14.vii.c, in which the brain predicts the sensory consequences of current motor activity and adjusts the relevant motor control if those predictions aren't borne out.
* In unsupervised learning, there are no desired outcomes or error messages—nor any reinforcers either (i.e. punishments or rewards). Rather, learning depends merely—as Hebb had suggested—on simultaneous activations of the pre-synaptic and post-synaptic neurones. Put crudely, cells that fire together, wire together (ft/wt). As we saw in Chapter 5.iv.b, Hebb himself gave two versions of the ft/wt rule; since then, there have been many further variations. If this seems to favour sequences built up by mere happenstance, perhaps it does: "The main problem with purely unsupervised learning is that *there is no guarantee that the representations learned will be useful for decision making and control*" (Wolpert *et al.* 2001: 490; italics added).
* In reinforcement learning, no desired outputs are specified beforehand. However, each actual output receives either reward or punishment from the environment. This may be the biological environment, or a human "teacher". Sometimes, whole sequences of individual outputs are strongly reinforced at their endpoint, in which case a problem of "credit assignment" arises: which of the individual outputs were most responsible for the happy ending? (Credit assignment is a common problem for non-connectionist AI too: see Chapter 15.vi.a.)

Returning to Selfridge, the promised caveat is that, according to the modern terminology, he sometimes conflated both supervised and unsupervised learning with reinforcement learning. He pointed out that animals, unlike Pandemonium, possess intrinsic measures of success, or innate reinforcers. (Even John Watson had allowed that a young baby will be frightened by loud noises: 5.i.a.) Moreover, he said, reinforcement tells the learner whether it has done well or badly, without providing detailed information on *just which* aspects of its decision were correct/mistaken (i.e. without what was later termed credit assignment).

Since Pandemonium couldn't judge whether one decision was "better" than another, it needed to be told. That is, it was restricted to supervised learning. Unsupervised learning might be possible, said Selfridge, but only if it rode on the back of supervised learning. For instance, if Pandemonium were to discover that the classes were very clearly divided, it might then reject classifications based on more ambiguous evidence.

Selfridge made three intriguing suggestions about how the functions, as opposed to the weights, of the computational and cognitive demons might be adaptively altered. This would enable the network to define its own operators.

(Pandemonium couldn't do this, but a daughter program did so a few years later: Uhr and Vossler 1961*a*/1963. That system initially learnt to recognize alphanumeric characters, and arbitrary doodles, by spotting—defining—their characteristic features for itself. But it was soon used also to learn to recognize spectrograms of spoken digits. These are complicated visual diagrams of acoustic output; non-experts can't distinguish them, but the program learnt to do so, even when the word was spoken by different people: Uhr and Vossler 1961*b*.)

His first suggestion, here, was that a relatively useless demon might be removed, or disconnected. Second, a new demon might be produced by "conjugating" two sub-demons, so that it coded the simultaneous presence of *two* specific features, or *one of them only*, or *one or both*, or *neither*, etc. (He was being influenced here not only by McCulloch and Pitts' 1943 paper, but also by Bruner's work on concept learning: 6.ii.b.) And third, a single demon might be randomly "mutated", and the best survivor retained.

(Simultaneous mutations were specifically excluded, because Selfridge didn't know how to attribute any ensuing improvement to *this* new demon rather than *that* one. In other words, the credit assignment problem again. We'll see in Chapter 15.vi.a that this nut was eventually cracked by John Holland—whose early modelling had located hidden contradictions within Hebb's verbal theory: Rochester *et al.* 1956.)

The implemented Pandemonium program was the first step in the construction of a machine to convert hand-keyed Morse code into a typewritten message. Its task was to learn to discriminate dots and dashes. This is more tricky than one might think: although dashes are in theory exactly three times as long as dots, in practice their length varies. Accordingly, there were only two cognitive demons: one for *dot*, one for *dash*.

But an automated Morse typewriter would need to do more than that: it would have to group the dots and dashes in appropriate ways. So Selfridge envisaged future programs having extra levels of cognitive demons, for computing "symbols" (e.g. *dot–dot–dot*), letters (e.g. *S*), and words (e.g. *SOS*). Beyond that, syntactic and semantic interpretation would require yet more levels.

The implication was that networks with many hierarchical levels exist in adult human brains, and might one day be modelled in computers. Perhaps all these levels could be learnt/constructed from scratch (by iterated conjugation, for instance), or perhaps they're largely built in—by evolution or by the programmer. Selfridge didn't address that question in this paper. But he soon would, as we'll see.

e. The perceptron

Exciting—and influential—though it was, Pandemonium was overshadowed by the near-simultaneous *perceptron*. Perceptrons were described in a leading psychological journal in 1958, shortly before Selfridge gave his NPL talk. (They were also described at the NPL meeting, so reached a widely interdisciplinary group: Rosenblatt 1959.)

The perceptron paper was a distillation of several years' work at Cornell, where the psychologist Rosenblatt had borrowed the Aeronautical Laboratory's IBM-704 computer to do his modelling. This arrangement had started as an inconvenience, necessary because his own department didn't have a suitable machine along the corridor. But it eventually helped spread his ideas. For while psychologists read about them in the *Psychological Review*, physicists—thanks to his borrowed colleagues—encountered them in *Reviews of Modern Physics* (H. D. Block 1962; Block *et al.* 1962).

It was Rosenblatt, even more than Selfridge, who fanned the smouldering fuse of connectionism into a shining flame. A perceptron's task is the same as Pandemonium's: to learn to discriminate input patterns. Indeed, Rosenblatt's diagram of a simple perceptron was highly similar to Selfridge's of Pandemonium (see Figures 12.1 and 12.2). But Rosenblatt's work was both more ambitious and more systematic than Selfridge's.

It was more ambitious, in that Rosenblatt assimilated learning to fundamental self-organization. Self-organization is the emergence of order from a relatively unordered state (see Chapter 15), so *all* learning exemplifies it, in a sense. But this terminology is especially appropriate when the starting point is highly unordered, and Rosenblatt focused on initially random systems. That is, he didn't start out—as Selfridge had done—with networks provided with "reasonable", or "appropriate", features and weights.

Selfridge soon argued that this focus was *too* ambitious. Random networks, he said, are useful only for small local tasks, such as correlating or classifying inputs (Minsky and Selfridge 1961). As we'll see in Section iii, his co-author here would eventually publish a mighty roar of disapproval at Rosenblatt's random-network approach. But that was for the future. Meanwhile, this new work was very well received.

It was more systematic than Pandemonium, in that Rosenblatt compared many different types of perceptron, involving a variety of learning rules. Some of these

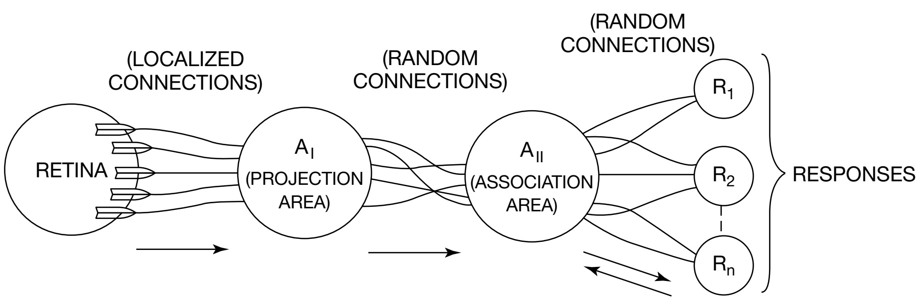

Fig. 12.2. Organization of a perceptron. Adapted with permission from Rosenblatt (1958: 389)

were defined in his paper for *Psychological Review*, others in his eagerly awaited book, previously available only as a lab report (Rosenblatt 1962). So although, as he admitted, "the mechanism for pattern generalisation proposed by Clark and Farley is essentially identical to that found in simple perceptrons" (1962: 24), he took their approach further.

Rosenblatt's ideas were expressed—and compared—in mathematical terms. However, the behaviour of the more complex perceptrons was described qualitatively, not numerically. In many cases, he backed up his theoretical discussion by precise measurements on experimental simulations.

His book included a speculative chapter on "back-coupled" networks. These contained at least one level of what are now called hidden units, plus "back-connections" whereby error messages could be passed backwards from level to level. Such error messages, he said, would enable "layers of units which are relatively remote from the sensory end of the perceptron [to] modify the activity of layers which are relatively close to the sensory end" (1962: 471).

He didn't give an algorithm by means of which this could be done. Nine years later, in 1971, Werbos did so—but no one realized this at the time. The first *recognized* algorithm for back propagation had to await the mid-1980s (see Section vi.c–d, below). Back in the early 1960s, however, Rosenblatt had explored how various ways of doing it—by magic, so to speak—would modulate the overall behaviour of the network.

For example, he argued that a particular back-coupled network illustrated "the simplest conditions under which 'selective attention' might be said to occur in a perceptron" (Rosenblatt 1962: 479). He outlined an experiment in which this back-connected perceptron would learn to distinguish not only triangles and squares and/or the top and bottom halves of the field, but triangle-in-the-top and square-in-the-bottom. It would be able to pick out (pay attention to) one of these stimuli at a time:

> [The] system should give a consistent description of one of the two stimuli, in terms of shape and location, and ignore the other stimulus; it will not name the shape of one and the position of the other, even though both shapes and both positions are simultaneously present. (p. 478)

Like Uttley, Rosenblatt was aiming for biological realism—hence the title of his book: *Principles of Neurodynamics: Perceptrons and the Theory of Brain Mechanisms*. But he did this in much more general terms than Uttley. A perceptron, he said, is:

> a hypothetical nervous system, or machine . . . designed to illustrate some of the fundamental properties of intelligent systems in general, without becoming too deeply enmeshed in the special, and frequently unknown, conditions which hold for particular biological organisms. (Rosenblatt 1958: 387)

So Pitts and McCulloch's 1947 attempt to model detailed neuro-anatomy (see 14.ii.b) wasn't an exemplar for Rosenblatt.

Nor was their 1943 paper. Quite the contrary. Rashevsky's followers in general, he complained, had produced "a profusion of brain models which amount simply to logical contrivances for performing particular algorithms . . . in response to sequences of stimuli" (1958: 387). Admittedly, they'd been more concerned with possibility proofs than with brains as such. But they assumed that it would require "only a refinement or modification of existing [logical] principles to understand the working of a more realistic nervous system" (p. 388). (This criticism was unfair. Certainly, the fashion at the time was logicist; but Rashevsky's biophysics group had long suggested using differential equations to describe neural networks: see Chapter 4.iii.c.)

Rosenblatt took a fundamentally different approach: no "idealized wiring diagrams" for him. Indeed, he was closer to the cybernetic tradition. Declaring Ashby (4.vii.c–d) and von Neumann as his intellectual ancestors, he aimed to show how an initially random network could organize itself.

(As for how it could identify the *relevant* stimuli in the first place, he argued that perceptual similarities aren't objective features, like McCulloch and Pitts' geometrical properties. Rather, they depend on the nature and history of the perceptual system itself: cf. Chapters 15.vii.c and 16.vii.c. In a sense then, the fundamental input sensitivities aren't random at all.)

The theoretical language needed, Rosenblatt said, wasn't Boolean logic but—as the cyberneticians had suggested—probability theory. Some network-modellers had already recognized this, as we've seen. However, "it is frequently hard to assess whether or not the systems that they describe could actually work in a realistic nervous system, and what the necessary and sufficient conditions might be" (p. 388). This two-pronged criticism was a clue to his own approach. He used both experimentation and mathematical analysis to study a wide range of machines.

In the simplest cases, a perceptron is a parallel-processing system comprising an input layer of sensory units (a "retina" of S-points), an output layer of response cells (R-units), and a single layer of associator neurones (A-units) between them. Once a classification has been learned, some individual R-unit fires if and only if the relevant pattern is input. In the ultra-minimalist version, there is only one R-unit, hence only one possible classification.

Each A-unit receives excitatory connections from several S-units, and each R-unit from several A-units. Between S-units and A-units, there are only feed-forward connections. But (usually) each R-cell has inhibitory feedback links to all the A-cells that *don't* excite it. This helps make the responses mutually exclusive: if this R-cell fires, then that one doesn't.

The units are all-or-none McCulloch–Pitts neurones: if the (fixed) threshold is reached, the cell fires. However, the activity of an A-unit has some graded (and alterable) "value", which makes it more or less effective in its influence on the relevant R-cell. The information in the system is thus stored, or represented, as a set of connections of varying strength.

Learning takes place by some form of negative feedback, which Rosenblatt termed "reinforcement". He usually ignored positive reinforcement: learning in simple perceptrons follows error, not success. (This fitted some theories of learning, such as Jean Piaget's, but was controversial nonetheless: see Chapter 7.vi.h.)

The paper described more complex perceptrons, too. And the complexities involved were many and various. I'll list some of them here (without discussing them), so as to convey a sense of the visionary scope of Rosenblatt's thinking at the time—and so as to allow specialist readers to compare his visions with today's achievements. For in effect, he was outlining a long-term research programme for connectionism:

* A network, he said, might contain a larger number of cells,
* and/or several associative layers.
* There might be lateral (inhibitory) connections between A-units.
* Or there could be R-units coding "discriminating features" instead of mutually exclusive responses (so seven R-units could represent 100 patterns).
* Another possibility was to have mini-networks of A-units, specialized to detect discriminating features.
* Further complications included changeable thresholds in the A-units,
* and continuously graded activity in the S-units, proportional to stimulus intensity.

That wasn't all:

* Complex perceptrons might employ a (probably more realistic) form of feedback, in which each R-unit excites its own A-units.
* There might be positive feedback (increase in connection strengths) as well as negative feedback.
* And the training might "force" some specific initial connections, the rest of the system organizing itself around them.
* Also, there might be a "projection" layer placed before the first associative layer.
* There might be systematic connections between S-units and the projection layer, to reflect "focal points" on the retina.
* And the system could be sensitive to temporal, as well as spatial, order.

The crucial point, irrespective of the complexity of the network, was that learning involves some change in the A-units or in their connections. For instance, an A-unit might output a weaker impulse; or there might be a change in the probability that its output will actually reach the relevant cell in the next layer.

Rosenblatt pointed out that there are various ways in which successful connections might be encouraged, and several different criteria for judging success. Usually, he relied on error correction. A connection would be strengthened if the R-unit failed to respond when it should have done, and weakened if it fired when it shouldn't have done. But various types of learning rule could achieve this:

> In the alpha system, an active cell [A-unit] simply gains an increment of value for every impulse, and holds this gain indefinitely. In the beta system, each source-set [all the cells that feed forward to a particular R-unit] is allowed a certain constant rate of gain, the increments being apportioned among the cells of the source-set in proportion to their activity. In the gamma system, active cells gain at the expense of the inactive cells of their source-set, so that the total value of a source-set is always constant. (1958: 392)

Different systems could be specified by substituting different numbers for the variables concerned.

When Rosenblatt did this, and measured the learning curves observed in his computer implementations, he found systematic differences across learning rules. What's more, these differences could be predicted from six quantities: the number of excitatory/inhibitory connections per A-unit, the threshold of an A-unit, the proportion of R-units to which an A-unit is connected, and the number of A-units/R-units in the system.

Connectionism, it seemed, had come a very long way from playing around with bits of abandoned B24 bombers. The B24 bricoleur himself would soon declare this apparent progress an illusion (see iii, below). But meanwhile, in describing his achievements and predicting their future, Rosenblatt didn't hold back. He even designed a secret weapon (not kept secret for long): a mathematical proof that perceptrons had astonishing potential.

f. Excitement, and overexcitement

Rosenblatt made bold claims for perceptrons. "*Each of [the six] parameters*", he pointed out, "*is a clearly defined physical variable, which is measurable in its own right*, independently of the behavioral and perceptual phenomena which we are trying to predict" (1958: 406). It followed, he said, that his system far surpassed behaviourist learning theories—including Clark Hull's, which he saw as the best of a bad bunch (Chapter 5.iii.b).

His theory, or so he claimed, was superior in respect of parsimony, verifiability, generality, and explanatory power. It enabled precise quantitative predictions of learning curves from neurological data, and vice versa. It could be used both to analyse the behaviour of biological organisms, and to guide computer modelling ("the *synthesis* of behaving systems, to meet special requirements"). Hebb had hinted at the organic substrate underlying behaviour, and at a plausible bridge between biophysics and psychology (5.iv.b–d). But, Rosenblatt declared, "[my] theory represents the first actual completion of such a bridge" (p. 407).

This was exhilarating stuff: Edward Tolman's schematic sowbug had been well and truly outdone (see 5.iii.c). To cap it all, Rosenblatt soon (in 1959–60) proved the "perceptron convergence theorem".

The convergence theorem applied only to simple perceptrons, with only a single layer of units between the input and output layers. It stated that a particular learning rule is *guaranteed* to find the correct set of connection values for any pattern that is in principle learnable by a perceptron. That is, a perceptron using this rule can learn to do anything that it's possible to program it to do.

The relevant rule was a form of error correction, in which the A-units' values are slightly raised or lowered whenever their R-unit fires incorrectly. It's true that, eventually, it would always converge on a solution. But that wasn't entirely clear at the time. For Rosenblatt's proof was very demanding, and so too was the simpler version produced by a physicist colleague (H. D. Block 1962, sect. 9b). Ironically, the theorem would later be proved more elegantly by Rosenblatt's fiercest critics (see Section iii.b).

No less exciting than the mathematics and the experiments was the long list of things that perceptrons—considered as a general class—could apparently do. Their capabilities, Rosenblatt reported, had already been *seen* to cover the following:

* both spontaneous and trained pattern recognition;
* tolerance of changes in size or rotation;
* recognition of examples never yet encountered;

* responsiveness to patterns in any sensory modality (or combination thereof), and in both space and time;
* sensitivity to visual contours;
* selective attention and recall;
* distributed memory (stored not, as in the localist Pandemonium, in a single high-level unit but in the collective activity of many units);
* damage tolerance;
* associative learning;
* trial-and-error learning;
* and learning of ordered sequences of response.

Was there anything perceptrons *couldn't* do? Yes, said Rosenblatt:

> The question may well be raised at this point of where the perceptron's capabilities actually stop . . . [Is it] capable, without further modification in principle, of such higher order functions as are involved in human speech, communication, and thinking? Actually, the limit of the perceptron's capabilities seems to lie in the area of relative judgment, and the abstraction of relationships. In its "symbolic behavior", the perceptron shows some striking similarities to [certain] brain-damaged patients . . . As soon as the response calls for a relationship among stimuli (such as "Name the object left of the square") . . . the problem generally becomes excessively difficult for the perceptron . . . Some system, more advanced in principle than the perceptron, seems to be required at this point. (1958: 404–5)

In his book a few years later, and especially in the final chapter, Rosenblatt admitted further limitations. For instance, a single-layer perceptron can't deal with multiple simultaneous inputs, such as a circle next to a square (although a multi-layer version could: see above). And no perceptron of the types he had considered was capable of using a "temporary memory", which is needed for many tasks (1962: 577).

Despite these caveats, however, many people were deeply impressed by Rosenblatt's claims. (Perhaps some who read the paper didn't read the book?) His ideas were soon widely applied (e.g. David and Selfridge 1962).

The flame he had lit ignited the journalists, too. Rosenblatt received "wall-to-wall media coverage" (J. A. Anderson and Rosenfeld 1998: 304). The media interest was caused partly by the 'brainlike' nature of perceptrons, and partly by his special-purpose hardware, the "Mark 1" perceptron (H. D. Block 1962, sect. 8).

This machine—which learnt, for instance, to recognize letters from the alphabet—used photoelectric cells for the retina, and (like Minsky's earlier gizmo) motor-driven potentiometers for varying the weights. It had a 20×20 input array, 512 associator units, and eight binary response units, with each S-unit having up to forty connections to the A-units. The eight R-units communicated and competed with each other, eventually agreeing on a (winner-take-all) single response. Rosenblatt found, as Minsky had done before him, that his hardware needn't be perfect. Change a few connections, knock out some units, or use somewhat unreliable components, and the Mark I might still give an acceptable result.

He himself was ambivalent about the publicity. Obviously, it had its advantages. But it usually involved a fundamental misunderstanding of what he was up to.

For the journalists, he was building a machine. It might be only the first in a long line of improved machines, but the object of the exercise was to engineer a gizmo. For

Rosenblatt, of course, that wasn't the point at all. In explaining why he'd coined the term "neurodynamics" (and used it in his book title), he said:

> The term "perceptron", originally intended as a generic name for a variety of theoretical nerve nets, has an unfortunate tendency to suggest a specific piece of hardware, and it is only with difficulty that its well-meaning popularizers can be persuaded to suppress their natural urge to capitalize the initial "P". On being asked, "How is Perceptron performing today?" I am often tempted to respond, "Very well, thank you, and how are Neutron and Electron behaving?" (Rosenblatt 1962, p. v)

He regretted the scornful scepticism aroused among other scientists by the media attention. The Office of Naval Research, who had funded his work (cf. 11.a), probably regarded it less as an exercise in neurodynamics than as a prelude to militarily useful pattern-recognizers. But scientists in general, reading the press reports, might think his aims were far more grandiose than either:

> [In] the first public announcement of the program in 1958 by the popular press, [they] fell to the task with all the exuberance and sense of discretion of a pack of happy bloodhounds. Such headlines as "Frankenstein Monster Designed by Navy Robot That Thinks" (Tulsa, Oklahoma *Times*) were hardly designed to inspire scientific confidence. (Rosenblatt 1962, p. v)

He was wise to be wary. The brouhaha helped trigger a hugely damaging attack from two critics at MIT (Section iii, below). In effect, Rosenblatt's research programme was killed off by it—or anyway, put into lengthy hibernation.

That wouldn't be the last time when "scientific confidence" in an entire area of research was undermined by overenthusiastic reports composed by, or even *for*, the press. Given the public's (and other scientists') tendency to see computer modelling as hubris, this is an occupational hazard of AI in general. A telling example of what can happen if one is too ready to boast to the press (and to everyone else) was described in Chapter 11.iv.

g. Enter the Adaline

Rosenblatt wasn't alone at that time in being fêted by the newspapers for building an intriguing adaptive machine. Widrow's Adaline (ADAptive LINear Element) and Madaline (a group of Many Adalines) also caused much media excitement.

One widely publicized example of Widrow's pattern-learning hardware, which he called "Knobby Adaline", was an electrical circuit with sixteen input switches and a manual threshold control. Another worked by electrolysis. The connections were made of copper-plated pencil leads, whose resistance varied with the thickness of copper gradually laid down on the graphite core.

You may be reminded of Gordon Pask's electrochemical "concept machine" mentioned in Chapter 4.v.e—which, like Pandemonium, had recently been described at Uttley's 1958 conference. This is no accident. The cybernetic movement had experimented with many adaptive machines based on physical (as opposed to programmed) functions, even including chemistry. And Widrow, as an electrical engineer trained at MIT in the years around 1950, was firmly rooted in the cybernetic tradition.

His special interest was digital filtering, wherein a signal is strengthened by compensating for the noise. Originally a topic for engineers, signal detection theory had been applied to psychophysics by David Green and John Swets at the famous 1956 symposium at MIT (see Chapter 6.iv.b). Widrow, however, was especially enthused by his experience of the 1956 summer school at Dartmouth.

Widrow questioned Wiener's (then orthodox) theory that one has to know the statistics of the signal in order to design the best filter. Widrow wanted an adaptive filter, which would optimize itself *no matter what* the relation of signal to noise.

Wiener had used "mean square error" to measure a filter's success. (*Mean*, because it's the average error that matters; *square*, because squaring a number always gives a positive number, so the direction of error can be ignored.) Widrow had to find a way of minimizing this error measurement automatically. This would require some form of supervised learning, wherein the machine could gauge the difference between actual and desired outputs. In other words, it would require something broadly similar to a perceptron. (This isn't a remark about Widrow's thought processes, for he didn't know about Rosenblatt's work until it hit the newspapers.)

Widrow's first solution resembled the perceptron convergence procedure, for it involved repeatedly making small changes in the filter's parameters and measuring the resulting error each time. Those changes which were found to give the greatest average improvement were then followed until improvement ceased. However, this method of gradient search by "steepest descent" required many successive measurements and calculations. In 1959 (having just moved from MIT to Stanford), Widrow and Marcian (Ted) Hoff together discovered a much more efficient way of finding the error gradient: the "LMS", or least mean square, algorithm (Widrow and Hoff 1960) (see Section v.a, below).

Within only half an hour, they had implemented the LMS algorithm on the department's analogue computer. The next day, they cobbled together an adaptive digital circuit with a 4×4 array of binary input switches—which they used as a demonstration model to amaze their colleagues, not to mention the press. "You'd be surprised how many different geometric patterns you can make with a little four by four array of switches," Widrow said later (J. A. Anderson and Rosenfeld 1998: 54).

That was the first hardware Adaline. The pencil-lead version—as it happens, the beginning of liquid-state electronics—was devised and commercially marketed soon afterwards. It was much more efficient than its predecessor, and also than the Mark I perceptron. Indeed, Widrow regarded the latter as "a disaster", because of its unwieldiness, slowness, and unreliability (J. A. Anderson and Rosenfeld 1998: 59).

One obvious commercial application of Adalines was in adaptive telephone modems, to filter out the noise in the telephone line. But *noise* is a generic concept, so these "adaptive neurons" were potentially useful for many different purposes, including some of interest to cognitive science. Clearly, they might be valuable in technological AI. Whether biological organisms can compensate for noise by using some equivalent of LMS was less clear, not least because LMS involved supervised learning. But the question seemed worth pursuing.

Where adaptive networks were concerned, then, at the turn of the 1960s all systems were *Go!* The interest aroused was phenomenal, and "probably sucked away 10 or 15 years of all the smartest people in cybernetics" (Minsky 1984*b*: 122).

Admittedly, as Widrow recalled many years later, the publicity hype that he and Rosenblatt received "infuriated" many of their colleagues (J. A. Anderson and Rosenfeld

1998: 65). But this annoyance could be dismissed, at least by enthusiasts and outsiders, as being driven by professional jealousy rather than reason. By the end of the 1960s, over 100 research groups in AI and psychology were focusing on perceptrons and similar systems.

Yet only ten years after that, a science journalist wrote: "[The perceptron] had fundamental limitations and has, in recent years, pretty much been abandoned" (J. Bernstein 1981*b*: 100).

"*Abandoned? Surely not! (Whatever happened to the shining flame?) And if so, why?*"—The "Surely not!" will be addressed in Section iv, where we'll see that the flame had been damped, but by no means extinguished. First, let's discuss the "Why?".

12.iii. Attack Without Apology

The journalist just quoted had interviewed Minsky at length. It was he who reported Minsky's story about being beguiled by his B24 bricolage before returning to "science". This probably explains his dismissive remark about connectionist research.

For in so far as perceptrons were "abandoned"—which they weren't, not entirely (see Sections iv–v)—it was largely Minsky's doing. If an outsider got the impression that connectionism was finished, talking to Minsky could have been responsible. This presumably explains also why the science journalist Pamela McCorduck, who knew Minsky personally but wasn't an expert in the field, wrote in her late 1970s history of AI that connectionism had "died" (McCorduck 1979: 47).

The extent of Minsky's responsibility for the Sleeping Beauty's going into hibernation is arguable, as we'll see. But that he had something to do with it is certain. He was one of the devilish duo—for so the connectionist community viewed them—who published a radical attack on Rosenblatt's methodology (Minsky and Papert 1969).

a. The devilish duo

That Minsky jeopardized network research may seem ironic. For he'd built one of the very first connectionist learning machines (see Section ii.a). In fact, Minsky's approach to the two main types of AI swung like a pendulum.

His initial work on learning was connectionist in spirit, as we've seen. But his early paper on neural networks was logicist, not probabilistic. Then, partly due to the influence of John McCarthy, he turned to GOFAI (property-list) methods, making them the focus of research in the AI Lab they co-founded at MIT (Chapter 10.ii.a).

Soon afterwards, he embarked on his first principled critiques of connectionism. These were early exercises in meta-epistemology (10.i.g). For example, he and Selfridge pointed out some intrinsic limitations of the work on perceptrons outlined above (Minsky and Selfridge 1961). And in his seminal paper 'Steps Towards Artificial Intelligence' (Minsky 1961*b*), he explicitly favoured symbolic AI above adaptive networks for modelling learning (10.i.g). In the late 1960s, he even described perceptrons as "sterile" (Minsky and Papert 1969: 232).

By the 1980s, however, his interest had swung back towards parallelism. His "K-lines" account of memory explained it as the partial reactivation (by single units) of *sets* of simple units, comparable to cell assemblies, working in parallel (Minsky 1980; 1985, ch. 8).

But he hadn't abandoned GOFAI (see subsection d, below). On the contrary, his intellectual pendulum had come to rest in an attempted integration of symbolic processes with parallel architecture (Minsky 1985). This hybrid position had been anticipated, in outline, a quarter-century before, in the 'Steps' paper.

Minsky was a hugely influential figure in early AI, as we saw in Chapter 10. He was respected by the wider computing community too. Not only was he the first AI person to receive the ACM's high-profile Turing Award, but his three predecessors were the pioneering 'pure' computer scientists Alan Perlis, Maurice Wilkes (3.v.b), and Richard Hammond. So when he attacked perceptrons, people sat up and listened. It's no wonder that he was so deeply resented by the connectionists: for them, it was a public relations disaster.

Minsky's partner in the devilish duo was Seymour Papert, a South African who'd left home in the 1950s to study mathematics at the University of Cambridge. They were brought together by McCulloch in autumn 1963, at a party in his house. (I was there—sitting on the carpet with Papert!) Papert had come straight from the airport, on his arrival from Geneva where he'd been working with Piaget for five years.

As a Piagetian, Papert saw learning not as the gradual self-organization of an initially random system, but as a process structured by a succession of internal schemata (see Chapters 5.ii.c and 10.v.f). So although he was already thinking about thinking in computational terms (he'd been commuting to London to use the NPL computer, no machine being available to him in Switzerland—Crevier 1993: 86), he was doing so in a way that was at odds with the connectionist approach. As for Minsky, he was already directing the NewFAI research dominant at MIT.

Besides these shared grounds for scepticism about perceptrons, the two men had already ventured into the relevant mathematical theory:

> We had both been interested in the perceptron since its announcement by Rosenblatt in 1957. In fact we had both presented papers related to its "learning" aspect at a symposium on information theory in London in 1960. (Minsky and Papert 1969: 239)

Eighteen months later, with McCulloch's encouragement, they were together at MIT—where they started a "serious" collaboration.

b. The opening salvo

Their joint critique was highly abstract. They didn't build and test actual computer models, still less "quit science for a while to watch the machine". They focused instead on the underlying principles, to determine the scope and limits of the methodology's computational power.

This wasn't a new departure: Minsky's 'Steps' had been written in that way too. In other words, they were doing what Drew McDermott and Alan Bundy had criticized NewFAI workers for not doing (11.iii)—and what Rosenblatt himself had been doing when he formulated the convergence theorem.

It's clear, however, that they were far from disinterested:

> Our first formal presentation of the principal results in [our] book was at an American Mathematical Society symposium on Mathematical aspects of Computer Science in April 1966 . . . We were pleased and encouraged by the enthusiastic reception by many colleagues at the A.M.S. meeting and no less so by the doleful reception of a similar presentation at a Bionics meeting. However, we were now involved in establishing at MIT an artificial intelligence laboratory largely devoted to real "seeing machines", and gave no attention to perceptrons until we were jolted by attending an IEEE Workshop on Pattern Recognition in Puerto Rico early in 1967.
>
> Appalled at the persistent influence of perceptrons (and similar ways of thinking) on *practical pattern recognition*, we determined to set out our work as a book. (1969: 242)

Even this passage gives little hint of the passion that had perfused the early drafts. According to Robert Hecht-Nielsen (1947–), these dripped with "vitriol" and amounted to "an unseemly personal attack" on Rosenblatt (J. A. Anderson and Rosenfeld 1998: 305).

Competition for money was certainly one factor. The DOD "was seriously thinking about funding Rosenblatt's work on the Perceptron" (Newquist 1994: 72). This alarmed Minsky and Papert, because every ARPA dollar devoted to Cornell would be one less for MIT. In the early 1960s that might not have mattered too much, given the depth of ARPA's coffers at that time. But "rumors swept through the [AI] research community around 1968 and 1969 that ARPA was going to cut back on its seemingly unlimited largesse" (Newquist 1994: 139). That may be why, having circulated the book in draft for some years, they now decided to publish it more widely.

There may well have been personal jealousies too. Minsky would understandably be annoyed by Rosenblatt's superman image in the media, especially the mistaken assumption that the Mark I was the first learning network ever built. Possibly, there was some long-standing rivalry: Rosenblatt and Minsky had been fellow pupils at high school in the Bronx. And it probably didn't help that, in 1957, Marshall Yovits of the Office of Naval Research—a friend of Minsky's, who had provided much of the early funding for AI—"had publicized Rosenblatt's work and made a big splash about it" (J. A. Anderson and Rosenfeld 1998: 99).

However that may be, and even though the later printings (after Rosenblatt's death) were dedicated to Rosenblatt's memory, it's pretty clear that "the whole thing was intended, from the outset, as a book-length damnation of Rosenblatt's work and . . . neural network research in general" (Hecht-Nielsen again: ibid.). Eventually, Minsky and Papert followed "the strong and wise advice of colleagues", and expunged almost all of the vitriol.

Those wise colleagues weren't trying to protect Rosenblatt. On the contrary, they wanted to ensure that the damning critique was all the more effective for being seen as objective. For Minsky and Papert weren't the only ones at MIT to doubt Rosenblatt. Cowan remembers attending a "terrible" lecture he gave there in 1958, at which the audience "went after him and really attacked him". "Almost everyone" at MIT, says Cowan, was very sceptical: "by and large, it was clear that the perceptron wasn't doing the things that Frank claimed it could do" (J. A. Anderson and Rosenfeld 1998: 99–100).

The scepticism was experienced with passion. Many of these critics were "infuriated" by Rosenblatt's media popularity partly because they feared that the irresponsible claims involved might cause a backlash against neural networks in general.

Their fears were justified. The VLSI engineer Carver Mead (1934–) would later attribute the "twenty-year famine" in neural networks to the "overhype" about perceptrons (J. A. Anderson and Rosenfeld 1998: 141). Even if Mead was exaggerating, there was much truth in his charge (see subsection e, below). And ARPA (soon to be renamed DARPA: see 5.iv.f), who had funded early 1960s neural-network research but withdrew their support because of the criticisms emanating from MIT, repeatedly warned against similar "hype" when they considered funding connectionism again (see Section vii.b, below).

In the final version, then, Minsky and Papert's critique had lost the invective that had peppered the drafts. It was expressed almost entirely in the ascetic terms of computational logic—or, as they put it, computational geometry.

So they defined various types of simple perceptron: all with a single associative layer, and all locally connected, with no feedback loops. And they compared their computational properties. For instance, they considered the effect of altering the number of S-units leading into an A-unit, and/or the size of the A-unit's receptive field. Mostly, they considered the behaviour of a single (output-layer) neurone, as opposed to the joint activity of several such neurones.

They saw their work as relevant not only to assessing the potential for practical applications, but also to theorizing about the brain. For if perceptrons can't do some of the things that brains do, then some neural processes must be different. Primarily, however, it was an exercise in the general theory of computation: a study of self-organizing machines that make decisions by weighing many independent items of evidence. As such, they suggested, it might throw light not only on the brain but even on "how the genetic program computes organisms" (Minsky and Papert 1969: 1).

The interest and optimism aroused by Rosenblatt's work had been due in part to his convergence theorem (see ii.f, above). Minsky and Papert agreed that it was "seductive" (1969: 14), even "amazing" (1988, p. xi). But they cautioned against taking it at face value.

A theorem, of course, is a theorem—and they even produced new (more elegant) proofs of their own (1969, ch. 11). They argued, however, that certain relevant questions had rarely, if ever, been addressed. These included:

* Is the perceptron an efficient form of memory?
* Does the learning time become too long to be practical even when [learning] is possible in principle?
* How do the convergence results compare to those obtained by more deliberate design methods?
* What is the perceptron's relation to other computational devices? (1969: 243–4)

The last of these questions became "more and more important" in their eyes. It prompted comparisons, for instance, with Ashby's Homeostat (Chapter 4.vii.c–d) and with GOFAI's techniques for problem solving and learning. Minsky and Papert detailed the threat of combinatorial explosion, arguing that scaling up simple perceptrons to deal with higher-order problems wouldn't be feasible.

As they pointed out, the existing successful perceptrons relied on operators specially designed for the task—such as Selfridge's low-level demons, or feature-detectors. This, they said, was no accident. In general, "significant learning at a significant rate presupposes some significant prior structure" (p. 16). This was a version of the lesson already learnt the hard way in GOFAI, that "general" problem-solvers are highly limited in power (see Chapter 10.iii.c and iv). In sum, perceptrons could be useful only for simple, pre-specified, problems.

One might think that the connectionists would have been grateful. After all, GOFAI was thriving despite the threat of the combinatorial explosion, and despite the fact that digital computers are only *approximations* to universal Turing machines. To warn against over-optimism about perceptrons isn't necessarily to dismiss them as a waste of time. Rosenblatt himself had suggested important limitations, as we've seen.

But Minsky and Papert went further. They concluded that this type of research could lead only to a dead end, since even idealized perceptrons aren't equivalent to Turing machines. In other words, the combinatorial explosion was only part of the difficulty. What, above all, put the sceptical cat among the connectionist pigeons was their proof that (simple) perceptrons cannot do certain things which, intuitively, one might have expected them to be able to do.

One intractable problem was the computation of parity. Although a "diameter-limited" perceptron (where each operator can inspect only a small part of the retina, or stimulus, at one time) can tell whether any particular part of an image contains a dot, it can't tell whether the number of dots overall is odd or even. Indeed, Minsky (with Selfridge) had already noted this point in 1960, and repeated it in 'Steps'. Similarly, McCulloch had already noted that a perceptron can't compute *exclusive-or* (so some of the disjunctive concepts studied by Bruner—see 6.ii.b—were out of reach).

Now, Minsky and Papert elaborated on these limitations, and identified more. In general, they showed that perceptrons can discriminate only between classes that are "linearly separable". (Suppose two classes are each represented by a set of points in some mathematical space: if a line can be drawn between the two sets, the classes are linearly separable.)

Most of the specific examples they discussed were clearly relevant to pattern recognition. For instance, they proved that although simple diameter-limited perceptrons can distinguish concave and convex lines, they can't compute spatial connectedness (pp. 12–13, 70–95). They can't say, for example, whether a scribble consists of one continuous line or several. (People sometimes fail too: the two doodles printed on the cover of their book were visually equivalent, but tracing-by-finger shows that one is connected and the other isn't.) Nor can such perceptrons recognize connectivities in line drawings of 3D solids, as the current GOFAI scene-analysis programs could (10.iv.b).

To many people, this was highly counter-intuitive. If perceptrons can cope with convexity, then surely they should be able to deal with connectedness too? Besides referring to existing scene-analysis programs (pp. 232–9), Minsky and Papert gave principled arguments to show that serial, not parallel, computation was required for recognizing connectedness (and parity). And they pointed out that, since all the biological receptor cells identified thus far were diameter-limited (see 14.iii.a–b), an animal needs "more than neurosynaptic 'summation' " to perceive connectedness.

Allen Newell (1969) hailed their critique as "a great book", not least because it furthered "the appropriate shaping of computer science into a disciplined field of enquiry". Many GOFAI scientists welcomed it for less laudable reasons, seeing it as a powerful weapon in a turf war for funding and prestige. But if people in symbolic AI welcomed it, connectionists understandably didn't.

Psychologists who had been excited by perceptrons saw the book as "a major disaster" (R. L. Gregory, personal communication). The network modellers themselves countered it by saying that their research had only just begun, and that Minsky and Papert had considered only very simple systems. Rosenblatt's co-worker Herbert Block (1970), for instance, argued that multi-layer perceptrons would be able to do everything they had said to be impossible.

The critical duo had anticipated this riposte. On their view, more complex, many-levelled, networks would offer no significant advance. They admitted that this was merely a hunch, meriting further research:

> The perceptron has shown itself worthy of study despite (and even because of!) its severe limitations. It has many features to attract attention: its linearity; its intriguing learning theorem; its clear paradigmatic simplicity as a kind of parallel computation. There is no reason to suppose that any of these virtues carry over to the many-layered version. Nevertheless, we consider it to be an important research problem to elucidate (or reject) our intuitive judgment that the extension is sterile. (Minsky and Papert 1969: 231–2)

They even allowed that "some powerful convergence theorem" might be discovered for describing learning in multi-layered machines. Clearly, however, they weren't holding their breath.

c. Intransigence

Twenty years later, it would seem—to many—that their judgement had been mistaken. The late 1980s saw an explosion of interest in connectionism, both from AI researchers and in the media. Besides countless intriguing applications, the results included parity recognition (Rumelhart *et al.* 1986*a*), a "powerful convergence theorem" for multilevel networks, and a multilevel learning rule of great generality (see Section vi.b–c). It was even proved that a three-layer network can in principle solve *any* problem (Hornik *et al.* 1989).

On top of all that, DARPA started funding neural networks again, explicitly admitting that their previous disdain had been "undeserved" (DARPA 1988: 23). In short, many people felt that Minsky and Papert had ended up with egg on their faces.

Not so!, they replied. For their judgement remained unchanged. Minsky made this clear in his contributions to the DARPA study, and also more publicly in a second edition of *Perceptrons*—the text unchanged, but with a new Prologue and Epilogue. He and Papert were unrepentant and unbowed:

> [We] were tempted to "bring [our] theories up to date". But . . . we found that little of significance had changed since 1969 . . . Our position remains what it was when we wrote the book. We believe this realm of work to be immensely important and rich, but we expect its growth to require a degree of critical analysis that its more romantic advocates have always been reluctant to pursue—perhaps because the spirit of connectionism seems itself to go somewhat against the grain of analytic rigour. (Minsky and Papert 1988, p. vii)

Their main complaint concerned that central topic of GOFAI research, the representation of knowledge (see 10.iii.a):

> What we discovered was that the traditional analysis of learning machines—and of perceptrons in particular—had looked in the wrong direction. Most theorists had tried to focus only on the mathematical structure of what was common to all learning, and the theories to which this had led were too general and too weak to explain which patterns perceptrons could recognize. As our analysis . . . shows, this actually had nothing to do with learning at all; it had to do with the relationships between the perceptron's architecture and the characters of the problems that were being presented to it. The trouble appeared when perceptrons had no way to represent the knowledge required for solving certain problems. The moral was that one simply cannot learn enough by studying learning by itself; one also has to understand the nature of what one wants to learn. No machine can learn to recognize X unless it possesses, at least potentially, some scheme for *representing* X. (Minsky and Papert 1988, p. xii)

That final sentence, of course, was a near-verbatim rendering of McCarthy's statement about learning in the early days of GOFAI (10.i.f), and a restatement of Minsky's concern with knowledge representation in 'Steps' (10.i.g).

They did make one concession. They answered the question "How much, then, can we expect from connectionist systems?" by saying "Much more than the above remarks might suggest, since reflective thought is the lesser part of what our minds do" (1988: 280). They even said: "We see no reason to choose sides . . . [And] we expect the future of network-based learning machines to be rich beyond imagining" (p. xiv).

But they were far from endorsing the purist type of self-organization envisioned by Rosenblatt and most, though not all, PDP workers (see Sections vi–viii, below). High-level intelligence, they said, does not and cannot arise from utter randomness, nor from a wholly non-sequential system:

> Most probably, the human brain is, in the main, composed of large numbers of relatively small distributed systems, arranged by embryology into a complex society that is controlled in part (but only in part) by serial, symbolic systems that are added later. (p. xiv)

d. The hybrid society of mind

Innocent readers might have been bemused by the passage just quoted, which was given no explanation. But it tacitly reflected a wide range of work done by cognitive scientists in the twenty years after the first edition. This included research on nativism and modularity (see Chapter 7.vi). Above all, however, it reflected Minsky's ideas on *The Society of Mind* (Minsky 1985). Strictly, one should rather say "Minsky and Papert's ideas", for they'd cooperated very closely in developing them.

The *Society* book had appeared (from a trade publisher, not an academic press) only recently, almost simultaneously with the PDP bible (see Section vi.a). But most cognitive scientists already had some idea of its main themes. Minsky had been mentioning them in conversation since the early 1970s, had given many people drafts from the beginning, and had published a "taster" ten years before (Minsky 1979). Indeed, it "was already cited in detail in a dozen books that came out before it did" (Brand 1988: 102). What they didn't expect was the rhetorical simplicity and structure of his text.

As for simplicity, the book was deceptively lucid. Minsky later said that during the ten years of drafting it, he'd ruthlessly removed jargon: "Whenever someone asked me what a term meant, I explained what it meant and took it out" (interview in Brand 1988: 102).

But the real surprise was the textual structure. The book consisted of 270 half-page to two-page snippets, each discussing a particular psychological and/or computational topic. These ranged from grasping blocks, through recognizing chairs, to emotion, jokes, self, and consciousness; and (as AI topics) from means–end analysis, through frames, demons, and defaults, to reinforcement in neural nets. The relevance of one snippet to another was largely tacit, the overall picture emerging only when the links had been activated in the reader's mind.

This apparent disorganization was deliberate. (It was widely rumoured that Minsky had wanted to present it in a loose-leaf folder, so that the pages could be endlessly rearranged, but that the publisher had refused; however, none of that is true: Minsky, personal communication.) The unusual structure of the book reflected Minsky's unorthodox ideas about the structure of the mind:

> My explanations rarely go in neat, straight lines from start to end. I wish I could have lined them up so that you could climb straight to the top, by mental stair-steps, one by one. Instead, they're tied in tangled webs.
>
> Perhaps the fault is actually mine . . . But I'm inclined to lay the blame upon the nature of the mind: much of the power seems to stem from just the messy ways its agents cross-connect. (1985: 17)

The questions he was addressing, and the general tenor of his reply, were broadly similar to those addressed in Aaron Sloman's theory of motivation and intelligence (see Chapter 7.i.e–f). For Minsky, too, was concerned with the mind as a whole, not just cognition—still less, a specific subset of cognitive abilities. And he too was concerned with architecture, not algorithms.

To be sure, when he could gesture towards an existing or plausible AI algorithm, he did so. ("Gesture", because he gave no references within the text: he left his specialist readers to decode his remarks using their previous knowledge, and provided a glossary to supplement the common sense of his general readers.) But the crux of his discussion was how the algorithms would fit together.

The fit he described was far from snug. Instead of likening the mind to a carefully designed top-down program, he compared it to a loosely organized collective, or society. A society is a distributed system made up of many different agents (see 13.iii.d). Each one has different skills, knowledge, and interests. And all of them do their own thing in parallel, though some may be dormant while others are active.

So it was for Minsky's theory of mind. Various types of communication between agents allowed for the emergence of ordered sequences, hierarchies, conflicts, negotiations, dominance, and cooperation. For example, different instincts or motives would compete for control of the hands, or of attention. Some "supervisor" agents would be able to prioritize one goal over another. But many motives—to eat or sleep, for instance—would spontaneously build up in strength until they broke through such top-down controls.

The GOFAI research of the past three decades, including work on hierarchy, planning, and learning, was a major source of ideas for Minsky's book. His Acknowledgment mentioned many well-known names in symbolic AI (1985: 322–5), and diagrams based on Patrick Winston's blocks-world arches adorned the chapter on learning (see 10.iii.d). But GOFAI concepts such as demons, production systems, blackboard architectures, and heterarchy (all parallelist in intent) were stronger influences than single-minded top-down programs such as GPS.

Connectionist AI was a strong influence too. So were Minsky's years of friendship with (among others) Pask, Hebb, Ashby, von Neumann, and especially McCulloch and Selfridge—all acknowledged in the text. And he leant heavily on his own theory of K-lines: a discussion of associationist memory (both semantic and episodic), and of the hardware likely to be best suited to it (Minsky 1980; cf. 1985, ch. 8).

Despite his long-standing infamy in connectionist circles, the K-line theory had already been greeted as "an important advance" by the organizers of the meeting that heralded the connectionist revival (see Section v.b, below). As they had put it:

> The central idea of the model, that partial mental states are re-created by activating particular agents that designate them, is an interesting intermediate position with respect to the issue of local versus distributed representations . . .
>
> The real value of Minsky's model will only be known when the model is specified in sufficient detail for it to be simulated, but the general approach of trying to implement sophisticated computational processes in parallel neuron-like hardware seems extremely promising. (Hinton and Anderson 1981: 23)

Another intellectual source (via the book's effective co-author, Papert) was Piagetian psychology. This highlighted the importance of developing new ways of organizing existing knowledge, as opposed to acquiring utterly new knowledge (see Chapter 5.ii.c and Section viii.c–d, below). Yet another was Sigmund Freud's psychodynamics. Unlike Kenneth Colby, Minsky didn't present a 'Freudian' program (7.i.a). But he used many Freudian ideas in his discussions of intelligence, motivation, emotion, humour, and self.

Not least, the book drew on evolutionary biology, with its emphasis on opportunistic bricolage rather than anticipatory design. As Minsky put it, the "messy ways [the] agents cross-connect [are] only what we must expect from evolution's countless tricks" (1985: 17). This supported his claim that the mind is a more or less well-integrated collection of separately identifiable systems (cell assemblies, networks, programs, procedures . . .) on many different levels.

That claim wasn't new. William McDougall (1923, 1926) had described the mind as "a colony of monads" (mindlike subsystems) interlinked by functional relations broadly similar to those posited for Minsky's "society" (see Chapter 5.ii.a). More to the point (since McDougall was by then almost forgotten), Hebb had stated this view clearly in 1949, and Herbert Simon had recommended hierarchy as a general principle of complex "design" (including evolution) some years later (1962). In addition, it had recently been stressed in various areas of cognitive science, for instance by David Marr and—as "mental modularity"—by Noam Chomsky and Jerry Fodor (Chapters 7.vi.d–e, 9.vii, and 16.iv.c–d, respectively).

But Minsky was especially interested in subsystems (modules) that were *not*, or not wholly, innate and *not* informationally encapsulated in Fodor's sense. How could they be learnt, and how could they come to interact and control each other? How could modules provided "by embryology" be honed by experience? In particular, how could cultural practices and beliefs (such as religion: Chapter 8.vi) develop, and enter into motivation and emotion as well as problem solving?

Minsky seemed to share Fodor's view that there was no hope of a detailed predictive science of higher mental processes (7.iii.d). But (like Sloman) he was aiming for a scientific understanding of the sort of computational architecture that can make such phenomena possible.

(Minsky's next book, *The Emotion Machine*, would develop these ideas further: see Chapter 7.i.e. As I write these words, it's not yet published. Or rather, it's not published *in print*. Draft chapters have been available for some time, however, on Minsky's web site: Minsky in preparation. Instead of dog-eared mimeographs or fiddly microfilms of "faint purple typewriting with handwritten annotations"—see Chapter 9.vi.a and ix.e—we have clearly legible and easily searchable text. And comments are welcomed, to be sent to Minsky's email address. In short, a good example of Solomon's House in cyberspace: see Chapter 2.ii.b. As for programs grounded in *The Emotion Machine*, he says: "It has almost enough (hidden) technical detail to program it. In fact we already have an early running version of its architectural structure, in which two robots cooperate to solve problems in a simple world, by communicating with some natural language"—personal communication, December 2004.)

The long-awaited *Society* book was rich in insightful comments, questions, and suggestions. But its hybrid spirit, sharing both GOFAI and connectionist insights, didn't fit either orthodoxy. (The need for hybrid systems had been hinted at in 'Steps', as we saw in Chapter 10.i.g; now, it was being made fully explicit.)

Even more to the point, it offered no mathematical analyses, no new techniques for instant application, and no new programs. As such, it was more likely to appeal to non-practitioners than to hands-on AI technologists. Daniel Dennett, for example, was strongly influenced by it (Chapter 16.iv.a).

However, Minsky being Minsky, the book couldn't be ignored by the AI community. It was given eighty pages of reviews/reply in the *Artificial Intelligence* journal (Stefik and Smoliar 1991).

One AI reviewer felt it "unfortunate that cognitive scientists have, for the most part, reacted to Minsky's book as though it were light reading or a minor conversation piece, to be relegated to a coffee table" (Stefik and Smoliar 1991: 321). But another, while allowing that the book was "fascinating and provocative", was less sympathetic:

> How, *exactly*, is this mediation [between agents in conflict] to be accomplished? Without an answer to this, the concept of an agent is an idea with no practical value; it is so general that it might encompass anything. The science, the engineering, the *value* of ideas lie in specifications and the associated falsifiable claims that Minsky chooses not to make.
>
> It is all well and good to invent interesting theories and speculate about their consequences, but such an approach almost inevitably leads to an examination of the strengths of these theories and not of their weaknesses—and Minsky's inability to choose between conflicting agents is indeed a weakness of his theory. A formal approach would have forced him to focus on this weakness until some resolution was obtained; his informality allows him to deal with it by sticking his head in the sand . . . All told, *The Society of Mind* is as Minsky describes it: an adventure in speculation, and not substantive science. It is well worth reading, but only in that light. (Stefik and Smoliar 1991: 338–9)

That was the polite way of putting it. I myself heard many exasperated complaints, even contemptuous dismissals. These were voiced by AI workers (including callow

MIT graduate students, hardly fit to lick his boots) more frustrated by Minsky's lack of technical detail than inspired by his subtlety and vision. His notorious disinclination to programming, and the lack of programs to illustrate his architectural ideas, didn't help (Chapter 10.i.a).

The complaints were understandable. But the dismissals were undeserved. The Popperian appeal (above) to "falsifiable claims" appeared to forget that Karl Popper himself had defended speculative metaphysics as a fruitful predecessor of "substantive science" (K. R. Popper 1935). In short, *Society* was setting an agenda for future AI much as 'Steps' had done over twenty years before (Chapter 10.i.f), albeit now in an even more informal way. The immediate difficulty was that neither symbolic nor connectionist AI was ready to get very far in working on it.

Minsky and Papert, clearly, were using connectionist ideas in their society-theory of mind. The "coffee table" book of 1985 emphasized K-lines, associative memory, and distributed systems. Why, then, were they so unrelenting in the (near-simultaneous) second edition of their notorious critique of Rosenblatt?

The reason was that, even by the late 1980s, most of the new perceptrons were conceptualized as initially unstructured self-organizing systems, doing only one thing—recognizing or expressing only one pattern—at a time (see Sections v–vi). The importance of domain-specific multilevel structure, whether emergent or inbuilt, was being acknowledged by some of the field's leaders. But it was a goal for the future rather than an achievement of the past (see Sections viii–ix). In respect of the *intellectual substance* of their earlier attack on connectionism, then, Minsky and Papert offered no apology.

e. Were they to blame?

As for their *historical influence* on the field, they insisted that—despite the demonology—they had nothing to apologize for. Yes, interest in connectionism had plummeted. But they weren't to blame. ("*Not us, guv!*")

Many readers were surprised by this. For it was—and still is—commonly believed that their 1969 book called a halt to connectionist research, which (with a few honourable exceptions) lay latent until the PDP-led renaissance of the late 1980s. Indeed, some commentators thought that such research had ceased completely.

For instance, a history of AI published in 1979 declared that GOFAI now dominated cognitive psychology, while "the attempt to imitate cell behavior [had] produced only trivial results, *then withered and died*" (McCorduck 1979: 47; italics added). Similarly, the Dreyfus brothers have said that "Everyone who knows the history of the field will be able to point to the proximal cause" of GOFAI's becoming "the only game in town": namely, the mid-1960s circulation of drafts of *Perceptrons* (H. L. Dreyfus and Dreyfus 1988: 21).

This descent into the "wilderness years", it's often added, was due not least to Minsky's unparalleled access to key personnel in the governmental funding bodies. Above all, he was close to Joseph Licklider (5.iv.f, 10.ii.a, and 11.i.b), whose good offices he'd procured for the type of AI being done in his laboratory at MIT. Hecht-Nielsen, for example, says:

Minsky and Papert's book, *Perceptrons*, worked. The field of neural networks was discredited and destroyed. The book and the associated conference presentations created a new conventional wisdom at DARPA and almost all other research sponsorship organizations that some MIT professors have proven mathematically that neural networks cannot ever do anything interesting. The chilling effect of this episode on neural network research lasted almost twenty years. (J. A. Anderson and Rosenfeld 1998: 305)

Certainly, most of the excitement, and the money, throughout the 1970s and early 1980s was in GOFAI rather than connectionism. There's even some suggestion that Rosenblatt himself could no longer get his papers published in the technical journals (Newquist 1994: 74). DARPA later admitted publicly that they had "largely abandoned" neural networks, seeing symbolic AI as "apparently more promising" (DARPA 1988: 23).

Nevertheless, the role of Minsky and Papert's critique is disputed. Widrow's comment, for instance, is very different from Hecht-Nielsen's:

[They] were able to prove that [the perceptron] could do practically nothing. Long, long, long before that book, I was already successfully adapting Madaline, which is a whole bunch of neural elements. All this worry and agony over the limitations of linear separability, which is the main theme of the book, was long overcome.

We had already stopped working on neural nets. As far as I knew, there wasn't anybody working in neural nets when that book came out. I couldn't understand what the point of it was, why the hell they did it. But I know how long it takes to write a book. I figured that they must have gotten inspired to write that book really early on to squelch the field, to do what they could to stick pins in the balloon. But by the time the book came out, the field was already gone. There was just about nobody doing it. (J. A. Anderson and Rosenfeld 1998: 60)

Their own assessment of their book's historical influence on the AI community explicitly rejected the received view:

How did the scientists involved . . . react to [our analysis]? One popular version is that the publication of our book so discouraged research on learning in network machines that a promising line of research was interrupted. Our version is that progress had already come to a virtual halt because of the lack of adequate basic theories, and the lessons in this book provided the field [i.e. AI in general] with new momentum—albeit, paradoxically, by redirecting its immediate concerns. (Minsky and Papert 1988, p. xii)

They (or anyway, Papert) admitted to a degree of "hostility" in their critique:

Did Minsky and I try to kill connectionism . . . ? Yes, there was *some* hostility in the energy behind the research reported in *Perceptrons*. . . . [Part] of our drive came, as we quite plainly acknowledged in our book, from the fact that funding and research energy were being dissipated on what still appear to me (since the story of new, powerful network mechanisms is seriously exaggerated) to be misleading attempts to use connectionist methods in practical applications. (Papert 1988: 4–5)

But the funding collapse that followed on the book was blamed by Papert not on their own quest for money but on the schismatic nature of 1960s AI (see Chapter 4.ix) and the "universalist" tendencies of their AI colleagues:

The desire for universality . . . was nurtured by the most mundane material circumstances of funding. By 1969, the date of the publication of *Perceptrons*, AI was not operating in an ivory-tower vacuum. Money was at stake. . . . [That's largely why our book was misinterpreted as claiming] that neural nets were universally bad. (p. 7)

Even more important, he said, was the computational weakness of the connectionist approach: "We did not think of our work as killing Snow White; we saw it as a way to understand her" (pp. 7–8). Moreover, he and Minsky pointed out that work on neural networks had become "virtually dormant" twice: once in the late 1950s, and again in the late 1960s (Minsky and Papert 1988, p. xi). The implication was that their 1969 attack wasn't to blame. The work had "stalled" because of its inherent limitations.

There's some evidence for their view in Widrow's comment, above, and there's more in Sections iv–v, below. Even so, their disclaimer is only a half-truth.

Drafts of their work had been circulating for at least eight years before the book appeared. What's more, they'd attacked perceptrons at several high-visibility meetings from the late 1950s on, such as the Chicago conference on self-organizing systems in 1962 (organized by Yovits: Yovits *et al*. 1962), and the Wiener Memorial meeting (in Genoa) in 1965. They'd also shared these critical ideas with the funding agencies: not just Yovits at the Office of Naval Research, but their contacts at ARPA too (J. A. Anderson and Rosenfeld 1998: 109). Those "contacts", of course, included Minsky's long-time friend Licklider, the supremo in charge of AI funding at ARPA/DARPA (Chapter 5.iv.f).

And people had listened. Cowan, who attended the Chicago meeting, says: "There's no question that after '62 there was a quiet period in the field" (J. A. Anderson and Rosenfeld 1998: 108). In short, if many researchers in 1969 were already disillusioned, the book's authors—if not the book itself—were largely responsible.

As for what they meant by giving "new momentum" to the field of AI, this involved a swing towards the central problem then being addressed by GOFAI:

> It seems to us that the effect of *Perceptrons* was not simply to interrupt a healthy line of research. That redirection of concern was no arbitrary diversion; it was a necessary interlude. To make further progress, connectionists would have to take time off and develop adequate ideas about the representation of knowledge. (Minsky and Papert 1988, p. xiii)

"In any case", they added, "the 1970s became the golden age of a new field of research into the representation of knowledge [see Chapter 10.iii.a]. And it was not only connectionist learning that was placed on hold; it also happened to research on learning in [symbolic AI]."

Their comment on symbolic AI was justified. Although Winston's model of learning had some influence, most of his GOFAI colleagues were working on the representation of knowledge for problem solving, planning, perception, and parsing (see Chapters 10 and 9.x–xi). Indeed, Minsky later admitted that "In all modesty, we were unduly influential" in dissuading GOFAI people from working on learning (Minsky 1984*b*: 122).

But whether connectionist learning really was "placed on hold" is questionable, as we'll now see.

12.iv. Lamps Invisible

The 1970s and early 1980s were the time of the Sleeping Beauty's sleep. Indeed, they're often called the Dark Ages of connectionism. But Cowan, for instance, has protested:

"I don't think it was the dark ages at all. There was a lot going on" (J. A. Anderson and Rosenfeld 1998: 110).

That's true. If the funding famine caused by the Minsky–Papert critique prevented connectionism from running riot, it didn't stop it in its tracks entirely. Nor did it prevent important neuroscientific work on connectionism, which didn't depend only on DARPA for financial support (see 14.v.a–b and x.a).

Most of the 1950s pioneers continued working throughout the 1970s. (Rosenblatt didn't: he died in a boating accident in 1971.) Some younger folk focused on networks as associative memories. (These generate pattern B on being shown pattern A; they include "content-addressable" memory, where A is a fragment and B the whole pattern.) And Marr and others, by the mid-1970s, diverted interest in AI vision towards connectionist models (see Chapter 7.v.b–d).

In short, by the time connectionism became publicly visible again in the mid-1980s, it rested on three decades of continuous research (J. A. Anderson and Rosenfeld 1998; Widrow 1990). The many enthusiastic outsiders who regarded it as "new" were thus sadly—or rather, happily—misguided.

Some of what went on in those "Dark Age" years excited fellow hibernators at the time, and those responsible would eventually bask in the limelight of the connectionist renaissance (see Section v). But some, discussed here, received scant attention even from like-minded colleagues. Uttley and Selfridge continued working but would never play a leading role again; and the pioneering John Andreae was unappreciated by his peers. (Werbos wasn't appreciated either: his contribution, an important learning rule, was recognized only in the post-hibernation period—see Section vi.d, below.)

a. Relegation to the background

Uttley, in the 1970s, was no longer regarded as an important force in cognitive science. On leaving NPL in 1966, he'd joined N. Stuart Sutherland's psychology group at the University of Sussex, where he implemented a large number of neural networks and moved increasingly towards computational neuroscience (see 14.ii.b). But, for reasons explained below, his ideas now fell on relatively stony ground.

By the standards of the time, Uttley's computer models were more complex than most. His numeral-learner, for example, contained over 200 units ("informons"), each with up to fifty variable inputs. And these might represent many more actual neurones: Uttley allowed that whenever he spoke of a "neurone", one could probably substitute "neurone pool". (Some of the more well-known connectionists said much the same thing.)

His mature theory, which described synapses in informational terms, was summarized in the *Journal of Theoretical Biology* (1975) and detailed in a large book soon afterwards (1979). One of the central ideas was that a single neurone can become a "classifier", not through external reinforcement or training but by "subset reinforcement". That is, the neurone calculates the input correlations, and disconnects itself from the uncorrelated inputs—thereafter responding only to the relevant subset. "Calculates" is the right word, here, for Uttley gave mathematical equations defining which probabilities were supposedly assessed, and how. (He didn't treat *all* learning as unsupervised: the neurones between cortex and muscle, he said, do need a teacher. In other words, they need conditioning.)

Uttley's work was nothing if not ambitious. For instance, he sketched networks explaining why Bach's music is perceived differently today from how it was appreciated in his own time. These ideas, in turn, rested on his more detailed account of how successive layers of neurones in auditory cortex may spontaneously (i.e. with attention, but without training) discover deeper and deeper relationships between musical notes. These were assumed to be hierarchical classifications, defined across time and in harmonic space.

He admitted that his approach threw little light on language. But he claimed that it helped us understand [take a deep breath, here] perception, motor skills, generalization, hierarchical concepts, memory, imagination and hallucination, music, art and craft, and purposive behaviour in general—even including birdwatching and religious belief. (He was a keen birdwatcher, and a committed Christian.)

Given these wide-ranging claims, one might have expected Uttley's *magnum opus* of 1979 to make a splash in the cognitive science community. However, it didn't.

Besides his failings as a communicator in face-to-face conversations (see Section ii.c), and the fact that he "was not someone who went out of his way to interact with other people" (A. Baddeley, personal communication), his highly abstract writing style didn't help. Even his shorter book, written a few years later to show "the enquiring layman" how adaptive neural networks can have mindlike properties, was beyond the capacity of most laymen, enquiring or otherwise (Uttley 1982). Valentino Braitenberg's (1984) contemporaneous account of mindlike "Vehicles" grounded in interacting reflexes was far more accessible (14.vi.a and 15.vii.a).

The main problem, however, was the change in popularity of his theoretical approach. Information-theoretic psychology and psychophysiology had fallen out of favour since around 1960. Even within behind-the-scenes connectionism, Uttley's circuit-based approach had been pushed aside by studies of random networks, and of single impulses rather than spiking frequencies. The focus was on trainer-led (supervised) rather than spontaneous learning, and conditioning had been replaced by pattern recognition as the centre of attention. (Interest in models of conditioning would revive in the late 1980s.) Indeed, the first—and highly influential—PDP conference was held in the very year that Uttley's technical book was published (see Section v.b).

Moreover, network models *in general* were still out of fashion in 1979. Most of Uttley's Sussex colleagues in cognitive science (myself included) were more interested in GOFAI approaches, and were concentrating on vision and knowledge representation rather than learning. This applied even to Geoffrey Hinton (1947–), who in the early to mid-1970s at Sussex was still using GOFAI methods (see below). The general feeling was shared by Uttley's postdoc William Phillips, hired to work with him at Sussex for four years on a reading aid for the blind (which wasn't successful):

> I didn't study Uttley's theories very closely, even though I had to help him give a presentation on the "Informon" to the Royal Society. At that time I was very much under the spell of Max Clowes's arguments for the necessity of a syntactic approach to cognition in general, including image processing and scene understanding. As Uttley's work did not seem relevant to those issues it didn't seem worth while spending much time on it. (W. A. Phillips, personal communication)

Ironically, Phillips—currently Professor of Psychology at Stirling's Centre for Cognitive and Computational Neuroscience—now favours information-theoretic and other essentially statistical perspectives on cognition. So he now appreciates Uttley's work better than he did then. But it had no overt influence on his development.

In sum, various factors combined to make Uttley's book invisible—even at very close range.

b. Run and twiddle

Selfridge, too, now received less attention than he deserved—especially from AI scientists. To be sure, he was still a respected voice within the core AI community. (He'd left academia for Bolt, Beranek & Newman but retained his links with his fellow pioneers.) And cognitive psychologists valued his earlier research. Pandemonium was highlighted in two early textbooks (Neisser 1967; P. H. Lindsay and Norman 1972), and fetchingly illustrated in one of them (see Figures 6.5 and 6.6). But his own theory of learning was so different from the then current GOFAI paradigm that most AI people ignored it. (Minsky didn't, but he was always a maverick.)

Even the embattled connectionists paid little or no attention. This was partly because Selfridge didn't make his new work easily available. A few brief accounts appeared in out-of-the-way publications, and drafts of his future book were circulated to friends—including myself (Selfridge 1981). But it was never officially published.

Focusing on *the whole animal* rather than isolated systems such as vision, Selfridge argued that the fundamental mechanism of all adaptive movement is a form of unsupervised trial-and-error learning. He called this "RT", or "run and twiddle", identifying the core principle as "if things are getting better, don't change what you're doing" (Selfridge 1984: 23). Even *E. coli* can engage in a random walk, follow a positive value gradient, and then stop if things don't get any better. In other words, he said, even simple creatures—unlike man-made perceptrons (which he criticized for this reason)—"want" something.

What *E. coli* wants is an optimal concentration of certain chemicals, which can be achieved by simple chemotaxis. Animals with more complex wants, or purposes, need more complex mechanisms to guide and structure their behaviour. That is, they need hierarchies of adaptive control loops—but how can such systems, and their development, be conceptualized? As he admitted, it was hard to know how to pose the relevant questions, never mind answer them.

(His answers today are posed in terms of "EAMs": Elementary Adaptive Mechanisms: Selfridge and Feurzeig 2002. Now based at MIT's Media Lab, Selfridge is working on DARPA's "ABC" programme. The abbreviation stands for Agent-Based Computing, an area currently of great interest to GOFAI too—see Chapter 13.iii.d–e.)

Another reason for the lack of interest in Selfridge's 1970s ideas was that unsupervised learning had become unfashionable. Thanks to perceptrons, Adalines, and—ironically—Pandemonium, most connectionism in the 1970s involved a human trainer. Those few people who were still modelling reinforcement were swimming against the current.

c. Reinforcement and purpose

One of the people still modelling reinforcement was Andreae (1927–), an Englishman based since 1988 at the University of Canterbury, New Zealand. He'd started in the early 1960s, with a model of noise-tolerant trial-and-error learning called STeLLA (Andreae 1963, 1969*a*; Gaines and Andreae 1966). (The name, and its typography, indicated Andreae's former post: Standard Telecommunications Laboratories Learning Automaton.)

STeLLA was interesting not least because it was an attempt to embrace both sides of the symbolic–subsymbolic and virtual–interactive dichotomies. That wasn't always recognized by Andreae's contemporaries, however. For example, Edinburgh's James Doran (1940–), who'd already simulated a "pleasure-seeking" rat robot inspired by the Grey Walter tortoises (Doran 1968*a*), said this:

> [It] is far from clear how such network systems can be persuaded to yield really complex behaviour. The results of the work [by Minsky and Papert: 1969] on perceptrons and other such self-organizing systems do not encourage optimism. (Doran 1969: 524)

Andreae described STeLLA as constructing, and being guided by, an internal plan of action and model of the environment. These were implemented as matrices coding probabilistic transitions between various pattern–action pairs. He soon realized, however, that probabilistic transitions weren't going to be enough. His associative robots needed to be able to learn fixed sequences too. They couldn't be programmed (for instance) to recite *one, two, three, four, five* ... flawlessly. But they should be able to learn to do so: even a 99 per cent probability of coming up, next, with *six* wouldn't be acceptable. So he redesigned STeLLA in the early 1970s, to produce a fundamentally different machine: PURR-PUSS (Andreae 1977, 1987; Andreae and Cleary 1976).

The acronym stood for Purposeful Unprimed Real-world Robot with Predictors Using Short Segments. The "PURR" coded Andreae's guiding aims: that the robot should set its own goals; learn patterns and behaviours that he hadn't anticipated (even though some "innate" biasing might sometimes be needed); and have real-world capacities comparable with ours, such as motor control, 3D vision, hearing, and even language. The "PUSS" coded the complex associations that were crucial in the robot's processing and performance.

For example, this new system was able to construct temporary memories on various hierarchical levels. These were broadly equivalent to the pushdown stacks and "contexts" used in GOFAI planning (Chapter 10.iii.c and v.b–d), in the sense that they enabled the system to monitor its own performance, keeping track of where it was in a plan structure. Instead of being stored as symbolic expressions, they were stored as associations with environmental changes (compare: tying a knot in one's handkerchief) or, more often, trivial bodily actions (compare: raising an eyebrow). Fixed sequences, by contrast, require long-term memories—but these too were stored as complex associations constructed by the system.

One of Andreae's papers (1969*a*) was chosen as the first item in the newly founded *International Journal of Man–Machine Studies*, whose readership included psychologists, and he contributed to an interdisciplinary encyclopedia co-edited by a linguist (Andreae 1969*b*). More recently, he has been cited in historical remarks in the reinforcement-learning literature (Sutton and Barto 1998: 19, 84, 109).

Nevertheless, and although he was respected by control engineers, he had relatively little influence on cognitive scientists.

One reason was place of publication. Most of his papers appeared in journals aimed at engineers. And the forty technical reports on PURR-PUSS that were lodged in leading libraries, including the Library of Congress, were easy to find only if one already knew about them. (Modulo information overload, the Web should decrease this sort of invisibility.)

A closely related reason was timing. Andreae's earliest work appeared when people excited by connectionism were looking in Rosenblatt's direction. By the time he described his second system, connectionism in general was out of fashion. One reviewer of his 1977 book (Schubert 1978), for example, wheeled out John McCarthy's GOFAI objection that one must understand a cognitive skill well enough to program it before one can enable a computer to learn it (Chapter 10.i.f). Andreae's position, by contrast, was that complex associative robots probably won't be fully intelligible, even to their designers. (The same may apply to detailed neuroscientific models: see Chapter 14.v.d.)

Only very recently, thanks to the renewal of interest in this area, has his later research been made widely available—although it remains to be seen how many people will read it (Andreae 1998). Previously, it was neglected: "*Unfortunately*, [Andreae's] pioneering research was not well known, and did not greatly impact subsequent reinforcement learning research" (Sutton and Barto 1998: 19; italics added).

12.v. Behind the Scenes

Although no behind-the-scenes connectionist was attracting much attention in the cognitive science community, some were making significant theoretical advances nonetheless.

Very few were talking to each other: their shared project didn't become truly communal until the end of the 1970s (see subsection b below, and Section vii). Meanwhile, they were working in very different disciplines, and on rather different problems.

a. Left alone to get on with it

If Andreae was unfortunate, Widrow—in his own estimation—wasn't. Not only did he (unlike Andreae) receive enormous attention in his early career, but he managed to escape the near-inevitable consequences.

On his view, the anti-perceptron backlash largely passed him by simply because he'd called his networks by a different name:

> I looked at [Minsky and Papert's] book, and I saw that they'd done some serious work here, and there was some good mathematics in this book, but I said "My God, what a hatchet job." I was so relieved that they called this thing the perceptron rather than the Adaline because actually what they were mostly talking about was the Adaline, not the perceptron. (J. A. Anderson and Rosenfeld 1998: 60)

Another reason for Widrow's lucky escape, perhaps, was that—unlike Rosenblatt—he hadn't provocatively presented his Madalines as models of human psychology.

He had, however, suggested in the paper on the LMS algorithm (Widrow and Hoff 1960) that AI could be hugely advanced by using "computers built of adaptive neurons". This suggestion may have looked like an afterthought to the contemporary readers of that paper, but AI was already close to Widrow's heart. He'd attended the Dartmouth Summer Project in 1956 (Chapter 6.iv.b), and decided then and there "to dedicate the rest of my life to that subject" (J. A. Anderson and Rosenfeld 1998: 49). Adaline-based computing, he believed, could do things that NewFAI couldn't:

> [Samuels's checkers-player] would be considerably more powerful if it were possible to extract from the memory previous situations that are *similar* and not necessarily *identical* to the current situation. Far less experience and storage would be needed to adapt to a given level of competence. (Widrow and Hoff 1960: 133)

In general, he said, AI needed not "rote memory" but "recall-by-association parallel-access memory systems"—which could be implemented in "Memistors". These were Adaline-based devices, providing a simple form of content-addressable memory.

A third reason why Widrow was less affected by the backlash was that, as a control engineer, he could demonstrate practical applications that undeniably worked.—But *how* did they work? The answer lay only partly in the special-purpose hardware. Even more important was the mathematics. If the journalists had been turned on by the switches and the pencil leads, the scientists were more excited by the learning rule:

> [The key to the LMS algorithm] was to get the gradient not by taking many samples of data and measuring mean square error over a long period of time. The idea was to be able to get the gradient from a single value of error—a single number, square it, and say that's the mean square error. Then when you work out the gradient of that error with respect to the weights, it's really simple. You get an algebraic expression and you realize that you don't have to square anything; you don't have to average anything to get mean square error. You don't have to differentiate to get the gradient. You get all this directly in one step. Not only that, but you get all components of the gradient simultaneously instead of having to make measurements to get one gradient component at a time. *The power of that, compared to the earlier method* [i.e. steepest descent], *is just fantastic.* (J. A. Anderson and Rosenfeld 1998: 53; italics added)

(*Plus ça change*... It became clear years later that the "fantastic" Widrow–Hoff adaptation rule was essentially the same as Hull's early 1940s equation for calculating habit strength: Sutton and Barto 1981; see 5.iii.b.)

Widrow wasn't the only one to address his work mathematically. In general, the behind-the-scenes research of the 1970s–1980s which—unlike that discussed in Section iv—*did* eventually receive recognition was mathematical in spirit. It aimed to find more powerful training procedures, especially for multi-layer nets (which Rosenblatt had found intractable).

The problem with multi-layer nets was that they contained "hidden" units. These weren't directly connected to *both* input and output units, and might even be directly connected to *neither*. And that fact carried unavoidable problems with it:

* How could an individual hidden unit be reached by a learning rule (which monitors the output, given a certain input)?
* Could one define rules that would enable multi-layer networks to adapt efficiently?
* Was there any multi-layer equivalent of the single-layer convergence theorem?

* What were the limits, if any, on the patterns or structures that specific kinds of rule and/or network could learn?
* How few hidden units would suffice for any given task? (Too many, and the system would in effect be a look-up table.)
* What could be said about the potential storage capacity of associative memories with different numbers of cells?
* And what were the functional merits of distributed memories as compared with localist networks, or with GOFAI?

Answers to these abstract questions were sought by a wide variety of people. Some were control engineers, seeking a multi-layer equivalent of the LMS algorithm. Some were computer engineers, keen to implement their answers in VLSI chips. Others were electrical engineers or physicists, interested in dynamical models of associative memory. Yet others were computer scientists already working in AI.

And many were mathematically minded psychologists, usually with experience of GOFAI modelling and/or interests in neuroscience. A few of them tried to model the nervous system in some detail (see 14.iv–v).

b. A problem shared . . . ?

One shouldn't assume that all these people communicated with each other, or even knew of each other's existence. During the Dark Ages most of them were working in isolation, separated not by monastery walls but by disciplinary boundaries. This is why priority disputes in this area are so common. Indeed, a recent collection of interviews abounds with coded and not-so-coded priority claims, backed up by hard-luck stories about lack of recognition in the wilderness years (J. A. Anderson and Rosenfeld 1998).

To be sure, GOFAI-based cognitive scientists already had a thriving interdisciplinary community (see Chapters 6–10), and many influential connectionists had strong links to that. Some had even developed GOFAI-inspired psychological theories.

For instance, David Rumelhart at UC San Diego had developed formal models of story plots, or "story grammars" (Rumelhart 1975). And he had used both ATNs and ideas from HEARSAY to model reading errors (see Chapters 10.v.e, and 9.xi.b). Indeed, HEARSAY was later acknowledged by the leaders of PDP as having "played a prominent role in the development of our thinking" (Rumelhart, McClelland, *et al.* 1986: 43). Rumelhart had also been excited by NewFAI's "semantic networks" (Chapter 10.iii.a), which had helped lead him and others to work on associative memories (Findler 1979).

Similarly, Christopher Longuet-Higgins had produced GOFAI models of musical perception (see Chapter 2.iv.c). Moreover, there was a small but growing community of connectionist workers on vision, including Marr, Tomaso Poggio, Stephen Grossberg, and Hinton. Although they were wary of GOFAI approaches, most of them had started from that base; and a few, such as Hinton, had worked on GOFAI projects for some years (see below, and Chapters 10.iv.b, 14.ii–iii).

However, specialists in AI and psychology, even if they communicated with each other, had little or no contact with engineers and physicists. If "A problem shared is a problem halved", there were no helpful interdisciplinary half-measures available.

This situation would begin to change in the summer of 1979, when many connectionists (including supporters of *non*-distributed memories) met for the first time. The occasion was a meeting on 'Parallel Models of Associative Memory'. It was hosted in the Cognitive Science Center in La Jolla, by Rumelhart and Donald Norman—key members of the PDP group (see below). (Ironically, 1979 was the year in which connectionism was announced to have finally "withered and died": Section iii.e, above.)

This was one of the many projects funded around 1980 by the Sloan Foundation, who were then switching support from neuroscience to cognitive science (see Chapter 8.i.c). The organizers were the psychologist Hinton and the neurophysiologist James A. Anderson (1940–), at Brown. Hinton was then based in the Cambridge University research unit that had housed Kenneth Craik, but he'd visited UCSD's Cognitive Science group and was about to return there. As for Anderson, he'd been at UCLA in the early 1970s but was now based at Brown.

(NB. One shouldn't confuse James A. Anderson with John R. Anderson, whose ACT* system was discussed in 7.iv.c. It's easy to do so, however, because they both did important work on associative memory. Indeed, Hinton and J.A.A. described J.R.A.'s ideas on this topic as "seminal"—Hinton and Anderson 1981: 15. In this chapter, "Anderson" refers to J.A.A. unless otherwise noted.)

Like Christopher Langton's "Call for Papers" for the seminal conference on A-Life (15.ix.a), Hinton and Anderson's invitation had been sent to a very varied group:

> We deliberately chose people from fields as diverse as neurophysiology, cognitive psychology, artificial intelligence, mathematics, and electrical engineering. *Most of the participants had not met each other previously and in some cases were unaware of each other's work.* Yet as things progressed, it became clear that there were large areas of agreement, as well as strong disagreement about details. (Hinton and Anderson 1981, p. vii; italics added)

The new-found community, however, wasn't destined for sweetness and light. Within a few years, the "strong disagreement about details" would help engender what Bart Kosko later described as "many feuding factions", some of whose leaders "literally hated each other's guts" (J. A. Anderson and Rosenfeld 1998: 402–3). Human beings being what they are, this lack of collegiality was largely due to jealous resentments caused by the *success* of the field, with its attendant publicity and commercial promise (see Section vii).

However, all that was yet to come. At the end of the 1960s, success seemed very far off. Quite apart from the Minsky–Papert fusillade, there were many practical difficulties.

c. How large is your memory?

One difficulty concerned multiple storage in associative memories. Both Rosenblatt and Widrow had found that their machines could store more than one pattern at a time—but the more patterns involved, the less efficient the storage: interference effects came to the fore.

This made sense, given that any one pattern was distributed across many different units, and that each unit might contribute to several patterns. Indeed, it raised the spectre of a rapid descent into chaos as the number of stored patterns increased. What was needed, beyond these empirical observations, was some *principled* (mathematical) estimate of the potential storage capacity of connectionist systems, and of the efficiency of distributed memories.

Such questions had been asked before, in relation to punch card systems as well as brains. Turing himself had been asked by John Z. Young "whether one can make an estimate of how much information can be stored in a brain with a given number of nerve cells", and had sketched the bare bones of a reply (S. S. Turing 1959: 145 ff.).

Moreover, Peter Greene, in the Chicago group founded by Rashevsky, had recently developed that earlier work. He'd shown how random superimposed ("hash") coding could be used both to store and to recall associative memories (Greene 1965). (Cowan regards this as "virtually identical with David Marr's cerebellum model, except it's not applied to the cerebellum"—J. A. Anderson and Rosenfeld 1998: 110; see Chapter 14.iii.d.)

But Greene's paper wasn't widely read. The first to reach an appreciable audience for these matters were Longuet-Higgins and his students David Willshaw (1945–) and Peter Buneman, at Edinburgh University (before Longuet-Higgins's move to Sussex in 1974). In the late 1960s, Longuet-Higgins outlined a quasi-holographic model of memory (1968*a*,*b*), and then collaborated with his two students on a non-holographic model (Willshaw *et al.* 1969).

He presented some of these ideas informally at one of the renowned Serbelloni meetings on theoretical biology run by his Edinburgh colleague Conrad Waddington (15.v.b). On that occasion, Cowan made him "absolutely furious" by saying they were "virtually identical with Steinbuch's learning matrix" in the late 1950s (J. A. Anderson and Rosenfeld 1998: 110). Longuet-Higgins in "absolutely furious" mode was, as all his friends know, fearsome to behold. But this storm in a teacup didn't matter. For the main audience wasn't the select group overlooking Lake Como, but the wide readership of the *Proceedings of the Royal Society*, Series B, and the even wider readership of *Nature*.

Later recalling the critical reception of his 1968 *Nature* paper, Longuet-Higgins said it "attracted altogether too much attention when it first appeared in print". But he had a ready defence:

> I should have known better than to speculate so shamelessly about the neural mechanism of temporal memory; the idea of a neuron's "learning" a particular frequency has scarcely a leg to stand on. But the discussion the paper provoked—in both physical and physiological circles—testified to the fact that ideas, however far-fetched, are the life blood of scientific research, and that a demonstration of how something could possibly happen (in this case, cued temporal recall) may be almost as welcome as the discovery of how it actually does happen. (Longuet-Higgins 1987: 367)

Quite apart from any second thoughts about that paper, he had other reasons for moving on to a non-holographic theory. Several people in the 1960s had likened the brain to a hologram, a newly invented device for storing optical images. Patterns in a hologram are not stored at specific points but are distributed across the whole system. They can be reconstructed from a damaged hologram or from a small part of it, so the device acts as a content-addressable memory.

The physicist P. J. van Heerden, when he originated the brain–hologram analogy in 1963, had compared holograms to Beurle's models of neural nets, which were inspired by current ideas about the cortex (see Section ii.b). And the neuroscientist Karl Pribram, co-author of *Plans and the Structure of Behavior* (6.iv.c), had likened them to brains in some detail (Pribram 1969). Later, in a memorial volume for his ex-teacher Lashley, he said:

> The properties of holograms are so similar to the elusive properties that Lashley sought in brain tissue to explain perceptual imaging and engram encoding, that the holographic process must be seriously considered as an explanatory device. (Pribram 1982: 176)

Willshaw and Longuet-Higgins, however, were sceptical.

Although the analogy was suggestive, they said, it breaks down on closer examination. They had recently generalized the hologram to deal with sound, in the "holophone" (Willshaw and Longuet-Higgins 1969*a*). But their main aim hadn't been to widen the technology (from optics to acoustics). Rather, they wanted to estimate the computational power of holograms *considered as a general class of device*. Since temporal patterns are one-dimensional, the holophone's mathematics would be relatively tractable.

Now, they argued that some crucial physical properties of holograms can't be attributed to brains (Willshaw *et al.* 1969). Moreover, the quality of the regenerated patterns is *in principle* unnaturally low: they'd wryly noted the "rather distressing noise characteristics" of the holophone (Willshaw and Longuet-Higgins 1969*a*: 356). As for computer modelling, holographic systems would be excessively slow in simulation: the holophone needs N^3 separate multiplications for a signal of length N. This was a theoretical point, but had been borne out by experimental simulations.

In short, holographic models of memory, although admittedly suggestive, didn't fit the biological facts. (Some neuroscientists, including Pribram, retained faith in them nonetheless: Pribram *et al.* 1974.) And they weren't computationally tractable either.

Instead of holographs, Willshaw and Longuet-Higgins offered a simple matrix schema of an associative network having the relevant functional properties (Willshaw *et al.* 1969). This schema was both easier to simulate and more biologically plausible. They predicted that it "may well find application in computing technology, especially when parallel computation techniques become generally available" (Willshaw and Longuet-Higgins 1969*b*: 351). And although their approach was primarily "a mathematical investigation", not an empirical hypothesis, they outlined how it might apply to actual synapses (Willshaw *et al.* 1969: 962; cf. Willshaw 1981).

Their matrix model could store more information than a hologram of comparable size, and could reconstruct patterns more faithfully. Indeed, "in optimal conditions [the network] has a capacity which is not far from the maximum permitted by information theory" (Willshaw *et al.* 1969: 960). Specifically, the informational capacity was 69 per cent of the theoretical maximum, and proportional to the number of possible connections.

This was encouraging: it meant that interference between superposed representations was less of a threat than had been feared. Admittedly, simulation had shown that "[even] in the absence of damage there is a fairly sharp limit to the number of associations that can be stored; if this number is exceeded the performance of the system degenerates rapidly" (Willshaw and Longuet-Higgins 1969*b*: 358). Nevertheless, the high potential efficiency (within that limit) of distributed systems was a strong point. The more patterns a memory model can store, the better.

Or so it seemed. At the turn of the next century, the ex-Ratio Club neurophysiologist Barlow would show that this assumption was mistaken (Barlow 2001*a*: 603–4). He'd already suggested as much, many years earlier (Barlow 1961). Now, he provided mathematical arguments to prove that *learning*, as opposed to mere *storage*, requires "sparse" representations—which use many more units to store each pattern (see 14.x.e).

At the turn of the 1970s, however, Willshaw and Longuet-Higgins's analysis seemed to be very good news.

d. Disillusion on distribution

The bad news was that learning in multi-layer nets was still intractable. When Willshaw and Longuet-Higgins published their work (and Minsky and Papert their broadside), disillusionment had begun to set in. Indeed, Widrow later said: "[The] field was already gone. There was just about nobody doing it" (J. A. Anderson and Rosenfeld 1998: 60)—see Section iii.e.

Widrow himself had given up in disgust. He'd returned to his early interests: "We stopped doing neural nets because we'd hit a brick wall trying to adapt multilayer nets. On the other hand, in adaptive filtering and adaptive signal processing, we were making great strides" (J. A. Anderson and Rosenfeld 1998: 61).

Some connectionists avoided these problems by focusing on localist memories, instead of distributed ones. In a localist system, a concept or pattern is represented by a single unit. An early 1980s example, published in a leading psychological journal (largely because it was closely compared with experiments on human subjects), was a model of word recognition broadly similar to the localist Pandemonium (McClelland and Rumelhart 1981; Rumelhart and McClelland 1982). In this model, letter strokes, letters, and (finally) words were recognized by three separate layers.

Localist networks have certain processing advantages, and were defended by Julian Feldman—co-editor of *Computers and Thought*—in the core journal *Cognitive Science* (J. A. Feldman and Ballard 1982). Moreover, the 1970s saw increasing experimental evidence for "grandmother cells" in the brain, and Barlow (1972) had proposed an influential theory that emphasized them (Chapter 14.x.e). So even if the cerebral cortex was a distributed system, it might have some important localist features.

Nonetheless, distributed systems seemed more interesting to most people. The authors of the word recognition network, for instance, were already moving firmly in that direction (see Section vi).

Gradually, the disillusionment lessened, as light became visible at the end of the distributed tunnel. The exciting new results included linear associative memories (in 1972), Hopfield nets (in 1982), the Boltzmann machine (in 1985), and above all back propagation (in 1986). Widrow, again: "We would have given our eye teeth to come up with something like backprop" (J. A. Anderson and Rosenfeld 1998: 60).

These ideas, all discussed below, provided complex networks with increasing computational power and efficiency. They also—up to a point—offered increasing biological plausibility.

(Only "up to a point". For one thing, back propagation is unrealistic: brain synapses don't transmit backwards. For another, connectionist theories and artificial networks were/are drastic oversimplifications of real neurones: see 14.i.)

e. Linear associative memories

Linear associative memories were independently defined in 1972 by James Anderson of UCLA (who had developed a simpler memory model in the late 1960s), and by Teuvo Kohonen (1934–) of the Helsinki University of Technology. Both men had long-standing interdisciplinary interests, but they came into cognitive science from diametrically opposite directions.

Anderson was an experimental neuroscientist whose teenage passions had been amateur radio and science fiction, whereas Kohonen was an electronic engineer whose "special hobby" at high school had been psychology—not least, Gestalt psychology (J. A. Anderson and Rosenfeld 1998: 242, 147). Whereas Anderson studied memory in a neuroscientific context, even developing a detailed "cortical model" of its implementation in the brain (J. A. Anderson 1972: 190 ff.), Kohonen entered from the engineer's corner. He was intrigued by various recent analyses of holographic memory, and by some suggested alternatives—including that of Willshaw and Longuet-Higgins (Kohonen 1972: 174).

Coming from distinct professional communities, Anderson and Kohonen knew nothing of each other's work for several years (although both attended the La Jolla meeting in 1979). Indeed, Kohonen had often found his professional background to be an obstacle in biological circles.

To be fair, even his fellow engineers were initially sceptical. He originally became interested in neural networks in 1962, and in the late 1960s submitted his first two papers on the topic to two very different journals: *Nature* and the *IEEE Transactions on Computers*. Both submissions "came back like a boomerang", because his views were considered so "weird" by the editors and referees (J. A. Anderson and Rosenfeld 1998: 150).

His theory of associative memory was eventually published in 1972. But it wasn't widely accepted until the 1980s. Part of the problem was that although he was "desperately trying to relate [his] networks to biology", he presented himself as "an inventor" (p. 160). He attended some neurophysiological meetings in the 1970s, but found it "very difficult to get an engineer's point of view accepted" (p. 155).

The engineer's point of view is more mathematical than the biologist's, even though neurophysiology had been moving in this direction ever since Rashevsky (see Chapter 4.iii.c). Anderson himself, whose own paper appeared in the successor to Rashevsky's journal, has said:

> It is interesting to see how differently the two authors develop the same basic idea: Kohonen is concerned with the mathematical structure, while Anderson is concerned with physiological plausibility . . . Kohonen does not make the neural analogies as explicitly as does Anderson, but the mathematics is identical. (J. A. Anderson and Rosenfeld 1988: 171)

The mathematics was not only identical, but also simple (linear): at base, multiplication and addition. These new systems—which Anderson called "interactive" memories and Kohonen "correlation matrix" memories—were in effect complex perceptrons, in which a *group* of *analogue* (not McCulloch–Pitts) units is connected to another such *group*. The crucial biological analogies were thus neuronal firing frequency, which *varies* with the strength of the stimulus, and cell assemblies (5.iv.c). Grandmother cells were tacitly denied, or anyway ignored (see Chapter 14.x.e).

The point to grasp, for those not mathematically inclined, is that these systems boiled down to *arithmetic*. Each cell group was represented by a vector (a matrix of many individual values) defined over its component units. And its activity level was expressed by adding the activity levels (summing the weights) of all the units. As for the synaptic weight changes that effected Hebbian learning, these were proportional to the product reached by multiplying the pre- and post-synaptic activity levels.

At the 1979 La Jolla meeting, Kohonen wowed the audience by presenting a "spectacular" example of content-addressable memory (Hinton and Anderson 1981: 9). To near-universal amazement, an entire face was reconstructed by inputting either a mere fragment, or a smudged version, of the image. Moreover, this was "unsupervised" learning, done without any feedback from the programmer.

Kohonen stressed that 100 different faces had 100 *distinct* representations in the network. But these were distributed ("holological") matrices, not localized units. More important, since even Simon had allowed that nothing in GOFAI-based psychology required that memories be stored at a specific point, the computational operations were *structured interactions* correlating these collective states (Kohonen *et al.* 1981: 107).

At one level, simple correlation matrix memories could be seen as "the extreme and purest cases of S–R mapping", since there is either no feedback whatever from response to stimulus, or (in certain recurrent systems) feedback involving *all* the stimuli (Kohonen *et al.* 1981: 112). At another level, they could be seen as models of real neural structures. Indeed, Kohonen made various comparisons between 3D matrices and laminar cortex, and between his auto-associative memories and synaptic learning.

Similarly, he suggested that his account of topographical mapping (Kohonen 1982) explained why there are various types of *interneurone* in the brain (see Chapter 14.x.a). (This work on topological mapping was akin to that of Willshaw and Christoph von der Malsburg, who were cited several times in Kohonen's paper: see 1.iii.h and 14.v.b.)

f. The physicists have their say

Ten years later, in 1982, a very different model of associative memory burst onto the scene: Hopfield nets. These are named after the Caltech physicist John Hopfield (1933–), who intended them as "a form of general (and error-correcting) content-addressable memory". They'd actually been described many times by others, earlier. But for various reasons, explored below, it was Hopfield who got the credit.

Hopfield nets were globally connected, in that every unit was linked to every other. So there weren't any separate layers: each unit acted as an input, output, and processing unit.

To be set up for an application, the inputs would be coded as (for example) sensory feature detectors, while the final output was the relevant concept, or pattern. The units were McCulloch–Pitts neurones. The (initially random) connection weights were continuous, and symmetrical (each unit would excite its 'pair' to the same extent). At each change point—which were random, not time-stepped—the unit would sum the weights of its synaptic inputs, and then 'fire' only if its threshold had been reached.

In physical systems made of many simple elements, said Hopfield, stable collective phenomena (such as vortex patterns in fluids) emerge spontaneously. The explanation is dynamical:

> The equations of motion of the system describe a flow in state space. Various classes of flow patterns are possible, but the systems of use for memory particularly include those that flow toward locally stable points from anywhere within regions around those points. (Hopfield 1982: 460)

In other words, the system undergoes myriad local changes until it settles into equilibrium. (Compare Steve Wolfram's four dynamical patterns in cellular automata, only one of which is suitable for computation: see 15.viii.a.) Memory storage is analogous to the stability of the relevant points (attractors). Error correction and generalization correspond to the fact that one and the same attractor will be reached from anywhere within the relevant region. And content addressability is comparable to the reconstruction of the attractor state from an approximation to it.

As for how this happens, in physics the settling-down process involves energy minimization. So Hopfield defined an algorithm, based on the theory of spin glasses, that enabled a simulated network to reach equilibrium in a comparable way. This is reminiscent of von Neumann's hunch that the logic of the brain might be closer to thermodynamics than to formal logic (see Section i.c).

The global "energy" of the network as a whole was defined by summing across all units. And the effect of (binary) state changes in the thresholded units was either to decrease this global measure or to leave it unaffected. When there were no more unit changes (i.e. when the network had settled down), this measure would have reached a minimum.

Having defined this class of networks, Hopfield ran a large number of simulations varying the numbers of units and the starting points (i.e. the binary values assigned to the units before the system was allowed to run). He asked (for instance):

* how many memories a network of a given size could store before producing retrieval errors, or even being totally overwhelmed;
* how many units needed to be set "correctly" at the start in order for the *closest* attractor to be reached;
* and how dissimilar two inputs must be if they were to be stored as distinct memories (distinct attractors).

Rosenblatt, too, had combined theoretical analysis with systematic simulation experiments (see Section ii.e–f). But Hopfield saw his networks as an advance on perceptrons in three ways:

* They involved backward as well as forward connections (this was implied by the symmetry condition);
* they focused on abstract emergent properties, as opposed to the specific results of encountering a particular pattern in the real world;
* and they didn't require synchronous change.

Similarly, the brain involves backwards connections (though not two-way synapses), and it doesn't work in time steps. However, the brain isn't made of McCulloch–Pitts neurones. Two years later, Hopfield generalized his results to cover more biologically realistic units. The paper's title said it all: 'Neurons with Graded Response have Collective Computational Properties Like Those of Two-State Neurons' (1984).

Hopfield's 1982 paper contained two exciting claims. One—echoing the comparable memory-network research described above—was that "the ability of large collections of neurons to perform 'computational' tasks may be in part a spontaneous collective consequence of having a large number of interacting simple neurons" (Hopfield 1982: 460). That is, intelligence could arise without the need for highly specific circuitry to be designed by evolution—or by technologists. The other was more novel, and more provocative: that "the model could be readily implemented by integrated circuits hardware" (p. 460).

It's not surprising that many people were enthused. For there was promise here for psychologists and technologists alike. Whereas Kohonen's first paper on neural nets had come back "like a boomerang", Hopfield's work was immediately acclaimed—and was soon featured in the *Los Angeles Times*.

When, only six years later, DARPA considered funding neural networks again, they would identify it as a watershed:

> From the mid-1950s to the mid-1970s, a wide variety of associative memory models were studied . . . Widespread interest in such models seems to have waned by 1975. Although many application areas were explored, these early memory models had little technological impact. The available technology favoured the use of [the digital memories used in GOFAI] . . .
>
> Hopfield rekindled widespread interest in associative memory when he proposed his 1982 energy minimization model based on the outer product storage rule. *While outer product memories had been studied extensively, Hopfield's version captured attention* because of its timeliness from a technological standpoint and the theoretical appeal of energy minimization. (DARPA 1988: 81; italics added)

Anderson agrees: "As far as public visibility goes, the modern era in neural networks dates from the publication of this paper" (J. A. Anderson and Rosenfeld 1988: 457).

The public, here, included not only the *Los Angeles Times* but also many of Hopfield's professional colleagues—a fact tartly remarked by the neurophysiologist Cowan:

> The theoretical physics community is like a swarm of locusts. There are far, far more theorists around than there are problems. There are only two or three problems, and whatever problem gets hot, a lot of them swarm onto it. That's what happened with the Hopfield paper. (J. A. Anderson and Rosenfeld 1998: 113)

Undeniably, however, the "locusts" helped advance the field. (And some stayed within it, rather than flying off to pastures new.) They had exceptionally keen mathematical skills, and a pre-existing body of theory (the physics of spin glasses) that could be applied in analysing these networks. The increase in mathematical expertise would be a lasting benefit, even if more neuroscientific data were also needed (see Chapter 14).

As for Hopfield himself, his careful analysis of the computational properties of 'his' networks was highly influential. It was more easily intelligible, for example, than Grossberg's many earlier remarks on such topics (see below, and 1.iii.h). It helped, of course, that Hopfield's paper had been published in the highly respected *Proceedings of the National Academy of Sciences*. So had some of Grossberg's (e.g. Grossberg 1971). But, characteristically, they'd covered a host of neuropsychological details that many readers would find distracting.

In addition, Hopfield himself was no shrinking violet. He "travelled all over the country talking about his results", even reaching itinerant visitors by speaking in small rooms located in major airports (Barrow 1989: 14). In other words, he was deliberately taking his ideas into the scientific marketplace (1.iii.h). As we'll see below, this was just one reason why many of his colleagues became deeply irritated by him.

But "the public" also included the many people in business, the military, and academia who hoped to gain from putting associative memories onto commercially marketable VLSI computer chips. Indeed, Mead—at the California Institute of Technology—achieved this within a few years.

By 1990, Mead had even designed silicon chips replicating a 2,500-cone human retina (Sivilotti *et al.* 1987; Mead and Mahowald 1991). These multi-layer networks—the first examples of what he termed "neuromorphic engineering"—provided not just photoreception but also various types of low-level visual processing, including automatic light adaptation. He also produced a VLSI cochlea, and a sound localizer based on the auditory brainstem (Mead 1989). Had Hopfield published the same paper ten years earlier, when VLSI was still confined to the research lab, it wouldn't have made such a splash.

All this is *not* to say that Hopfield was the first to have the core idea of energy minimization. A number of researchers interviewed by Anderson and Edward Rosenfeld (1988) for their fascinating "oral history of neural networks" insisted—with some force, not to say venom—that several people had already had much the same idea. Some had even explicitly mentioned spin glasses.

At least eight such individuals were named in these interviews, including two as far back as the 1950s. And two interviewees picked out Shun-Ichi Amari (1936–), of the University of Tokyo, as the real pioneer.

Amari had been modelling associative networks since the late 1960s. In 1977 he defined "learning based on potential" in terms of a mathematical function identical to Hopfield's (Amari 1977: 275). Although he gave only fourteen lines to this topic, he situated it within an elegant (and equally condensed) mathematical discussion of various learning rules, of the differing effects of noise, of two new "convergence theorems", and of recurrent networks in which the output is fed back as the input. Hopfield cited Amari (alongside Kohonen, Willshaw and Longuet-Higgins, Anderson, and Marr—but not Grossberg) as a precursor. But whereas Amari had given only fourteen lines to the idea, Hopfield discussed it at greater length.

Hecht-Nielsen, in these same interviews, mistakenly accused Hopfield of stealing Amari's idea *without* citing him (J. A. Anderson and Rosenfeld 1998: 301). This mistake, I assume, was an overflow from his general irritation at the attention, indeed the publicity, that Hopfield received. Hecht-Nielsen's lasting irritation, and the venom of the other interviewees' remarks, was due in part to Hopfield's relentless self-promotion, and in part to his repeated failures to cite other people's work, as a result of which he got the credit for priority.

A glaring example was his paper comparing networks composed of binary (McCulloch–Pitts) and continuously graded (sigmoid) neurones. The opening page announced "new" computational results, "unexpectedly" discovered (Hopfield and Tank 1986: 265). This appeared in the high-prestige journal *Science*, whose referees evidently didn't know that these results weren't new at all. But others did, and wrote in to complain vociferously. Most unusually, the editor agreed to publish several Technical Comments pointing out not only that Hopfield and Tank's contribution wasn't original but also that others had already taken them further.

One brief comment ended by saying drily that "The application of neural network theory to technology would be expedited by further consideration of known results," and gave a footnote citing several reviews of "early [*sic*] and recent" relevant work (Carpenter *et al.* 1987: 1227). That was for public consumption. What was said in private on the grapevine, which was part-surfacing in those oral-history interviews, was much less tactful. (So much, again, for the Legend: 1.iii.b.)

g. The power of respectability

The main reason why Hopfield's 1982 paper had attracted so much more attention than its predecessors was his reputation *as a physicist*. As Anderson has put it:

> John Hopfield is a distinguished physicist. When he talks, people listen. Theory in his hands becomes *respectable*. Neural networks became instantly legitimate, whereas before, most developments in networks had been the province of somewhat suspect psychologists and neurobiologists, or by those removed from the hot centres of scientific activity. (J. A. Anderson and Rosenfeld 1988: 457; italics added)

What can happen when someone isn't perceived as "respectable" is indicated by Werbos:

> So he [Grossberg: see Chapter 14.v.a] handed me his papers. I can honestly say, based on those papers—this was really early, like '71,'72—I know that he was talking about what we now call Hopfield nets because that's what was in those papers. He was having trouble getting it published. It may be that what had happened with Grossberg is in part what happened with me [with respect to backprop: see Section vi.d]—namely, we had the exact same idea in the exact same form [as someone else did later], but people weren't willing to publish it. He had to dance it through and change it and modify it and screw it up before people would allow it to get through the system. *And then after the screwed-up version got through, then people would allow the full form of it to come in from places that they trusted. We were not people they trusted, neither Steve nor I.* (J. A. Anderson and Rosenfeld 1998: 343; italics added)

Grossberg first wrote about these ideas—his "Additive Model"—as a freshman (at Dartmouth) in 1957, and had published "at least fifty papers on it" by the time the current label was coined. (One of those "fifty" papers was a review article, which one might expect to have been widely read: Grossberg 1974.) Naturally, he resents Hopfield's high visibility: "I don't believe that this model should be named after Hopfield. He simply didn't invent it. I did it when it was really a radical thing to do" (J. A. Anderson and Rosenfeld 1998: 172, 176).

One of the problems with priority claims is that if an idea is very new, it may not be intelligible to other people even if they do come across it. That's especially so if it's presented alongside many other novel ideas, and a range of highly disparate empirical data that the writer is seeking to explain. As remarked above, Hopfield's abstract, data-free, work was more influential than Grossberg's "equivalent" for these very reasons.

Werbos apparently understood Grossberg's ideas on first reading. But Rumelhart has confessed that he (as a research student in mathematical psychology), *and* his more senior colleagues at Stanford (including William Estes), didn't:

> [In about 1966, Grossberg] sent them a copy of his big, fat dissertation, which had all of these differential equations and everything, and this big cover letter in which he explained how he had solved all the problems in psychology. Of course, the people at the Institute for Mathematical Studies in Social Sciences were a little perplexed about what this could all be about. I remember *we spent a great deal of time and effort trying to figure it out and failed completely, I should say, to understand* what it was that Grossberg had actually done. In the end, I guess I gave up on it. (J. A. Anderson and Rosenfeld 1998: 271; italics added)

As we'll see in Chapter 14.v.a, the people at Stanford were sufficiently impressed to invite Grossberg there as a graduate student. Nevertheless, even first-rank mathematical psychologists were "perplexed".

I shan't attempt a definitive priority judgement here (Grossberg? Amari? Hopfield? . . .). As remarked in Chapter 1.iii.h, identifying "the same" idea, even in mathematical contexts, is often a highly subtle matter. *The very same equation* may be presented in two different ways, so that the 'second' presenter is understandably, and perhaps even justifiably, regarded as the 'first'. I suggested, above, that this applies in the case of Hopfield and Amari, respectively. It may well apply in the case of Hopfield and Grossberg too, but mathematical skills way beyond my own would be needed to say this with any confidence. It's undoubtedly true, however, that Hopfield was heard immediately whereas Grossberg, a quarter-century before, wasn't.

Whomever one credits with having had the idea of energy minimization first, the great advantage of Hopfield's presentation—and of his respectability—was that it attracted the "locusts". Their analytical skills helped people to understand the fundamental principles of the networks they discussed.

However, there were two problems, one sociological and one theoretical. First, most physicists knew nothing about psychology (and many couldn't have cared less). Occasionally, they looked at neuroscience: Hopfield himself had regularly attended neurobiological conferences and Princeton seminars in the 1970s. But Kohonen was exceptional in choosing psychology as a "hobby". So they couldn't simulate the experimental data, nor identify theoretically significant psychological problems on which to test out their ideas. It wouldn't have occurred to them, for example, to model the formation of the past tense (Section vi.e, below), or the visual perception of colour and form (see 14.v.d).

Second, Hopfield faced the difficulty that Selfridge had faced with Pandemonium (see ii.d, above): the danger of getting trapped in a local minimum. (*Minimum*, this time: in hill climbing the relevant quantity is increased, whereas in energy minimization it is decreased.) As remarked above, his algorithm never allowed the overall energy measure to rise, no matter what changes took place in the units. There was therefore no way in which the system could escape from a local minimum, even if a much deeper "valley" existed nearby in the state space. For Hopfield's immediate purposes (namely, storing memories), this didn't matter: all that was required was that *some* attractor be found. But if, for any reason, one wanted to locate the attractor with the lowest minimum of all, Hopfield's method would usually miss it.

As we'll see in Section vi, both these problems would be solved a few years later by Hinton and his colleagues in the PDP group—to some extent inspired by Grossberg's recent papers (especially 1976*a*,*b*, and 1980).

Between them, the members of the PDP group had many years of experience in AI modelling and/or computational psychology, drawing on both GOFAI and connectionism. For example, in the early to mid-1970s Norman had co-authored the textbook that used Pandemonium as a theoretical motif (see Figures 6.5 and 6.6), Rumelhart had developed computational theories of reading errors and story grammars, and the two had co-edited a collection on computational models (D. A. Norman and Rumelhart 1975).

Hinton's experience was especially relevant, however. For even before joining the PDP group he'd devoted several years to Hopfield's core question—and had offered a similar answer.

h. Hinton relaxes

The "core question" was how a computational system making many different local decisions could reach an internally coherent (and stable) state. Hinton, being a psychologist not a physicist, thought of it in terms of a specific example: how can a vision program simultaneously satisfy many different constraints when interpreting a line drawing? Where Hopfield would minimize overall "energy", Hinton had minimized overall "inconsistency".

Hinton first worked on this issue in the early to mid-1970s, as a student of Longuet-Higgins (in Edinburgh and then Sussex) and a colleague of Sloman and Max Clowes, both AI vision experts in the Cognitive Studies Programme at Sussex. Having been told about neural networks by his schoolfriend Inman Harvey (now a key researcher in A-Life: see 15.vi.c), he got interested in distributed memories. That's why he sought out Longuet-Higgins (who was by then working on GOFAI models of music and language). While still at Edinburgh, he decided to address some of the basic issues in the context of vision. Later, he worked as a Research Fellow on Sloman's POPEYE vision project at Sussex for a year or two (see 10.iv.b).

He started from an idea drawn from scene labelling, a method of interpreting line drawings pioneered by Clowes: the Waltz filter. This was a form of depth-first search that involved the sequential propagation of constraints (10.iv.b). However, there was a danger of what I remember Hinton calling "computational gangrene". A contradiction at any point would lead to the permanent abandonment of search below that point—so if one of the labels happened to be mistaken, the solution would be blocked. In short, noise was disastrous.

But noise is also ubiquitous. In particular, it's inescapable in grey-scale images: a light-intensity gradient in the image may or may not represent an edge in the scene. David Waltz had already added new labels for line drawings, representing shadows for instance. And Marr (1975*a*,*b*) had recently suggested a set of constraints (in effect, labels) involved in interpreting grey-scale images, corresponding to edges, textures, reflectances, and orientations (Chapter 7.v.b–d). Hinton wanted to find some way of maximizing the mutual consistency of any such set of low-level labels.

He was aiming for optimal, though not necessarily perfect, constraint satisfaction. This required parallel processing and alterable decisions, guided by a measure of inconsistency that was minimized as the system moved towards the optimum interpretation.

The first published version of such a method was called "relaxation" (Rosenfeld *et al.* 1976), and Hinton used this term in his own work (1976, 1977). His contour-finding program provisionally assigned continuous numerical values (between 0 and 1) to hypotheses about various areas in the image: that this is an edge part, for instance. If it is an edge part, then colinear edge parts are to be expected nearby. They aren't guaranteed, however. The edge part may be the endpoint of a sharp corner, or its continuation may be prevented by some other object obstructing the view—or it may not correspond to a real edge at all.

Whereas the first relaxation technique had allowed individual hypotheses to interact (support or inhibit) directly, Hinton's didn't. Instead, the logical relations *between* hypotheses were also expressed as numbers, which acted as feedback loops guiding the local decisions. The overall measure of logical consistency could be calculated, and was used to achieve the optimal overall value in the circumstances. At that point, each hypothesis would be announced "true" or "false", and contradictions (by now, minimized) would be ignored.

In other words, whereas Waltz had dealt only with *strong* constraints (which must be satisfied), Hinton focused on *weak* ones (which need be satisfied only so far as possible). That was a significant advance.

But this method, like Hopfield's, was threatened by extremity traps. And now it mattered, since the aim was to find the best *global* interpretation. Suppose the image were ambiguous—not in the sense that two alternative interpretations are equally consistent (as in the vase/faces of Figure 5.1), but in the sense that one of two plausible interpretations is better than the other. For instance, consider a photo that could be of either Jill or Mary: which is the more likely? If Hinton's system happened to reach the less consistent solution first, it would never find the other one. (Eventually, Hinton would show how to escape such traps: see Section vi.b.)

One counter-intuitive finding of Hinton's early work on vision had nothing to do with relaxation labelling. This was his proof that the most efficient way of coding for features (to recognize shapes, for example) is to use a few very coarsely tuned units, not a large number of finely tuned ones (Hinton 1981; cf. Hinton *et al.* 1986: 90–4). Overlapping groups of coarsely tuned receptive units, within specified size constraints, can compute spatial properties with specifiable gains in efficiency. So the fact that biological neurones don't respond to a perfectly defined narrow class of stimuli may be a strength, not a weakness.

As he pointed out, this is a mathematical result. As such, it applies to distributed processing in general, not just to vision.

i. Passing frustrations

If the main problems facing Dark Ages connectionism were mathematical, there were technical obstacles too. In a nutshell, the computers weren't up to it.

In the 1970s, computers were still relatively limited. Procedures requiring many cycles of simultaneous calculations weren't feasible. As a result, some good theoretical ideas couldn't be implemented by AI modellers, or only in a drastically cut-down form. And some were even ignored by them.

This applied to Holland's work on evolutionary computing, for instance. Although he'd long solved the problem that had defeated Selfridge, namely how to deal with *multiple* mutations, his theory couldn't be implemented and wasn't yet widely known (see Chapter 15.vi.a–b). Similarly, it was clear from the early 1970s that linear associative memories were promising. But they couldn't yet be used to deal with complex patterns, because large vectors need very many multiplications and additions. Connectionism couldn't flourish without much-increased computer power. This finally became available in the 1980s.

Implementation aside, however, in the wilderness years plenty had gone on behind the scenes. By the early 1980s, the actors were waiting in the wings—and their voices were beginning to be heard, at least by members of the AI community.

For example, Douglas Hofstadter (personal communication) gave a well-attended seminar at MIT in 1983–4, in which he covered a wide variety of parallelist models. These were HEARSAY, PDP (including a recent simulation of typing errors: Rumelhart and Norman 1982), simulated annealing, sparse distributed memories, and his own computer models of cognition—which included a network of nodes with spreading activation (see Section x.a, below). And Hinton's work was exciting many members of AISB in the United Kingdom, not just his erstwhile colleagues in Sussex.

Outside certain sub-groups of the cognitive science community, however, even PDP was still unknown. Moreover, connectionism in general was widely thought to have been *proven* useless (see Section iii). The money and public attention were directed elsewhere. AI was constantly featured in the media, thanks to Japan's Fifth Generation project (11.v). But it was expert systems and chess programs that were discussed, not connectionist AI. Similarly, most philosophers discussing AI, whether pro or con, considered only symbolic computation (see Chapters 11.ii.a–d and 16.iii–vi).

Hubert Dreyfus was no exception. In 1979, the very same year as the La Jolla conference, the revised edition of his book *What Computers Can't Do* contemptuously declared:

> Since those pursuing this course [the study of self-organizing systems], sometimes called cybernetics, have produced no interesting results—although their spokesman, Frank Rosenblatt, has produced some of the most fantastic promises and claims—they will not be dealt with here. (H. L. Dreyfus 1979: 130)

To make it worse, he was so confident in this dismissal that he even quoted his own arch-enemy, Minsky, in support.

The frustrated neural networkers could be forgiven for resenting this cultural invisibility—and they did. Passions ran deep, and sometimes surfaced in surprising ways. In 1981 for instance, in an otherwise highly convivial twenty-person weekend on adaptive systems organized by Selfridge, a leading cybernetician (never mind who . . .) expressed the most extraordinary personal hostility at my merely *mentioning* symbolic AI.

By the end of the 1980s, however, the shoe would be on the other foot.

12.vi. Centre-Stage

Connectionism exploded into the public consciousness for the third time in 1986. Granted, Douglas Hofstadter's hugely popular writings had already alerted his readers to the ideas of "subcognitive" parallel processing and "active" memory (see Section x.a, below). But there'd been no accessible account of *just how* this could be implemented. When one finally appeared, the fuss was even greater than had attended Rosenblatt and Widrow, or Hopfield.

It reached across the general public, from professional philosophers to the tabloid-reader on the Clapham omnibus. In the late 1980s it seemed that one could hardly turn on the television without seeing some reference to the magical new machines.

"Magical", in the popular view, because they had no clearly identifiable memory traces, because they could learn without being explicitly taught, and because some could start out from a merely random state.—And impressive, too. For these network machines really did seem to be a sort of "artificial brain". In fact, this 1950s phrase was now widely resurrected.

The type of connectionism concerned was the newly named "parallel distributed processing", or PDP for short. Localist and circuit-based connectionism were largely ignored. Many people didn't even know of their existence.

Moreover, the subtext—not to say the propaganda—changed. Previously, the focus of connectionism had been wholly positive: to discover the nature of associative memory. Now, it was largely negative: to counter GOFAI's influence on theoretical psychology and the philosophy of mind. In this context, the central message was that effortless intuitive thinking is *not*, as GOFAI had assumed, just like conscious inference but without the consciousness.

The downplaying of GOFAI was one reason for PDP's popularity with the public. At last, it seemed (but see Sections viii–ix, below), the 'dehumanizing' image of mind-as-von-Neumann-computer had got its come-uppance.

The leading connectionists themselves were less thoroughly dismissive of symbolic AI:

> It would be wrong to view distributed representations as an *alternative* to [GOFAI] representational schemes like semantic networks or production systems . . . It is more fruitful to view them as one way of implementing these more abstract schemes in parallel networks, but with one proviso: Distributed representations give rise to some powerful and unexpected emergent properties. These properties can therefore be taken as primitives when working in a more abstract formalism. [Examples are] content-addressable memory, automatic generalization, and the selection of the rule that best fits the current situation. (Rumelhart, McClelland, *et al.* 1986: 78)

But those wise words were largely ignored. Most outsiders, and many insiders too, evidently felt the humbling of GOFAI to be far too satisfying to pay attention to them. (Some exceptions are discussed in Sections viii–ix, and especially ix.b.)

a. The bible in two volumes

The new name, and the sudden surge of interest, arose with the publication of the two-volume PDP bible in the autumn of 1986 (Rumelhart, McClelland, *et al.* 1986; McClelland, Rumelhart, *et al.* 1986). This was PDP's manifesto, a clarion call to join the new movement.

Unlike the cognitive science manifesto (*Plans and the Structure of Behavior*: see 6.iv.c), its hand-waving was relatively restrained. Most pages reported work that had actually been done—some (in volume I) defining general methods, some (in volume II) applying those methods to specific topics. This made the argument more persuasive than an informal account would have been, but it also made for fairly dry reading. Fortunately, many readers had been prepared—and hugely excited—already. A Pulitzer-prizewinning book published seven years earlier had introduced the *idea* of distributed processing by a host of memorable, and intuitively intelligible, examples (see x.a, below). Now, the bible was adding mechanism to idea.

Like Norman and Rumelhart's GOFAI collection *Explorations in Cognition* (1975) and Minsky's *Semantic Information Processing* (1968), the PDP bible was a collection of papers largely written by research students or only-just-postdocs. If that sounds boring, it wasn't: these two volumes were even more influential than their GOFAI predecessors.

The editors were Rumelhart and James, or Jay, McClelland (1948–) at UC San Diego. (Almost immediately after the bible was published, Rumelhart moved to Stanford, where he worked from 1987 to 1998.) Hinton had originally been an editor too, but withdrew to concentrate on the Boltzmann machine. He hadn't been a mere dogsbody editor: Terrence Sejnowski described him, years later, as "the seed that led to PDP" (J. A. Anderson and Rosenfeld 1998: 323).

Further members of "the PDP Research Group" were officially based both in and outside San Diego. They included (among others) Norman, Sejnowski, Ronald Williams, Paul Smolensky, Jeffrey Elman, Michael Jordan, and Francis Crick.

Crick's name implies an interest in biology, and the PDP bible did contain several neuroscientific papers—one of which stressed the very *un-neural* character of artificial networks (Crick and Asanuma 1986) (see Chapter 14.i). The book even declared that the PDP group accepted "the brain metaphor" in place of "the computer metaphor". But although the (limited) biological plausibility "definitely enhanced" their approach, the neuroscience was strictly secondary:

> We are, after all, cognitive scientists, and PDP models appeal to us for psychological and computational reasons. They hold out the hope of offering *computationally sufficient* and *psychologically accurate* mechanistic accounts of the phenomena of human cognition which have eluded successful explication in *conventional computational formalisms* [i.e. GOFAI]; and they have radically altered the way we think about the time-course of processing, *the nature of representation*, and the *mechanisms of learning*. (Rumelhart, McClelland, *et al.* 1986: 11; italics added)

The italicized phrases are the keys to why other cognitive scientists were so interested. *Computational sufficiency* seemed to be provided by the Boltzmann machine and back propagation (see below). These alleviated two of the major mathematical difficulties of the Dark Ages.

Psychological accuracy was the aim of PDP models of experimental data, some of which had great theoretical interest. For instance, the past-tense learner described below challenged Chomsky's nativism (Chapters 7.vi.a and 9.vii). More broadly, the PDP perceptrons—unlike Rosenblatt's simple versions—allowed a role for success. There was "extensive experimental evidence" suggesting that "learning when the organism is correct usually appears to be more important than learning when a mistake is made" (Hinton and Anderson 1981: 15).

The criticism of *conventional computational formalisms* cast doubt not only on the psychological relevance of GOFAI, but also on philosophies of mind that shared the same conceptual roots (see 16.iii–iv). The suggestion that *representation* could be thought of in a new way was exciting not only for psychologists but also for philosophers (Sections viii–x, below). And the notion—not new, but resurrected—that machines could *learn* without being explicitly taught added the promise of commercial applications.

Having these intellectual delights to offer, plus the increased computer power of the 1980s that made persuasive demonstrations possible, the PDP group had been hopeful about prompting interest in connectionism. However, they realized that this would need some special effort on their part.

Their report on the 1979 conference had kicked off with the warning: "This is a difficult book" (Hinton and Anderson 1981: 1). It was indeed—not least because state vectors specifying holistic activity patterns were a mathematical nightmare for many people. They were unfamiliar to non-physicists, and very different from GOFAI instructions in LISP's 'English' (10.v.c). Now, they decided to provide not only a research report but a tutorial too.

The PDP bible was intended to fulfil both functions. Because they especially wanted to get the youngsters interested, they wrote it in an unusually accessible way. Moreover, they reduced the cost by doing all the typesetting and proof-reading themselves, and even paying for the preparation of the camera-ready copy. They hoped to have well-thumbed, coffee-stained, volumes on students' desks—not pristine pages sitting on library shelves.

But even they were amazed by the scale and immediacy of their success. There were so many advance orders for the PDP books that the second printing was started even before the first had been released. Forty thousand copies were sold in the first seven years.

The scale of the advance orders suggests that the rumour-mill in the final years of the Dark Ages had primed many people to be receptive. Sejnowski recalls that even a few months before publication "very few people knew what was happening by word of mouth" (J. A. Anderson and Rosenfeld 1998: 324). Nevertheless, enthusiastic students "from everywhere" turned up at the pre-publication Connectionist Summer School he and Hinton organized at CMU. Some may have been drawn in by Hinton's easy-to-read description of Boltzmann machines in the popular magazine *Byte*, in 1985. And some may even have found out about it when "somebody at MIT put out a spoof [announcement] advertising a connectionist cooking summer school" (J. A. Anderson and Rosenfeld 1998: 324).

Primed or not, what readers found on opening the books was a fascinating mix of abstract theory and psychologically significant models. As Rumelhart recalled later, the former had had a long gestation:

> [In the late 1970s, Jay McClelland and I developed our interactive model of word recognition that] turned out to very much like these models that settle into stable states. Indeed, it was those features that we eventually worked out. But what I remember are hours and hours and hours of tinkering on the computer. *We sat down and did all this in the computer and built these computer models, and we just didn't understand them. We didn't understand why they worked or why they didn't work or what was critical about them. We had no important theory yet.* We struggled and

struggled and began to get insights into the nature of these interacting systems and became totally obsessed by them. (J. A. Anderson and Rosenfeld 1998: 275; italics added)

The "important theory" they'd been hoping for was eventually achieved. It included, for instance:

* new methods of analysing hidden units (see below);
* Hinton's proof about the efficiency of coarsely tuned units (Section iv.h);
* McClelland's recasting of GOFAI's HEARSAY architecture in PDP terms (Section iv.b);
* and Smolensky's harmony theory.

But the most exciting theoretical advances, and the ones that received the most attention, were

* the Boltzmann machine, and
* back propagation.

b. Bowled over by Boltzmann

Boltzmann machines were announced informally in 1984, in a Carnegie Mellon Technical Report. This was written by Hinton (then at CMU) and the CMU computer scientist David Ackley, together with Sejnowski—an ex-physicist turned neurobiologist, whom Hinton had met at the 1979 La Jolla function.

Sejnowski (1947–) was first drawn to neurobiology by Charles Gross's research on feature-detectors (14.iii.b), and had been won over (in 1978) by studying electroreception in fish:

[Seeing the molecular receptors with the electron microscope] changed my life. After that I wasn't interested anymore in just abstract understanding of the brain. I really wanted to understand how it was made. I was committed to the idea that you had to understand the actual substance that the brain was made from if you're going to understand how it works. (J. A. Anderson and Rosenfeld 1998: 321)

By the mid-1990s, his prime interest would be "using techniques and tools from network modelling to understand different pieces of the brain" (J. A. Anderson and Rosenfeld 1998: 329). In the early 1980s, however, he was still doing 'abstract' connectionism. There was no neuroscience in NETtalk, for instance (see subsection f, below)—nor in Boltzmann machines.

The title of the CMU report described these machines as "constraint satisfaction networks that learn", so highlighting the topic that Hinton had been researching for a decade (see Section v.h, above). But three new features had been added. These were energy minimization, simulated annealing, and learning.

The first of these was borrowed from Hopfield. In the summer of 1982, Hinton and Sejnowski—already cooperating on relaxation models of vision—attended a small meeting of connectionists at the University of Rochester. There, they heard Hopfield give a talk on his about-to-be-published work. As Hinton remembers it,

As soon as Hopfield gave that talk, I realized that what you wanted to use these nets for was to solve constraint-satisfaction problems. You wanted to let the energy function correspond to the objective function you were minimizing. I'm not sure Hopfield had really understood that. He was using these nets for memories at that point, 1982. (J. A. Anderson and Rosenfeld 1998: 372)

In other words, "energy" could be made to stand for "inconsistency". And Sejnowski recalls:

Both Geoff and I within seconds realized that this was the convergence proof we needed to show that our constraint-satisfaction scheme in vision could actually be implemented with hardware. That's how the Boltzmann machine was born. (J. A. Anderson and Rosenfeld 1998: 322)

But translating relaxation into energy minimization wouldn't be enough: the problem of local minima would remain. It was Sejnowski who saw the way out.

He recalled some recent work by Scott Kirkpatrick (at IBM) on optimization by simulated annealing (Kirkpatrick *et al.* 1983). As long ago as 1953, physical chemists had used the Boltzmann equations of statistical mechanics in a method (the Metropolis algorithm) that modelled collections of atoms in equilibrium at various temperatures. Kirkpatrick had recently broadened the notion of equilibrium to cover optimization in general, including computer circuitry design and the travelling salesman problem (i.e. *How can one find the shortest route for visiting several scattered towns?*). Moreover, he had added simulated annealing (see below) to find the equilibrium more quickly.

Now, Sejnowski suggested doing the same thing. The Boltzmann machine "was the result of a week of solid thinking about what would happen if we had a noisy Hopfield network" (J. A. Anderson and Rosenfeld 1998: 322).

Annealing is a technique used by metallurgists to cool metals evenly. The quickest way is to start off at a high temperature, and cool the metal down gradually. Analogously, in Hinton and Sejnowski's networks equilibrium was reached by allowing the changes in the first few cycles to be relatively large ('noisy'), becoming smaller as time went on (Ackley *et al.* 1985; Hinton and Sejnowski 1986). This made it unlikely that the system would be trapped in a sub-optimal attractor.

Hopfield would have left it at that. Indeed, Hopfield would have spared the words and gone to town on the equations. To him, and to his fellow "locusts", the mathematics would be obvious. Kirkpatrick had offered more explanatory text than Hopfield. But he too had addressed his paper to people familiar with the mathematics: namely, computer scientists and engineers. The PDP group were aiming for a much wider audience and, thanks largely to their rhetorical skills, they reached it.

For example, in the PDP book (though not in their paper for fellow professionals, in *Cognitive Science*) Hinton and Sejnowski took pains to describe simulated annealing in intuitive terms. They imagined a ball-bearing on a two-dimensional landscape, and asked how one should shake the whole system to get it to lie still at the bottom of the deepest valley (see Figure 12.3).

Violent shaking, they pointed out, wouldn't do. For the ball-bearing would constantly jump from one valley to another—often, upwards. Gentle shaking would do the trick—but it might take a very long time. "A good compromise", they said, "is to start by shaking hard and gradually shake more and more gently" (Hinton and Sejnowski 1986: 288). With that strategy, the ball-bearing would probably find the bottom point and stay there.

Admittedly, in a landscape with hills and valleys at sufficiently awkward heights and locations, it might not. But they remarked that interesting problems have many

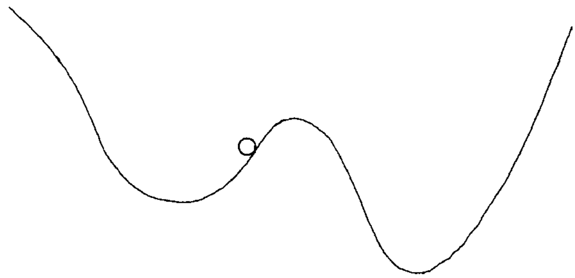

Fig. 12.3. Ball-bearing on an (energy-)landscape. Reprinted with permission from Rumelhart and McClelland (1986: 287)

dimensions, which implies many more potential pathways between one valley and another—especially when one shakes hard. (They predicted that simulated annealing would work well only for high-dimensional state-spaces.)

They spelt these things out because their intended audience was unfamiliar with neural networks, and perhaps even with physics. Hopfield's fellow locusts were very welcome to read the books too, but they weren't the primary target. The PDP bible was an educational enterprise aimed at cognitive scientists in general—and, as such, it worked. It even reached the more intrepid members of press and public.

The Boltzmann machine was—dare one say it?—a *general* problem-solver. Given suitable input units, the system could discover the appropriate consistency relations for itself. Or they could be provided beforehand, in the connection weights.

For example, the authors pointed out that one could use a Boltzmann machine for visual interpretation (Hinton's long-standing interest). The input units would fire when the relevant features (light-intensity gradients, texture cues, etc.) were present, and the weights would ensure that optimal equilibrium corresponded to the correct interpretation (cf. Ballard *et al.* 1983).

In principle, any 'environment' of interacting constraints—visual, linguistic, logical, financial . . . —could be implemented. So this approach could be applied to many issues in theoretical psychology. What's more, it could be applied to many practical problems in industry and commerce.

These networks were multi-layer perceptrons, whose units were not deterministic (as in Hopfield nets) but stochastic. The relative probabilities of the possible states of the system, and of the activity of the hidden units in different contexts, were defined by Boltzmann equations. And where Hopfield nets had modelled memory but not learning, the Boltzmann machine modelled both. The network was said to have learnt a pattern when the probabilities in the net matched those in the environment. In reaching this match, the system would in effect have identified (mimicked) the higher-order structure of the environment—which need not have been known beforehand by the programmer.

The new learning rule which brought about this match was simple (though slow), but far from obvious. It estimated and compared the probabilities of co-excitation of unit pairs in two equilibrated situations: with the environmental input present, and in the free-running state. ("Having the input present" meant clamping the input and output units into the appropriate states, before allowing equilibration across the hidden units.) Using these statistics, it gradually altered the connection weights so that the output layer would spontaneously adopt the relevant activity pattern even without any input, and complete the pattern if only part was provided.

The equilibria were reached by simulated annealing. In principle, the learning rule could have involved annealing too, but Hinton and Sejnowski couldn't implement that. However, the noise in the probability measures sometimes enabled it to escape from a local minimum anyway.

The Boltzmann learning algorithm provided what Minsky and Papert had asked for in 1969: a powerful convergence theorem *guaranteeing* successful learning in multi-layer nets (see Section iii.b). This was the aspect of their work of which Hinton and Sejnowski were most proud:

> Perhaps the most interesting aspect of the Boltzmann Machine formulation is that it leads to a *domain-independent* learning algorithm that modifies the connection strengths between units in such a way that the whole network develops *an internal model which captures the underlying structure of its environment* . . . [When a network with hidden units] does the wrong thing it appears to be impossible to decide which of the many connection strengths is at fault. *This "credit-assignment" problem was what led to the demise of perceptrons* [Minsky and Papert 1969; Rosenblatt 1962]. The perceptron convergence theorem . . . could not be generalized to networks of [decision] units when the task did not directly specify how to use all the units in the network.
>
> This version of the credit-assignment problem can be solved within the Boltzmann Machine formulation. (Ackley *et al.* 1985: 641; italics added)

The underlying reason for this guarantee was that the Boltzmann equations in physics guarantee thermal equilibrium. Some day, sun and moon and everything else will have the same temperature—but there's a very long time to wait. Analogously, this new convergence theorem (like Rosenblatt's) showed what's inevitable in principle, not what's feasible in practice. Even if one could be sure that one was dealing with a problem for which a satisfactory set of weights in principle exists, one couldn't be sure of finding them.

In practice, the learning rule was very slow, and useless for large networks. That's why, despite the huge interest aroused on publication, relatively few people besides the authors themselves actually used Boltzmann machines for psychological research (but see Plaut and Shallice 1993). As Hinton and Sejnowski had pointed out, even small networks could be problematic:

> [One] difficulty is that there is nothing to prevent the learning algorithm from generating very large weights which create such high energy barriers that the network cannot reach equilibrium in the allotted time. Once this happens, the statistics that are collected will not be the equilibrium statistics required for [the relevant equation] to hold and so all bets are off. We have observed this happening for a number of different networks. They start off learning quite well and then the weights become too large and the network "goes sour"—its performance deteriorates dramatically. (Hinton and Sejnowski 1986: 298)

There were other difficulties, too—not least, that more training would make the network "go sour", its performance getting worse and worse.

In brief: Boltzmann machines were mathematical magic. But they cast their spells unreliably in the real computational world.

c. Backprop hits the headlines

A more trusty piece of mathematical magic announced in the PDP volumes (and simultaneously in the high-prestige *Nature*) was back propagation (Rumelhart *et al.* 1986*a*,*b*). This was the idea which Widrow "would have given [his] eye teeth to come up with" (see v.d, above).

Backprop, too, solved the credit assignment problem for multi-layer networks, and although it was still slow it was much faster than the Boltzmann machine. (In the ensuing years, a lot of effort was put into speeding it up.) Although it couldn't be *proved* to converge, it was certainly applicable to a wide range of problems. At the end of the 1980s, it was judged to be "the most effective current learning algorithm for complex, multilayer systems" (J. A. Anderson and Rosenfeld 1988: 674).

Back propagation was a generalization of the long-familiar LMS algorithm, or "delta rule" (see ii.g, above). But it corrected errors on several levels, instead of just one. It did this by tracing responsibility back from the output layer into the hidden layers, identifying the individual units that needed to be adapted *even though* many units had been acting simultaneously. It was thus analogous to Holland's contemporaneous bucket-brigade algorithm (Chapter 15.vi.a).

Backprop requires the programmer to know the precise state of the output layer when the network is giving the right answer. A unit-by-unit comparison is then made between this exemplary output and the output actually obtained from the network being trained. Any difference between an output unit's activity in the two cases counts as an error. (Unlike the Boltzmann machine, the units here were deterministic.)

So far, so familiar. But the (current or desired) state of the hidden units isn't known, for they can't be directly inspected. The backprop algorithm therefore *assumes* that the error in an output unit is due to error(s) in the hidden units connected to it.

It attributes a specific amount of error to each hidden unit, depending on the connection weight between it and the output unit. Blame is shared between all the hidden units connected to the mistaken output unit. If a hidden unit is linked to several output units, its mini-blames are summed.

Proportional weight changes are then made to the connections between the hidden layer and the preceding layer. That layer may be another (and another . . .) stratum of hidden units. But ultimately it will be the input layer, and the weight changes will stop. This process is iterated until the discrepancies at the output layer disappear.

The resulting overall state of the hidden units was taken to be the "internal representation" of the input. Such representations were necessary, the authors said, whenever "the similarity structure of the input and output patterns are very different" (Rumelhart *et al.* 1986*a*: 318). "A classic example of this case", they pointed out, is the *exclusive-or* (XOR) problem, which single-layer perceptrons had been notoriously unable to solve (see Section iii.b). Pandemonium could solve it, because (as pointed out in Section ii.d) it could embody demons looking out for just that logical feature. But there had been no learning rule—no convergence theorem—that *guaranteed* success in this general class. Backprop, by contrast, did.

Backprop aroused enormous interest. The need for it had long been recognized:

* Rosenblatt himself had speculated about "back-coupled" perceptrons twenty years earlier, but he hadn't defined an algorithm for computing and communicating the error messages (see Section ii.e, above).
* His arch-critic Minsky, in his hugely influential AI prospectus of the same period (1961*b*), had named credit assignment as one of the key problems that would have to be solved (10.i.g).
* And Widrow had "hit a brick wall trying to adapt multilayer nets" in the early 1960s, largely because he couldn't solve it.

Now, someone had mastered it at last.

Those words "at last", however, are highly misleading. The adulation—not to mention Widrow's eye teeth—might have been offered long before. For backprop wasn't strictly new. Quite apart from Holland's analogous work, it had been independently discovered several times already.

d. Backprop anticipated

Even within the PDP group, backprop had been several years a-brewing. Rumelhart had prepared a talk on it for a meeting in 1983, but chose "at the last minute" to give another talk instead (J. A. Anderson and Rosenfeld 1998: 279).

A full year later, he mentioned the idea to Sejnowski. He "immediately understood" and was the first to use it for a large task (in NETtalk: see below). Rumelhart himself had attempted only toy problems.

When Rumelhart first mentioned it to Hinton, by contrast, Hinton declared that it could never work. Nevertheless, and despairing of getting the Boltzmann machine to work efficiently, a few months later Hinton thought he might as well try backprop. His research students were so sceptical that none was willing to program it, even though he assured them that "It would only take a day or so" (J. A. Anderson and Rosenfeld 1998: 377). So he (with Williams) implemented it himself, and then spent some months improving it. Their description of the 'new' technique was added as an extra chapter just as the PDP volumes were going to press. This was a full three years after Rumelhart's phantom talk.

Even more to the point, there were others outside the PDP group who had come up with much the same idea.

The PDP authors themselves cited two "similar" learning rules. These had been published very recently (in 1985) by David Parker and Yann le Cun. Indeed, in 1982 Parker had tried to get it patented by Stanford, but was rejected because they thought it had no commercial value (S. Grossberg, personal communication).

Moreover, several people had defined it long before that. Grossberg had done so, as we saw in Chapter 1.iii.h (and his then current version allowed for many brain/behaviour facts ignored by the PDP group—Grossberg 1987*a*: 232–40). Several non-biologists had done so too. Its mathematical core (the chain rule of differentiation) had been discussed in the 1960s by control theorists (Bryson and Ho 1969), and by Amari also (1967). And, even more significant, it had been *implemented* in the early 1970s, as a routine statistical technique for automatic calculation.

The person who did that, and who (so far as is known) was the true originator of backprop *as a computerized algorithm*, was Werbos (1947–). And he did it for the most surprising of reasons.

Werbos was a highly interdisciplinary animal: a mathematician interested in the intersection of psychology, economics, and political science. While a new Ph.D. student at Harvard in 1970 or so, he had suggested using "this little method for adapting multilayer perceptrons". But he didn't want to use it for modelling supervised learning. Rather, he wanted to translate Sigmund Freud's ideas on psychic energy into mathematics.

Werbos's overall aim had been to model intelligence. His elders and betters weren't impressed:

> I had an adaptive critic backpropagated to a critic, the whole thing, in '71 or '72. I actually mailed out copies of that paper to some people out at Stanford and certain people around Harvard.
>
> The thesis committee said, "We were skeptical before [i.e. when he had mentioned the mathematics but not the AI], but this is just unacceptable. This is crazy, this is megalomaniac, this is nutzoid." (Werbos, interviewed in J. A. Anderson and Rosenfeld 1998: 342)

Even allowing for the verbal embroidery, Werbos's frustration (remember "We were not people they trusted, neither Steve nor I": v.g, above) is understandable. Not until he'd presented his ideas as statistics rather than neural networks, and as applied political science rather than AI, did Harvard (in 1974) agree to pass the thesis. The blandly respectable title was *Beyond Regression: New Tools for Prediction and Analysis in the Behavioral Sciences*—but Werbos used the ideas to make some highly influential predictions about the conduct of the Vietnam war (J. A. Anderson and Rosenfeld 1998: 339–40, 349).

Meanwhile, finding himself penniless, Werbos had got a full-time job on a joint MIT–Harvard computing project. This sustained him while he was doing the Ph.D. He generalized his algorithm to deal with time-varying processes, and put it into the "Time Series Processor" as part of MIT's standard software. Besides being included in the official report to the military funding agency, a description of the algorithm (which he called dynamic feedback) sat on many people's desks: "It was part of the computer manual, so the first publication of backpropagation was in a computer manual from MIT for a working command for people to use in statistical analysis. I was a second author of that manual" (J. A. Anderson and Rosenfeld 1998: 348).

Computer manuals, of course, aren't high-profile publications. DARPA reports are. But—most unusually—Werbos's mid-1970s research report to DARPA containing details of his method was never published, nor even officially listed. The reason was that it also contained politically embarrassing results (J. A. Anderson and Rosenfeld 1998: 351).

Moreover, Werbos's 1978 paper (in an IEEE journal) announcing that he'd defined a powerful method of "dynamic feedback" was printed without the Appendix, because of length limits. Without the details, why should readers get excited, or even believe him?

Another publication, in 1982, even added discussions of neural nets and various parts of the brain. It provided diagrams of multi-layer perceptrons, doing reinforcement learning by back propagation. But although this paper got Werbos some job offers, backprop was still left on the shelf. His new employers tried to get MIT's engineers to implement it as a useful analytical tool: they wouldn't.

So much for the vicissitudes of Werbos's dynamic feedback. The sources for Parker and le Cun were similarly inaccessible. They were (respectively) a Technical Report of MIT's Center for Computational Research in Economics and Management Science, and a low-profile journal and edited collection.

Rumelhart and colleagues, by contrast, published simultaneously in the hugely influential journal *Nature* and (at much greater length) in a book written in a highly accessible style, with a provocative overall theme. That book was an instant best-seller, as we've seen. And everyone who was a scientific anyone read *Nature*. Their version of back propagation became famous virtually overnight. Until Werbos was remembered/discovered by the neural network community some years later, the PDP group were mistakenly given the credit for defining and/or implementing the "first" backprop algorithm.

e. Wonders of the past tense

There was another reason, besides the elegant mathematics, why the PDP approach became famous overnight. Namely, the 'bible' described simulations of a number of important psychological phenomena. In other words, it seemed to be describing the real world, not just doing exercises in fancy mathematics. And the "real world", here, was the world of human beings—not spin glasses.

Perhaps the most widely read chapter in this category was Rumelhart and McClelland's (1986). It described a Kohonen associative memory (with 460 input units and 460 output units), equipped with Rosenblatt's perceptron convergence procedure. This network modelled how a child learns the past tense of English verbs—which most of the bible readers, of course, would have heard in their own infant children or siblings.

Outsiders (and locusts) might have asked "Who cares? What's important about that?" But cognitive scientists did care, because this model presented a fundamental challenge to two closely related orthodoxies: nativism and rule realism. (By rule realism, I mean commitment to the psychological reality of processing rules, of which grammatical rules are a special case.)

Both of these orthodoxies were prominent in Chomsky's linguistics and Fodor's philosophy of mind (see 9.vii and 16.iv.c–d). And the second was a linchpin of Allen Newell and Simon's psychology (6.iii, 7.iv.b, and 16.ix.b). These four men had been hugely influential in the formation of the field. So it's not surprising that nativism and rule realism were accepted, even assumed, by most cognitive scientists at the time.

Rumelhart and McClelland questioned all that:

> We propose an alternative to explicit inaccessible rules. We suggest that lawful behavior and judgments may be produced by a mechanism in which there is no explicit representation of the rule. Instead, we suggest that the mechanisms that process language and make judgments of grammaticality are constructed in such a way that *their performance is characterizable by rules, but that the rules themselves are not written in explicit form anywhere in the mechanism*. (Rumelhart and McClelland 1986: 217; italics added)

The italicized claim had been made years earlier by Dreyfus, as we saw in Chapter 11.ii.a. But whereas he couldn't say anything positive about what such mechanisms might be like, beyond a vague reference to "bodily skills", Rumelhart and McClelland could.

They even claimed to have demonstrated success. If they were to be believed, Chomsky, Fodor, Newell, Simon, and almost everyone else in cognitive science were barking up the wrong tree.

Rumelhart and McClelland started from the fact remarked in Chapter 7.vi.a, that young children go through three stages in forming the past tense. First, a few past-tense verbs, and no mistakes; then, more past tenses, plus frequent over-regularization (*he goed* or *he wented* instead of *he went*); finally, lots of past-tense verbs, without mistakes. This development is gradual, and also includes more detailed changes—in the relative frequencies of *he goed* and *he wented*, for instance.

Their PDP model apparently produced the very same sort of behaviour. ("Apparently", because this claim was later challenged: see Section x.d, below.) But it was neither provided with, nor did it develop for itself, any explicit rules about past-tense formation. The patterns in its behaviour were based in memories (sets of connection weights) implicit in the network as a whole—and which reflected the statistical structure of its environment.

(Sets of connection weights were often referred to as "memories", largely in order to stress the radical difference between PDP and GOFAI representations. However, that could be misleading, because the word normally suggests something that is closely related to the inputs presented—which the weight sets produced by PDP learning rules are not. In some connectionist systems, inputs—sentences, for instance—are stored verbatim, and processing is done on the collection of examples when the system is presented with a query.)

Here, the "environment" was the language that the system—child or computer—experienced as input. The input to the computer wasn't continuous speech. Rather, it was (phonological representations of) a set of stem/past-tense pairs.

Rumelhart and McClelland claimed that the number of recognizable past-tense verbs heard by the infant is at first so small that there's little scope for spotting statistical regularities. Moreover, many everyday (i.e. frequent) words (*go, come, give, take, get* . . .) are irregulars, so the very early corpus includes a relatively large proportion of past-irregulars, such as *he went*. So the first input they provided consisted of only ten verbs: eight irregular, two regular; later, another 410 would be added. Present–past pairs (for instance, *go–went*) are evidently learnt by rote, as one-offs. As more speech is heard, however, the regular verbs massively outnumber the irregular ones.

In other words, the addition of *-ed* (and other past-tense rules) is increasingly prominent in the input statistics. The PDP model—and, its authors suggested, the child—picked up this statistical fact, and reflected it in its own performance. Only much later, after numerous repetitions of *went* had made it a statistically recognizable exception, did the network generate it reliably again.

The past-tense learner was theoretical dynamite:

* It cast doubt on nativism and modularity, for it suggested that a domain-general learning rule—namely, Rosenblatt's perceptron convergence procedure—can suffice for the acquisition of grammar.
* And if grammar, why not other cognitive structures too? (Twenty years later, McClelland would argue much the same point in respect of semantic categories such as *animal* and *plant*, which are often described as innate: see Chapter 8.i.d.)

* It undermined belief in the psychological reality of explicitly represented processing rules,
* and of explicit (symbolic) representations.
* And it threatened the then popular forms of philosophical functionalism (Chapter 16.iii–v).

Little wonder, then, that people flocked to read Rumelhart and McClelland's chapter.

f. Escaping from the black box

Very soon after the past-tense learner, other 'sexy' psychological simulations were described, and hit the media in their turn. Among the most visible—or perhaps one should say "audible"—was NETtalk (Sejnowski and Rosenberg 1986, 1987).

This network, which used phonetic representations that could be fed into a speech synthesizer, gradually learnt to pronounce English words. Listening to its increasingly human-like output, one was reminded irresistibly, and eerily, of an infant passing from babbling to speech. In short, it was guaranteed to *épater les bourgeois*—and in 1986 it did so, on the *Today* show.

But it captured the attention of cognitive scientists, too. For it addressed a methodological problem that faced PDP in general: namely, how to analyse the behaviour of a complex network, instead of treating it as an unintelligible black box. (Compare Minsky's confession "we sort of quit science for a while to watch the machine", and Rumelhart's: "[We'd] built these computer models, and we just didn't understand them . . . why they worked or why they didn't work or what was critical about them.")

Of course, one could always specify the learning rule being used. But what, exactly, had been learnt? Or, to put it another way, what exactly were the hidden units doing? How, for example, was the network representing the hard 'c' in 'cat' and the soft 'c' in 'city'?

NETtalk was developed at Johns Hopkins University in 1985–7, by Sejnowski and the psychologist Charles Rosenberg. Using backprop, it learnt the correct pronunciation of printed English words (from a 20,000-word dictionary) after only three months of work on their part. Indeed, to their amazement it took only one day to master the very first (100-word) version of the task. Three months later, it could learn a 2,000-word corpus in the same time. But just how it was doing it, and just how one might find out, were mysteries.

The inputs weren't letters or sounds, but phonetic representations called Wickelgren features. These are trios coding the target phoneme and its immediate predecessor and successor. So NETtalk didn't have to learn to distinguish the many English vowel sounds, for instance. Much of the power of the system was due to this choice of representation.

That fact illustrated an important point about PDP applications as a class. Just as GOFAI's "General" Problem Solver relied on the programmer to choose and articulate the problem, so a "general" connectionist learning rule works on a representation selected by the designer. One can't simply take a problem and set the learning rule to run on it, any more than one can state the missionaries and cannibals puzzle in English and expect GPS to solve it. This had been true ever since Rosenblatt's first perceptron, but—perhaps partly because "knowledge representation" was a prime focus of the rival, GOFAI—it wasn't much discussed.

Though small by today's standards, the network was very large for its time. It had 309 units, 18,629 connections, and about 30,000 weights. There were 26 output units, 80 hidden units, and 203 input units. Given this complexity, explaining its final performance—as opposed to stating the learning rule—wasn't easy. It took the designers not three months, but three years.

In the end, Sejnowski and Rosenberg recommended three different methods for analysing NETtalk's behaviour in terms of what the hidden units were doing. These analyses were based on network pathology, records of unit activation, and cluster analysis.

Network pathology involved systematic "lesioning" of the network, either before or after it had learnt its task. The authors suggested that this method could be used to throw light not only on artificial networks but on clinical neurology too. For instance, NETtalk might help in studying acquired dyslexias.

Soon afterwards, the British clinician Timothy Shallice (one of the dyslexia experts they'd cited) worked with Hinton on a connectionist model of reading, parts of which they deliberately disabled in a variety of ways. Forty stimulus words, from five semantic classes, activated twenty-eight (position-specific) letter-detecting units; in addition, sixty-eight semantic units represented features such as size, texture, typical location, use, and so on. On average, each input word was supposed to activate fifteen semantic units, with much overlap between words of similar meaning (such as *cot* and *bed*) and less between semantically different words (such as *cot* and *cat*). Hinton and Shallice found that the system exhibited a range of "dyslexias" that are qualitatively similar to those seen in human patients. Various neuroscientific hypotheses were suggested, accordingly (Hinton and Shallice 1989/1991).

Unit activation, they suggested, was related to neuroscience too. After learning, any one of NETtalk's hidden units seemed to be responding to several different input characters, so had no obvious coding or single interpretation. A few years later, follow-up studies found that some units responded more strongly to certain phonetic classes (vowels, for example), but that strict localization didn't develop (J. A. Anderson and Rosenfeld 1988: 662).

As for cluster analysis, this identified the associations most often used by the system in partitioning the "space" of its performance. It turned out—to the authors' surprise—that the network had developed an implicit hierarchy of (nearly eighty) distinctions like those explicitly defined in phonetics: vowels and consonants, voiced and unvoiced consonants, and so on. A GOFAI speech system might have employed an explicit representation of this phonetic structure, but NETtalk didn't. Rather, it implicitly reflected the statistical structure of its environment (English words, each one input as a series of trio-phonetic representations). And this, as we've seen, is what the past-tense learner had done, too.

Statisticians (such as Werbos) might have accused them of reinventing the wheel, for cluster analysis is a common method in statistics. Indeed, it became increasingly clear through the 1990s that many 'insights' of connectionism were differently named versions of statistical techniques. (And of behaviourist equations too: we saw in Section v.a that the Widrow–Hoff algorithm was equivalent to Hull's "habit strength".)

This was pointed out by Donald Michie, a long-time worker in AI learning—mostly of the GOFAI variety (Michie *et al.* 1994). It was also remarked by an outsider, Warren Sarle of the SAS Institute, North Carolina (Sarle 1995).

SAS produces software for statistics, artificial neural networks, data mining, etc. It's not surprising, then, that Sarle remarked that networks learning from noisy data are doing data analysis—which is what statistics is all about. Neural net researchers concentrate on the algorithms, statisticians on their results. And neural networkers tend to ignore the distributional assumptions they have made, whereas statisticians explore their consequences. Nevertheless, there are many close parallels.

Sarle listed over seventy near-equivalences between connectionist and statistical concepts. Let's pick out just two examples. First, feed-forward nets with one hidden layer are closely related to what statisticians call projection pursuit regression. And second, probabilistic neural nets are identical to what's called kernel discriminant analysis. In general, he said,

> many results from the statistical theory of nonlinear models apply directly to feedforward nets, and the methods that are commonly used for fitting nonlinear models . . . can be used to train feedforward nets. (Sarle 1995)

Sarle's analysis confirms Gerd Gigerenzer's (1994) view that "new ideas" in science commonly arise from pre-existing tools, and that experimental psychology in general has long exploited statistics in this way. It also confirms the central claim of this section and the preceding one: that connectionism needed mathematical advances to progress. The growth in computer power helped. Indeed, it was essential. But it would have been useless without the mathematical *ideas*.

12.vii. The Worm Turns

The explosive response to the PDP bible, and to the first summer schools at CMU and San Diego, revived the flagging fortunes of connectionism. It wasn't just intellectual appreciation that was involved, but financial support too.

a. Joyful jamborees

Much as a family gathering can be all the more joyous if it brings together people long parted, so an intellectual meeting will be all the more appreciated if it unites people from many different directions. If some or all of these can be cast in the role of the prodigal son, so much the better for fostering satisfaction all round.

The first connectionist conferences are remembered with great pleasure by many of the contributors to the oral history of connectionism (J. A. Anderson and Rosenfeld 1998). They played an important role, not only in raising the confidence of the field but in showing that it *was* a field—and a large one—in the first place.

Connectionism had always included two streams. There were those (like Rosenblatt and the PDP group) who leant towards psychology and/or neurobiology. And there were those (like Widrow and Hopfield) who came from engineering, physics, computing, and/or mathematics. In the 1970s and early 1980s, as we've seen, the two streams rarely mixed.

In the late 1980s, however, several international conference series were initiated which deliberately involved both. The first connectionist jamboree had been in 1979 at La Jolla (see Section v.b, above). But that was a mere taster. These new initiatives were more meaty.

The first "fairly large" neural network meetings were held in Santa Barbara in 1985, and at Salt Lake City's Snowbird Conference Center in 1986 (J. A. Anderson and Rosenfeld 1998: 300). The Snowbird meeting, organized by researchers at AT&T Bell Labs, is fondly recalled by several of the contributors to the *Talking Nets* oral history (a fascinating set of reminiscences and hindsighted judgements, arising in conversations between leading connectionists: J. A. Anderson and Rosenfeld 1998).

Primarily, it's remembered for the exciting mingling of people and sharing of ideas. Indeed, it later gave rise to the NIPS (Neural Information Processing Systems) series of meetings, now regarded by many as the premier scientific conference on neural networks. But it's remembered also, at least by the electrical engineer Robert Hecht-Nielsen, for the organizers' bizarre ideas on how to win friends and influence people:

> They had created this obnoxious conference registration form, where you wrote a little paragraph justifying why you should be invited to this meeting, and then underneath there were two boxes that they could check. One was "accept" and one was "reject". And as I understand the numbers, there were approximately five hundred of these forms returned, and something on the order of 125 of them were accepted. The others got them back saying "rejected". To say the least, there were a lot of angry, disenfranchised people. (J. A. Anderson and Rosenfeld 1988: 300)

Quite apart from his disgust at the crass way in which the Snowbird selection had been carried out, Hecht-Nielsen regretted that it had been done at all. Given the "sudden enthusiasm" for the topic, it was clear to him—and to his friend Bart Kosko—that "having a major meeting with unrestricted attendance was an absolute prerequisite for further growth and progress in the neural net field".

Accordingly, the two electrical engineers organized another, larger, meeting in 1987: the first IEEE International Conference on Neural Networks, for which Grossberg was the general chairman. This was intended as an educational exercise, rather than a straightforwardly scientific one. For the newly visible field was riven by priority disputes, and by worrying examples of ignorance and resentment that threatened its future. As Hecht-Nielsen later put it:

> There was already [in 1987] a very large clash under way between people who had been in the field for a long time and who had really prepared the foundation in the field and had all the good ideas, and new people who had come along and really didn't add much to the field, if anything, except perhaps an infectious enthusiasm and a following . . . There was this body of individuals who really had created the field and really had all the original ideas at that point, who didn't even exist as far as maybe a majority of the new people interested in the field were concerned. (J. A. Anderson and Rosenfeld 1998: 301)

One of the main aims of the meeting, then, would be "to firmly and unequivocally establish the history of the field in people's minds in a more correct sequence of events"

(p. 301). This meant inviting as many as possible of the half-forgotten originators, as well as the newly fashionable ones. But, as the co-organizer Kosko remembered:

> By the fall of 1986 we . . . went around to the many feuding factions in neural networks. The feuds were really beginning to heat up now. The PDP books were out. There were different camps, and we felt the only thing to do was have a level playing field . . . Many of the leaders of the neural field [whom we invited] literally hated each other's guts . . . (J. A. Anderson and Rosenfeld 1998: 403)

Given this unhappy background, Kosko and Hecht-Nielsen were far from confident that all the invitees would accept (they didn't), or that many other people would bother to turn up. But they were willing to put their money where their mouths were. Together with the local branch of the IEEE, they took on a million-dollar risk to underwrite the conference. (Sheraton hotels don't come cheap.) In the event, however, 2,000 people signed up.

Almost as many attended the summer 1987 meeting on neural networks at San Diego. A few months before that, Grossberg, Kohonen, and Amari had co-founded the International Neural Network Society (INNS), with Grossberg as its first President. They also invited papers for a new journal, *Neural Networks* (Grossberg was Editor-in-Chief). INNS held its first conference in Boston in 1988, co-sponsored by six IEEE societies. As for IEEE itself, it ran a 750-person scientific meeting (on 'Neural Information Processing Systems—Natural and Synthetic') in Denver in November 1987; and the second IEEE 'Neural Networks' conference—no longer a source of financial nail biting—took place in San Diego in July 1988.

Very soon (in 1989), these two series of meetings (INNS and IEEE) would unite as the International *Joint* Conference on Neural Networks. There were over 1,800 participants, including many from industry, at the initial assembly. The atmosphere of the first IJCNN reminded one participant of the movie mythology of *Star Wars*:

> There was very much a sense of excitement, almost euphoria. The Neural Network Jedi had returned and a rebellion was in progress. Bernie Widrow, one of the pioneers of the field, was perfectly cast in the role of Obi-wan Kenobi. The Evil Empire of AI, which had wrongfully suppressed and oppressed the innocent, was already declared to be dead. A new millennium was about to dawn. (Barrow 1989: 6)

One didn't need to be in Hollywood's home nation to share the sense of excitement. Other meetings were springing up all around in 1986–7, in the UK/Europe and Japan as well as in the USA.

The PDP group, in particular, put a lot of effort into stirring the pot. They instituted a series of highly successful summer schools, to introduce both students and fellow cognitive scientists to hands-on experience of connectionist computing. These were equivalent in intent to RAND's summer 1958 "Research Institute" and the other GOFAI summer schools (see Chapter 6.v.a). Just as in RAND-1958, a number of already established cognitive scientists welcomed the opportunity to be trained in the new methodology—and the new way of thinking about mind and psychology.

In addition, there were various attempts at commercial application. As Mead said later, these were interesting because they involved "actually looking at what [neural networks] do rather than making up stories about what they might do" (J. A. Anderson and Rosenfeld 1998: 142).

b. DARPA thinks again

At much the same time as these sudden and worldwide developments, DARPA began to have second thoughts about their current funding—or rather, no-funding—policy. ("No-funding" isn't quite fair: they'd supported a few selected projects from 1982 onwards, and had funded Hecht-Nielsen in building neurocomputers.)

The key trigger of their rethinking was the series of lectures given by Grossberg at MIT's Lincoln Laboratory in 1986–7, videos of which were circulated in the lab and reached the Director. He found them impressive, but there was no unanimity: some scientists and DARPA offices still held to the Minsky–Papert critique. He therefore persuaded DARPA to set up an urgent five-month enquiry into neural networks (DARPA 1988). Grossberg (personal communication) was invited to head it, but had to decline because of his other commitments. (As we've seen, besides doing his own research he was then the founding President of INNS, and editing the new journal *Neural Networks*.) Widrow was appointed as Director instead.

The enquiry was kicked off, in October 1987, by a two-day symposium at the Lincoln Laboratory. The task of the symposium was to outline the study's central themes. The fourteen speakers included several cognitive scientists and neurophysiologists. These were Feldman, Rumelhart, and Sejnowski; Grossberg and Gail Carpenter, both of whom spoke on vision; and David Hubel, Nobel prizewinner for research on visual cortex (see 14.iii.b).

The team who undertook the subsequent work, and eventually wrote the 650-page Report, were drawn mainly from computer science and engineering (in industry as well as academia). They included Hopfield and Hecht-Nielsen, as well as Widrow. But there were cognitive scientists, too: Grossberg, Carpenter, Selfridge, Waltz, Feldman, Williams, Rumelhart, and Richard Sutton.

In addition, the six Panels consulted many individual researchers, some of whom were invited to give a talk to the official DARPA team. Not the least of these was Minsky, who soon used his response as the core of his intransigent comments in the second edition of *Perceptrons* (Minsky and Papert 1988) (By this time, of course, he was both criticizing connectionism and using it in his own work: see Section iii.c–d, above.)

The reason behind this particular choice of speakers and Panel members was simple: DARPA's concerns were military. Neuroscience and psychology were included not for their own sake, but because they might help in producing useful working systems—where the military decided what was "useful". (There was little new in that. AI had been largely funded by military money from its inception: see Chapters 4.vi.a, 11.i, and 9.x.a.)

The Report baldly stated that any money that might be forthcoming would support "advancement of technologies critical to the development of next-generation, fire-and-forget, autonomous weapons" (DARPA 1988, p. xxv). Hence the emphasis on vision—for instance, Hubel's involvement. But any research topic might be relevant, if it advanced the understanding of connectionist systems in general. So, for instance, Sejnowski was invited to speak on 'Analysing the Hidden Units in Multilayered Neural Networks', one of the methodological issues raised by NETtalk.

As Hecht-Nielsen's remarks (above) clearly show, there were social sensitivities to be respected here. Widrow, as Study Director, noted that "there are many different and even conflicting views of what neural networks are, what they can do, and how they should be implemented", and disarmingly pointed out that "representatives of every school of thought in neural networks were consulted" (DARPA 1988, pp. xxix, xxx).

There was also the delicate matter of why DARPA had seemingly been so blind, in their near-refusal to fund connectionist AI for the last twenty years. Largely, no doubt, because—like Yovits—they'd been persuaded by Minsky in the 1960s (see Section iii.e, above). But there was another reason too, which was mentioned repeatedly in the Report: counter-productive hype on the part of connectionists themselves.

As Widrow put it in his introduction,

> Among scientists, the presence of hype and extravagant claims casts a dark shadow and makes the work controversial in scientific circles and amongst the world at large. (DARPA 1988, p. xxix)

The study specifically asked whether connectionism was "just a repackaging of old ideas and promises", as "some" (notably, Minsky and Papert) were claiming, and whether it was more "hyperbole" than achievement (DARPA 1988, pp. xxvii, xxix). Connectionist hyperbole, both past and present, was sternly noted. Media publicity and consorting with venture capitalists were decried too. Widrow tacitly defended DARPA's long-standing absence by complaining that "involvement is difficult . . . in the presence of hype" (p. xxv).

For all their disapproval of hype—plenty of which was now being spread by the PDP groupies, if not by the PDP group themselves—the scientific Panels didn't react as Sir James Lighthill had reacted to GOFAI sixteen years before (see Chapter 11.iv). As a result of their detailed assessment, DARPA decided to initiate "a major new program in neural networks beginning in 1989" (p. xxv).

As though this revenge wasn't sweet enough, Minsky and Papert were given a coded rebuke: "Neural network research is not new—it is, rather, newly revived from an obscurity and even disrepute which is now understood to have been undeserved" (DARPA 1988: 23). What Mead had called the "twenty-year famine" was over.

12.viii. A la recherche . . .

In the late 1980s, work on the new perceptrons ballooned. Much was largely 'more of the same', in the form of an ever-lengthening list of commercial applications driven by the venture capital remarked on by DARPA.

Examples ran all the way from mineral prospecting in the field to banking in the City of London or Wall Street. (Physics graduates were snapped up by the money men, to use 'thermodynamic' networks for financial predictions of various kinds.) These applications exploited PDP's power of pattern recognition, which Mead soon affirmed in uncompromising terms:

> [Recognition problems are] an area where it's very hard to do anything without a neural net. The AI people tried for years. With a neural network, you can do better in a week than people have done fooling around with AI programs for years . . . With real-world data, where you don't know what the information is, neural network paradigms can pull out that information and make it useful. That is very, very clear. It wasn't clear five years ago [in the late 1980s]. Then it was a gleam in all of our eyes, but at that time it wasn't clear to anybody who was objective about it that

it was going to be better than sitting down with a smart guy and writing a program. Now it's clear that there's no contest at all. That's been a big change. (J. A. Anderson and Rosenfeld 1998: 141)

It was also clear—within the field, if not in its press releases—that "Every silver lining has a cloud, and PDP is no exception" (A. J. Clark 1989: 127). Specifically, there's more to intelligence than pattern recognition. It followed that PDP wasn't the answer to every maiden's prayer—nor to every businessman's, either.

Relying not on madeleines but on arguments, some critics exhorted the new enthusiasts to remember, and try to recover, some key abilities of symbolic AI. For various things that had been easily achieved by GOFAI—notably, serial order and hierarchical planning—weren't yet possible using PDP.

Hierarchy couldn't be ignored, for it wasn't merely (merely?) a characteristic of intellectual thought. As Lashley had pointed out, it's a feature of skilled behaviour in general:

There is a series of hierarchies of organization; the order of vocal movements in pronouncing the word, the order of words in the sentence, the order of sentences in the paragraph, the rational order of paragraphs in a discourse. *Not only speech, but all skilled acts* seem to involve the same problems of serial ordering, even down to the temporal coordination of muscular contractions in such a movement as reaching and grasping. (Lashley 1951*a*: 121–2; italics added)

Propositional reasoning was impossible too, but the new connectionist modellers didn't even try to recapture that. (As you'll remember, the superiority of symbolic AI for representing propositions was one reason why it overtook cybernetics/connectionism in the 1950s: see 4.ix.b.) Even today, it's still an unconquered obstacle (but see Section x.e, below).

It wasn't clear that these things ever would be achievable by connectionist means. Perhaps only GOFAI could do certain sorts of problem solving, and/or perhaps the new networks would have to simulate GOFAI systems if they were to do so too. If one wants accurate reasoning or precise rule following, the famed noise tolerance of PDP may even be a disadvantage: two plus two really does equal four—not "probably 4", "maybe 3", or even 4.0001. Even "binding" different predicates (e.g. colour and shape) together to apply to *one-and-the-same* object—child's play in GOFAI—is problematic in connectionism.

These doubts were similar, at base, to Walter Reitman's doubts about the capacities of purely "Hebbian" programs (see Chapter 7.i.b). Now, some thirty years later, they engendered a new generation of PDP systems, doing things the ancestor networks couldn't do.

Admittedly, a few connectionists had already addressed these problems. Andreae had been doing so in working systems since the early 1970s (see Section iv.c, above). Minsky, in his "society" theory, had been attempting this too (iii.d, above). And John R. Anderson had combined localist networks with GOFAI insights about goal-directed thinking (7.iv.c). But the high-visibility (i.e. PDP) connectionist modellers had focused primarily on pattern recognition, not on hierarchy or sequence. Now, they made those the aim of their research.

(Meanwhile, two rather different things were going on. From around 1990, some young members of the recently named A-Life community developed a new form of neural net, which worked in continuous time and could simulate smoothly changing dynamical systems: see Chapter 15.viii.d. In addition, the now unfashionable GOFAI workers carried on, pushing their achievements still further: see Chapter 13.)

a. Emulating the ancestors

The first of these descendant networks had been conceived in 'biblical' times. For the PDP group themselves shared some of Minsky and Papert's continuing doubts about perceptrons. Indeed, they agreed with Minsky's hunch in his 'Steps' paper of 1961, that some *combination* of neural networks and GOFAI would be needed (see Section iii.b).

Even in their biblical volumes they admitted that, in order to do many kinds of problem solving, a PDP network would have to emulate a von Neumann machine. And Hinton, for example, had already tried to enable a PDP system to perform logical inference (Touretsky and Hinton 1985), and to implement a production system (see 10.v.e) (Touretsky and Hinton 1988).

Unlike some of their followers, then, the PDP group didn't claim that GOFAI had been a "false start" (Graubard 1988) or that it had "failed" (H. L. Dreyfus and Dreyfus 1988: 34; Dreyfus 1992, p. ix). Still less did they see "fooling around with AI programs" as a waste of time. On the contrary:

> [The] idea of distributed representations is consistent with some of the major insights from the field of artificial intelligence concerning the importance of structure in representations and processes. (Hinton *et al*. 1986: 104)

> [Mental] processes that take longer [than 0.5 seconds], we believe, have a serial component and can more readily be described in terms of sequential information-processing models. For these processes, a process description such as a production [see Chapter 7.iv.b] would, we imagine, provide a useful approximation. (Rumelhart *et al*. 1986*c*: 56)

The mental processes in question were characteristic of human thinking—the main focus of traditional AI (and of many group members' early research). Rosenblatt himself had surmised that perceptrons couldn't embody "such higher order functions as are involved in human speech, communication, and thinking" (see ii.f, above). Similarly, the PDP group admitted almost thirty years later that:

> The PDP system is fine for perception and motor control, fine for categorization. It is possibly exactly the sort of system required for all of our automatic, subconscious reasoning. But [we] think that more is required—either more levels of PDP structures or other kinds of systems—to handle the problems of conscious, deliberate thought, planning, and problem solving . . . People interpret the world rapidly, effortlessly. But the development of new ideas, or evaluation of current thoughts proceeds slowly, serially, deliberately. People do seem to have at least two modes of operation, one rapid, efficient, subconscious, the other slow, serial, and conscious. (D. A. Norman 1986*b*: 541–2)

The *microstructure* of the serial mode, they believed, is connectionist. This provides welcome emergent properties such as content addressability and graceful degradation, which sequential processing can exploit though not explain. Nevertheless, they recognized that PDP work would have to build on the "major insights" gained by years of GOFAI research.

Even in 1990, they weren't expecting any quick success. Hinton, by then based at the University of Toronto, edited a special issue of *Artificial Intelligence* on how connectionists might add "symbol processing" to pattern recognition. But the lost strengths of GOFAI weren't going to be resurrected overnight:

> [In future, if current learning] techniques can be applied in networks with greater representational abilities, we may see artificial neural networks that can do much more than just classify patterns. But for now, the problem is to devise effective ways of representing complex structures in connectionist networks without sacrificing the ability to learn the representations. *My own view is that connectionists are still a very long way from solving this problem* . . . (Hinton 1990: 3; italics added)

As for just how one can make a PDP network pretend to be a serial machine, the PDP books offered a number of ideas. For example, one chapter suggested that sequential thinking might be modelled by pattern matching in *multi-level* networks (Rumelhart *et al*. 1986*c*).

It described a simple computer model that used two mutually influential self-equilibrating networks to produce successive moves in a game of noughts and crosses (tic-tac-toe). The relaxation constraints of both networks embodied the rules and strategy of the game, but one network represented "player's move" and the other "opponent's move". The perceptual (input) model of each opposing move could drive equilibration in the player network, so as to produce an appropriate counter-move. In that case, the seriality would depend on the environment. But if the perceptual models were stored, or internalized, they could then be used by the player network to plan (and evaluate) hypothetical moves—in other words, to deliberate.

The ensuing years, to the end of the century, saw important advances such as recurrent nets, developmental minimalism, representational trajectories, input histories, multi-networks, hybrid systems, and constructive networks.

Each of these approaches lessened the distance between PDP and traditional AI. And each engaged with fundamental issues in computational psychology and philosophy of mind—not least, hierarchical structure and nativism. The first four are closely linked, and are described here; the last three will be discussed in Section ix.

b. Recurrent nets

Lashley had pointed out long before that serially ordered behaviour, such as speech, requires anticipatory (planning) mechanisms that define the 'place' of a behavioural unit in the overall sequence—typically, by imposing a hierarchical structure on it (see Chapter 5.iv.a). Planning had been a prime focus of GOFAI, and of GOFAI-based psychology. But whereas list processing had been ideally suited to represent both sequence and hierarchy (10.v.b–c), it wasn't obvious how—some doubters even said "whether"—a PDP system could do so.

Jordan (1956–) took up the challenge, and confronted the doubters with a recurrent network that could plan (Jordan 1986/1989). The general idea of recurrent networks, in which the output from some later layer is fed back as input to some earlier layer, wasn't new. It had been stressed by the cyberneticians, in their focus on "circular causation" and self-stimulating circuits (see Chapter 4.iii.c and v). But the early network-modellers had avoided feedback loops, because of the complex mathematics involved (the input to a given level changes continually). Now, Jordan provided a functioning model that could be used to generate ordered sequences of behaviour.

Constant feedback from output units to input units enabled Jordan's net to keep track of where it was, with respect to the sequence concerned. For instance, if a quickstep were represented as *slow, slow, quick, quick, slow* the net would know whether it had just output a *slow*, and which one of the three possible *slows* this had been. This information could affect the next signal from the input layer to the hidden layer, which in turn would determine the next output step.

So far, so rigid: a particular starting state would always trigger the same sequence. So Jordan added "plan units" to the input layer, which sent their own signals on to the hidden layer. Whether a hidden unit fired depended on the input it received from *both* the ordinary input units (receiving continual feedback) *and* the plan units. Hence: different plans, different behaviour—even though the perceptual input at the start might be identical.

As described so far, this required the researcher to specify all the unit thresholds and weights involved. In the toy networks (some less than a dozen units) described by Jordan, this was feasible. But pre-setting a network to execute 'at will' the plan of either 'Three Blind Mice' or 'The Death of Cock Robin', or any one of dozens of nursery rhymes (as humans can do) would be an impossible task. Clearly, what was needed was for the network to learn how to produce those sequences for itself. In other words, it had to learn to predict the next item in the behavioural sequence—and to reflect, in its own behaviour, any hierarchical structure in the input domain.

The pioneer in making this possible was Elman (1948–), who was working on speech processing (1990, 1993). This had been a key topic for connectionism since its beginnings. McCulloch, Pitts, and Selfridge had been involved in MIT's early project of developing an automatic speech-typewriter; and Rosenblatt, Longuet-Higgins, and Willshaw had all considered temporal input patterns, as we've seen.

Classical AI had modelled speech processing too, notably by HEARSAY in the early 1970s (see 9.xi.g and 10.v.e). In principle, this GOFAI model was a parallel-processing system, using multiple constraint satisfaction to interpret its auditory input. Over a decade later, and partly inspired by HEARSAY, Elman's PDP networks learnt to do much the same thing.

Elman's recurrent networks differed from Jordan's in using constant feedback from the hidden units (not the output units) to a special group of "context" units (which replaced Jordan's predetermined plan units). But the general principle was similar. An Elman network kept track of what the immediately preceding state of the hidden units had been. Indeed, it implicitly stored information about *all* its earlier states, because—given that the context units sent signals back to the hidden units—the current activity of a hidden unit would indirectly reflect its previous state, which in turn would have reflected *its* previous state . . . and so on. The context units (unlike Jordan's plan units) could learn, for the signals they sent to the hidden units were automatically adjusted by back propagation at each cycle.

These networks learnt to predict temporal dependencies, including dependencies within dependencies. For example, they learnt to predict phonemes so as to pick out individual words from continuous auditory input (Elman 1990). Sometimes, they'd get it wrong: *anelephant* would be segmented as *a nelephant*—a mistake that children often make too.

Given strings of individual words (Elman 1993), they distinguished verbs from nouns, from adjectives . . . and even animate from inanimate objects. And they learnt to reflect nested grammatical hierarchies. A plural noun at the beginning of an output sentence, for instance, would be matched by a plural verb later, even if there was an embedded relative clause in between; and a *subject-noun* would always be followed by some *verb*, and sometimes preceded by *adjectives*. (Strictly, this is an exaggeration: the longer the sentence, the less reliable the network's performance.)

All this was achieved in virtue of the distributional statistics of the various words. The Bloomfieldians, then, would have been happy (see Chapter 9.v). But whereas they had measured (timeless) coexistence within a whole corpus, Elman's networks were assaying the temporal statistics of sentences presented to them word by word and one by one.

The grammatical structures weren't represented explicitly, just as the rules of the past tense hadn't been stored *as such* in the past-tense learner. Network analysis showed, however, that the activities of the hidden units differed according to the grammatical role of a given word: e.g. *cat*, used as subject or as object.

In other words, Elman's networks posed yet another challenge to Chomsky's nativism. As already remarked, they were closer to the structuralist linguists who had preceded him. They had no inbuilt English grammar, nor any domain-specific Language Acquisition Device. Where SHRDLU and LUNAR (see Chapter 9.xi.b) had been provided with procedural definitions of English syntax, these PDP systems seemed to be able to pick it up for themselves by relying on domain-general principles of learning.

This was a "challenge" rather than a refutation, not least because backprop isn't biologically plausible. Synapses don't run backwards, nor are brains provided with error corrections by some outside supervisor. Moreover, Elman didn't ask whether there are types of 'grammar' that can be learnt by unstructured PDP systems but *can't* be learnt spontaneously by humans. If there are—which later turned out to be so (N. V. Smith 1999: 134–5)—then his results didn't disprove Chomsky's claim that humans depend on innate linguistic structure.

Nevertheless, his work revived questions about the development of language which Chomskyans—which is to say, most cognitive scientists at that time—had thought already settled.

c. Start simple, develop complex

Elman's work also raised other questions about children's language learning, which led to a general idea that one might call developmental minimalism. This sees development as passing from simple types of representation to more complex ones, where each of the higher levels is constructed 'on the shoulders' of the one below. (As remarked in Chapter 7.iv.h, it's a special case of the boundedness of rationality being a Good Thing.)

For example, Elman (1993) soon found that his networks failed to learn satisfactorily if the initial input set contained complex structures. By experimenting, he discovered that if the first inputs were all simple, more complex sentences could be learned later. It was as though the basic syntax was distinguished first, initiating a series of stepping stones leading to the full grammar.

This result fitted well with the view of some psycholinguists at the time, that parents use a special dialect ('motherese') when talking to infants (see Chapter 9.vii.c). The syntactic simplicity of motherese, it was said, enables the child to acquire grammar. However, those claims were by now controversial; and Elman, in particular, wasn't convinced. One problem was that even if parents do use motherese, children overhear adult conversation too—so why aren't they confused by that? Is the mere lack of active engagement enough to protect them?

Accordingly, Elman changed his strategy. Instead of minimalizing the network's input (environment), he now minimalized its memory. That is, he added a procedure that automatically 'emptied' the context units after every third or fourth input word, by resetting their activity to zero. So whereas these units had originally been designed to save traces of *all* of the network's previous activity (see above), they now held the impress of only the previous one to four words.

Clearly, the revised network had a good chance of learning *John punched Jack*, but not *John punched Jack hard on the nose*. And so it turned out: the new network could learn only sentences within the memory span of the context units. Once that had been achieved, however, Elman gradually increased the memory span, and found that this enabled the system to learn increasingly complex sentences. This strategy wasn't wholly 'artificial': evidence already existed suggesting that limits on human memory span affect the complexity of parsing, and explain 'garden-path' sentences (Chapter 7.ii.b).

The moral Elman drew was that if a recurrent network—whether artificial or biological—is learning something from scratch then a weaker, smaller-span, memory isn't a flaw (as he had earlier assumed). On the contrary, it's an advantage. Hence the subtitle of Elman's 1993 paper: 'The Importance of Starting Small'.

Babies and infants, he assumed (he wasn't an unreconstructed nativist: see 7.vi.g), learn virtually everything from scratch. Suppose there were some maturational process—myelinization of nerve fibres, perhaps?—that gradually extends the child's memory span. If so, it could afford domain-general assistance, and would result in abilities developing from simpler to more complex forms.

Developmental minimalism had started (for Elman) as an ad hoc computational trick, designed to avoid disappointing empirical results. But it was soon recognized as relevant to learning and development in general. The central principle was the need for repeated recoding, or representational trajectories.

d. Pathways for representation

The term "representational trajectories" was due to Andy Clark, a philosopher at the University of Sussex (1993, ch. 7). But the basic idea had been stated in the 1970s by Annette Karmiloff-Smith, then working with Piaget in Geneva, and formed the core of her theory of "representational redescription", or RR (1992). As we saw in Chapter 7.vi.h, RR theory posited the spontaneous development of increasingly powerful and flexible representations in the infant's mind.

Now, in the 1990s, she and Clark related it to the constraints faced by *any* learning system (A. J. Clark and Karmiloff-Smith 1993; Clark 1993). And soon afterwards, Clark and Chris Thornton (an AI colleague at Sussex) outlined a method whereby a PDP system could use representational trajectories to learn increasingly complex structures (A. J. Clark and Thornton 1997; Thornton 2000).

Their key insight was that the new perceptrons were limited in principle much as the old ones had been. Instead of linear separability, the focus now was on statistical regularity. Some regularities in the input are so clear that even an 'uninformed' learner can spot them. (Hence Mead's triumphalist remark quoted in the preamble of this section.) Others are more subtle, more elusive. In these ("Type-2") cases, the learner needs to know something about what regularities to look for if he/she/it is to have a realistic chance of finding them.

In effect, this was a generalization of Chomsky's anti-empiricist argument about the need for some innate grammar to support language learning (Chapter 9.vii). But unlike Chomsky, Clark and Thornton allowed that a suitably 'informed' learner may *either* be built/evolved to possess such guidance from the start, *or* may somehow learn, or construct, it for itself. What is needed in either case is a recoding of the input data, to make the marginal regularities stand out. A sequence of such recodings is a representational trajectory.

One example is Elman's research on increasingly complex grammars; indeed, Clark and Thornton described their work as an extension of Elman's.

* Another is the sequence of redescriptions posited by Karmiloff-Smith, whereby an automatic skill—such as drawing, or speech—develops into a flexible, generalized, and consciously self-reflective activity (see Chapter 7.vi.h).

* Yet another is the series of visual computations involved in constructing the Marrian Primal Sketch (Chapter 7.v.b–d).

* And yet another is the history of scientific theories and analogies used in developing current optics (P. M. Churchland 1995: 271–86) or astronomy (Thornton 2000, ch. 3). If Aristotle, or even Isaac Newton, were to come back today, we couldn't teach them modern physics by simply *telling* them: they'd need a sequence of conceptual bootstraps.

In general:

> [A] wide variety of superficially distinct ploys and mechanisms can be fruitfully understood in these terms. Such ploys and mechanisms range from simple evolved filters and feature detectors all the way to complex cases involving the use and reuse of acquired knowledge. The goal, in every case, is to systematically reconfigure a body of input data so that computationally primitive learning routines can find some target mapping—that is, to trade representation against computation. (A. J. Clark and Thornton 1997: 57)

The "ploys" used by *Homo sapiens* include a host of examples based in language, writing, technology, and cultural institutions. These are all "adaptations enabling this representation/computation trade-off to be pursued on an even grander scale" (p. 57), and are essential for, even intrinsic to, distinctively human thinking. So far, so psychological—but Clark would soon use this point to ground an unorthodox philosophy of the self (see Chapter 16.vii.d).

Non-human animals can't generate these language-based "cognitive technologies" (Clark's term, borrowed from Bruner: 6.iii.c). But even they needn't possess inbuilt modules suited to every structure they can learn, provided that they can recode the current information. If we want to understand why different species have different learning limits, we must ask how their representational trajectories differ, and why.

At the end of the century, Thornton told a fairy story about a Machine That Can Learn Anything—let's call it MTCLA (Thornton 2000, ch. 1). According to its designer, and to "no fewer than three TV stations", this machine never failed to make the correct association (to pick up the regularity concerned) in the majority of cases, *no matter what* problem it was presented with. What's more, the designer wasn't lying. Nonetheless, it turned out as the story proceeded that MTCLA was a confidence trick—or rather, three.

* First, its achievements were too few to be useful. A success rate of 50.01 per cent would satisfy the "majority of cases" criterion, but for any practical purpose it needs to be much higher. (Whether 100 per cent reliability is required, or even possible, is a question discussed by philosophers of science as well as by stockbrokers: Thornton 2000, ch. 9.)
* Second, the users of the fabled machine had to specify its learning tasks in a highly restricted way. In short, the power lay in the input representation. (Compare the so-called *General* Problem Solver: see Chapter 6.iii.c.) If no suitable input could be found, the machine wouldn't actually *fail*, because it couldn't be presented with the problem in the first place.
* And third, every problem that could be presented was trivial: a simple statistical trick sufficed to learn the regularity.

In fact, this wasn't a mere fairy story. The networks of Rosenblatt, Widrow, Hopfield—and now, PDP—had involved comparable hype, and comparable con tricks. The moral of Thornton's mocking tale was that, even after forty years of connectionist research, the core of (non-trivial) learning had hardly been touched.

If we really want a machine that can learn anything, he said, we must provide a domain-general method whereby the learner can produce useful truths from what looks, initially, like "trash". It looks like trash because of what Clark had called "snowblindness" (1993: 149), in which the system is (at first) so overwhelmed by detail that it can see neither the high-level regularities nor even the lower-level ones. Building on their joint 1997 paper, Thornton described an incremental process of recoding ("recursive relational learning") that provides a series of "scaffolds" for learning.

On this account, learning is continuous with creativity:

> Without the ability [for] relational learning, an agent is . . . effectively *trapped* within its immediate sensory space. Its only recourse is the establishment of simple partitions within that space. But [with] relational learning, the agent acquires the ability to escape its immediate embodiment—to interact with properties that are not explicitly manifest in the world to which it has direct sensory access. (Thornton 2000: 181)

As the number of recoding levels rises, the highest ones are "substantially the creative artefacts of the learner's *own* processing . . . [i.e.] their properties are [less] severely constrained by the source data" (p. 193).

Thornton didn't claim that his method could learn literally *anything*, nor that the human brain can do so. There may be inescapable constraints on the recodings that are possible in human thought. It's sometimes suggested, for example, that we won't ever understand the relation between brain and consciousness, much as dogs won't ever learn arithmetic (see Chapter 14.x.d). But if we want to understand systems that even *approximate* an MTLCA, we must allow for representational trajectories.

e. The importance of input history

As for just what these trajectories will be, it became increasingly clear that the input history—the temporal sequence of the trash—matters. For instance, how (and whether) a PDP system learns to emulate rule-governed syntactic processing depends on its training history.

Elman's decision to present simple sentences before complex ones was an early illustration of this point. But in the early 1990s, the effects of more subtle variations of the training set were explored by the Oxford developmental psychologist Kim Plunkett, with Virginia Marchman and Chris Sinha (Plunkett and Marchman 1991, 1993; Plunkett and Sinha 1992). Their test bed was an improved version of the past-tense learner described in Section vi.e (they'd added a hidden layer, and backprop).

Instead of artificially 'splitting' the input, they presented a fixed vocabulary set in varying quantities and proportions, and in varying orders. They found that both gradual and sudden (stagelike) changes in performance are driven by internal reorganizations that depend crucially on the input history. For instance, a training sequence can sometimes inhibit later learning that would have been possible if a different input sequence had been used.

In doing this study, they had to analyse the network's performance in greater detail than Rumelhart and McClelland had done. Beyond considering the overall statistics, they tracked the learning of individual verbs, and of distinct sub-groups of regulars and irregulars. They found many differences in the pattern of errors and error recoveries concerned, often including "regressions" in which old errors returned and/or new ones appeared as learning progressed. Another interesting result was contamination by irregulars, as certain regular verbs were apparently assimilated to subclasses of irregulars.

In all these cases (and others), developmental linguists had recently observed similar error patterns in children. In both humans and PDP systems, then, the learning of the past tense is a more complex—and contingency-driven—phenomenon than had previously been suspected.

But why stop at the past tense? Plunkett found that the effects of different input histories were often predictable, given the general properties of the PDP system concerned (the learning rule being used, and the constraints necessarily involved in storing many distributed patterns in a single network). The moral, then, was that *in general* input histories matter. One might say this insight wasn't new: as we've seen, Hopfield had asked how many units should be set correctly at the start to give optimal results. But no one had studied the effects of *extended* training histories in such detail.

12.ix. Still Searching

The four advances considered so far—recurrent nets, developmental minimalism, representational trajectories, and input histories—were closely linked, as we've seen. The other three were more diverse.

Research on multi-networks, hybrid systems, and constructive networks used very different methods to increase the power of connectionist systems. One even risked betraying the faith by resurrecting GOFAI, though admittedly only in combination with networks. By the turn of the twenty-first century, however, these too still left much to be done.

a. Assemblies of cell assemblies

An early instance of a multi-network was described in the PDP books, namely, the noughts-and-crosses player mentioned in Section viii.a. An even earlier example had been outlined by McCulloch in the late 1960s, in his controller for a Mars robot (Chapter 14.iv.a). Others were sketched or implemented later.

For example, Clark and Karmiloff-Smith (1993) suggested that a new network might come to represent the inner structure of an older one in a more "symbolic" way as a result of skeletonization (cf. Chapter 7.g). This technique copies an initial net into another one, and then prunes the connections that correspond to inessential, relatively inactive, connections in the first (Mozer and Smolensky 1989).

But two-network systems, such as these, are unrealistic. Hebb had argued long ago that adult human brains must involve numerous cell assemblies; and if Minsky and Papert's "society of mind" theory was on the right lines, then complex intelligence requires many interacting networks (iii.d, above). The PDP group agreed. As Norman put it in their manifesto:

> [People] can do multiple activities at the same time, some of them quite unrelated to one another. So, in my opinion, a PDP model of the entire human information processing system is going to require multiple units. That is, the complete model requires that the brain consists of several (tens? hundreds? thousands?) of independent PDP-like systems, each of which can only settle into a single state at a time. (Norman 1986*b*: 542–3)

Moreover, each of these "independent PDP-like systems" would very likely be a modular hierarchy itself.

This claim may have seemed strange to readers over-impressed by the connectionists' constant references to representations being "distributed over the *whole* network". But the PDP group's earlier work in GOFAI had already alerted them to the need for hierarchical structure. What's more, backprop had been designed with this in mind:

> One of the best and commonest ways of fighting complexity is to introduce a modular, hierarchical structure in which different modules are only loosely coupled [here, Hinton cited Simon's *Sciences of the Artificial* (see Chapter 7.iv.a)] . . . Self-supervised back-propagation was originally designed to allow efficient bottom-up learning in domains where there is hierarchical modular structure . . . It is possible to learn codes for all the lowest-level modules in parallel. Once this has been done, the network can learn codes at the next level up the hierarchy. The time taken to learn the whole hierarchical structure (given parallel hardware) is just proportional to the depth of the tree . . . [although] it is helpful to allow top-down influences from more abstract representations to less abstract ones, and [this has been done in] a working simulation. (Hinton 1989: 228)

Hinton's recommendation of "top-down influences from more abstract representations" was yet another example of GOFAI footsteps preserved in the connectionist sand.

If PDP could provide massive modularity in principle, however, it didn't follow that it could do so in practice. Hinton's reference (above) to a "working simulation" didn't mean that large multi-network systems were practically feasible by 1990, for they weren't. But it was already clear that one of the most important aims of PDP research into the next century would—or anyway, should—be to master this problem.

That qualification ("or anyway, should") is necessary because there was surprisingly little work on this topic in the 1990s. To be sure, the anthropologist David Hutchins (1995) modelled the interacting roles within a ship's crew (a part-hierarchical assembly) by way of *networks of networks* (see Chapter 8.iii.b). And some researchers, including Jordan and Hinton, soon developed pattern recognition systems within which distinct sub-networks emerged that were sensitive to different aspects of the input—men's, women's, or children's voices, for example, or a particular vowel (Jacobs *et al.* 1991).

This was done by extending the 'winner-takes-all' approach from single units to groups of simultaneously active units. (In a winner-takes-all network, the learning rule doesn't increase the weights on *all* the units, but only on the most highly activated one.) A higher-level 'referee' sub-network was backprop-trained alongside the emerging experts, to decide which mini-network should be the winner when more than one was activated by a certain pattern.

In effect, this was a self-organizing PDP system that learnt to mimic a simple version of Pandemonium. But a multilevel Pandemonium, or the interacting "multiple unit" hierarchies mentioned by Norman, would be harder to implement—never mind to learn.

Much as the early computational psychologists had abandoned multi-motive systems, because getting a program to pursue one goal was difficult enough (see Chapter 7.i.b), so PDP workers found that getting a network to achieve a single task was more challenging than they had expected. This is just what Thornton's analysis would predict: many interesting tasks are Type-2 problems, requiring one or more levels of recoding—which 1990s networks couldn't deliver. Accordingly, hardly anyone tried to address the sort of multi-network complexity that Norman had in mind. (An interesting exception, based partly on his own psychological theory, is described below.)

Many focused instead on continuing the mathematical turn described in Sections iv–v, seemingly forgetting that the original purpose of perceptrons had been psychological. As Thornton put it in 2001 (personal communication):

> My perception is that connectionists are currently executing a kind of mass retreat into mathematics, perhaps in a subconscious attempt to deny operational reality. Certainly the kind of psychologically-aware approach pioneered by Geoffrey Hinton [in his models of semantic memory] doesn't get much of a look-in these days. (Thornton 2001, personal communication)

To be sure, the 1990s had seen significant work on 'real' learning, some of it deeply informed by psychological and/or neuroscientific data (O'Reilly and Munakata 2000). But, as yet, there was little overlap between the biologically oriented connectionists and their more analytically oriented cousins. The conferences described in Section vii.a (above) were driven by the hope that empirical and analytic workers would collaborate, the distinction between them becoming much less clear. That hope hadn't been fully satisfied—which is why most of the research described below is more mathematical than psychological, and more psychological than neurological.

b. Hands across the divide

The assumption—shared by the PDP group and society-Minsky—that much human thinking requires some *combination* of connectionist and GOFAI methods led to a new research field: hybrid systems. This term is sometimes used to mean programs/robots that combine situated and deliberative procedures (see 7.iv.b and 13.iii.c). More often, however, it's used to mean systems combining connectionist and symbolic architectures.

The general idea of combining two very different types of computation in one machine wasn't new. Indeed, it dated back to the earliest days. MacKay, with McCulloch's encouragement, had suggested developing part-analogue, part-digital computers in the late 1940s (MacKay 1949/1959). By the mid-1960s, he was even saying:

> We on the circuit side had better be very cautious before we insist that the kind of information processing that a brain does can be replicated in a realizable circuit. *Some kind of 'wet' engineering may turn out to be inevitable.* (Mackay 1965: 329; italics added)

Minsky had said in his widely read paper 'Steps Toward Artificial Intelligence' (available in draft from 1956 on, and published in 1961) that hybrid architectures would probably be needed (Chapter 10.i.g). A few years after that, Reitman (1965) had built Argus as an exercise in combining sequential and parallel processing (see 7.i.b). Since then, however, hardly any work had been done on it.

Some commentators in the mid-1990s expressed impatience that this combination hadn't already been achieved:

> The whole field has been hovering around this issue, pendulum-like, for over three decades and it is time that these two approaches are reconciled, so that we can begin to take advantage of and build on the strengths of both. (Honavar and Uhr 1994, p. xiii)

After all, the two types of AI were in principle equivalent, since both were using general-purpose computational systems. In practice, however, they were different. The *degree* of difference was a matter of taste, not to say self-regard or professional pride (I was reminded of the horse in *The Wizard of Oz*, whose colour changed with the lighting as it trotted along: Boden 1991). But there were differences nonetheless, and it wasn't clear how they could be surmounted. (For the record, it still isn't.)

The organizers of a 1995 conference on the topic located the core problem in the ontologies we use to describe the world. As they put it, we must somehow "reconcile the static ontologies of standard knowledge representation with a continuously changing world described using the ontologies of physics" (Hallam 1995, p. v). In other words, we must find a way to translate effectively between von Neumann's "primary" and "secondary" languages (see Section i.c). What is needed, they said, is "a theory able to treat continuous and discrete processes and their interactions in a uniform way"—and that was still distant.

Perhaps, other authors added, it was even impossible:

> There is no clear method for ensuring the preservation of a symbolic algorithm in a dynamical equation that does not itself constitute an algorithm; nor one for ensuring the preservation of a symbolic semantics (or function) in a connectionist account of the discipline of real world entities . . . There is no possibility of an exact mapping between the connectionist and the symbolic. (Franks and Cooper 1995: 69)

This question couldn't be decided, they argued, until we have a better way of individuating algorithms. The current definition relies on the intuitive notion of a "step", which might be interpreted in differing ways. This raises questions about all computer models, hybrid or not, and "the issue remains to be solved by the cognitive sciences" (p. 70).

Meanwhile, a useful distinction was made between three types of hybridization—only one of which reflects hybrid psychological theories (Franks and Cooper 1995). In the first, two *physically* distinct types of computer architecture are used to compute different functions. For instance, a rule-based expert system implemented in a von Neumann machine might use neural networks on VLSI chips to recognize some rule-triggering patterns. This may be fine for engineering purposes, but it doesn't reflect the physical construction of the brain.

In the second type, the hybridness is viewer-dependent, since it rests on how one chooses to *describe* the system. For instance, the past-tense network can be described either as a PDP model or *as if* it were a rule-learner. The psychological theory being modelled, however, was purely connectionist. Only the third type is "truly" hybrid, in that the system's behaviour is generated by both connectionist and symbolic functions, *and* by theoretically significant causal relations between them.

The PDP bible itself had suggested that, in doing paper-and-pencil arithmetic, one combines perceptual pattern matching with rule-governed mathematical reasoning. Most PDP modelling wasn't driven by psychological theories that featured strong interactions between symbolic and connectionist processing. But Hinton (1988/1990) made an early attempt, by combining PDP with localist connectionism in order to represent part–whole hierarchies—such as family trees, for instance.

The localist network was a reduced version of the distributed one, wherein the 'relevant' units could be identified and accessed more directly. In other words, "the very same object can be represented in different ways depending on the focus of attention" (Hinton 1988/1990: 65). Putting the same point the other way around, he said:

> [Some] patterns of activity in [the network] need to exhibit the double life that is characteristic of symbols. The patterns must allow remote access to fuller representations, but so long as the patterns are also reduced descriptions this remote access need only be used very occasionally (e.g. a few times per second in a person). Most of the processing can be done by parallel constraint satisfaction on the patterns themselves. (p. 49)

And rationality, as opposed to intuitive thinking, was shown *not* to be a matter of seriality. Its defining characteristic, rather, was that "the way in which entities in the domain are mapped into the hardware *changes* during the course of the inference" (p. 50; italics added). It followed that the crucial GOFAI assumption—that fast intuitive inference is similar in form to conscious inference, but without the consciousness—was judged by Hinton to be "a major psychological error" (p. 72).

Hinton's 1988/1990 approach was soon developed by others (J. B. Pollack 1990; Chalmers 1990; Plate 1995; Sperduti 1992; Sperduti and Starita 1994; Goller and Kuchler 1996; Goller 1999). So his *distributed reduced descriptors* later gave way to *recursive auto-associative memory* (RAAM), *holographic reduced representations* (HRRs), *labelling recursive auto-associative memories* (LRAAM), and *folding architecture networks* (FANs). In general, these new acronyms named methods by which vectors representing the individual components of a compositional structure were combined into a single vector standing for the whole structure. However, although they were more powerful than Hinton's family-tree program, they still couldn't deal with large-scale tasks: only small examples were tractable.

Hierarchy is important not only in linguistic behaviour, such as family trees or syntactic parsing. As Lashley pointed out (5.iv.a), it's an observable feature of motor skills in general. And if Simon was right in his *Sciences of the Artificial*, it's also near-inevitable, for reasons of processing economy. Indeed, recent neurological work shows that the spinal cord itself (not just the brain) stores a number of basic motor functions as *patterns* of individual muscle activations, which mini-hierarchies are combined in various ways to produce larger-scale action sequences (Mussa-Ivaldi 1999; Tresch *et al.* 1999). It follows that weakness in handling hierarchy is a severe drawback for any computational methodology that hopes to simulate even non-intellectual behaviour.

By the mid-1990s, there were several part-PDP working models that took psychological hybridization seriously. (The long-established family of ACT architectures outlined in Chapter 7.iv.c were hybrid in spirit, but didn't come from the PDP stable.)

One of these learnt to cope with simple arithmetic—specifically, the multiplication tables (J. A. Anderson *et al.* 1990*b*). The number-names were stored symbolically, but the numbers were also represented (according to their size) on a "sensory" topographic map. The justification for this was the fact that many (most?) humans seem to represent numbers spatially, especially when making judgements about relative size.

"Coping with" arithmetic, in this case, didn't mean conquering it. Like Dr Johnson's dog walking on two legs, the wonder was not that the system did its task well but that it did it at all. For it made many mistakes: 30 per cent errors in multiplying two integers. However, most of these were "intuitively reasonable", and matched a variety of error-types observed in human beings. Tongue-in-cheek, the authors declared: "It may seem remarkable to spend hours of supercomputer time to obtain the wrong answers to simple arithmetic, but that is cognitive science."

Another PDP hybrid was implemented by the neuropsychologist Shallice (now at UCL's Institute for Cognitive Neuroscience) and other London-based colleagues (Cooper *et al.* 1995). It was based on the theory of action that Shallice had developed in the late 1970s with Norman, a PDP group member who had worked for many years on the psychology of error (D. A. Norman and Shallice 1980/1986).

Whereas Norman had focused on everyday cases, such as typing errors (Rumelhart and Norman 1982), Shallice added clinical examples. Besides his interest in dyslexia (which he and his colleagues continued to model: Plaut and Shallice 1993; Plaut *et al.* 1996; Plaut 1999), Shallice was an expert in clinical ataxias, or disorders of action.

For instance, brain-damaged patients may apparently forget that the letter should be put in the envelope before the sticky flap is licked, or frequently get into bed on going upstairs to change their clothes, or pick up the kettle when they mean to pick up the teapot. Similar mistakes—errors of *order*, *capture*, and *object substitution*, respectively—occur occasionally in all of us (and Norman had asked "Why?"). But they're much more common in certain clinical syndromes. Moreover, brain-damaged patients can't easily recognize or correct them, whereas normal people can.

In 1977–8, on first reading about GOFAI planning, Shallice told me of his hopes that this approach might help him analyse such errors. But he soon decided that connectionist ideas were needed too. He and Norman argued in 1980 that over-learned action is generated by one or both of two types of control. Errors, of differing classes, occur when one or both of these controls breaks down at specific points.

The first control mechanism ("contention scheduling") is automatic. It involves competition between various interacting and hierarchically organized action schemata. Control goes to the one whose activation passes some threshold.

The second mechanism ("executive control") is attentional—that is, conscious. Because this involves deliberate supervision and modulation of the operation of the first, it's sometimes called the supervisory attentional system. (An action schema is defined by a goal, and a partially ordered set of sub-goals; each schema controls a partially ordered sequence of actions.) It's required in five types of situation:

* planning or decision making;
* especially difficult actions;
* repairing mistakes;
* inhibiting a strong already learnt response;
* and learning new actions.

The original theory had been purely verbal: the techniques available in 1980 couldn't produce a computer model. Fifteen years later, Shallice's team built a model that simulated both normal error-free behaviour and, with different parameter settings, patterns of error seen in various clinical syndromes, including Parkinson's disease.

Their prime example was coffee making. This wasn't a trivial, spur-of-the-moment, choice. They focused on coffee making partly because it's a familiar multilevel action schema. But they picked it also because it had been closely studied in neurological patients. In short, there was already a detailed 'library' of errors in coffee making, observed in both normal and brain-damaged people.

This study, which turned out to be very influential, was part of a more general programme of research in computational psychology (Cooper *et al.* 1996). One of the core collaborators was John Fox, of the Imperial Fund for Cancer Research—a long-standing leader of expert-systems work in Great Britain. That was no accident, for the team saw both GOFAI and PDP as essential:

> The implementation is hybrid in that it contains components which carry out continuous-valued operations using a broadly interactive activation approach [based on the late 1970s work of Grossberg, McClelland, and Rumelhart] and other components which carry out discrete symbolic operations. (Cooper *et al.* 1995: 28)

They pointed out that this connectionist–symbolic mix wasn't a mere implementation detail, or engineering 'fix', but crucial to the psychological theory being modelled. The discrete, serial, symbolic aspect concerned the *selection* of this or that action schema or goal (sub-schema, sub-goal . . .) at a given point in the action sequence. The connectionist aspects regulated the *levels of activation* of the schemata in varying circumstances.

To some extent, the activation levels depended on the simulation of neuroscientific factors, such as lateral inhibition and dopamine concentration. Future research, the team said, would consider a range of neurotransmitters; differing reaction times for different senses; finer-grained object representations; and the attentional level of control (the 1995 program concerned only the automatic level). Each of these additions should result in a more discriminating and more realistic model of errors.

For instance, suppose that the sugar sachet mentioned in the plan schema were represented not only (as in the 1995 model) by *is-sachet* and *contains sugar*, but also by other perceptual and semantic features. In that case, one would expect more "substitution" errors, in which one object is picked up instead of another which shares some features and/or associations with it.

Besides applying to everyday errors and to debilitating psychopathology, the Norman–Shallice theory has been applied to hypnosis (see Chapter 7.i.g). With the help of philosophical work defining various levels of "explicit" and "implicit" representation, hypnosis can be explained as executive control *without* the highest level of explicitness—at which the person not only has an intention but knows that, and can report that, they have it (Dienes and Perner forthcoming). The intention can be monitored and flexibly executed by the hypnotized person. But these processes go on without conscious attention.

In sum, there's a growing appreciation that we need both GOFAI and PDP to model the mind. Michael Arbib, when he was interviewed for the "oral history" of connectionism, put it like this:

> I don't believe that neural nets are a magic panacea. I think there's still a place for knowing how to add numbers exactly, rather than using a neural net. *I think in the future we'll see hybrid systems* where we have something like schema theory [see Chapter 14.vi.c] or modular design to understand how to take a complex problem, break it into pieces, and then for *some* of those pieces find that neural nets will do the best job. (J. A. Anderson and Rosenfeld 1998: 236; italics added)

c. Constructive networks

Quite soon, connectionists began to experiment with "constructive" networks. In these, the number of hidden units didn't have to be decided by the designer. For hidden units could be deleted or added during the running of the system. (A wide range of examples are compared in Fiesler 1994.)

Self-deleting networks were defined by Rumelhart as early as 1987. Starting with many hidden units, these were selectively pruned—weights were permanently reduced to zero—so long as this reduced the overall error. This approach was sometimes compared to 'neural selection' in the brain, in which profuse neuronal connections are progressively pruned as a result of experience (Chapter 14.x.d). In essence, however, it was a slight variation of the normal PDP network: some weights were eliminated once and for all, not merely (temporarily?) reduced.

The complementary type of constructive network, in which hidden units are added, is more interesting. One influential example was developed by Fahlman (Fahlman and Lebiere 1990). His "cascade correlation" networks started out with no hidden units at all: the input units were directly connected to the output units. But they added new ones incrementally until the error couldn't be further reduced. Each newly added unit would be randomly connected to the input layer, and would receive input also from the previously added hidden unit—hence the name, *cascade* correlation.

This network construction was a cycle of two phases. Even before the first hidden unit was added, some learning would take place, during which the (direct) input–output weights were adjusted in the usual way. Cascade learning would start when these weight changes had settled to equilibrium. A number of potential hidden units would be provisionally added, and their performance monitored. The one found to be most efficient in reducing error would then be permanently included. After another 'normal' learning phase in which the whole network (now carrying a new hidden unit) adjusted its weights, the cascading would kick in again—and so on, until no current provisional unit was able to improve performance.

Cascade correlation enabled networks to emulate certain aspects of GOFAI programs. For example, we saw in Chapter 7.vi.g that Piaget's developmental theory of seriation—the ability to produce rank order, as in building a staircase out of blocks—posited a final stage in which the child apparently plans his/her actions as a rationally ordered sequence. We saw, too, that his three-stage theory was first simulated by GOFAI programs (e.g. Richard M. Young 1976). This is perhaps just what one would expect, given the GOFAI-ish nature of the final behaviour. But we also noted that a connectionist model of RR for seriation was achieved twenty years later (Shultz 1991; Shultz *et al.* 1994, 1995). This was done by using cascade correlation. Two separate output layers were required: one to decide which block to move, the other to decide where to put it.

One might object, however, that this seriation network involved cheating. For the error assessment didn't use a perceptual test, but relied on Piaget's formal–operational rule for building a staircase: *Move the smallest block that is out of place into its correct place*. In other words, it's not clear that the connectionist system was generating GOFAI-type performance 'spontaneously'.

d. What had been achieved?

By the end of the century, as we've seen, the lost strengths of symbolic AI hadn't been fully recovered. Research, not to say *Recherche*, remained necessary.

In practice, many people decided to *combine* rather than to *recover*. As Arbib said in 1993:

> There is so much fast-computing hardware around that a lot of ideas which were purely theoretical in the '70s are now eminently practical in the '90s . . . A lot of work now has to be either very focused, on a very specific application, or you have to develop a hybrid system where you apply some standard signal-processing and some standard AI expert systems stuff, using a neural net for a module or two. I think the day of the magic single neural network has gone. (J. A. Anderson and Rosenfeld 1998: 235)

But there were now many more ways to skin a connectionist cat (and yet more arcane statistical mathematics used to do so). To mention just a few, most of which have been discussed above:

* Some networks used basic computing elements (as identified by the mathematics) that were implemented not as single units but as groups of interconnected units, or "neuron pools" (Amari 1977).

* Besides a variety of learning rules that adjusted weights on existing connections, there were others that added new links and pruned old ones.

* Some learning happened across generations instead of in individuals, using the newly popular technique of genetic algorithms (Chapter 15.iv); an example involving a PDP group member, namely Elman was (Nolfi *et al.* 1994).

* Some connectionist work led back to Hopfield rather than PDP: 'attractor' neural networks were completely connected nets, understood as dynamical systems converging towards various attractors (global equilibrium states) as a result of different inputs, or 'perturbations'.

* The puzzle of how to enable ANNs to deal with hierarchy was addressed by methods in which a network could contain representations of a whole as well as representations of its parts—although, as remarked above, only small-scale tasks were tractable.

* Some people, such as Shallice, developed truly hybrid systems, in which neural networks and GOFAI components were combined.

* Judea Pearl (1988) described how to use (non-recurrent) Bayesian networks to do approximate inference, or reasoning, not mere pattern recognition.

* And, building on Pearl's work, methods for "loopy belief propagation" (LBP) enabled recurrent networks containing many loops, of different sizes, to converge instead of running endlessly (McEliece *et al.* 1998; Murphy *et al.* 1999; Yedidia *et al.* 2000). LBP is now being used for various purposes in computer vision (e.g. Coughlan and Ferreira 2002; Sigal *et al.* 2003; Isard and MacCormick in preparation), and applied also to make inferences of a type that would previously have been handled by a GOFAI expert system—medical diagnosis, for example.

Moreover (as we'll see in Chapter 14), the distinction between neural networks as an AI technology and as a way of modelling the brain was becoming less clear. For example, attractor networks were studied in relation to Walter Freeman's dynamical theory of the neurophysiology of perception (see Chapter 14.ix.b). And in 1998, Hinton was appointed head of the new Gatsby Computational Neuroscience Unit, at University College London.

Hinton's reputation, already high in the 1980s, had soared still higher: Cowan said the best advice he could give to a young researcher would be to "try to work with Geoff Hinton" (J. A. Anderson and Rosenfeld 1998: 124). At the outset of the new century, he received the first Rumelhart Prize for "contributions to the formal analysis of human cognition". This wasn't, you'll notice, a prize confined to connectionists. Accordingly, it was awarded at the 2001 (Edinburgh) meeting of the Cognitive Science Society.

More generally, connectionists moved towards techniques inspired by neuroscience (see Chapter 14). Some new learning rules, for instance, took account of spiking frequencies and synchronies, while others modelled the effects of widely diffusing chemicals in the brain. One, based on the functioning of the cerebellum, was "two to four orders of magnitude faster" than backprop (McKenna 1994: 79, 82).

The influences went both ways. A persuasive computational argument for localism—recently swamped by the D in PDP (*pace* Hinton's localist–PDP mix: see above)—implied that neuroscientists should *expect* to find grandmother cells as well as cell assemblies. The localist resurrection (and grandmother's revenge), however, had to await the new millennium (Chapter 14.x.e). In the last twenty years of the old one, unalloyed PDP was the most high-profile form of connectionism.

12.x. Philosophers Connect

The high visibility of PDP, described in Sections 8.vii–viii, was largely due to its *philosophical* interest. At an informal level, this was true of its appeal to journalists and the general public. But the professional philosophers were involved too. PDP was widely perceived by them as a more human alternative to classical functionalism (Chapter 16.iii–v), and also as a counter to Chomsky's nativist philosophy of mind (9.vii). Most of the interest came from analytic philosophers already sympathetic to cognitive science—although, as remarked in Chapter 1.iii.d, some postmodernists saw connectionism as buttressing their own, very different, approach (Globus 1992; Canfield 1993; Wilson 1998). But the GOFAI classicists fought back, as we'll see.

The widespread debate involved not only card-carrying philosophers, but also leading model-builders on both 'sides' of AI.

a. A Pulitzer prelude

Many philosophers first became aware of (broadly) connectionist ideas in 1979–80, as a result of Hofstadter's book *Gödel, Escher, Bach: An Eternal Golden Braid* (1979). This extraordinary intellectual and rhetorical feast drew many people to cognitive science, including what would later be called A-Life, for the first time. In addition, it inspired some already within the field to think about computation in a fundamentally new way.

One example of the latter was Mitchel Resnick, whose work on StarLogo was the result (Resnick 1994, p. xvii, and Chapter 12.iii.d). Another was Randall Beer (personal communication), then a graduate student writing GOFAI programs. His vision of how one might approach AI problems was irreversibly broadened by reading the book (see 15.vii.c and viii.c).

Begun in the early 1970s, the manuscript was essentially complete when Hofstadter joined Indiana University in 1977, in his first 'real' job. (He remained at Indiana thereafter, apart from interludes at MIT in 1983–4 and at the University of Michigan from 1984 to 1988.)

Being utterly impossible to pigeonhole, and very long to boot, it didn't easily find a publisher. This was so even though Hofstadter himself would do the highly complex, and potentially expensive, 'typesetting'. Fortunately, Martin Kessler of Basic Books was prepared to fight for it, provided he could find a non-US partner to share the risk. As the co-founder of the British publishers (Harvester Press), I had to fight for it too. On being told (by the other co-founder) that it was "totally unintelligible", I said it would either "fall deadborn from the press" like Hume's *Treatise* or become a cult book—but that we shouldn't be publishing at all if we weren't willing to accept such a hugely original, and insightful, manuscript.

A cult book, indeed, it turned out to be. And the cult was worldwide: *GEB* was translated many times. It soon won a Pulitzer Prize, and is still much admired. In 1999 the *New Scientist* magazine asked the mathematician John Casti to invite several people to choose a science book from the last quarter-century to take to a desert island; three, including Casti and myself, chose this one. (I had to make a second choice, as a result. I picked Andrew Hodges' biography of Turing: a rich book for British social history, not just for science/mathematics.)

Hofstadter explored, and insightfully interrelated, many superficially diverse topics—enough for many years on a desert island. These included the art of fugue, visual metamorphoses, translation, analogy, creativity, paradoxes, Gödel's theorem, GOFAI, *Alice's Adventures in Wonderland*, ants and bees, life, DNA . . . and connectionism.

Connectionism was presented, here, less as an AI modelling technique than as a guiding idea expressed through metaphor and analogy. Ant colonies were as relevant as brains, life as mind, memory as mathematics. The fundamental notion concerned association and interaction within a highly fluid parallel-processing system, an active memory from which higher-level properties of adaptation and intelligence emerge.

Surprising as it may seem, Hofstadter hadn't been turned in this direction by the connectionist work discussed earlier in this chapter, but by the pioneering HEARSAY program:

> Perhaps the deepest influence on me personally . . . was the Hearsay II speech-understanding system, which was developed in the mid-1970's by a team headed up by Raj Reddy, and including Victor Lesser and Lee Erman, among others. Hearsay II was a highly parallel system (it actually ran on truly parallel hardware), and it was the original implementation of the famous "blackboard architecture". I still think, personally, that the ideas in the Hearsay project are every bit as deep and as important as those in the PDP volumes. (personal communication)

As this recollection shows, HEARSAY II wasn't a typical GOFAI program. Nor was the first version of HEARSAY, in so far as it was parallelist in spirit (Newell *et al.* 1973; Reddy *et al.* 1973; Reddy and Newell 1974). Nevertheless, the original research was done within the GOFAI stable, and headed by one of GOFAI's high priests: namely, Newell. This, then, is yet another reminder that the two types of AI aren't so wholly opposed as they're often assumed to be.

Soon afterwards, besides co-editing a volume on "self and soul" with a leading philosopher of mind (Hofstadter and Dennett 1981), Hofstadter wrote several pieces on analogy and creativity in the *Scientific American* (many of these are reprinted in Hofstadter 1985*a*). He'd been invited in 1981 to alternate with Martin Gardner in a regular column, and ran it alone for a while on Gardner's retirement in 1982. And in 1983 he wrote a paper for an interdisciplinary volume which, when it was reprinted—with a new Post Scriptum—alongside some of his *Scientific American* pieces two years later, was also widely influential. The message of 'Waking Up from the Boolean Dream' was this:

> [Until] AI has been stood on its head and is 100 percent bottom-up, it won't achieve the same type of intelligence as humans have. To be sure, when that type of architecture exists, there will still be high-level, global, cognitive events—but they will be epiphenomenal, like those in a brain. They will not in themselves be computational. Rather, they will be constituted out of, and driven by, many smaller computational events, rather than the reverse. In other words, *subcognition at the bottom will drive cognition at the top*. And, perhaps most importantly, the activities that take place at that cognitive top level will neither have been written nor anticipated

by any programmer. This is the essence of what I call *statistically emergent mentality*. (Hofstadter 1983/1985: 285/654; italics in 1985 original)

However, although this paper was more explicit in comparing traditional and connectionist AI than *GEB* had been, it was still rhetorical rather than technical—deliberately so, for Hofstadter was addressing a mixed, non-specialist, audience. *Precisely how* a parallel-processing system could implement concepts—and model their role in perception, memory, analogy, and thought—wasn't explained.

In the Post Scriptum of 1985, Hofstadter mentioned the PDP group, whom he'd recently visited in San Diego. He hailed their work with "delight", as "a hotbed of subversive PDP activity" (Hofstadter 1983/1985: 654). But he gave no details. He also dropped hints, in the *Scientific American* as in the Post Scriptum, about his own computer model of concepts and creative analogy (13.iv.c)—but again, no details.

He'd given seminars on his model at MIT in 1984, and a detailed lab report was made available to the cognoscenti a few years later (Hofstadter *et al.* 1987). But official publication was long delayed (Hofstadter and Mitchell 1993/1995). Indeed, actual implementation—as opposed to mouth-watering promises—had to wait until the end of the century (McGraw 1995; Rehling 2001).

In the event, then, this intriguing but difficult work made much less of a splash than *GEB*. It didn't even enthuse the professional community, in part because it didn't exemplify the now all-conquering PDP approach. Hofstadter's model of analogy was parallel and distributed, but only partially non-symbolic. So it was connectionist only in the broad sense.

Indeed, he never considered himself part of the "connectionist" movement, and avoided their conferences (personal communication). His deepest influences from cognitive science were the HEARSAY "blackboard" model and Rumelhart and Norman's work on errors (see Chapter 10.v.e and Section ix.b above, respectively).

In 1986, of course, the *Precisely how?* question was given an initial answer in the PDP manifesto (see Section vi.a). By that time, *Gödel, Escher, Bach* and 'Waking Up from the Boolean Dream' were already part of the general intellectual background. Without such hugely popular heralds, the two technical volumes from San Diego, reader-friendly though they were, might not have found such a wide and immediate welcome.

b. Connectionist concepts

The main philosophical interest of Hofstadter's approach had been his insistence that *concepts* are active, interactive, fuzzily defined (holistic), and constantly changing. This was clearly opposed to the GOFAI picture, in which "a passive memory [consists of] data-structures [that] simply wait around to be inspected or manipulated" (Hinton and Anderson 1981: 11).

Ludwig Wittgenstein had argued for a broadly similar view, rejecting the logicism of his own—and McCulloch's—younger days (Chapters 9.x.d and 4.iii.c). For him, and for his many followers, concepts marked overlapping "family resemblances" rather than lists of necessary and sufficient conditions.

In addition, philosophers in touch with cognitive psychology knew of the experimental evidence that concepts function as "prototypes" with an ill-defined penumbra of similar cases (see 8.i.b). (Few realized, however, that James Anderson, for instance, had been relating this evidence to connectionism since the mid-1970s.) So Hofstadter's ideas had fallen on well-prepared philosophical ground.

The PDP volumes endorsed such views. In general, their authors made a point not only of describing their models clearly (ball-bearings in valleys) but also of indicating their philosophical implications. In particular, they repeatedly argued that concepts aren't cut-and-dried, but inherently fuzzy. This rhetorical strategy helps explain why their books were so crucial to the culturally prominent connectionist renaissance described in Sections vi–vii. But the philosophy would have been less persuasive without the technical details.

These showed, at last, how various puzzling phenomena could happen:

* how a single concept could be distributed over an entire network;
* how several different concepts could be stored simultaneously;
* how multiple constraint satisfaction could tolerate unclarities, and even contradictions;
* how a single unit could contribute to the representation of many concepts, and
* how it could 'mean' different things in different contexts;
* how 'one and the same' concept used in two different contexts could involve different sets of units;
* how two different inputs could be classified under the same concept;
* how semantically similar concepts could be represented by similar activity patterns;
* and how a fragmentary memory could excite a whole concept.

PDP systems, then, seemed to do 'naturally' many things which brains can do—and which might underlie the conceptual abilities long highlighted by philosophers unsympathetic to GOFAI.

Strictly, the phrase "at last" (above) is unwarranted, for others had shown these things before, as we saw in Sections ii and iv–v. But very few philosophers knew that. In England, some of those at Sussex did, largely because of Longuet-Higgins's and Hinton's presence there (I myself, for example, had been writing about connectionism since the mid-1970s). But, on both sides of the Atlantic, philosophers who weren't on the AI grapevine didn't.

This applied even to Paul Churchland. He had argued since the early 1970s that the philosophy of mind, and of science, should be based on brain dynamics (16.iv.e). But while still at the University of Manitoba, and even for some time at Stanford (where he went in the early 1980s), he was unaware of connectionist AI:

> At the time [when I wrote my 1979 book] I would have guessed that a new paradigm [based on the brain] was at least twenty-five years away, and probably more like fifty.
>
> In this I was wrong, for in fact it already existed and had existed, at least in stick-figure form, since the late fifties. By 1959 F. Rosenblatt had developed the Perceptron paradigm of vector-to-vector transformations in a parallel network of neuronlike processing units . . . Unfortunately, that paradigm did not catch on, and for two decades it was almost forgotten . . . [and] faded to invisibility. (P. M. Churchland 1989, p. xiii)

Churchland first "stumbled across" ideas about massive parallelism and vector transformations in 1983, when reading about the cerebellum (see Chapter 14.viii.b–c). He used these neuroscientific ideas to buttress his long-standing philosophical views, in essays written early in 1984 and published two years later—one of them in *Mind*

(P. M. Churchland 1986*a*,*b*). Thanks to *Mind*'s high profile, that item was widely read by philosophers. But whether it convinced many of them is another question. Its account of the processes underlying conceptual thought (and sensori-motor integration) was highly speculative, and there was no mention of existence proofs from computer modelling. It was the near-simultaneous publication of the PDP bible which *proved* to Churchland's *Mind* readers that vector-transforming parallel systems really could do interesting things. In short, the PDP volumes were a revelation to most philosophers, even including those already committed to a science-oriented approach.

Functionalism seemed to have widened its grasp, to include mental—and computational—phenomena very different from the formalist Turing tables highlighted in its initial definition by Hilary Putnam (16.iii.b). The PDP group encouraged such views, saying that:

> [PDP models] in no way can be interpreted as growing from our metaphor of the modern computer . . . [and involve] a new form of computation, one clearly based upon principles that have heretofore not had any counterpart in computers. (Norman 1986*b*: 534)

Anti-logicist doctrines that had previously seemed vague now appeared to have clear empirical support, vindicating those Wittgensteinians—notably Dreyfus—who had argued for years that GOFAI misdescribed concepts (see 11.ii.a).

Indeed, Dreyfus (and his brother) soon hailed connectionism as a philosophical advance, because it allowed sub-conceptual units and didn't presuppose that there must be an explicit theory of every domain (H. L. Dreyfus and Dreyfus 1988). Their paper was one of a set of 'reviews' written for the *Artificial Intelligence* journal, but reprinted under the tendentious title *The Artificial Intelligence Debate: False Starts, Real Foundations* (Graubard 1988). This new-found sympathy for connectionism belied Dreyfus's 1979 opinion that it had produced "no interesting results" (cf. Section iv.i).

From the late 1980s onwards, then, many people saw PDP as offering a scientifically respectable philosophy of mind that made room for mental subtleties previously ignored. However, there were dissenters.

Dreyfus himself rejected connectionism, despite seeing it as less implausible than GOFAI, saying that "building an interactive net sufficiently similar to the one our brain has evolved may be just too hard" (H. L. Dreyfus and Dreyfus 1988).

Indeed, neo-Kantians in general held that a "scientifically respectable philosophy of mind" is a chimera, since there can be no naturalistic account of meaning or normative rationality (Chapter 16.vi–viii). They saw even neuroscience as philosophically irrelevant, never mind GOFAI or PDP. And John Searle, who disagreed with them on the latter point, was no more convinced by connectionist functionalism than he had been by the GOFAI variety (see 16.v.c).

Even within the functionalist camp, PDP didn't sweep the board entirely. For the leading GOFAI computationalists resisted this newly fashionable view. The central point of contention was the relation between connectionist and symbolic processing.

c. The proper treatment of connectionism?

According to Paul Smolensky (1955–), a member of the PDP group, "the proper treatment of connectionism" was to regard it as concerned with *subsymbolic*, or *subconceptual*, processing. That is: "the units do not have the same semantics as words of natural language" (Smolensky 1988: 6), and do not correspond to the categories we use "to consciously conceptualize the task domain" (p. 5). This conscious conceptualization includes not only everyday examples, but also the verbal protocols observed in problem-solving experiments (see Chapters 6.iii.b–c and 7.iv.b).

Typically, a PDP unit represents some tiny detail or microfeature, whose individual significance may be very difficult to express in non-technical terms and quite impossible to access introspectively. In a system-modelling stereopsis, for example, each unit codes a comparison between the light falling on corresponding points on the two retinae (see Chapter 7.v.d and 14.iv.f). To be sure, the system as a whole computes the *depth* of the object being looked at. But no single unit does so. Similarly, NETtalk units represent not whole words, but Wickelgren features—and very few people have heard of those.

Even when some units do code for familiar features, as in Hinton's (1988/1990) model of Jets and Sharks (coded as married, single, divorced . . .), they don't do so in a "symbolic" way. For—as Smolensky pointed out—a PDP unit's meaning may vary according to context (i.e. the simultaneous activity of other units), whereas the meaning of GOFAI symbols is fixed.

In sum, when people introspect they aren't aware of the computations actually involved: "serial, symbolic descriptions of cognitive processing are *approximate* descriptions of the higher level properties of connectionist computation" (Smolensky 1987*a*: 103; italics added). So folk psychology, though not wholly illusory, isn't the true picture of thought. For Smolensky, as for Hofstadter, concepts and cognition properly so called exist only as emergent properties of processes occurring at the subsymbolic level. For certain purposes, that processing can be ignored and the symbolic level taken for granted. But even symbolic thinking is, at base, a PDP phenomenon—and this must be remembered, if human thinking is to be understood.

Two philosophers who agreed with this wholeheartedly were Paul and Patricia Churchland (1942– and 1943–). They had discovered PDP on moving to San Diego in late 1984—by which time the neuroscientifically oriented *Mind* paper was already "in the system". Unsurprisingly, given their earlier philosophical views, they welcomed it with alacrity.

Those earlier views had included a concern with neuroscience. Indeed, Patricia Churchland was already moving towards philosophically informed neuroscience, as opposed to neuroscientifically informed philosophy (P. S. Churchland 1986). She soon collaborated with the neurophysiologist Christof Koch and with Sejnowski, of NETtalk fame, in defining "computational neuroscience" as a distinct research area (Sejnowski *et al.* 1988: see Chapter 14, preamble). Later, she and Sejnowski would plan neuroscientific experiments together, and co-author a textbook (P. S. Churchland and Sejnowski 1992). Paul Churchland, however—while keeping abreast with neuroscience—stayed closer to 'pure' philosophy.

As we'll see in Chapter 16.iv.e, he was already well known as a proponent of eliminative materialism. This doctrine holds that the mental states named by everyday psychological language have no scientific basis, and do not really exist: beliefs, desires, hopes, regrets . . . all these are as illusory as the medieval humours, or witches (P. M. Churchland 1979, 1981). On encountering PDP, he immediately appropriated it to reinforce his long-standing eliminativism, and to develop his early ideas about the philosophy of science (1989). Later, he would apply PDP modelling and neuroscience to moral and political philosophy too (1995).

Much as Hofstadter had spoken of perception, explanation, and analogy in terms of fluid and inter-associated concepts, so Paul Churchland gave a "non-sentential" account of science—and of thought in general. He'd already argued that perception is fundamentally imbued by scientific theories, and that cognitive representations aren't language-like (Chapter 16.iv.e). Now, he said that the classical view of science—theories-as-sentences, related by deductive rules of explanation—should be replaced by a PDP-based account in which explanation boiled down to analogy.

He saw this as a truer picture of scientific knowledge and explanation, and also as a way of avoiding certain notorious difficulties that attend the classical view. Citing PDP models such as NETtalk, he argued that concepts could be represented as prototype-plus-penumbra within a (tacitly) hierarchical activation space. And he related this account to various aspects of scientific observation, learning, skilled experimentation, and reasoning—including Kuhnian paradigm shifts, and the stubborn opposition that typically greets them (1989: 191 ff.).

Anticipating the objection that this was psychology, not philosophy, Churchland said that philosophers must respect the facts about how scientists think—not least, because only thus would certain seeming difficulties (about the role of simplicity in science, for instance) be resolved. Against Popper and the neo-Kantians alike, he argued that *even if* rationality and epistemology are irreducibly normative notions, facts about how concepts are implemented in the brain can be philosophically relevant, since normative claims have empirical presuppositions which may in fact be false (1989: 195–6).

Churchland insisted that when the system is learning some generalization, it is "*theorizing* at the level of the hidden units, exploring the space of possible activation vectors, in hopes of finding some partition or set of partitions on it that the output layer can then exploit . . ." (1989: 179). He even said:

> [It] is clear that no cognitive activity whatever takes place in the absence of vectors being processed by some specific configuration of weights. That is, no cognitive activity whatever takes place in the absence of some theory or other.
>
> This perspective bids us see even the simplest of animals and the youngest of infants as possessing theories . . . [Their] theories are just a good deal simpler than ours, in the case of animals. And their theories are much less coherent, less organized, and less informed than ours, in the case of human infants. Which is to say, they have yet to achieve points in overall weight space that partition their activation-vector spaces into useful and well-structured subdivisions. But insofar as there is cognitive activity at all, it exploits whatever theory the creature embodies, however useless or incoherent it might be. (pp. 188–9)

Many philosophers, not least the neo-Kantians (Chapter 16.vi–viii), would predictably disagree. But computational philosophers had been accustomed to the assimilation of perception to scientific theorizing ever since the "New Look" pioneered by Bruner and Gregory (see Chapter 6.ii). So one might have expected them to be sympathetic.

Some were. Paul Thagard (1988, 1989, 1990), for example, was already developing a philosophy of science similar to Churchland's, and implementing various computer models accordingly (Holland *et al.* 1986; Thagard *et al.* 1988; Holyoak and Thagard 1989). Indeed, he used these empirical studies to challenge the Fregean orthodoxy

(2.ix.b) about the relation between logic and psychology, and spoke of "revising logical principles in the light of empirical psychological findings" (Thagard 1982).

Others, however, were not.

d. The old ways defended

Fodor in particular was not. Although strongly influenced by Bruner in the 1950s, by the early 1980s he was arguing for "mental modularity" (Chapters 7.iii.d and vi.d, and 16.iv.d). This led him to reject Churchland's account of perception as theorizing (Fodor 1984).

Perception (Fodor argued), being modular, is *not* theory-laden through and through. Admittedly, evolution may be said to have built certain assumptions, even "theories", about the world into our perceptual apparatus. But these aren't changeable: our fundamental perceptual processing isn't cognitively penetrable by the theories of science. So the sorts of perceptual shift envisaged by Churchland even in the 1970s, and by Thomas Kuhn before that, are impossible. (For Churchland's reply, see his 1989.)

Fodor had other reasons, too, for rejecting connectionism. In a widely read critique co-authored with the psychologist Zenon Pylyshyn, he described PDP as old wine in new bottles—and fatally adulterated, at that (Fodor and Pylyshyn 1988; cf. Pylyshyn 1984).

The old wine, here, was associationism—which had been laid down in philosophy's cellar three centuries ago (see Chapter 2.x.a). Expressing a "gnawing sense of *déjà vu*", he claimed that Hebb and Hull had been "conclusively" refuted twenty or thirty years before, and that PDP had merely added frills to their ideas. Indeed, this seemingly modern high-tech approach threatened to lead us back over 200 years, to "a psychology not readily distinguishable from the worst of Hume and Berkeley" (Fodor and Pylyshyn 1988: 49, 64).

More specifically, Fodor (contra Churchland) accepted the psychological reality of belief, desire, and other folk-psychological categories—which he glossed, significantly, as "*propositional* attitudes" (Chapter 16.iv.c–d). As such, they involve sentence-like mental representations, composed of concepts and processed by unconscious formal rules. These rules aren't mere emergent patterns of behaviour, but have psychological reality in their own right. Similarly, concepts aren't inherently fuzzy patterns of activation or prototypes-plus-penumbra, but semantically interpretable formal symbols, whose meaning—unlike that of Smolensky's "subsymbolic" units—is fixed irrespective of context (see also Fodor 1998*a*: 22).

These disagreements were closely linked to another. Fodor (and Pylyshyn, who regarded even visual imagery as "propositional": Chapter 7.v.a) insisted that PDP, in principle, couldn't model sequence and hierarchy in general, or language and conceptual thought in particular. A holistic pattern of activation, they argued, doesn't have the sort of internal structure that's required by the compositionality, productivity, and systematicity of language.

Specifically, they said, the holism of PDP can't allow that the meaning of a sentence depends recursively on the meaning of its component parts, enabling the production of indefinitely many new sentences. Nor can it admit that a concept has the same meaning irrespective of context. And nor can it satisfy the generality constraint (G. Evans 1982), that one and the same concept can be used in indefinitely many systematically related thoughts. For instance, someone able to think *John loves the girl* must also be able to think *The girl loves John*; and someone who thinks that roses are red and violets blue must also be able to think that roses are blue and violets red. A PDP network, said Fodor and Pylyshyn, might represent any of these thoughts without being able to represent its permutational partner, because it treats them as holistic patterns—not as *thoughts*, at all.

Lastly, Fodor—like many others influenced by Chomsky—was committed to nativism (see Chapters 7.vi.d–e and 16.iv.c–d). And nativism had been challenged by PDP. The challenge based on representational trajectories was still in the future (see Section viii.d, and subsection e below). But the past-tense learner had already thrown the connectionist cat among the nativist pigeons. This network was taken by PDP enthusiasts to prove not only that explicit rules aren't needed for using grammar, but also that an inborn Language Acquisition Device isn't needed for learning it. *Pace* Chomsky, mere statistical analysis of the input seemed to do the trick.

The most influential Chomskyan reply, which Fodor in general endorsed, came from linguists Steven Pinker and Alan Prince (1988). They crawled over the past-tense learner with a fine toothcomb, devoting 120 pages to their critique. The connectionists had claimed that the network made the same errors as children do (errors which Chomskyans regarded as strong evidence for nativism). But Pinker and Prince showed that the network's errors were *not* precisely the same as children's, and they argued that some of the errors made only by children can be explained by GOFAI but not by PDP.

It turned out later that the psychological data on which both they and Rumelhart and McClelland relied were faulty. For example, psycholinguists had reported, or anyway implied, that—for a while—children always over-regularize all irregular verbs. But they don't: they over-regularize only 5–10 per cent of irregulars, and correct uses co-occur with the incorrect ones. Moreover, psychologists hadn't reported any *irregularizations* of *regular* verbs—which, indeed, a Chomskyan would never expect. However, they do happen. Both these unexpected phenomena, and many others, fell out 'for free' from the network statistics explored in the early 1990s by Plunkett and Marchman (see Section viii.e).

Some of Pinker and Prince's criticisms of the past-tense learner could be applied to PDP in general, at least as it existed around 1986. For instance, the training set had contained no sentences (made up of nouns, adjectives, and variously tensed verbs), but only associative pairs: the *stem/past tense* of 420 verbs. Moreover, these pairs were input in two stages, in the first of which only ten (including eight irregulars) were used. In effect, then, the network had been given grammatical structure for free—or anyway, pointed so firmly at it that the learning required was trivial (compare Thornton's MTCLA: Section viii.d, above). Real parents, by contrast, don't tiptoe around their children mouthing only ten verbs.

But if the past-tense learner was in this sense too weak, in another it was too strong. Pinker and Prince complained that a connectionist learning rule could in principle learn *any* linguistic regularity, whereas children *do not* (because natural languages share certain structures, and lack others) and *cannot* (because some pre-existing bias is needed to enable interesting structure to be picked out). Even non-Chomskyans had to admit that if people find it difficult to learn a grammatical structure (mirror-image reversal of word strings, for example), then a PDP simulation should do so too. What's more, said Pinker and Prince, all the microfeatures were treated equally: the statistical learning picked out the most frequent patterns, not the most important ones. Top-down influences could counter this—but these go against the spirit of connectionism.

The question arose, then, as to what connectionism *could* offer to cognitive science. Fodor and Pylyshyn's answer, in effect, was "Not much". They saw it as a theory not of cognition as such, but of its implementation. All very well, perhaps, for neuroscience. But, given the functionalist assumption of multiple realizability (Chapter 16.iii), facts about implementation have no relevance for philosophy, or even for cognitive psychology properly so called. Newell and Simon agreed. Connectionism deals with the microstructure of (the implementation of) thought, but nothing below 100 milliseconds of brain activity, on their view, is significant in the study of cognition (Newell 1980, 1990).

In short, these computationalists still insisted that language and thought must be explained in formalist terms. The philosophy of mind needs the language of thought (alias LOT: Chapter 16.iv.c) and/or Physical Symbol Systems (16.ix.b), not connectionism. As Fodor put it, both then and later, a GOFAI-based psychology is "the only [theory of cognition] we've got that's worth the bother of a serious discussion" (2000*b*: 1).

Worth the bother or not, serious discussions of PDP soon abounded. The disputes outlined above triggered a huge, and still growing, philosophical literature. Paul Churchland's work had been provocative from the start, and it continued to raise philosophical hackles. As for Fodor and Pylyshyn's critique, Smolensky published a counter-blast even before it was officially published—to which Fodor soon replied (Smolensky 1987*b*; Fodor and McLaughlin 1990). Other professional philosophers soon joined in.

e. Microcognition and representational change

The most important newcomer to the debate was Clark. Besides bringing a taste of PDP connectionism to a general philosophical audience in an Aristotelian Society paper (1990), he provided countless details in a highly influential book, *Microcognition* (1989). This described PDP technology in plain English, and related it to many issues in the philosophy of mind and language—including the disagreements mentioned above.

For instance, Clark countered Pinker and Prince by pointing out (among other things) that "importance" could be coded by assigning higher weights to some microfeatures than to others, and that Karmiloff-Smith had already outlined how GOFAI-like processing might develop from a PDP base (see Section viii.d).

He also rejected Churchland's eliminativism. Individual thoughts (beliefs, hopes, intentions . . .), he said, could conceivably map onto identifiable computational states in the brain, even though these states aren't sentence-like. And even if they don't, it doesn't follow that they aren't "real". The reason is that the categories of folk psychology are holistic interpretations of behaviour, logically independent of the underlying causal mechanisms (cf. 16.iv.a–b). Ironically, Clark's anti-eliminativism was directed also against the arch-realist Fodor:

> Fodor's approach is dangerous. If one accepts the bogus challenge to produce syntactic brain analogues to linguistic ascriptions of belief contents, he opens the Pandora's box of eliminative materialism. For if such analogues are not found, he must conclude that there are no beliefs and desires. The mere possibility of such a conclusion is surely an effective *reductio ad absurdum* of any theory that gives it house space. (A. J. Clark 1989: 160)

As for Fodor and Pylyshyn's arguments about systematicity, Clark wasn't convinced by these either—though he admitted that productivity was more problematic than sequential order (1989, ch. 8; 1991*b*). His main point was that compositionality needn't be built into the basic architecture, but could emerge from it.

The core idea, here, was mental modelling (see Chapters 4.vi, 7.iv.d, and 14.vii–viii), together with the PDP group's suggestion that our reasoning capacity may result from "our ability to create artefacts—that is, our ability to create physical representations that we can manipulate in simple ways to get answers to very difficult and abstract problems" (Rumelhart *et al.* 1986*c*: 44; cf. A. J. Clark 1989: 223). Given that words are external (publicly accessible) things, which can be modelled in the mind/brain just as physical objects can, Clark saw the compositionality of thought as derived from that of language. That is, the brain somehow creates a *virtual* machine with formalist properties—and conceptual thought is a property of this machine. It follows, said Clark, that GOFAI-explanations of thought and language aren't mere *approximations* to finely detailed subsymbolic accounts, as Smolensky had claimed, but are *true* (or in some cases *false*) descriptions of the relevant virtual machine. (The implication was that only humans have language-like internal states; for Fodor, by contrast, even animals—if they have representations at all—possess some innate language of thought: see 16.iv.c.)

As we saw in Section ix.b, Hinton had recently suggested a model that tallied with Clark's approach (Hinton 1988/1990; cf. A. J. Clark 1991*b*: 215). Each concept, Hinton had said, might have *two* representations: a localist (single-feature) "reduced description", and a distributed "expanded description" involving many microfeatures. The first might be manipulable in a GOFAI-like way, even though the second isn't. But the reduced description isn't an empty syntactic token, as a GOFAI symbol is (cf. Searle 1980), because it is linked to the expanded one—whose microfeatures can be accessed if the concept's *meaning* needs to play a role. As Clark put it: "Classical representations, minus such a sub-structure, threaten to be brittle and contentless shells" (1991*b*: 217). In sum, "even when a classical virtual machine is somehow implicated in our processing, its operation may be deeply and inextricably interwoven with the operation of various connectionist machines" (1991*b*: 215).

Clearly, then, Clark—despite being the leading philosopher of connectionism—was never committed to *pure* PDP, the view that "Every cognitive achievement is psychologically explicable by a model that can be described using only the apparatus of PDP" (1989: 128). This position, he said, was just as implausible as its GOFAI-equivalent. Even in his first book, he argued for mental "multiplicity":

> I am advocating that cognitive science is an investigation of a mind composed of many interrelating virtual machines with correct psychological models at each level and further accounts required for the relations between such levels. Only recognition of this multiplicity of mind, I suspect, will save cognitive science from a costly holy war between the proponents of PDP and the advocates of more conventional approaches. (A. J. Clark 1989: 141)

Whether any of these virtual machines is as closely GOFAI-like as Fodor claimed was another matter. But this, for Clark (as for Hinton), was an empirical question. As for the answer, he was agnostic: he closed his second book by saying "No one knows" (1993: 227).

If Clark's second book still didn't answer the question about the relevance/irrelevance of GOFAI, it did offer some important advances. Earlier, he'd described symbolic reasoning as "merely ingenious icing on the computational cake" (1989: 135). Now, he asked how that icing could have been concocted in the first place. In other words, his interests had shifted from established (static) conceptual abilities to representational change. He now tried to show *how* "mental multiplicity" could develop from a PDP base. And his answer described the scaffolding of learning by various recodings of existing representations (1993, esp. chs. 7–8)—see Section viii.d.

As we've seen, he'd recently collaborated on this issue with a leading *developmental* psychologist, Karmiloff-Smith. She was one of a group of developmentalists who were reinterpreting the idea of innateness (Elman *et al*. 1996). Specifically, they'd revived Piaget's biological concept of *epigenesis*: a series of self-organizing interactions between pre-existing mechanisms and the environment (both in and outside the organism), by which the embryo/infant bootstraps itself into maturity (Chapters 7.vi.g–i, 14.ix.c, and 16.vii–viii). Unlike Piaget, this group had the advantage of PDP techniques and developmental neuroscience. Like Clark, then, they asked how a connectionist system—whether natural or artificial—could undergo representational changes in epigenetic development.

In other words, "Is it innate?" was no longer being treated as a *Yes/No* question (cf. 7.vi.g–i and 9.vii.c–d). The new "Minimal Nativism", as Clark termed it (1993, ch. 9), drew the sting of the nativism debate, for it stressed both inbuilt and bootstrapped processing biases ("knowledge"), as well as environmental interactions.

By the 1990s, there was a wide range of empirical research (not all done from a computational perspective) suggesting what these biases and interactions might be. Some philosophers interested in mental development called on cognitive neuroscience (see Chapter 14.xi.b). Others stressed the mother–child interactions that naturally scaffold the development of pointing, turn-taking, and language, and/or culture-specific scaffolding in the form of language and artefacts—what Bruner (6.iii.c) had called cognitive technology (E. L. Hutchins 1995—cf. 8.iii; Hendriks-Jansen 1996; A. J. Clark 2001, ch. 8). By the end of the century, then, research on (lifelong) conceptual *development* was influencing the philosophy of mind and cognitive science.

f. Non-conceptual content

Interest in development was evident also in philosophical work on the relation between concepts and non-conceptual content. One might say that these correspond to Hinton's reduced and expanded descriptions respectively, but that would be misleading: the distinction arose within 'pure' philosophy, and—as we'll see—was linked to connectionism later.

Non-conceptual content is meaning (intentional content) carried by sensory-perceptual experience and/or action that's untouched by language. One familiar example is the content *bug* that's supposedly available to the frog in virtue of the 'bug-detector' cells in its retina (and the adaptive links to the muscles of its limbs and tongue): Chapter 14.iii.a.

The word "supposedly" is needed here because the notion of non-conceptual content is controversial. René Descartes had seen no need for an equivalent (and is widely reviled for callousness as a result: Chapter 2.ii.e). Even today, some philosophers argue that there can be no such thing: in their view, the very idea of non-conceptual content, or purely sensory experience, is incoherent (Chapter 16.viii.b). Many others disagree. Indeed, the suggestion that there is some middle ground between adult human experience and the mental vacuum of insensate beings has a strong intuitive appeal—not just to pet-owners and zoo-keepers, but to people wanting to understand the *human* mind.

The Oxford philosopher Gareth Evans (1946–80), for instance, argued that non-conceptual content is the base from which true concepts develop (G. Evans 1982). He recognized that it's difficult to pin it down. Does the frog really employ the content *bug*—or, rather, *bug-over-there* or *edible-object-to-upper-right*, or *black spot there*, or . . . ? The answer, he said, lies in the frog's sensori-motor skills. For to have access to non-conceptual content of a certain sort just is to have bodily skills of a certain kind. The skills aren't mere evidence for (symptoms of) the existence of the content, but are criterial of it. As for concepts, Evans defined these in terms of the generality constraint (see above). The frog lacks the concept of "bug", for it can't respond to bugs in many different ways, nor (use language to) think of them in many different contexts. In other words, it can't conceive of bugs *objectively*—which is to say that it can't conceive of them at all.

But the same applies to babies: as Piaget had pointed out long before, being able to shake and suck a rattle, or to pick it up and drop it, isn't the same as being able to think of rattles in indefinitely many ways. Evans, then, was less concerned to give dumb animals their due than to explain the origin of concepts in humans, whether in evolution or infancy.

Largely inspired by Evans's intellectual legacy (he died in 1980, aged only 34, and his book was published posthumously), Adrian Cussins (1960–) drew on connectionist ideas in trying to show how this conceptual development could take place (Cussins 1990). While still a Research Fellow (at Oxford and Stanford) in the late 1980s, he produced the C3-theory of cognition, so called because it dealt with the 'Connectionist Construction of Concepts'. Almost all of the C3 paper dealt with *just what counts* as content, and *just what counts* as a concept. Having discussed these two questions for sixty pages, he closed with a brief section arguing that connectionism might show how, in practice, concepts emerge from a non-conceptual base.

Theories based on GOFAI (such as Fodor's), he said, don't explain the origin of conceptual content but instead take it for granted. In this, he was echoing Searle, for whom GOFAI was "all syntax and no semantics" (Chapter 16.v.c)—and, for that matter, Fodor himself (in his discussion of methodological solipsism: 16.iv.d). Both Searle and Fodor had argued that GOFAI can't explain how concepts in someone's mind can refer to objective facts or events. Cussins suggested that his theory can do so, for it shows how there can be "organisms *in* the world which are capable of thinking *about* the world" (Cussins 1990: 368).

Following Evans, he took non-conceptual content to be the representation of the world that is implied by the possession of language-free bodily skills. These include visual navigation, knowing the position of one's limbs, and catching a bug with one's tongue. Our friend the frog has such skills—but no concepts. We need to explain both how non-conceptual content can arise and how concepts can progressively be constructed from it. Concepts and objectivity (the mind–world distinction) are essentially connected, and to explain objectivity we must show how conceptual representations can have semantic properties such as reference, truth, and falsity. As Cussins put it:

> We need to understand how there can be a principled, if not sharp, distinction between creatures like paramoecia and creatures like us, between infantile and adult cognition, perhaps also between normal and demented cognition. With a fair grasp of the principle of this distinction, we can *then* address . . . how best to model the computational processes that can transform a creature from lying on one side of the distinction to lying on the other side. (Cussins 1990: 414; italics added)

His answer (again, following Evans) was that "contents are non-conceptual in virtue of being perspective-dependent" (p. 425), and that concepts can be constructed from a non-conceptual base by learning increasingly perspective-independent abilities. In humans, this process culminates in the "emergence" of objectivity and the mind–world distinction. At that point, the person satisfies not only the generality constraint, but also objectivity conditions such as referring to specific objects in the world, assessing truth-values, making valid inferences, and—in general—making judgements and perceptual discriminations that are independent of their own perspective.

So far, so philosophical: this was a theory of C2 (the Construction of Concepts), not C3. Connectionism now entered the picture, albeit briefly. Cussins commended Smolensky's account of the "proper treatment" of connectionism, and rebutted Fodor and Pylyshyn's claim that connectionists can't explain systematicity. And he suggested that this methodology might be able to show how concepts arise in practice (pp. 429–37).

However, he didn't discuss any specific models illustrating the movement towards objectivity that he had in mind. He might have cited Marr's theory of vision (it was mentioned in a footnote, but in a different context). For this had indicated how a connectionist system might construct decreasingly perspective-bound representations (see Chapter 7.v.b–d). From the retinal image, through the Primal Sketch, to the $2\frac{1}{2}$D sketch and beyond, Marr had pictured a subjective-to-objective progression satisfying some of the criteria noted by Evans and Cussins.

He might have cited Hinton too, for Hinton had already outlined how a visual network could construct increasingly viewpoint-independent representations of arbitrary 3D shapes (Hinton 1981; cf. Boden 1988: 80–6). ("Outlined", because he'd modelled his abstract theory only in toy systems.) Indeed, Hinton would have been a better example for Cussins's purposes than Marr, because his objective representations didn't depend, as Marr's did, on top-down influences from ready-made concepts (object models).

An even better example was soon provided by Ronald Chrisley (1965–), a Sussex philosopher with hands-on programming skills who developed Cussins's suggestion about a connectionist base for objectivity (Chrisley 1990, 1993; Chrisley and Holland 1995). He designed a recurrent PDP network called CNM (Connectionist Navigational Map), which would enable a robot to learn to navigate (to reach "home"), gradually decreasing its perspective-dependence as learning proceeded.

A series of experiments showed how various types of spatial generalization were, or were not, generated (in the hidden units) by distinct representational codes. For example, how could CNM (first) learn to identify specific locations, and (then) to relate them to each other more or less systematically? (This wasn't straightforward, for the robot's "sensations" and "actions" weren't associated one-to-one: the same action sometimes yielded different sensations, and different actions might yield the same sensation.)

CNM could be seen as an exercise in robotics. Chrisley compared it also to empirical work on learning (artificial) grammars, on spatial maps in the hippocampus, and on the development of object permanence in children. But his primary aim was philosophical: to clarify what sorts of representational trajectory might count as "increasing objectivity".

Cussins and Chrisley were both firmly rooted in analytic philosophy (they were fellow graduate students at Oxford in the 1980s). But their work on objectivity exemplified the growing stress on *embodiment* that characterized cognitive science in the 1990s, and which was often expressed in terms of the very different phenomenological tradition (see Chapters 15.vii and 16.vi–viii). Indeed, Cussins—and Clark (1997, 2005), too—moved increasingly towards that approach (Cussins 1992).

By the end of the century, then, Dreyfus was only one of many proclaiming the importance of bodily skills. Even Evans had highlighted such skills, in his account of non-conceptual content. But neither Dreyfus nor Evans had discussed connectionist implementations of intelligence, and Cussins had done so only in the sketchiest terms. Chrisley, by contrast, tried to show how specific PDP networks might be used to illuminate the grounding of objective thought in the dynamic interplay of bodily action and perception.

Although Cussins was exploring a core assumption of connectionism—that concepts can emerge from a subsymbolic base—he had fewer readers than Fodor, Churchland, or Clark. He was a philosopher's philosopher, whose highly abstract and closely argued work bristled with technical terms. Indeed, his C3 paper had been rejected as "too philosophical" by the editor of the interdisciplinary *Behavioral and Brain Sciences*, himself a philosopher—namely, Stevan Harnad (Cussins, personal communication).

He influenced the field, nevertheless. Paul Churchland was so impressed by the C3 paper that, shortly after it appeared, he invited Cussins to join him at San Diego. *Mind* published his second paper on content and embodiment soon afterwards (Cussins 1992). Clark referred to C3-theory in developing his own account of representational change (A. J. Clark 1993: 73–6). Chrisley spelt out the third 'C' in C3 in some detail, as we've seen. And Brian Smith (1996) was strongly influenced by Cussins's publications on embodiment, and (even more) by his ongoing research on content, objectivity, and ontology. As we'll see in Chapter 16.ix.e, Smith was attempting a major upheaval in the philosophy of mind and computation, in which insights of the analytical and phenomenological schools would be combined.

g. An eye to the future?

I said above (viii, preamble) that the late-century connectionists didn't try to tackle propositional reasoning. However, Clark (2005, in preparation) has very recently outlined a research programme aimed at doing so—and at taking *embodiment* seriously in the process. As a philosopher, he won't be doing hands-on modelling. But he will be taking modelling techniques into account—and empirical psychology and neuroscience too.

He sees language as a form of cognitive technology, whose origin and use can be understood as an aspect of embodied cognition (Clark 2003*a*; and 16.vii.d). Its epistemic artefacts aren't axes, pencils, or computers but publicly audible/visible words—and internal representations of them, and of the motor actions we've learnt to associate with them. At base, these are forms of perceptual imagery, not language-specific types of representation.

Clark isn't the only philosopher, today, to stress the embodied, perceptual, aspects of language. A similar idea imbues Jesse Prinz's radically empiricist philosophy of mind (Prinz 2002). And cognitive linguists such as Larry Barsalou and Rolf Zwaan have recently developed "situation semantics", which holds that words don't *have* meaning so much as *prompt* it (Barsalou 1999*a*,*b*; Zwaan 1999; Feldman and Narayanan 2004).

The abstract aridities of Montagovian semantics are here left far behind (see 9.ix.c). For on this view, language works by eliciting specific perceptual and motor imagery in the hearer/speaker, who thus *simulates* the relevant semantic content. Situational linguists can call on psychological studies of visual imagery (e.g. Stanfield and Zwaan 2001), and on fMRI (brain scanning: see 14.x.b) data showing that words elicit activity in the neurones that are normally active when the person senses, or enacts, the relevant thing or action (e.g. Tettamanti *et al.* 2005). They can also call on seventy years' work on schema theory, thanks to Frederic Bartlett and his many successors (see 5.ii.b, 7.i.c, and 14.vi.c, and Fauconnier and Turner 2002).

The idea that the concepts named by words may be based in concepts derived from the body isn't new to cognitive science. For instance, George Lakoff and Mark Johnson suggested a quarter-century ago that abstract concepts, such as *justice*, may be metaphorical extensions of body-grounded concepts, such as *balance* (Lakoff and Johnson 1980; M. D. Johnson 1987); and some even earlier claims about the bodily origins of language, including syntactic structure, are cited in Boden (1981*a*). What's new is the greater attention to psychological *processes*, that is, the suggestions about *how* language works within our minds.

Applying this approach to the language of *belief*, *desire*, and *intention* (the core vocabulary of Theory of Mind), it may seem that "simulation theory" has won out over "theory theory", at last. However, this depends—as we saw in Chapter 7.vi.f—on *just what* sub-personal cognitive machinery is involved. And that's not easily discovered. The current empirical evidence for simulation semantics has resulted from presenting either single words or isolated sentences describing simple actions. But fMRI can't distinguish *Man bites dog* from *Dog bites man*, nor reflect *reasoned series of propositions*. One of Clark's aims is to grasp those nettles.

He reminds us that a biological niche containing self-constructed nests, or webs, enables birds or spiders to do things they couldn't do without them. Similarly, a cultural niche containing axes and pottery (and shipboard instruments: 8.iii.a) enables us to do things, and to think things, that would otherwise be impossible. In addition to specific artefacts such as these, the spatial organization of objects can be used as a memory-prompt enabling us to perform potentially difficult tasks with relative ease. Consider, for example, the physical arrangement of the instruments aboard ship (8.iii.a), or of unfilled glasses on a bartender's counter (K. Beach 1988); and remember the many times you've positioned the salt and pepper pots to make a *non-spatial* point.

But language, given what linguists call "the arbitrariness of the sign" (9.iv.c), is even more generally useful than is arrangement-in-space. Words can stand in for non-spatial and/or abstract items and relations, from sameness/difference to justice. It thus provides a "superniche", in which we can represent *all* external epistemic tools. Uniquely "poised between the inner and the outer, the public and the private", it acts to "stabilize, anchor, and scaffold individual thought and interpersonal coordination" and helps to create "our selves" (A. J. Clark 2004: 725).

This explains the special power of language. Words lead us to do things which we wouldn't, couldn't, have done otherwise. They do that by selectively *directing our attention* to other items in our minds—including other words, and representations of bodily actions. As Clark puts it, "Words aren't meanings, but clues to meanings." (Here, he's quoting Elman, who in turn was quoting a remark made in conversation by Rumelhart many years ago—Elman, personal communication, and 2004: 301; for Rumelhart's explanation of it, see Rumelhart 1979: 85.)

Associative processes can link internal representations directly with each other, without any current engagement with the external environment. For instance, we can remember something we did, said, or thought yesterday. In general, we can monitor and control our own thoughts (beliefs, intentions, moral principles . . .) by using language to focus our attention on them—an ability that makes human 'freedom' possible (7.i.g). In short, our high-level knowing can be 'decoupled' from our sensori-motor behaviour, despite being mediated by representations that are grounded in embodied perception and bodily action. It's this, Clark argues, which causes the undeniable discontinuity between *Homo sapiens* and other species, despite the continuity of the basic psychological mechanisms (i.e. perception, association, and bodily skills).

Clark mentions many examples of empirical work which support his view. For instance, chimps trained to discriminate between sameness and difference pairs (e.g. cup–cup and cup–shoe) by picking out a red or blue tag are able later to learn to recognize higher-order sameness and difference—as in cup–cup and shoe–shoe, or cup–cup and cup–shoe (Thompson *et al.* 1997). Chimps who'd learnt the lower-level discrimination but *without* using a separable token to mark it couldn't learn to recognize the higher-level property. The experimenters suggested that what the tag-trained chimps were actually doing was to compare *a memory of a red tag* with *a memory of a blue tag*—which is a lower-order problem. (So Thomas Evans's task for his ANALOGY problem, one might say, was to provide his NewFAI program with the relevant tags: 13.iv.c.)

Another example cited by Clark is work done by the Paris-based group led by cognitive neuroscientist Stanislas Dehaene. This shows that arithmetical reasoning involves both verbal and visuo-spatial representations (Dehaene 1997). Experiments on animals and infants indicate that a primitive visuo-spatial sense of number has evolved independently of language, but can be supplemented by language in mature human beings (Spelke 1994; Dehaene *et al.* 1998*a*). Prior to linguistic development, there seem to be two core visuo-spatial "codes" for counting: one exact (for numbers up to between three and five), and one approximate (for larger quantities). Exact calculation of larger numbers requires language (Pica *et al.* 2004).

Experiments with bilingual subjects display systematic differences between arithmetical reasoning that's exact or merely approximate, and which relies on over-learned associations in one language or the other (Dehaene *et al.* 1999). These differences concern not only the time taken to complete the task, but also the locus of fMRI-scanned brain activations. And they appear to depend on the extent to which the reasoner employs *words functioning as perceptual cues*. For exact calculations, the solution is faster if the sums are presented in the language in which they were taught—and the brain's language area is activated. For approximate calculations, the language-of-teaching is irrelevant, and a different (parietal) brain area is activated.

Clark sees these results as showing that what we normally regard as high-level reasoning may be grounded in visual perception, but improved by words—which are *essential* for certain reasoning tasks. Even for those tasks, however, words function by means of learnt associations to language-specific perceptual (auditory and visual) imagery.

All very interesting . . . not least, because it can be seen as a twenty-first-century version of Hume's talk of "impressions" and "ideas" (2.x.a). (It's also an updated version of the Whorfian hypothesis, at least where vocabulary is concerned: see 9.iv.c.) But there are two major, and familiar, problems: hamsters and hierarchy.

If language and reasoning rest on perception and association, or in other words what Elizabeth Bates called "sundry old parts" (see 7.vi.c), why can't hamsters learn English? Why have all the attempts to teach language to non-human animals foundered, just as Descartes predicted (2.iii.c and 7.vi.c)? We've seen that Clark rejects Chomsky's nativist answer, and Fodor's too. He also rejects Kim Sterelny's (2003) recent suggestion that the brains of newborn humans today are representationally and computationally deeply different from those of early hominids, due to some combination of genetic changes and the effects of our unique developmental cocoon. He admits (personal communication) that there must be *some* inherited difference between animals' brains and ours, but has nothing convincing, nor even intriguingly plausible, to say about just what it might be.

As for hierarchy, the rock on which Burrhus Skinner's theory of language foundered (9.vii.b) and—as we've seen—one still unconquered by PDP, Clark ignores it. His project focuses on individual words and over-learned phrases, not whole newly generated sentences. Apart from saying (correctly) that a representation of structure X doesn't have to be X-structured, he has nothing to add about hierarchy.

So why mention his work here? In particular, why mention a largely speculative project, still (in February 2005) in the process of grant application? Why not confine the discussion to already peer-reviewed, or anyway already drafted, research reports? This book, after all, is history—not futurology.

The reason is that Clark's chosen problem is highly important, with significant implications for every discipline within cognitive science. Maybe he won't achieve the breakthrough that he's hoping for. But he'll probably come up with something of interest—a better understanding of attention, for instance. Psychologists have done a huge amount of work on this, including much which today would be described as the study of consciousness (6.i.a–c and 14.ix.a), but the concept is still far from clear. Again, his work may help to fill some of the gaps in situation semantics: the currently popular "blending theory", for instance, abounds with hand-waving about *just what* computations might be involved, and *just how* they can be triggered (Fauconnier and Turner 2002). Other goodies may ensue too—though we can't be sure of that now (see 17.i). Science-as-she-is-done, and philosophy-in-the-making too, isn't always a matter of dotting the *i*s and crossing the *t*s. It also involves speculation, hunches, boldness . . . in a word, risk.

12.xi. Pointing to the Neighbours

Connectionist AI/psychology had two next-door neighbours, and another directly opposite. The next-door neighbours were experimental psychology and neuroscience. The one facing across the street was symbolic AI.

These fellow residents spoke to each other less than one might think. As we've seen, a large part of connectionism's project was *negative*: to deny GOFAI's claims to ground a science of the mind. So cosy chats on the doorstep weren't very likely there. But even neighbour neuroscience was largely neglected by the connectionists I've discussed in this chapter. Indeed, the neglect ran both ways: for many years, most neuroscientists were territorially suspicious of computer models brought onto their patch (see 14.iv.d and v.c).

There were some exceptions. Clark, for instance, clearly realized that if his philosophy of mind/language is to be vindicated, it must be consistent with the data of experimental psychology and neuroscience. And the Churchlands drew even more inspiration from neuroscience. However, very few philosophers of connectionism paid much attention to either. Indeed, many of the *hands-on* connectionists, especially those coming from physics or engineering, near-ignored these experimental sciences too. Even if they considered psychology carefully, which they didn't always do, they sidelined neuroscience. (Again, there were exceptions: some individuals, such as Sejnowski and J. R. Anderson, came into the field from neurophysiology.)

Their networks were inspired by the brain, to be sure. But they focused on mathematical analyses of general computational properties: pattern recognition, distributed representation, associative memory, learning, development, and the low-level grounding of high-level thought. They took on board some very general features of biological neurones, but didn't pay attention to detailed aspects of the nervous system. Their work wasn't much help, for instance, if one wanted to know *just how, in fact,* a frog manages to catch a fly with its tongue, or *just how, in fact,* someone recognizes their grandmother.

Potentially, the connectionism and neuroscience neighbours had much to teach each other. Both were concerned with the probabilistic properties of cell networks (cf. 14.ii.b); and hypotheses about what *computations* (what information processing) the nervous system is performing could guide neuroscientific questions about the bodily mechanisms involved. In some cases, the party wall between the next-door residences was pretty thin. In other words, the distinction between connectionism and computational neuroscience was fuzzy.

With advances in neuroscience, it's getting fuzzier. One indication of that is that a recent textbook written by two students of McClelland is significantly more neural/biological than the first PDP volumes were (O'Reilly and Munakata 2000). Indeed, it's boldly subtitled *Understanding the Mind by Simulating the Brain*. Published at the turn of the century, it presages a new phase of research for the new millennium. To be sure, associative memory isn't being explained directly in terms of ion channels.

But the brain—and even ion channels—is being given more attention than before. (In part, of course, this is a result of neuroscientists' having learnt more about it.)

Twentieth-century computer models that tried to cast specific spotlights on the brain will be considered in Chapter 14. Before talking to the next-door neighbour, however, let's look at what happened to the neighbour across the street.

The spectacular rise of PDP didn't cause GOFAI to collapse. If Fodor and Pylyshyn hadn't given up on the symbolic approach, neither had their GOFAI colleagues. And much of what they were doing had implications stretching beyond technology, into cognitive science.

13

SWIMMING ALONGSIDE THE KRAKEN

The long-submerged connectionist Kraken identified in Chapter 11.vi surfaced in 1979, and leapt into the air a few years later (see 12.v–vi). There's no denying that it posed a threat to symbolic AI. It commanded philosophical interest, stole public sympathy, and—after DARPA's U-turn in 1986 (12.vii.b)—competed for funds. But it didn't chase GOFAI from the seas.

While the monster frolicked in the limelight, symbolic AI carried on swimming steadily. It's been doing that for twenty-five years now, during which time a mini-Kraken has risen to visibility—situated, or embodied, AI. (That too, the ninth bombshell, was spawned around mid-century: Chapter 4.viii.)

This chapter describes some work from GOFAI's post-Kraken period. I've ignored natural language processing as such, because various examples of post-Kraken work in NLP were described in Chapter 9. However, it's worth mentioning that current AI models of planning and multi-agent cooperation, including virtual-reality set-ups in which a VR agent interacts with a human being (Section vi.b, below), owe much to earlier NLP research on the recognition of intentions and beliefs (see 9.xi.f).

Some of the chosen themes—VR, for instance—have a decidedly modern feel. But every one was presaged in the very earliest days of NewFAI. In short, the harbingers (10.i) were coming home to roost.

Not all, however, found a comfortable place to perch. Logicism's efforts to do so are described in Section i. Some post-Kraken criticisms of logicism, and of the explosion of expert systems dating from the early 1980s, feature in Section ii.

Next, I focus on five topics which despite being heralded in the harbinger papers attracted scant attention until around 1980. These are (in Section iii) diagrammatic reasoning; the situationist attack on planning; agents and distributed cognition; inductive learning; and (in Section iv) creativity. GOFAI's contribution to human–computer interfaces and VR is outlined in Sections v and vi, which also explore some potential psychological effects of VR.

Finally, I give a historical perspective on two common beliefs: that AI isn't a discipline so isn't worthy of respect, and that GOFAI has failed.

13.i. Later Logicism

Post-Kraken work on classical AI themes included the use of logic to represent knowledge. This research programme had been announced in 1959 by John McCarthy, and was given a huge boost ten years later by McCarthy and Patrick Hayes (10.i.f and iii.e). Since the late 1970s there have been many developments.

Some of these, as McCarthy and Hayes predicted, concern classical metaphysical questions. For instance, Judea Pearl's long-standing logicist research has focused on causation and counterfactuals, on probability, and on the nature of scientific explanation (Pearl 1988, 2000; Halpern and Pearl 2005*a*,*b*). It's hardly surprising that it has drawn the attention of professional philosophers. For causation was grist to the metaphysician's mill even in Aristotle's time; counterfactuals have vexed logicians ever since the Middle Ages; probability has perplexed philosophers for 200 years; and scientific explanation was much discussed in the twentieth century (e.g. Popper 1935; Salmon 1989; Lipton 1991).

Overall, GOFAI's logic-based advances have included work on at least three fronts. Namely, non-monotonic logic, naive physics, and an AI encyclopedia (not to be confused with an encyclopedia of AI). But whether these three (described below) should really be called "advances", as opposed to *continued research activity*, is highly controversial. For it's still not universally agreed within AI that logic is a suitable medium for KR.

It still has champions around the world. For instance, Germany's Wolfgang Bibel, asked to comment on "AI's greatest trends and controversies" for the millennial issue of a leading computer journal, insisted that "the language as well as the inferential machinery of logic [is] fundamental for the endeavor of realizing an artificial intelligence" (Hearst and Hirsh 2000: 8). But a recent President of AAAI devoted much of his Presidential Address to casting grave doubts on this (Waltz 1999). In short, by no means all of today's AI is imbued by the McCarthyite passion for logic.

a. Less monotony

"Monotony" was lessened by post-Kraken GOFAI in order to deal with the (second sense of the) frame problem—namely, situations involving incomplete knowledge (see 10.iii.e). Symbolic systems now have a flexibility way beyond what was achievable in 1980.

In ordinary (monotonic) logic, any conclusion that follows from a set of assumptions, or premisses, also follows from any *larger* set of assumptions. If the original assumptions were true, then the conclusion is true, no matter what other true premisses are added. In non-monotonic reasoning, by contrast, the entailment of the conclusion can in some circumstances be annulled.

Consider the common-sense decision to abandon one's plan to take the train, and to take the bus instead—because on reaching the station one discovers that the trains aren't running today.

Using a monotonic logic, one would have to avoid inconsistency by *revising* one's initial assumptions ("Drat! I thought the trains were running today, but they aren't. Delete that premiss") and then replanning the journey. (So-called *truth-maintenance* techniques use monotonic logic, and attempt to restore consistency whenever new information comes in which contradicts some previous assumption.) Using a non-monotonic logic, one could *add* the new premiss "No trains today", but allow it to override the older premisses so as to *avoid* drawing the conclusion that "I shall take the train today".

That's an illustration of what's sometimes called the "qualification" problem: the fact that reasoning from incomplete knowledge is unavoidably risky. If new information comes in, one may have to change one's mind in some way. Various attempts to compensate for incomplete knowledge had been discussed in the 1970s (e.g. A. M. Collins *et al.* 1975; Norman and Bobrow 1975). Among them was GOFAI work which, following McCarthy and Hayes (1969), aimed to do this without abandoning representation-by-logic.

Ways of doing that had begun to poke their heads above the water in the 1970s (Winograd 1980*b*). For instance, Uppsala's Erik Sandewall (1945–) extended predicate calculus logic by defining the *Unless* operator, which prevented the system from making inferences it would otherwise have drawn (Sandewall 1972; cf. Raphael 1971). If told both *A* and *A Unless B implies C*, Sandewall's program would set up a sub-goal to assess the truth of *B*, before deciding whether to infer *C*. (This could happen on several goal levels, as *Unless* was recursive.) Similarly, the default slot-fillers in AI 'frames' led programs to assign default values *only if* those slots hadn't already been given some other value (Hewitt 1969; Minsky 1975). And Earl Sacerdoti's ABSTRIPS prevented failures by postponing on-the-spot executive planning until the last minute (10.iii.c).

In all those cases, disaster was pre-empted by *avoiding or delaying* decisions. In "fuzzy logic" too, contradictions were pre-empted—in this case, by using probabilistic reasoning (Zadeh 1965, 1972, 1975; for an 'update', see Bouchon-Meunier *et al.* 1995). Since there was no firm commitment to the truth of the conclusion, there was no contradiction if it turned out to be false.

In non-monotonic reasoning, by contrast, decisions/conclusions were actually made—only to be withdrawn later. Work of this type began in the mid-1970s, and a small workshop on the topic was held at Stanford in 1978. By that time, several ways of enabling a logic-based program to 'change its mind' were being suggested.

McCarthy himself developed "circumscription" as a possible solution (1977, 1980*a*,*b*, 1986). The key idea was that the program should assume, at any given time, that it knows all the relevant facts. Consider the missionaries and cannibals problem, for example:

> Imagine giving someone the problem, and after he puzzles for a while, he suggests going upstream half a mile and crossing on a bridge. "What bridge", you say, "No bridge is mentioned in the statement of the problem." And this dunce replies, "Well, they don't say there isn't a bridge." You look at the English and even at the translation of the English into first order logic, and you must admit that "they don't say" there is no bridge. So you modify the problem to exclude bridges and pose it again, and the dunce proposes a helicopter, and after you exclude that, he proposes a winged horse or that the others hang on to the outside of the boat while two row. (McCarthy 1980*a*: 30)

Clearly, given the inventiveness of "this dunce", no additions to the axioms of the problem could ever defeat him.

The only strategy, said McCarthy, is to assume that all the relevant facts are known—so if bridges aren't mentioned they're not needed. In *puzzles*, like the missionaries and cannibals brain-teaser, that's actually so. But in real-life problems, *that all the relevant facts are known* is an assumption, not a datum. It may turn out to be false. If so, the problem-solver must be prepared to reconsider some of the previous conclusions. (Fuzzy logic wouldn't help, he said. For not only can we not assign meaningful probabilities to bridges or to Pegasus, but we don't even think about them. Nor should we: when would such thinking ever stop?)

As McCarthy pointed out, circumscription wasn't an example of non-monotonic *logic*, but of non-monotonic *reasoning* that augmented ordinary first-order logic. (So was Jon Doyle's "truth maintenance system": Doyle 1979. This stored the reasons for its conclusions, and used backward chaining to revise its beliefs if a reason statement turned out later to be untrue.)

McCarthy advised against altering the logic itself, because it's difficult to ensure that all such modifications are compatible (1980*a*: 37). Non-monotonic logics were suggested nevertheless, by Drew McDermott and Ray Reiter (McDermott and Doyle 1980; McDermott 1982*a*,*b*; Reiter 1980). Reiter's "default reasoning", for example, was extended by a complete proof theory for a large class of common defaults, which could be presented to a resolution theorem-prover.

It wasn't always easy to compare the various forms of non-monotonic reasoning. Reiter, for instance, said that a particular result "suggests some deeper relationship between closed world default theories and [McCarthy's] method of circumscription although I have been unable to discover just what this might be" (1980: 129). McCarthy, besides offering technical comparisons between his own approach and Reiter's (McCarthy 1980*b*), argued that default reasoning in general is less useful than circumscription, because it's less generalizable (1980*a*: 37). For example, a block *x* that isn't explicitly stated to be on block *y* is taken (by default) not to be on *y*; similarly, for block *z*; but there's no way of inferring what circumscription allows one to assume: that there are *no* (unmentioned) blocks on *y*.

In 1980 non-monotonic reasoning was the subject of a special double issue of the *Artificial Intelligence* journal. This heralded an explosion of work in the area. Some of it was soon to be featured in the widely read compendium of 1985 that also included Brian Funt's and Aaron Sloman's thoughts on analogical representation (see iii.a, below).

Many people—even McDermott himself (ii.a, below)—pointed out that none of these attempts to formalize non-monotonic reasoning could solve the frame problem in the general case. (Hayes agrees.) But not all reasoning concerns the general case. Just as expert systems can be useful if they're restricted to a certain topic, so programs can approximate common sense where the types of rethinking that may be needed can be specified beforehand. Accordingly, research on non-monotonic reasoning (and logics) continued despite the critics' strictures. And it still does (cf. Gärdenfors 1992; Besnard 1989; Antoniou and Williams 1997). Indeed, just as this book was going to press McDermott received the AAAI Classic Paper Award for an influential paper on the topic (Hanks and McDermott 1986), and for his work on "causal and temporal reasoning in a wide variety of fields" (Leake 2005: 3).

As for the frame problem, it's still exercising many billions of brain cells. Hayes himself co-edited a collection of sixteen papers on it in the early 1990s, and also took time out to write a summary for Stevan Harnad's online journal *Psycoloquy* (Ford and Hayes 1991; P. J. Hayes 1992). Unsolvable though it may be, the problem won't lie down.

b. More naivety

Just as non-monotonic reasoning was presaged in 'Some Philosophical Problems', so was Hayes' work on naive physics (1979, 1985*a*,*b*). Hoping to rescue AI from the "toy problems" so characteristic of NewFAI, his goal was to capture "a sizeable portion of common-sense knowledge about the everyday physical world: about objects, shape, space, movement, substances (solids and liquids), time, etc." (P. J. Hayes 1979: 242).

These highly abstract questions were relevant to a wide range of practical problems. Many robots then being envisaged would need some mastery of the answers; and some expert systems, as his past collaborator was saying (McCarthy 1983), would need it as well.

Hayes relied on his own intuitions about what naive physics is. He didn't run any experiments, such as those done by the psychologist Michael McCloskey (1983*a*,*b*). McCloskey asked, for example, how people envisage the trajectory of a stone (held at shoulder height) dropped by someone walking fast. He found that his subjects' expectations were usually mistaken. Most said the stone would fall straight down (although a few thought it would move backwards, to land behind the point of its release); even Ph.D. students of physics often failed to give the right answer—a parabola. In other words:

> [our misconceptions] appear to be grounded in a systematic, intuitive theory of motion that is inconsistent with the fundamental principles of Newtonian mechanics [but] resembles a theory of mechanics that was held by philosophers in the three centuries before Newton. (McCloskey 1983*b*)

McCloskey suggested that these false beliefs arise from specific visual illusions (to which the medievals were also subject), a perceptual base which makes them highly resistant to modification by reason ("many [students of physics] emerge with their intuitive impetus theories largely intact"). However, *everyone* in McCloskey's experiments assumed that the stone would fall to the ground *somehow*. Indeed, he didn't bother to ask whether or not they formed that expectation: it was too obvious to mention.

That shows why Hayes didn't run experiments. What he wanted to make explicit was *that the stone would fall*. Also, he wanted to spell out just what that means: that it would follow a smooth, roughly vertical, downward path ("parabola or straight line?" wasn't relevant), ending on the ground roughly where it was dropped ("ahead, behind, or underneath?" wasn't relevant). Likewise, he wanted to say just what it is to *drop* something. (If a piece of fluff falls from my coat, have I dropped it? If I release a bird from my hand and it flies away, have I dropped it? If I'm lying face down on the floor clutching a pencil and I unclench my fingers, have I dropped it? . . .)

His two 'Naive Physics Manifestos' were a valiant attempt to make explicit a myriad of things which even McCarthy's "inventive dunce" wouldn't have thought of mentioning. These taken-for-granted assumptions and inferences pervade our everyday action, thinking, and language. They're just as crucial for subtle NLP as for successful manipulation and flexible problem solving. (Indeed, Roger Schank's "conceptual dependencies" had been an attempt to capture some of what Hayes was trying to express more thoroughly: 9.xi.d.)

Hayes asked, for instance, what happens when liquid pours out of a tilted glass. Or, to put it another way, just what is it for liquid to pour out of a container? What generally causes it? And what generally results from it? What's the difference in meaning between *pour*, *flow*, *spill*, *drop*, and the like? How might a robot be enabled to see that a container was just about to spill its contents? And how could it select a specific action to prevent the spillage, or to pre-empt a particular unwanted result of it?

As Hayes pointed out, in our everyday thinking we don't get our answers to such questions from theoretical physics. Even when someone happens to know the physics, they don't usually rely on it (a fact which McCloskey's experiments confirmed). What we rely on is naive (intuitive) "qualitative" reasoning. What we need for AI purposes, then, is a formal representation of that. And predicate calculus, according to Hayes, should be a suitable formalism.

Naive physics, alias qualitative reasoning, became an important focus of post-Kraken research. The journal *Artificial Intelligence* published a special volume in 1980, and two brief retrospectives in the early 1990s (Kuipers 1993*a*,*b*). Two influential collections appeared within six years of each other (Bobrow 1984; Weld and de Kleer 1990), and work in this area has continued ever since (Kuipers 2001).

One question that received attention was whether one should assume, following Hayes, that naive physics is *consistent*. Andrea DiSessa (1988) said it wasn't. He posited a number of "phenomenological primitives" (not theoretical principles), such as an intuitive notion of *impetus* as an unanalysed combination of force and motion. His logically fragmented view of intuitive physics allowed different, and potentially conflicting, primitives to be activated in different situations. It was similar in spirit, then, to contemporary theories of "simple heuristics" in psychology (Chapter 7.iv.g).

Another general question, which became increasingly insistent over the 1990s, was whether a purely intellectualist approach, consistent or otherwise, can capture our everyday physical knowledge. Sceptics argued that it's our *embodied experience* of solids and liquids which gives us access to their properties. For these critics, it wasn't only naive physics which was under attack. The whole of "disembodied" GOFAI, including plan-driven robotics, was put in doubt (Chapters 15.viii and 16.vii, and iii.b–d below).

Tacit conceptual structures exist for naive psychology too (7.vi.f), and for animals, plants, and time (8.i.b and d). Their core aspects are universal, not culture-specific. And they underlie thoughts that go way beyond common sense: notably, myth and religion (8.vi). In short, all human thinking involves intuitive reasoning—what Hayes called naivety.

c. The AI en-CYC-lopedia

If all human thinking involves intuitive common sense, it follows that an encyclopedia can't be understood without the reader's relying on it. But if the "reader" is an AI program, that common sense has to be explicitly supplied. This fact (or fancy?) informed the mid-1980s hope of building an AI encyclopedia: an organized body of knowledge to be consulted not by people, but by other programs.

The AI encyclopedia was Douglas Lenat's (1950–) CYC project. With the enthusiastic backing of Edward Feigenbaum, by then the public champion of expert systems, CYC was launched in late 1984 at the newly founded Microelectronics and Computer Technology Corporation (MCC) in Texas, and officially announced in the business-oriented *AI Magazine* (Lenat *et al.* 1986).

Why would the business community be interested? Well, Lenat had found in his survey of expert systems (Davis and Lenat 1982) that time was often wasted by one AI team's effortfully representing knowledge already expressed by others. Moreover, naive physics was usually ignored, since the introspection encouraged by the interview techniques of knowledge engineering wasn't capable of capturing it. A central store of common-sense knowledge, accessible by many different expert systems, would thus be extremely useful. It was the hope of attaining this practical goal which led to CYC's hugely generous funding: $50 million, enough for "two person-centuries" of work, to be spread over ten years (Lenat and Feigenbaum 1991). (Later, the funding was upped to reach six person-centuries.)

The key idea was that concepts/facts would be represented in organized frames (10.iii.a), with just a million frames sufficing to store all (non-idiosyncratic, non-arcane) human knowledge. Lenat and Feigenbaum (1991: 210) allowed that their "million" was speculative, but pointed out that two AI leaders (Marvin Minsky and Alan Kay) and a group working on electronic dictionaries had all made comparable estimates. (These included the "back-of-the-envelope calculations" mentioned in Chapter 1.iii.g.) In other words, instead of building common sense into the logic, as default reasoning, it was to be expressed within the widely shared knowledge base (Lenat and Feigenbaum 1991).

Once the encyclopedia had reached a certain size, said Lenat, it would (like McCarthy's notional Advice Taker) be able to learn new things not by hand coding, but simply by being told. And the telling would involve not only semantic inheritance, but analogy and questioning too.

For instance, CYC might be told that *a tiger is a big, fierce, cat with black and orange stripes, living in the jungle*. The system's previous knowledge of *cats* would be wheeled in, to be modified only in respect of size, fierceness, stripes, and habitat. That a tiger is a carnivorous furry mammal, with four legs and a heart, susceptible to hunger and to gravity . . . wouldn't have to be stated anew. All that information would already be included in the 'cat' frame, and automatically inherited by the 'tiger' frame. If CYC chose to ask the human being what specific type of meat tigers eat, it could do so—and slot the answer into the relevant frame accordingly.

Moreover, jungles would have been represented as *large, hot, rainy, forests with abundant flora and fauna*. So CYC would know, without needing to be specifically told, that tigers like hot, rainy, places. Given appropriate inferential mechanisms to access such knowledge when needed, an expert system for zoo-keepers would be able to advise that the tigers shouldn't be housed on the artificial ice-floe with the polar bears.

All this, however, was easier said than done. To make CYC work would require powerful AI techniques for analogical thinking (see iv.c, below). Significant effort—and, ideally, psychological research—would have to go into choosing the central case of each class, what Eleanor Rosch had called the prototype (8.i.b). Otherwise, why not define a cat as a sort of tiger? A variety of inference mechanisms would need to be provided. Eventually, CYC ended up with thirty: some already familiar—such as inheritance, demons, and if–then rules—and others not, such as following metaphorically sensible links.

The database would inevitably contain global inconsistencies, so the CYC team would have to provide non-monotonic reasoning. They'd have to provide modal operators too, including some dealing with the non-truth-functional logic of intentions, knowledge, and belief. (For instance, if Mary knows that Jack lives at No. 5, it *doesn't* follow that she knows that Poppy's uncle lives at No. 5—even if Jack is, in fact, Poppy's uncle.) To do all that, they'd have to create "a powerful constraint language which is essentially predicate calculus" (Lenat and Feigenbaum 1991: 211–12).

The amount, and range, of knowledge to be entered into the system by Lenat's thirty staff members was daunting. It concerned "thousands of everyday activities like shopping, football, visiting doctors, and so on" (Brand 1995: 236). So Schank–Abelson scripts (7.i.c) had found a new home, expressed in CYC's new language. Last but not least, the tacit knowledge that Hubert Dreyfus had said protected humans from the frame problem was to be explicitly incorporated in CYC. That meant that all of Hayes' questions would have to be answered. CYC would need mastery of naive physics—and naive psychology and folk biology too.

Whether that "mastery" was to be conceived in logical or pragmatic terms, however, was controversial. Lenat himself leant towards the second option, and favoured it even more strongly after some years of experience in building CYC. In the early 1990s, he said this:

> We avoided the bottomless pits that we might have fallen into by basically taking an engineering point of view rather than a scientific point of view. Instead of looking for one elegant solution, for example, to represent time and handle all the cases, look instead for a set of solutions, even if all those together just cover the common cases. (interviewed in Brand 1995: 237)

The philosopher Arthur Prior (1914–69), who'd pioneered work on temporal logic, would have been turning in his grave. And the logicist proponents of "neat" AI were uneasy too. But the a-theoretical "scruffies" were more accepting. Their question, in general, was not *Is it logically consistent?* but *Does it work?*

The *neat/scruffy* distinction between thinking styles is an old one, although those labels didn't come into common use in AI until about 1980. Then, they spread throughout cognitive science as a rampant meme (8.v.c). (They originated with Schank, according to his closest colleague: R. P. Abelson 1981*b*.)

The distinction is often seen as separating those driven by respectable intellectual standards from those too lazy to be bothered. That "good guys, bad guys" dichotomy informed William Woods's published critique of Schank's NLP, for example (9.xi.e), not to mention the scathing remarks he made face to face on conference panels, and in private. But some self-confessed scruffies offered strong arguments in defence of their position.

Minsky (1994), for instance, gave various reasons for believing that in *any* highly intelligent system, "consistency and effectiveness may well be incompatible". And forty years earlier, in 'Steps', he'd already argued that various types of non-logical computation are in practice essential even for proving theorems in formal logic (see 10.iii.b). As co-author of the fiercely analytical *Perceptrons*, he couldn't be accused of being intellectually lazy or scared by logic. Neither could Alan Bundy, who outlined how to combine the strengths of the two methodologies in undergraduate teaching without being misled by "slogans", or trapped into narrow AI "apprenticeships" (1981).

As an indication of CYC's *effectiveness*, Lenat—in the early 1990s—mentioned that when asked *Show me an image of shirtless young men in good physical condition*, the system had delivered a picture captioned "Pablo Morales winning the men's 1992

Olympics 100-meter butterfly" (Brand 1995: 240). The caption was crucial here, for CYC had no visual ability. But how had that query been linked to that caption?

The annotated transcript showed that a variety of common-sense knowledge had been involved. Some items were logicist axioms, such as *If X won event Y, then X participated in event Y*. Some were property-inheritance frames, implying for instance that *All Olympic men's events are instances of men's sports competitions*. Some were frames including common-sense default assumptions, such as *Participants in sports competitions are young* and *Participants in sports competitions have an athletic physical build*. Some were axioms grounded in common-sense knowledge, such as *Men who are swimming wear swim trunks*. And some were McCarthyite circumscription assumptions, such as *If CYC can't infer that a person is wearing X, assume he isn't wearing X*. So although CYC couldn't *see* that Morales was athletic, or shirtless, it found his picture in response to the user's request nevertheless.

One may wonder just how far this proffered example was a set-up. As in Lenat's Automated Mathematician (AM) program (Section iv.c, below), cynics might suspect that certain heuristics or frame-slot fillers had been provided precisely *in order that* specific 'discoveries'—such as this one—would be made. Such doubts could be allayed by inspecting CYC's data and finding that it included very much more than sport and swimming trunks, and by testing it with unexpected queries about a wide range of topics.

Lenat's original plan had been for CYC to achieve self-learning by 1994, and "completion" by 2000. Two mid-term reports—a book, and a brief résumé for the AI professionals—appeared in the early 1990s (Lenat and Guha 1990; Lenat and Feigenbaum 1991, esp. 210–28). MCC technical reports gave further details, some too recent to be mentioned in Lenat's book: e.g. further aspects of CYC's ontology of causality; early work on its taxonomy of types of change, such as transfer, destruction, etc.; and suggestions on how it might communicate with programs having simpler ontologies—Guha and Lenat 1989. (Another brief paper aimed at his peers came off the press more recently: Lenat 1995.)

CYC was proudly announced to be "still on schedule", even though "almost ten times as many" frames were required as had been expected. The team still hoped to "finish" by 1994, where this meant:

> [reaching the point] where it will be more cost-effective to continue building CYC's knowledge base by having it read online material, and ask questions about it, than to continue the sort of manual "brain-surgery" approach we are currently employing. (Lenat and Feigenbaum 1991: 212)

As it turned out, by the end of the century CYC had a core ontology of 6,000 concepts with 60,000 facts—allowing the system access to about a million facts in all (S. Russell and Norvig 2003: 363–4). These included: trees are usually found in the open air; a person, or a robot, should hold glasses of liquid the right way up; and (a particular favourite of mine) when people die they stop buying things. Countless other examples were reported by CYC's programmers, but those three items alone indicate the range of applications they were hoping to aid and abet.

By that time, several other attempts at designing and filling large common-sense knowledge bases were under way (S. Russell and Norvig 2003: 364). And a conference series on 'Formal Ontology in Information Systems' had been established, plus various web sites describing examples of ontology research around the world (e.g. <http://ksl-web.stanford.edu/kst/ontology-sources.html>).

In part, this activity was driven by a shared vision of the so-called Semantic Web, an extension of the World Wide Web foreseen by its 1989–90 inventor Tim Berners-Lee (2000: 21, 30, ch. 13). This would be "a web of data that can be processed directly or indirectly by machines" (2000: 177). It would allow not only keyword search—by Google, for example—but also automatic communication between programs, eventually by means of the "intelligent agents" mentioned in iii.d, below. For computers on the Semantic Web will achieve "at first the ability to describe, then to infer, and then to reason" (Berners-Lee 2000: 184).

Although web pages contain much which can't be understood/processed by machines, there is "a vast amount of data in them, such as stock quotes and many parts of online catalogues, with well-defined semantics" (Berners-Lee 2000: 180). If the well-defined semantics can be standardized, and the ill-defined semantics upgraded, the possibilities for automatic data search will be hugely augmented. So "the desperate need for the Semantic Web" (ibid.), given the explosion of information present but not practically accessible on today's web pages, is behind much of the current work on KR ontologies.

It's difficult even to merge very simple databases (Doan and Halevy 2005). For instance, if one database on the Web uses three descriptors for houses (*location*, *price* ($), *agent id*) and the other uses four (*area*, *list price*, *agent address*, *agent name*), how can the merging system match these schemata so as to get a sensible result? It's even more difficult to enable knowledge sharing that will support/involve simple reasoning. Consider, for example, an automated version of searching the Yellow Pages, so as to match *the books I want to buy* with *the books available from various sources* (Burstein and McDermott 2005).

Even that task is relatively cut-and-dried. The sharing of general knowledge is more taxing still. If the basic ontology of concepts like *space*, *move*, *time*, *cause*, and *animal* (and perhaps *goal*, *intention*, *purpose*, and *choice*) differs from program to program, then knowledge sharing will be faulty or impossible. Similarly, if one wants robots (e.g. Mars rovers or autonomous vehicles) to be able to communicate with each other then they must have a common ontology. Otherwise, a suggestion from robot A that robot B follow plan X in order to achieve situation Y couldn't be properly assimilated by the intended recipient.

This partly explains why, by the end of the century, the construction of "formal encyclopedias of knowledge and methods and techniques for tailoring them to particular ends", ultimately covering "all human knowledge and methods", was being listed as one of the long-term goals of AI (Doyle and Dean 1997: 98). In short, the CYC team's claims, in a discussion of the foundations of AI (Kirsh 1991*a*), that something like their approach was essential for the advance of AI *in general* had been widely accepted (Lenat and Feigenbaum 1991).

Widely . . . but by no means universally, as we'll see (ii.a–b, below). In any case, these were promissory notes rather than reports of actual achievements. With respect to the latter, what verdict should one reach on CYC's contribution?

If the money men's hopes of providing expert systems with full common sense hadn't been realized, it didn't follow *even from the point of view of the neats* that nothing of interest had been learnt. CYC had taught AI workers a great deal about the problems, and some of the tentative solutions, involved in ontology building. And it had contributed also to AI thinking about KR-by-frames, non-monotonic inference, analogical reasoning, and prototype-based thought.

Something had been learnt, too, about the topics that concern metaphysicians. As was already evident from 'Some Philosophical Problems', AI logicists got some of their ideas from previous work done by philosophers. Where Warren McCulloch had been inspired by logical atomism, the later logicists drew on Prior's (1967) temporal logic; on Willard Quine's (1953*a*) account of natural kinds and Donald Davidson's (1980) of events; on Saul Kripke's modal logic and ontology of possible worlds (1963, 1980); and on Richard Montague's model-theoretic semantics (9.ix.c) . . . to name just a few. Two AI scientists who've worked in this area (and on CYC) for many years have concluded that

> The discipline imposed in AI by the need for one's theories to "work" has led to more rapid and deeper progress than was the case when these problems were the exclusive domain of philosophy (although it has at times also led to the repeated reinvention of the wheel). (S. Russell and Norvig 2003: 363)

Whether these results were worth the initial $50 million, never mind the larger sums provided later, is controversial. Minsky, for one, wanted an even larger investment:

> [One] can imagine a system that acquires most of its knowledge by experience. [However, in 1994] we still don't have suitable learning techniques. Lenat and I agree in the view that in order to learn as a person does, one will need to begin with a considerable body of built-in knowledge about a variety of effective ways to learn. The problem is we have not done enough research yet to know how to do this . . .
>
> It seems to me there is a tragic aspect to the present situation. Over the last 15 years, almost all theoretical effort has gone into seeking alternatives where none exist. Consequently, all those years have slipped by, with no project other than CYC under way. The result is, we're all waiting to see how Lenat's work comes out, while doing nothing to help or compete . . .
>
> I find it heartbreaking there still are not a dozen other such projects in the world, while there are thousands each of attempts committed to logical deduction systems, situated action and autonomous robot schemes, feed-forward neural networks, and rule-based expert systems. Each of these has particular virtues, but none of them show much promise of making inroads into that problem of scaling up the exploitation of large accumulations of knowledge. (Minsky and Riecken 1994: 27–8)

Those words "tragic" and "heartbreaking", unusual as they are in scientific discourse, show that Minsky firmly believes a much-improved CYC to be possible—if only we try hard enough, and dig deep enough into our communal pockets. Indeed, his sci-fi novel *The Turing Option* features a futuristic CYC much as Arthur C. Clarke's *2001* featured the futuristic HAL (A. C. Clarke 1968; H. Harrison and Minsky 1992). (For the record, Minsky had been a technical consultant for the film *2001*; since Clarke's book was based on the Clarke–Kubrick screenplay, one could even say that Minsky was part-responsible for that novel, too.)

Lenat may not see CYC as a close rival to HAL, but he does hope that a future version will (for instance) help Alzheimer's patients to remember things they used to know, or prevent someone who's just broken their leg from receiving online advertisements for running shoes (Brand 1995: 239, 242). What's more, he thinks it's already good enough to be useful. In 1994 he founded a company called CyCorp, whose officially declared aim is "to create the world's first true artificial intelligence, having both common sense and the ability to reason with it". He launched an open-source version (OpenCyc) early in the new century (later than originally planned, as the expected release date of April 2001 was delayed). Clearly, then, he expected many people to find it practically serviceable. (A wide range of potential applications are listed on the web site: <http://www.cyc.com>.)

13.ii. Choppy Waters

If GOFAI was still swimming, it was doing so in choppy waters. The late-century critics of logicism and applied AI were provoked, and emboldened, by the huge attention being aroused by CYC, and by the explosion of expert systems triggered by the Fifth Generation project. To some extent, their complaints had been prefigured in NewFAI days, by Dreyfus and Joseph Weizenbaum (Chapter 11.b). But there was now much more work to attack, and the new attacks were more detailed accordingly.

Predictably, perhaps, McCarthy was recalcitrant. He still insists that "the best hope for human-level AI is logical AI, based on the formalizing of commonsense knowledge and reasoning in mathematical logic" (2005: 39). But not all his AI colleagues agree. Even his co-author Hayes has had second thoughts, as we'll see.

Some post-Kraken criticisms came from social scientists who shared Dreyfus's philosophical sympathies. The British sociologist of science Harry Collins (1943–) was a prime case in point. Others came from legal researchers sympathetic to Weizenbaum, such as Philip Leith (1954–). But some came from within the AI community itself.

a. Apostasy

Logicism's opponents didn't need to send in any Trojan horses. For this long-standing area of technical research was being attacked from within.

One such assault was mounted by the computer scientist Brian Cantwell Smith. He wrote a bitingly critical paper on CYC for the multiple review in *Artificial Intelligence* (B. C. Smith 1991). Although CYC was at the bull's-eye, logicism in general was targeted in the surround.

However, Smith had always been a maverick. His radical views on the semantics of programming languages had received the accolade of being included in the major collection on KR (B. C. Smith 1985). But his further work on computation was a very different kettle of fish. Although it wasn't yet officially published (that would happen in 1996), it had been circulating in draft for some years. It was brilliant, or crazy . . . or maybe both. What it *wasn't*, was orthodox. Indeed, it was deeply counter-intuitive in a host of ways (see 16.ix.e). It was relatively easy, then, for logicists to ignore Smith's critique of CYC. If not a true outsider, he wasn't a typical insider either. His views could be more readily dismissed as a result.

More worrying, from their point of view, was the fact that the arch-logicist Hayes was growing more pessimistic about the logicist programme as a whole:

> [With respect to] the extent to which formal logical ontologies can be said to adequately capture human intuitive knowledge . . . I've become very cynical as I grow older. For example, remember

the Frame Problem? That was a warning flag: we should have thought about that a lot harder, and seen it as a critique of our inadequate ideas, rather than trying to solve it with a technical hack. (personal communication 2004)

His new-found "cynicism" covered more than the frame problem. It also applied to formalizations of common-sense notions such as knowing what one is doing; having a sense of oneself; understanding the instruction "Proceed with caution"; and making, keeping, and breaking promises. How could a program, or a robot, have such abilities?—"We don't have any idea of how to begin answering questions like this" (personal communication). He didn't (and doesn't) think that AI is impossible. But the problems of representation were more difficult than most logicists believe.

Accordingly, he now had doubts about the extent of CYC's relevance to AI. It was generally accepted that CYC would need mastery of naive physics and naive psychology. On Hayes' view, its mastery of such matters wouldn't need to match ours. It wouldn't need to know (for instance) how a robot could obey instructions to be "careful", or how it could make or break a promise. So much the better for Lenat: if CYC didn't need to know such things, he didn't need to worry about them. But so much the worse for the prospect of CYC's realizing the goal of logicist AI as a whole: "Even if CYC had succeeded beyond Doug's wildest dreams, it wouldn't be making a jot of progress towards answering questions like these" (Hayes, personal communication, 2004).

One might object that CYC *would* have to understand promises, if it were to include entries about contracts or international treaties, and carefulness if it were to include items about legal negligence. Lenat could point out, in reply, that it had never been intended as an encyclopedia of politics or law. But some logic-based expert systems had been—and are now—intended to deal with legal matters such as these (see subsection c, below). So Hayes' late-century views on the difficulty of formulating naive physics and, especially, psychology were very uncomfortable for committed logicists to hear.

At least Hayes stopped short of accusing logicism of *impossibility*. But to the consternation of many in the AI community, another leading figure in the development of logicism had now abandoned it entirely. This was genuine apostasy, and as such highly disturbing.

McDermott, who'd tried so hard to define a non-monotonic logic, was now describing the solution of the frame problem as impossible in principle. In a paper cheekily called 'A Critique of Pure Reason' (1987), first given at a small AI meeting at the end of 1985, he argued—against his own previous convictions—that the dream of representing everyday knowledge by predicate calculus (even with modal knobs on) is unattainable.

This 'Critique' was unexpected, and all the more shocking for that. For he'd only recently published several logicist papers on cognitive science, and an AI textbook recommending the McCarthy–Hayes approach to beginners (McDermott 1978, 1982*a*, 1985; Charniak and McDermott 1985). Now, he undermined it. His new paper criticized some well-known cases, offered a general diagnosis of the "meagre results" attained so far, and rebutted six familiar logicist "defences" (including reliance on non-monotonic logics).

So, for instance, he faulted Hayes' work on naive physics and Stanley Rosenschein's (1981) on planning. These were among the best exemplars of logicism but, McDermott argued, they'd failed. As one illustration, Hayes' (1985*b*) account of liquid pouring into a container such as an open bath or a closed tank included "[what] seems like a beautiful pair of arguments". On closer inspection, however, Hayes had deduced a *reductio ad absurdum* so as to refute an assumption, but had then inferred that an assumption not thus refuted was therefore *proved*.

As for the most highly visible, not to say notorious, example of logicism, namely CYC, this—said McDermott—was doomed to failure. It didn't follow that nothing of interest to AI (and psychology, and even philosophy) would be found out by Lenat's project. As he'd remarked in his 'Natural Stupidity' paper (1976), failures can be instructive. But Lenat was hoping for more.

For all that, McDermott remained committed to GOFAI in general. He *wasn't* emulating Dreyfus's attacks on the formalization of common-sense knowledge, for his faith in formalizability was intact. His doubts concerned axiomatizing knowledge, not programming it.

The crucial logicist fallacy, he said, is to confuse deduction with computation, so to assume that all thinking is essentially deductive merely because—as he still believed—it's computational. (In 'Natural Stupidity' he'd already accused AI of misusing the term *deduction*: 11.iii.a.) This explained the paradox of an expert philosophical logician such as Hayes making the apparently elementary mistake noted above. The various efforts by AI logicists, himself included, to define non-monotonic logics had failed to deal with everyday temporality, for instance (McDermott 1982*a*). Yet we, as normal human beings, deal with it successfully as a matter of routine.

The inferences actually made by people, or by programs, may of course be formally describable even if they're not strictly deductive. Indeed, McDermott still retained his faith that this is so. However, since axiomatic analysis is restricted to deductive domains, non-deductive AI programs can be *scientifically* understood only by means of a general theory of non-deductive inference. This, McDermott pointed out, had long been sought by philosophers but not found.

Admitting the troubling possibility that much of AI may be dead-end research "buoyed by simple ignorance of the past failures of philosophers", McDermott still hoped nevertheless that its concepts and techniques will help us discover the general theories which traditional epistemology has not. Until then, on his view, there can be no comprehensive science of intelligence.

Some people assumed that this meant that AI is mere pragmatism, a technology with no scientific pretensions and, in particular, no implications for cognitive science. In other words, all one could say in 'justification' of a non-deductive AI program was *Look, Ma: it works!* But that wasn't—and isn't—McDermott's view.

He's still convinced that AI can help us understand intelligence as a *computational* phenomenon, even if it isn't an axiomatic/deductive one. So in his recent book *Mind and Mechanism* (2001*b*), he argues that programs based on probability theory or heuristics aren't deductive. They can, however, be rationally justified, in that they prevent consideration of irrelevant possibilities, and/or prune these possibilities more efficiently than other programs do. Perhaps the human mind does the same sort of thing.

b. Can the fox catch the rabbit?

A rabbit may elude the fox because although the fox sees it, and wants it, he can't run fast enough to catch it. Or the fox may not realize that the rabbit's there, so doesn't even try to catch it. Both sorts of elusiveness found analogues in logicism, and in expert systems too. And both led to attacks on late-century GOFAI.

Consider the observant but slow-running fox, first. The reasoning used by NewFAI's DENDRAL and MYCIN had been restricted to theoretical chemistry and IF–THEN logic. By the end of the 1970s, however, some people were trying to include reasoning of other kinds—causal inferences, for example. So an expert system designed for cardiology included an early causal model of how the several components of the heart lead to distinctive ECG, or electrocardiogram, traces (Bratko and Mulec 1981; cf. Bratko *et al.* 1988). Such research was driven by McCarthy's harbinger-hope of giving AI programs common sense.

That was a tall order. Obviously, satisfying McCarthy's hopes would be a useful achievement. (The rabbit was clearly visible.) But even if it was in principle possible to formalize common-sense notions such as *cause*, which in itself was controversial, it certainly wasn't going to be easy. (The fox would have to run very, very fast.) A great deal of AI work in the final decades of the century was aimed at that goal, as we've seen.

And besides, there was the (second) question of the visibility of the rabbit. In other words, there was the question whether professional expertise is describable, even in *words*, in its entirety. A fundamental assumption of the expert-systems enterprise was that it is. (The rabbit could be seen if the fox looked hard enough—and if seen, it could eventually be caught.) However, that assumption had been roundly criticized well before expert systems came on the scene.

Sometimes, it was criticized merely by a telling example. For instance, as early as 1950 the computer scientist Lord Bowden had said:

> a machine is unlikely to be able to answer satisfactorily such a question as this. "If a man of twenty can gather ten pounds of blackberries in a day and a girl of eighteen can gather nine, how many will they gather if they go out together?" (Bowden 1972, p. vi)

As he went on to observe, "it is problems like this which dominate the thinking of ordinary human beings".

Sometimes, however, the assumption was dismissed more systematically, in terms of a specific epistemological theory. The chemist–philosopher Michael Polanyi (1891–1976) is a good example here. He had long stressed the importance of "tacit" knowledge in science (1958, 1966, 1967). He allowed that tacit knowledge, once identified, can be made explicit. But he held that some (unspecified) tacit knowledge will always remain:

> Tacit knowing is the fundamental power of the mind which creates explicit knowing, lends meaning to it and controls its uses. Formalization of tacit knowing immensely expands the powers of the mind, by creating a machinery of precise thought, but it also opens up new paths to intuition. (Polanyi 1966: 18)

Polanyi had used his critique to oppose philosophies of science, such as Karl Popper's, which took scientific knowledge to consist only in (explicit) theories, hypotheses, and empirical data. But it was later applied by his followers to expert systems, too.

One of the younger generation of scholars deeply influenced by Polanyi was Dreyfus. Another was Collins—who was led to consider AI largely by Dreyfus's critique of it.

Dreyfus had pointed out, for example, that if you tell an automated travel agent that you'd like a flight to San Francisco leaving "a little earlier" than its first suggestion of 6.30, you don't want it to come back to you with a flight leaving at 6.29 (Pagels *et al*. 1984: 340). Moreover, adding a rule saying *"Earlier" means at least fifteen minutes earlier, and at most two hours earlier* would often help—but not always. As Dreyfus put it, this expert system "doesn't contain any knowledge of human temporality—what spans of time are important to human beings".

Towards the end of the century, Collins explored that line of thought in writing at length about expert systems (1989, 1990; Collins and Kusch 1998). His prime motive was to attack cognitive science, to persuade his readers that *mind-as-machine* is a philosophical absurdity. That's not our main interest here (but see Chapter 16). Rather, our question is what worried him about post-Kraken expert-systems *technology*, and what AI could learn from him about its own practices.

What it *could* learn, not what it *did* learn. Partly because they associated him with Dreyfus, most AI workers didn't bother to read Collins, or didn't take him seriously if they did. He certainly wasn't a friendly voice. Nevertheless, he said some things worth hearing.

In comparing rule-following expert systems with human experts, including scientists, Collins showed that our knowledge is indeed largely tacit. So far, so familiar—from the point of view of the AI practitioner. For by the time Collins's book appeared, knowledge engineers—whether they'd read Polanyi or not—had long recognized that professional skills are largely unstated. Indeed, the interview techniques they'd established had been developed precisely in order to uncover normally hidden inferences and assumptions, including informal heuristics that wouldn't be found in the textbooks (see 10.iv.c).

But Collins had two more arrows in his quiver. One was that scientific understanding is largely a matter of practical, bodily, skills. As such, these skills can't be fully described in verbal/logical terms. Again, this was familiar territory to readers of Polanyi. Another sociologist of science, Donald Mackenzie, would soon make the same point—in a reassuring, not apocalyptic, spirit—with respect to nuclear-weapons technology (see 4.ix.a). But Collins made it with specific reference to expert systems.

He drew much fascinating evidence from his closely detailed case study of laboratory work in crystal growing, and of an attempt to write an expert system for this domain (1990, chs. 10–12). This evidence cast doubt on whether AI programs could be relied on to interpret new experimental data. "DENDRAL had done pretty well", an AI defender might say. But Collins would have replied that the novel spectrographic data were perceptually monitored by a human being, to check for noise, before being passed on to the program (1990: 128–32). Without such monitoring, DENDRAL could easily have been misled (cf. the discussion of BACON in H. M. Collins 1989).

In addition (the last arrow left in the quiver), Collins argued that *using* an AI system requires one to draw on background skills and assumptions that aren't normally made explicit. Indeed, he said, the same applies with respect to using a hand-held calculator, or even adding on one's fingers.

For example, in counting on one's fingers one must be able to recognize a finger, to remember when a finger has been used, and so on (Collins 1990: 48). Any or all of these skills might be lost after neurological damage. And in using a calculator to work out someone's height in centimetres, one must know what type of answer counts as "correct" (pp. 53–8). To say that a man who is 5 foot 9 inches tall has a height of 175.26 centimetres, because the calculator says so, is *not* to use the machine properly.

In that case, of course, the calculator does at least *do the arithmetic* correctly. But Collins described several intriguing examples where the computer gets the arithmetic wrong (pp. 66–70). For instance, 7 divided by 11, multiplied by 11, came out on one machine as 6.9999996. On another, the same sum resulted in 7; but *the very same machine, set to work more "accurately"* also delivered the answer 6.99999988079071. In such cases, an arithmetically sensible human being is needed to retrieve the situation. If they have some glimmering of understanding of the machine concerned, so much the better—but this isn't strictly necessary.

Moreover, using numbers, never mind using computers, is a community-specific practice. It's governed by norms of correctness that one learns—or not—from one's culture. These norms don't merely influence the numerical exactitude we deem suitable in describing someone's height, but also determine what doing arithmetic *is*. (The same applies to mathematical proof, and to its automation: Mackenzie 1995.) "In lands remote from Western culture", said Collins, "the calculator is no more an arithmetician than two sticks rubbed together are a slide rule" (p. 71).

Similarly, one must have some sense of the purposes and limits of an expert system to be able to use it properly. In other words, an expert system *purely by itself* doesn't, and can't, supply reliable answers. It can do so only when used by a person. And that person, besides having common sense and a vast store of worldly knowledge, is a member of a community, whose norms of "correctness" matter:

> The intelligent computer is meant to counterfeit the performance of a whole human being within a human group, not a human being's brain. An artificial intelligence is a "*social prosthesis*". In the Turing Test the computer takes part in a little social interaction. Again, when we build an expert system it is meant to fit into a social organism where a human fitted before. An ideal expert system would replace an expert, possibly making him or her redundant. It would fit where a real expert once fitted without anyone noticing much difference in the way the corresponding *social group* functions. (1990: 14–15)

Although he didn't say so here, it had been the express intention of many expert-systems builders that their programs be consulted *in lieu of* human experts. The resulting consultation might not happen "without anyone noticing much difference". But in the absence of the AI system, it might be that no consultation would happen at all. (Human experts are expensive, and geographically focused too.)

Collins didn't dismiss the AI enthusiast's claim that expert systems can be useful, even *very* useful. By 1990, after all, their usefulness had been demonstrated over and over again. And Polanyi himself had said that formalization "immensely expands the powers of the mind". For many practical purposes, then, Collins's argument could be ignored. But it came into its own in contexts where expert systems were being considered for purely automatic use. If Collins was right, the human being should never be taken out of the loop.

During the 1970s, very few people had been considering doing that. Even Kenneth Colby's plans for computer psychotherapy, already denounced as "obscene" by Weizenbaum, hadn't suggested that the psychiatrist be sidelined, nor (yet) that patients self-administer the computer therapy in their own homes (see Chapter 7.i.a). At that time, expert systems clearly weren't good enough to be left to run the show by themselves.

In the 1980s, however, expert systems entered deeply into the business world—and the military world too. Many in the AI community found this deeply worrisome, and some passionately resisted the US government's "Star Wars" plan for using automatic AI experts in defence (see 11.i.c). Most of that resistance drew its power from their expert realization that the *technical* correctness of huge AI programs couldn't be guaranteed. But some of it was based on considerations similar to those which Collins would publish a few years later.

For instance, Henry Thompson (an NLP specialist at the University of Edinburgh) told the salutary tale of a nuclear near-disaster which had been averted only because common sense—and a sense of human community—had led someone to doubt what the computer was saying (H. Thompson 1984). A nuclear red alert in the USA had been caused by an unknown object on the horizon. The reason why this frightening episode didn't escalate further was that someone ruminated that the Soviets hadn't been making especially threatening remarks recently. The norms of political behaviour, even during the Cold War, therefore made it highly unlikely that this mysterious object was a Soviet attack. And the same norms deemed it inadmissible to launch defensive nuclear weapons on the basis of such weak—i.e. *politically* implausible—evidence. Accordingly, the computer was overridden. (The unknown object eventually turned out to be the rising moon: 11.i.c.)

That's not to say that whenever someone uses their common sense to contradict the computer, they're right. Consider another salutary tale, the story of the 1979 Three Mile Island accident in Pennsylvania (Reason 1990, ch. 7). There, a nuclear meltdown very nearly happened (and all children and pregnant women were evacuated, by order of the Governor) when someone sensibly decided to ignore the computer's advice—"sensibly", because the advice would have been disastrous *in any circumstances other than the highly improbable situation which actually obtained*.

That particular decision might have been prevented by a better human–computer interface. For it happened largely because the operator was overwhelmed by myriad dials changing simultaneously: nearly 200 alarms went off within the first few minutes (Michie and Johnston 1984: 57). After the official inquiry into this crisis, the instrumentation in some manned control rooms was simplified accordingly. But there's no way of avoiding such mistakes entirely.

Nevertheless, if the person in Thompson's moonrise story, with their community-sensitive political antennae, had been taken out of the loop then he might not have been there to tell the tale, and you might not have been here to read it. Many less dramatic examples were discussed in warnings given by other AI-friendly writers besides Thompson. For instance, people working in or sympathetic with the field of expert systems gave various warnings about their use in psychotherapy (7.i.a), law (see below), medical diagnosis (Dennett 1986), and other socially relevant areas (Boden 1977, ch. 15; Council for Science and Society 1989, chs. 3–5).

Some Western AI scientists advised using the Japanese term "job assistant systems" instead, because it made the responsibility of the human user, and the (partial) inferiority of the program, more evident (Council for Science and Society 1989: 5). Some warned their fellow AI professionals not to mislead the public by hyping their programs, and asked that they try to prevent the marketers from doing so too—backed up, preferably, by an official "Code of Conduct" for the profession (Bundy and Clutterbuck 1985; Whitby 1988). And some even included specific warnings in their programs and/or the accompanying literature, to ensure that users didn't ascribe real intelligence or, worse, responsibility to the machine (Sieghart and Dawson 1987).

In sum, Collins's hostility to AI in general and expert systems in particular didn't prevent him from having some highly pertinent things to say. Whether many AI researchers (as opposed to Collins's philosophical sympathizers) actually bothered to read them is another matter.

c. Matters-in-law

As a special case of the type of worry raised by Collins, and one which raises many issues within other areas of cognitive science, let's consider expert systems in law. After outlining (in this subsection) how these have been developed over the years, we'll look (in the next) at some of the "human" problems regarding their use today.

When Herbert Simon modelled Supreme Court decisions as wiring diagrams in the 1940s (6.iii.a), he was doing this *post hoc*: there was no suggestion that the electronic circuits might be used by the judges themselves—still less, that they might take over. And when Lucien Mehl, at the famous NPL meeting in 1958 (6.iv.b), envisaged using automated logic for legal inference he was scolded in the discussion by Yehoshua Bar-Hillel for being "very premature, to put it mildly" (Mehl 1959: 783).

Premature, it certainly was. But in principle, not totally unrealistic. In 1976, when Weizenbaum published his impassioned critique of "AI judges" (11.ii.d), a few people were already starting to speculate about how legal reasoning might be modelled by AI.

Bruce Buchanan (with Thomas Headrick of Lawrence University) had written a speculative paper on this topic for the *Stanford Law Review* some six years earlier (Buchanan and Headrick 1970). And two years after that, in April 1972, the Stanford Law School had held a 'Workshop in Computer Applications to Legal Research and Analysis'. Most of the twenty-eight participants were lawyers (including one from the early-established Institute of Computing and Law in Toronto). But they also included Feigenbaum, Buchanan, and Stanford's L. Thorne McCarty (1944–).

Whereas Feigenbaum and Buchanan (and Headrick) talked about AI and expert systems in general, McCarty (1973) reported on the "pilot" for TAXMAN. For despite his modest disclaimers "I don't yet have any results . . . [only] tentative and incomplete [remarks]" and "Most of what I describe has not yet been implemented" (pp. 1, 4), he'd already started programming the first expert system in law.

TAXMAN's area of expertise was the taxation of corporate reorganizations. Its aim wasn't to do arithmetic ("You owe $350,000 in tax") but to identify tax-free, or relatively tax-free, reorganizations. In addition it should argue for *and also against* the case that a particular reorganization would be free of taxes. The data—including rules defining legal concepts such as *stock*, *voting stock*, *equity*, *control*, *acquisition* . . .—were represented in a semantic net, modifiable at any time. (Interaction with users, McCarty intended, would improve the system continually.) Every assertion was linked to an additional data structure giving its legal justification—and also "some indication of how it can be subsequently attacked" (p. 6).

McCarty saw TAXMAN as having wide potential. Part of his reason for choosing corporate taxation as the topic was that

> the law here has an interesting history: it shows a complex interplay between broad common-law judicial concepts and specific statutory declarations, and this developmental process is one aspect of the law that I want the TAXMAN program eventually to focus upon, however difficult that may be. (McCarty 1973: 2)

For example, the crucial concept of "business purpose" was probably *not* capturable by a set of legal rules, but was grounded in "a complex set of arguments based on a vast collection of knowledge about [corporations] and the purposes of the reorganization laws" (p. 10). It remained to be seen how far this could be captured by AI heuristics. If case law were ever to be included, this would require programs for dealing with analogies/disanalogies between cases: a problem "more important and interesting than any I have talked about so far", and "the really challenging part of the research" (pp. 12, 14).

But even in the case of failure, he said, everyone would gain. On the one hand, legal analysis would be as helpful for advancing AI in general as chess, blocks world, or even mass spectrometry (i.e. Feigenbaum and Buchanan's DENDRAL: 10.iv.c). On the other, the attempt to write legal AI programs would provide insights into jurisprudence and the nature of legal reasoning.

McCarty was right (Rissland *et al.* 2003). However, he was a lone voice at that time. Buchanan was interested, as we've seen. But his energies were focused more on chemistry (DENDRAL) than law. It would be some years before any serious attempts, other than McCarty's (1977, 1980), were made to design legal reasoners as opposed to speculating about them.

The most influential of these was due to the PROLOG-implementer Robert Kowalski. In the mid-1980s, he and his student Marek Sergot would be invited to participate in an IJCAI Panel Discussion on the legal implications of AI (Boden *et al.* 1985). Whereas some panellists focused on questions about legal responsibility for the use/non-use of expert systems in general, Kowalski and Sergot discussed computer representation *of the law itself*. Today, their influence is still strong: many current legal AI systems are based on their pioneering example (and Sergot has been a President of the International AI and Law Association).

Their first exercise in this area was a PROLOG version of the British Nationality Act (BNA) of 1981 (Kowalski and Sergot 1985; Sergot *et al.* 1986; Kowalski 1992). Soon afterwards, they produced comparable programs representing legislation in other areas: immigration, government grants to industry, pensions, and taxes; and sick-pay regulations (Sergot *et al.* 1986: 385).

They'd chosen to model the BNA for three reasons. Two are unsurprising: the BNA was an example of statute law, which is "basically definitional in nature" and so less difficult to handle than case law; and, being then so recent, it was still relatively free of "the complicating influence of case law" (Sergot *et al.* 1986: 370).

The third reason was less obvious—and less open to counter-cultural scorn. For they chose this piece of legislation partly because it was highly controversial. The civil rights movement in the UK was up in arms, because the recent Act had introduced several new classes of British citizenship. Instead of all citizens being equal, some were now more equal than others. "We hoped", said Kowalski, "that formalization of the various definitions might illuminate some of the issues causing the controversy" (ibid.).

His hope was reasonable. For even if—as critics of logicism would have said—the attempt to corral legal concepts of nationality within strict PROLOG definitions was doomed to failure, it might help clarify the concepts concerned. Indeed, trying to write laws in the form of expert systems often exposes unrecognized gaps or ambiguities, just as it does for psychological theories.

By the mid-1980s, for instance, one US state legislature was already drafting its regulations in programmed form for this reason (Council for Science and Society 1989: 23). Similarly, a program produced at much the same time to mimic the initial selection of applicants for St George's Hospital Medical School in London was exposing previously unsuspected racism in the human selectors' procedures (CRE 1988). The racism may have been (to borrow Weizenbaum's word) obscene, but the whistle-blowing program wasn't.

Kowalski and Sergot's early systems were never used as a matter of routine. They weren't installed in lawyers' (or civil servants') offices and let loose on legal/administrative decision making. But besides any help they may have provided to legislators in drafting, they did have a strong influence on many advice-giving systems—such as an adviser on social security entitlements (Browne and Taylor 1989).

Today, BNA-type programs are being used by companies and governments in the UK, Europe, Australia, and USA (M. Sergot, personal communication). These deal, for instance, with building regulations, safety rules, and tax laws. The human–computer interfaces are hugely better now than in the 1980s, but the logical core is broadly similar.

So Kowalski's vision has been vindicated? Well, yes and no. For Kowalski's main interest was/is in cognitive science, not technological AI. (The same applies to McCarty.) His main aim wasn't to produce AI programs for lawyers to use. Rather, it was, and still is, to understand and help to improve everyday thinking in general—even including conflict resolution where, as in the Palestine–Israel dispute, the two sides have logically incompatible goals (Kowalski 2001, 2003, in preparation; Kowalski and Toni 1996). He sees legal thought as a helpful halfway house between logic and full informality. The hardy perennial of default reasoning, for example, is somewhat clearer in legal/administrative contexts than in idle gossip about the day's latest news (Bondarenko *et al.* 1997).

However, technological AI has benefited too, for logic programming as such has been affected. Kowalski (2002) has recently suggested several extensions based on types of language and argument needed in legal and everyday contexts. One of these adds "ordinary negation" to "negation by failure" (see 10.iii.b and v.f).

Whereas Kowalski and Sergot came to AI-and-law from their expertise in GOFAI, others came to it from law and jurisprudence. Leith, now Professor of Law at Queen's University, Belfast, is a well-known supporter of the use of computers in law, but a long-standing critic of AI models of legal reasoning. He was among the first to criticize logicist programs such as Kowalski's (Leith 1986*a*).

His core complaint was, and remains, that law is not—or not usually—a matter of cut-and-dried rules, but involves social negotiations of various kinds on the part of the barristers and judges who interpret the law:

> It seems to me to be all very well to draw up a collection of rules from legislation; but, as lawyers all know intimately, a piece of legislation is but one thing in the legal world. (Leith 1986*a*: 551)

In principle, of course, certain interpretations can be favoured in an AI system. But if that's done, then other possibilities are tacitly excluded.

Leith follows up Kowalski's admission that common law is especially difficult to model in AI terms, and that a concern for precedents can complicate even statutory law. Precedents in law provide the human paradigm of "case-based reasoning", a technique whose AI versions are widely used in many different contexts (Kolodner 1992, 1993; Leake 1996). For example, it was incorporated in the MINSTREL storytelling program, enabling it to generate the concept of *suicide* from that of *killing* (S. R. Turner 1994; see iv.c below).

In case-based reasoning, a previous problem/solution is identified, somehow (methods vary), as being similar to the current problem, and is then used as a template for solving it. Various aspects of the previous case's structure, with modifications as necessary, are mapped onto the current situation. This isn't straightforward, for both the identification and the modification involve analogical reasoning.

Modelling case-based reasoning in law, as McCarty had forecast in the early 1970s, would require a very powerful theory of analogy (Rissland 1985). But analogy isn't a simple matter—which is why the initial judgement of one person (lawyer) can be altered by reasoned negotiation with another. Common sense, not to mention cognitive scientists' work on relevance (7.iii.d), suggests that programs will interpret the law in ways much more crude, and much less just, than humans do. That applies even to legal expert systems with a case-based component (e.g. Rissland and Skalak 1991; Skalak and Rissland 1992; O'Callaghan 2003; O'Callaghan *et al.* 2003*a*,*b*).

More recently, Leith (1992) has pointed out that law-in-use typically involves spoken argument, not only in court but also in preparation (identifying the "facts" and the core issues, and even negotiating with clients about their instructions). This adds further cognitive dimensions, over and above those relied on by readers of law books. And it's not only computer scientists who forget this. Academic lawyers forget it too:

> The history of academic thinking about law and legal analysis in the 20th century has been the history of the textual nature of law. This most solid strand of legal thought has almost completely dominated and blotted out all other views; it is the view that all that lawyers need to know about law sits on the bookshelves of law. (Leith 1992: 227)

Legal *practitioners*, said Leith, know better. But they don't write the law books. (They may, of course, write novels and screenplays, in which the narrative can turn on just what's said in the witness box, even on *just how* it's said; remarks in letters can have similar effects on juries: e.g. the insurance assessor's "You must be stupid, stupid, stupid" in John Grisham's *The Rainmaker*.) Deep analysis of rules is all very fine for the legal academic, Leith admitted, but "if we want to develop and encourage gifted lawyers, then [we should focus on] the communicative skill of rhetoric—as the essence of advocacy" (p. 233). This realization, he continued, "takes us far away from current research strategies in AI and law" (p. 234).

He was right: AI modelling of 'law as she is spoke' is a tall order. This is evident, for instance, from Bernard Jackson's (1995) subtle exploration of the numerous interpretative complexities. And although some current AI work does focus on the rhetorical structure of legal arguments, it's still relatively crude (e.g. Ashley 1990; C. Reed 1997; Reed and Norman 2004). Grisham needn't fear that an AI-advised rival will replace him on the best-seller lists.

Law, logic, analogy, even rhetoric . . . it's clear that this is a wide-ranging area. Both professional lawyers and AI researchers take part in the ongoing International Conference on AI and Law (the ninth in the series was held in Edinburgh in 2003). Similarly, both contribute to journals such as *Artificial Intelligence and Law* and the *International Journal of Law and Information Technology*. And very recently, in November 2003, the core *Artificial Intelligence* journal published a special issue on AI and law, with contributions from both sides of this disciplinary fence. In addition, the more general research is sometimes reported also at cognitive-science meetings (e.g. Ashley and Keefer 1996).

The technical discussions range from dedicated models of specific legislation to wide-ranging work on the psychology of case-based reasoning and argument structures. In short, insights from AI, law, and psychology contribute to what is an essentially interdisciplinary enterprise.

d. Judgements about judges

Not all of the discussions on AI and law are "technical", however. Some are ethical. Indeed, we've seen that some law programs, such as Kowalski's version of the British Nationality Act, were written partly in order to clarify morally troubling aspects of the law.

But that was clarification, not application. Now that various legal programs are actually being used, and more are in the Establishment-approved pipeline, arguments about their appropriateness abound (e.g. Susskind 1987, 1993, 2000; Leith 1986*a*,*b*, 1988, 1992; Whitby 1996*b*: 44–63). The disputants include lawyers, as well as AI and cognitive-science researchers.

Many of these disputes concern the reliability of expert-systems representations of statute and/or common law, including computational and jurisprudential questions about the relation between law and logic. Others spill over into by-now-familiar questions about how to model the flexibility of human thought. For instance, the psychologist Jerome Bruner has recently discussed the combination of system and messiness in legal reasoning; he sees this as being grounded in case-based reasoning, but stresses the *narrative* aspect of the "cases" concerned (Bruner 2002; Shore 2004: 148–9). Yet other disputes express worries about situations in which the human being might cede responsibility for judgment to the program.

In general, the concerns differ according to just who is (or will be) using the expert systems, and why.

Most law-related programs today are intended for in-house use in lawyers' offices, or by people giving advice to citizens on entitlement to benefits and other regulatory matters. Examples include the latest version of TAXMAN, and the regulatory programs modelled on the work of Sergot and Kowalski. "Merely information retrieval", you may say. But even these programs can raise Collins's worry about removing human discretionary judgement from the loop (Browne and Taylor 1989).

Others are intended for use in the law courts, to aid decisions on the verdict (in non-jury trials) or on sentencing by judges or magistrates. These are even more problematic.

For they revive the McCarthy–Weizenbaum question (11.ii.d): whether computers might ever replace judges—and if so, whether this is desirable.

Just in case you think that it so obviously *isn't* desirable that it's simply not worth discussing, you should remember the remarks of the several young black Americans quoted in Chapter 11.ii.f. For instance:

> I know that if I ever had to go before some judge, there is a good chance that he is going to see my face and he is going to think "nigger".
>
> The computer judge would have a set of rules. He would apply the rules. It might be safer. (quoted in Turkle 1995: 292–3)

The question, then, is whether such fairness could be achieved (whether "the rules" could be adequately expressed), and if so whether this would do significant harm to the human dimensions of the law courts.

Such topics are no longer maverick, and many people today share some of Weizenbaum's concerns. For instance, in 1989 the UK's Council for Science and Society, an opinion-forming group with close links to both Houses of Parliament (and other sectors of the Establishment), predicted that an expert system might in future be used to help a Crown Court judge pass sentence. So the judge might say:

> Norman Stanley Fletcher, you have pleaded guilty in this court to a series of offences. In the light of your previous record, my normal inclination would be to put you on probation. However, I have consulted DISPOSAL, the expert system [in the laptop] I have on the Bench with me. Having entered all the relevant particulars about you, it tells me that the prospects of your responding favourably to probation are only in the range of 14 to 17 per cent, and that the statistical significance of this result is very high. It also appears that the prospects of success of any other non-custodial sentence that I might consider would be even lower. Accordingly, I have no option but to sentence you to a term of imprisonment of seven years . . . (Council for Science and Society 1989: 26)

Whether a successful appeal in such a case could be based on the judge's admission that he overruled his own judgment because of "what his microcomputer 'told him' ", the Report continued, "is an intriguing question".

That wasn't a joke—even though Norman Stanley Fletcher was the lead character in a hugely popular TV sitcom set in one of Her Majesty's prisons. (You may also feel that it's no joke.) This particular section of the CSS Report was drafted by the prominent British lawyer Paul Sieghart, a few months before his unexpected death in 1988. Sieghart was the founder of CSS, and also of an influential group (Justice) for considering tricky juridical/constitutional questions, especially in the area of human rights. Several important law reforms have been instigated by him, and he's still honoured by an annual Memorial Lecture that's been given by some of the country's most renowned judges and legislators. In short, he was a provocative thinker whose provocations often ended up being accepted as common sense. Moreover, he can't be written off as someone with no human sensitivities. Sieghart may have been smiling when he wrote those words, but they were seriously meant.

Comparable worries have been addressed by Richard Susskind (1961–). He's the Gresham Professor of Law and Visiting Professor at Strathclyde University's Centre for Law, Computers, and Technology. But he's no cloistered academic. (Is anyone, nowadays?) Besides his academic posts, he's the official adviser on IT to Lord Woolf, Lord Chief Justice of England and Wales. As such, his opinions are more influential than most.

Susskind has long held that "there are no theoretical obstacles, from the point of view of jurisprudence, to the development of rule-based expert systems in law of limited scope [such as the Scottish law of divorce]" (1987, p. vii). Accordingly, he's broadly in sympathy with the BNA-based approach. Indeed, he's helped to develop several similar implementations (e.g. Capper and Susskind 1988).

With respect to the Weizenbaum–McCarthy debate, he said this (in the late 1980s):

> A detailed study of this matter is sorely needed both to dispel the profusion of misconceptions and to assure the public that while computers will no doubt provide invaluable assistance to the judiciary in the future, it is neither possible *now* (or in the conceivable future) nor desirable *ever* (as long as we accept the values of Western liberal democracy) for computers to assume the judicial function. (Susskind 1987: 249)

As for what one might expect a "detailed study" to show, Susskind was very clear about the difficulties involved:

> Moreover, any legal theorist will recognize that construction of an expert system in law that could solve *all hard cases* would require . . . the development (explicitly or implicitly) of theories of legal knowledge, legal science, individuation, structure, legal systems, logic and the law, and of (judicial) legal reasoning, all of a far greater degree of richness, sophistication, and complexity than those that have been generated by the most adept jurisprudents in the past. (p. 250; italics added)

In other words, *Don't hold your breath!* Without using inflammatory terms such as "obscene", Susskind was echoing Weizenbaum's plea for human judges.

He's repeated this plea recently, by reissuing an early paper (1986/2000) in which he expressed his "horror" at McCarthy's reply to Weizenbaum, pointing out that among the many capacities of judges which computers don't possess are "moral, religious, social, sexual, and political preferences" and "creativity . . . intuition, commonsense, and general interest in our world that we, as human beings, expect not only of one another as citizens but also of judges acting in their official role". (Consider the scorn meted out to the judge—perhaps apocryphal, or joking—who asked "Who are the Beatles?")

The 1987 quotation, above, mentions "hard" cases. But even "clear" cases may not be so clear as is sometimes assumed. Susskind, again:

> In any clear case, *according to positivists*, the judge is committed—perhaps by the value of legality—to making one particular legal decision (or else, we might say, the case is not clear). If the judge wishes to abide by the principle of legality, or for some other reason decides to remain faithful to the law, he has no choice but to make that decision, even if he finds it morally unacceptable . . . As a matter of logic, then, there is no need for judgment in clear cases; there is nothing required other than a conclusion/decision reached through the inexorable application of deductive inference procedures . . . (1986/2000: 286; italics added)

The positivist separation between law and morals, Susskind argues, is mistaken. However, many arguments intended to refute it do no such thing (pp. 282–92). In particular, arguments assuming that positivism, mistakenly, "tends to see judges as computers; as, at least in clear cases, simply certifying what in fact the law is, without necessary moral commitment" (p. 282) are often flawed. They fall foul of logical non sequiturs, to the author's failure to be "a natural lawyer" (p. 291), and—significantly—to ignorance of AI in general.

In sum, Susskind (like Collins) sees many problems regarding tacit judgements lying in wait here. Nevertheless, his views on jurisprudence don't outlaw AI from legal offices, nor even—as quasi-intelligent aide-memoires—from the judge's bench. The relatively clear cases, at least, are potential grist to the computational mill. Like Sieghart, Susskind is an influential voice in the British legal profession. So we can reasonably expect to see AI entering the law courts. Whether it will always be reasonably used there, and/or reasonably regarded by the lay members of the court, remains to be seen.

13.iii. Advance and Attack

If logicism was a key research focus right from the beginning of AI, many other themes mentioned by the NewFAI pioneers were not. They couldn't be fruitfully studied until other matters (e.g. KR) had been advanced. In the closing quarter of the twentieth century, however, they came into their own.

The result was both advance and attack. Some late-century advances delivered on promissory notes issued in the 1950s. Others went so far beyond the early efforts that they engendered a very different (i.e. non-psychological) research spirit. One development, rooted in old ideas, attacked the most cherished of NewFAI assumptions: this mini-Kraken, namely situated AI, is regarded as a 'hot' topic today. Similarly, "distributed" cognition, in which *multiple* agents (human and/or artificial) collaborate, is now "one of the main directions for AI research in coming years" (Doyle and Dean 1997: 95; cf. Grosz 1996).

a. Gelernter revivified

Herbert Gelernter's late 1950s implementation of Minsky's back-of-the-envelope sketch (10.i.c) turned out to be much more than a nine days' wonder. For the general idea of using *a model, or schema, of the problem* (of which a diagram is a special case) had a lasting effect on techniques for controlling search. Moreover, diagrammatic reasoning itself attracted increasing interest in the last two decades of the century.

For instance, in 1980 Funt described an ingenious way of implementing diagrams-as-analogue-spatial-representations (as opposed to Gelernter's diagrams-as-symbolic-line/angle-specifications). He used a simulated parallel processing 'retina' (a 2D visual array) made of many individual cells, wherein image transformations could be defined spatially rather than symbolically. One application modelled the image-rotation experiments that had caused such excitement in experimental psychology in the 1970s (Chapter 7.v.a); not only could the system decide whether one image was indeed a rotation of another, but the time it took to do so was proportional to the degree of rotation involved (Funt 1983). Another, even more relevant here, was the WHISPER program (Funt 1980).

WHISPER solved problems about stability and "chain reactions" in the blocks world. But unlike Scott Fahlmann's BUILD (10.iii.c), it didn't use abstract reasoning about

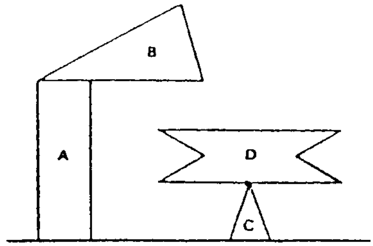

FIG. 13.1. Is block B stable? If not, what will happen when it falls? Adapted with permission from Funt (1980: 214)

physics to do so. Instead, it used qualitative knowledge about physics, and ways of continuously transforming one retinal image into another, to infer what would happen in certain situations. For instance, it could 'see'—or anyway, 'imagine'—that object B in Figure 13.1 is unstable, and that on falling it will hit object D, which will then tip over until the lowest point rests on the floor to the left of object C (Funt 1980, esp. 213–29).

WHISPER's method of representation was very different from most AI programs, and Funt's 1980 paper was chosen as one of those reprinted in the influential *Readings on Knowledge Representation* (Brachman and Levesque 1985). Given that this collection offered a thirty-page bibliography of relevant publications which hadn't been included, that was no small accolade.

Alongside it was a theoretical paper on analogical representation by Sloman (1975), whose earlier work on this theme had inspired Funt to build WHISPER in the first place (Sloman 1971; cf. 1978, ch. 7). As the editors of the *Readings* pointed out (p. 431), Sloman was one of the few people to have thought deeply about the difference between analogical and formal representations—a topic that was causing huge controversy in psychology at that time (7.v.a).

A main aim of Sloman's 1971 paper had been to clarify what's going on in "intuitive" reasoning. Since WHISPER's inferences were based on its imaginative transformations on the retina, they were intuitive rather than deductive. Indeed, this is true of diagrammatic reasoning in general. But how could logicians or mathematicians be confident that intuitive reasoning is valid?

Over the past quarter-century, Alan Bundy's research group at Edinburgh have addressed that question, seeking to justify intuitive reasoning in deductive terms. Specifically, they've worked on mathematical induction, in domains ranging from program synthesis, through arithmetic, to geometry (e.g. Bundy 1988; Bundy *et al.* 1990). In mathematical induction, of which diagrammatic reasoning is a subclass, specific results (achieved by intuitive "eureka steps") are used to justify general conclusions.

The Edinburgh group's general "theory of diagrams" enabled them to show how a diagrammatic proof can be generated, then schematized, and finally verified (Jamnik *et al.* 1998; Jamnik 2001). More recently, their interactive program "Dr. Doodle" has helped students to reason more easily about a mathematical domain that's usually represented algebraically (Winterstein *et al.* 2004). (One shouldn't assume that diagrams or visual images always aid problem solving; sometimes, they block it—Boden 1990*a*: 100–10.)

Many others, too, took up Gelernter's baton. In the 1980s, the journal *Artificial Intelligence* ran a 400-page special number on geometric reasoning (Kapur and Mundy 1988). By that time, too, researchers were able to knit new AI garments by wielding it alongside Ivan Sutherland's baton of computer graphics (v.c, below). Sutherland's pioneering ideas of the early 1960s had now been properly implemented, so that diagrams of three-dimensional structures could be generated, moved, rotated (with automatic deletion of hidden lines if necessary), and transformed. Plane geometry doesn't need such changes, but some diagrammatic thinking does.

In brief, diagrams have come in from the cold. Even McCarthy now allows (or "I would, if I had a definite idea of what a diagram is": personal communication) that they may be a more efficient form of representation for some purposes than logic is—although where logic can be used in a running program it's preferable, and it should in any case be used to specify what a program does. Today, there's a biennial interdisciplinary conference called 'Diagrams' (devoted to "the theory and application of diagrams in any scientific field of enquiry"), besides sessions and workshops scattered across various other meetings.

The 'Diagrams' series attracts people from AI and cognitive psychology, through education and human–computer interaction, all the way to architecture and cartography. So besides being highly interdisciplinary, it involves both psychological and technological AI.

b. Planning attacked—

The NewFAI researchers, one might say, had been committed Marxists. For Karl Marx had stressed the role of anticipatory planning in intelligent human labour:

> [Man] sets in motion the natural forces which belong to his own body, his arms, legs, head and hands, in order to appropriate the materials of nature in a form adapted to his own need . . . [So do animals—but human labour is different.] A spider constructs operations which resemble those of the weaver, and a bee would put many a human architect to shame by the construction of its honeycomb cells. But what distinguishes the worst architect from the best of bees is that the architect builds the cell in his mind before he constructs it in wax . . . Man not only effects a change of form in the materials of nature; he also realizes his own purpose in those materials. (Marx 1890: 283–4)

Simon, Fahlman, Sacerdoti, Allen Newell, Gerald Sussman, Richard Fikes, Nils Nilsson . . . all had agreed. Indeed, it would be difficult to name any NewFAI scientist, or any psychologist following MGP's manifesto (6.iv.c), who didn't. Many NLP researchers in the 1980s, for example, studied ways in which communicative (and other) plans can be recognized and/or put into effect (Cohen *et al.* 1990). And mainstream robotics continued to rely on planning (Brady 1985).

In the mid-1980s, that comfortable consensus was challenged. The attack came from several different research areas: behaviour-based robotics, interactionist AI, and situated automata theory.

The common theme uniting these "situationist" approaches was their focus on "[systems] having an intelligent ongoing interaction with environments that are dynamic and imperfectly predictable" (S. J. Rosenschein and Kaelbling 1995: 149). They emphasized embodiment, and rejected planning (and mental representations in general). In effect, they advised workers in AI/robotics to emulate Marx's spiders and to forget his architect. (It was even suggested—by David Cliff: 15.vii.b—that "AI" should be read not as "artificial intelligence" but as "artificial insects".)

Their work was soon dubbed nouvelle AI (which also covered animate vision, in which the creature's own movements provide crucial information: 15.vii.b). It sparked methodological changes in robotics research and philosophical changes in cognitive science. Eventually, it excited members of the general public too.

Situated automata theory was the first to make its mark. It was originated in the early 1980s by the computational linguist Stanley Rosenschein at Stanford's CSLI, and developed with Leslie Kaelbling at Brown (S. J. Rosenschein 1981, 1985; Rosenschein and Kaelbling 1986; Kaelbling 1988). The theory was used to design robots—the first, disarmingly named Flakey. But Flakey and SHAKEY, despite the rhyming similarity, were very different:

> [Situated agents] are very difficult to program because of their close interaction with the environment in which they are situated. Specifications of correctness for situated agents amount to specifications of their interactions with the environment: what action should the agent take when the environment is in a particular configuration? . . .
>
> The emphasis on an agent's connection to its environment is *an important change* from that of traditional theories of representation and control. [We] use high-level symbolic languages to describe the informational content of agents *without* requiring the symbolic structures to be implemented in the agent. (S. J. Rosenschein and Kaelbling 1995: 149–50; italics added)

Rosenschein used a logical specification of the task, and a model-theoretic semantics of motor action, to design robots driven by hardware circuits rather than programs. The circuits ensured that a specific action would take place in a specific situation, and the logic ensured that the overall task would be achieved. Flakey's designers later rejected the "folk wisdom" that representation and situated automata were incompatible (1995: 150). Nevertheless, it was clear that they understood *representation* in a way far removed from the GOFAI norm.

Their approach had some influence within AI, and was later used to design mobile robots for exploration and factory use (Kaelbling and Rosenschein 1990; S. J. Rosenschein and Kaelbling 1995). But it was too austere to excite outsiders. The most widely prominent situationists came from the other two groups mentioned above.

The most well known were the situated roboticists, hard-headed engineers building mobile (and media-friendly) gizmos to perform practical tasks. Some of these gizmos were dubbed "epigenetic robots", because their control systems and behaviour *developed* according to the features of their physical and social environment (see 15.viii.a). But intellectual waves were made also by the interactionists: maverick computer scientists who hoped to develop Heideggerian philosophy into a new way of doing AI. (Increasingly, some people fitted both descriptions: M. W. Wheeler 2005.)

The situated roboticists made four positive claims, and a negative one. Positively, they said:

1. that "intelligent" robots could be engineered rather than programmed, and would be faster, more reliable, and more ecologically valid as a result;

2. that modelling/understanding human intelligence will be possible, if at all, only if we have first modelled/understood simpler animals, such as insects;
3. that AI needs to model *complete* sensori-motor systems (what had been termed "the whole iguana": Dennett 1978*c*), as opposed to specialist AI sub-areas; and
4. that biology should be respected, not ignored.

The last claim reflected the fact that late-century neuro-ethologists were describing reflex mechanisms showing how Marx's spiders construct their delicate "operations" (Barth 2002), and how various other animals manage to live their lives.

In new-style robotics labs around the world, cockroaches and crickets inspired artificial creatures with ne'er a plan in sight (see Chapter 15.vi.c, vii.b–c, and viii.c). These were far less shaky than SHAKEY, being capable (as ever: up to a point) of walking on rough ground and climbing over obstacles, and of adaptive response in real time. By the end of the century, they would be used for applications ranging from Mars rovers to hugely popular children's toys (R. A. Brooks 1999). Some jokers, as we've seen, remarked that "AI" now stood for "artificial insects".

The negative claim was that intelligence doesn't require planning—indeed, that it doesn't need internal representations of any kind. (That was the extreme version. Sometimes, it was stated more ambiguously: the key situationist paper remarked that "much" human-level activity needs no representations, tacitly implying that logical/linguistic thought might do so—R. A. Brooks 1991*a*: 148–9.)

This claim was guaranteed to raise the hackles of functionalists (16.iii–iv)—which is to say, all traditional cognitive scientists. By contrast, it delighted people who were already hostile to cognitive science, and especially to GOFAI. Unsurprisingly, then, it spread apace. The seductive combination of telegenic robots and fierce attacks on symbolic AI attracted significant public attention—and sympathy.

Often, these new roboticists used a catchy phrase to express their view: *the cheapest store of information about the real world is the real world*. In fact, this remark was so catchy that they'd apparently caught it unawares from their predecessors. For that very phrase, and near equivalents, had been used long before by the now-scorned NewFAI folk: for instance, Feigenbaum (1969: 1011), Donald Michie and Richard Gregory (Michie 1970: 76), and even MGP themselves (G. A. Miller *et al*. 1960: 78). However, that didn't prevent its being true. GOFAI robots, such as SHAKEY, did indeed take an unconscionable time to update their world models, and to decide what to do next. Besides the huge computational expense, this put them at the mercy of events even in a sluggishly changing world.

The most high-profile iconoclast was MIT's Rodney Brooks (1954–), with Case Western's Randall Beer (1961–) as runner-up in the visibility stakes. Brooks was known to roboticists by the mid-1980s (R. A. Brooks 1986, 1987). But he opened the 1990s with a more generally noticeable splash, publishing two highly provocative papers previously available (as MIT memos) only to the cognoscenti. In them, he made the four positive claims distinguished above and drew the obvious implication: that symbolic AI was a waste of time—at least if one's "dreams" were for psychological understanding, rather than techno-dollars: "traditional Artificial Intelligence offers solutions to intelligence which bear *almost no resemblance at all* to how biological systems work" (1991*b*: 1; italics added). And he defended the negative claim too:

[In building several autonomous robots we] have reached an unexpected conclusion (C) and have a rather radical hypothesis (H):

(C) When we examine very simple level intelligence we find that explicit representations and models of the world simply get in the way. It turns out to be better to let the world itself serve as its own model.

(H) Representation is the wrong unit of abstraction in building the bulkiest parts of intelligent systems. (1991*a*: 139–40)

In a sense, this was a step back in time. For the anti-mentalist (fifth and sixth) tenets of behaviourism were being revived, even though the underlying physical/neurophysiological causes were now being considered (5.i.a). GOFAI-based computational psychology, by implication, was on the wrong track.

Despite having his home in an AI lab, Brooks's work was widely regarded by the mid-1990s as an example of A-Life, not of AI. Indeed, he often published in A-Life sources (e.g. Brooks 1992), and he co-edited some A-Life volumes (Brooks and Maes 1994; Steels and Brooks 1995). (That's why I've chosen to describe his—and Beer's—robots in the A-Life chapter, rather than this one.) Moreover, his negative attitude to GOFAI was shared by A-Lifers in general. Accordingly, the media-hyped success of situated robotics didn't persuade the general public that AI had advanced, but that it had failed (see vii.b, below).

The negative claim was argued also by the interactionist Philip Agre (1960–), initially at MIT and then at UCSD. He did much of his early work in cooperation with David Chapman at MIT, and the anthropologist (and ethnomethodologist) Lucy Suchman at Xerox PARC, who'd arrived at a similar position independently (Suchman 1987; Agre 1990).

In the 1990s, Agre would focus on human–computer interaction (Agre and Schuler 1997; Agre and Rotenberg 1997), and on human–human interaction too (his advice on the social conventions for Internet communication became a widely cited item on the Net: Agre 1998–2003). He even developed a "participatory" account of computation *as such* (see 16.ix.d). But the seeds had been sown in his interactionist research of the mid- to late 1980s.

In his MIT thesis written at that time, Agre had attacked planning even more explicitly than Brooks was doing. He said that, of all the non-classical AI work being done at the time, Brooks's was "by far the most similar project to my own" (Agre 1988: 247). But whereas Brooks started from robots and insects, Agre started from (largely introspective) human psychology and philosophy—especially Martin Heidegger. (Believe it or not, his thesis was supervised by none other than Michael Brady—not someone whom one readily associates with Heidegger.)

Calling for "an inversion of values" in both cognitive science and technological AI, he declared:

Faced with an empirical phenomenon to explain, our first explanatory recourse should be to dynamics, not to machinery. Faced with a technical problem to solve, our engineering should begin with dynamics, not with machinery. (1988: 27)

Dynamics, he said, "concerns the interactions between an individual (robot, ant, cat, or person) and the world" (p. 22).

The "ant", here, was Simon's ant, whose path across the beach was continuously determined by the sand grains it encountered (Chapter 7.iv.a). And the "person" was any one of us, engaged in our everyday activities. Most of these, said Agre, are routine, involving little conscious thought and no anticipatory planning.

Like the anthropologist Anthony Wallace (Chapter 8.i.a), Agre picked his daily journey to work as a prime example. But his approach was very different. Whereas Wallace had analysed "driving to work" in terms of Plans and TOTE Units, Agre described "walking from his home to the subway" as a routine consisting of a number of major steps, either run off automatically or triggered by interaction with (aka perception of) the environment (1988: 39–51). Even automatic actions, however, would be executed slightly differently each time, depending on the specific situation (the height of the kerb, the location of other pedestrians, and so on).

Agre's descriptions of routine activity were heavily influenced by the transactional psychologist Eric Berne (1964, 1972), the ethnomethodologist Harold Garfinkel (1967), and the anthropologist Pierre Bourdieu (1977). But he went beyond these speculative theorists by implementing his ideas in an AI program, called Pengi (Agre and Chapman 1987, 1991; Agre 1988: 189–233).

This was a LISP Machine reimplementation of a commercial video game called Pengo in which humans used a joystick and a button to control a cartoon penguin. The Pengi penguin controlled itself—or rather, it was controlled by the events happening in its simulated world. The penguin had a goal: to evade simulated killer bees, while trying to zap them by kicking virtual ice cubes at them. But it didn't Plan how to achieve that goal, nor represent it internally as a goal-state. Rather, it engaged in "an improvisatory interaction with continually evolving surroundings" (Agre 1988: 189). Instead of "elaborate world models", it used temporary "deictic" (situation-bound) representations—*the-ice-cube-I-am-kicking*, *the-direction-I-am-headed-in*, *the-bee-I-am-attacking*, *the-bee-on-the-other-side-of-this-ice-cube-next-to-me*—to organize its interactions with its environment from moment to moment (pp. 190–5).

Agre reported that the program played the game about as well as he did, although less well than Chapman. And he claimed that it played in much the same way as humans do—indeed, in much the same way as people engage in any routine activity. Planning, on his view, is neither necessary nor even possible. He remarked (as Karl Lashley had done long before him: 5.iv.a) that some skilled motor action is so fast that it simply can't be controlled by deliberate plans and decisions. Pengo experts, for instance, can push the right buttons amazingly quickly when responding to what's on the screen.

More accurately, he thought that Planning-with-a-capital-P (i.e. as envisaged by NewFAI and by MGP) is impossible. People do plan and make plans. But a plan, he said, is very different from a Plan:

> No plan could ever be so exhaustive that you could mechanically "execute" it. Carrying out a plan requires continual improvisation, interpretation, and fine judgement—especially about whether to revise or abandon the plan in mid-course . . . Real plans can be concise compared to Plans because they can rely on many aspects of how, where, and by whom they'll be used. (Agre 1988: 40–1)

ABSTRIPS, of course, had been an attempt to capture this run-time flexibility (10.iii.c). And as Agre pointed out, even "the very earliest definitions of Planning", by MGP and the LT–GPS team, had emphasized that the lower, tactical levels "can often be left unelaborated until it comes time to execute them" (1988: 235). But the elaboration, when at last it did come, was itself envisaged by GOFAI as a Plan.

Agre went even further: mental representations, the theoretical core of functionalist cognitive science, were denied. Deictic representations were admitted, but "objective" world models weren't. Mentalism was rejected:

> Mentalism refers to any psychology or philosophy organized around metaphors of Inside and Outside . . . Above all, mentalism leads one to make theories that posit objects and processes residing entirely within the head. (1988: 19)

> Mentalism provides a simple formula that provides plausible answers for all questions: put it in the head. If agents need to think about the world, put analogs of the world in the head. If agents need to act in situations, put datastructures called "situations" in the head . . . The tacit policy of mentalism, in short, is to reproduce the entire world inside the head: a "world model". (p. 20)

In arguing this position, Agre relied heavily on neo-Kantian philosophers such as Heidegger, Dreyfus, and Richard Rorty (Agre 1988: 36–7; see 16.vi–viii). But he was influenced also by cybernetics (4.v–viii) and what was about to be named A-Life (15.vii–x). That's clear from this list of "interactionist words" chosen to describe his own account: *interaction*, *conversation*, *involvement*, *participation*, *servocontrol*, *metabolism*, *regulation*, *cooperation*, *improvisation*, *turn-taking*, *symbiosis*, *routine*, and *management* (1988: 20).

"Mentalism and interactionism", he continued, "are incompatible . . . [Each] offers its own distinctive way of approaching every phenomenon of human existence." He made a seeming concession to mentalism: "Sure, perhaps some of these structures *are* entirely inside of agents' heads, but that's just an unusual special case with no particular privilege" (p. 20). However, whatever structures there might be inside our heads were assumed to be very different from the GOFAI norm. (A plan, remember, was not a Plan.)

Nouvelle AI quickly became a fashion, not to say a fad. It was reviving themes that had been neglected by most computationalists: notably, ecological validity (7.iv.g and v.e–f), animal intelligence (2.ii.d–e and 15.vii), and embodiment (16.vii). One of the people hugely influenced by its stress on reactivity and on dynamics was the young Beer (personal communication), who abandoned GOFAI partly as a result of Pengi (see 15.vii.c and viii.d).

Especially intriguing, to many observers, were the philosophical implications. The Cartesian ego engaged purely in thought (2.iii.a), and the sensori-motor sandwich (10.iv.b), were shunned—to be replaced by an alternative that had been waiting in the wings since the eighteenth century (2.vi).

Ironically, then, Brooks's (and Beer's) anti-mentalist emphasis on nuts-and-bolts engineering encouraged a renewal of interest in the type of philosophy favoured by the counter-culture. Heidegger and Maurice Merleau-Ponty, long wheeled in by Dreyfus to criticize GOFAI, were now names for cognitive scientists themselves to conjure with (M. W. Wheeler 1996, 2005). Even Brooks referred to Heidegger: he said of his own approach "It isn't German Philosophy", despite "certain similarities" to Agre's Heidegger-inspired research (R. A. Brooks 1991*a*: 155). Clearly, and whatever his private opinion (if any) about German philosophy, he realized that his name was being spoken in the same breath as Heidegger's by many of his fans.

c. —and defended

Not everyone, however, jumped on the situationist bandwagon. One who resisted it was the philosopher David Kirsh (1950–). He'd been at MIT for five years (before leaving for San Diego in 1991), so was familiar with Brooks's MIT memo on 'Intelligence Without Representation' (1987). Indeed, he organized a small Workshop on 'The Foundations of AI' at MIT's Endicott House, at which Brooks was an invited speaker.

When Brooks's MIT memo was officially published, in a special volume of *Artificial Intelligence* based on the Workshop, Kirsh's reply appeared alongside it (Brooks 1991*a*; Kirsh 1991*b*). Although specifically directed at Brooks, much of what he said ran counter to Agre as well.

Concentrating on the situationists' negative claim, Kirsh argued that any behaviour that involves concepts needs internal representations. He allowed, as Brooks had done too (1991*a*: 149), that "representation" is a weasel word, carrying multiple ambiguities. But *conceptual* representations were needed for a wide range of behaviours.

Full-blooded concepts, he said, enable a creature to recognize perceptual invariance, to reify and combine invariances (in referring predicates to names, for instance, or in drawing inferences), and to reidentify individuals over time.

They also allow creatures to engage in anticipatory self-control (i.e. planning), and to negotiate between, not just to schedule, potentially conflicting desires. (That robots might use reflex mechanisms to schedule conflicting motives had been pointed out twenty years earlier by the MIT team asked to design a Mars robot: see 14.v.a.) Moreover, they enable one to think counterfactually, to use the cognitive technology of language to create new abilities (6.ii.c), and—by teaching these abilities to others—to make cultural evolution possible (8.v–vi). Human adults possess all these capacities, chimps most of them, dogs some of them, and newborn babies hardly any (see 7.vi).

Kirsh wasn't arguing that non-human animals must possess symbolic, compositional, representations. He allowed that non-linguistic concepts and/or meanings may be implemented in other ways (see 12.x.f, 14.viii, and 16.iv.c). He even welcomed situated robotics, for having extended the domain of concept-free behaviour and for indicating the wide range of mechanisms that may be termed representations.

But he insisted that logic, language, and thoughtful human action all require symbolic computation. These may be, as Agre had put it, a "special case" of intelligent behaviour. But they're there. And they're significant. In sum, GOFAI might not be needed when studying cockroaches, but it was essential for modelling important aspects of human minds.

Simon, the high priest of GOFAI, also fought back against the situationist tide. As Brooks himself pointed out (1991*a*: 149), Simon had long allowed that intelligent systems are largely directed by the environment (7.iv.a). He'd already reformulated planning, now seeing it as a complex web of reflexes, or productions (7.iv.b). However, he thought of these as mental representations, some containing abstract variables to be instantiated before the rule could be run. (That's why Brooks, besides denying that his work was German philosophy, denied also that it was "production rules", and why Agre rejected production rules, ACT*, and SOAR—R. A. Brooks 1991*a*: 155; Agre 1988: 240–4.)

In a paper written with the psychologist Alonso Vera, Simon expressed the essence of situationism thus:

> In its extreme form, the SA [situated action] view argues that there is no need to include internalized world models in the equation. Such internal states, some proponents of this view have said, have no causal effect on behavioral output. (Vera and Simon 1993: 12)

Reiterating his Physical Symbol System approach (16.ix.b), he argued that "no one has described a system capable of intelligent action that does not employ at least rudimentary representations" (p. 38). He insisted that the situationists themselves used representations in their models. And, doffing his hat to his famous ant, he pointed out that GOFAI systems could be highly responsive to environmental control.

The GOFAI–situationist dispute aroused great interest. Kirsh's critical paper, for example, was soon assigned in AI seminars at MIT and elsewhere (personal communication). The special number of *Cognitive Science* carrying the Vera and Simon paper presented Replies by Agre (1993), Suchman (1993), and others. Agre allowed that *Pengi* had "internal state" (e.g. deictic representations), but disputed Simon's assumption that *any* internal state counts as a cognitive representation. And he claimed that Simon had missed the crucial point: "The critical issue is whether one's categories locate things in agents and worlds separately or in the relationship between them" (1993: 68–9).

The debaters were soon accused of having "shed more heat than light . . . with neither side yielding enough ground to reach a point of productive dialogue" (M. D. Byrne 1995: 118). But dialogue, productive or otherwise, continued. Two consecutive volumes of *Artificial Intelligence* were devoted to interactionist AI in the mid-1990s, and prompted so much attention that they were soon republished as a book (Agre and Rosenschein 1995). And the 1991 papers by Brooks and Kirsh were reprinted in various collections on the philosophy of AI and cognitive science (e.g. Boden 1996; Haugeland 1997; Chrisley 2000, vol. iii).

Today, the Brooks–Kirsh battle is still undecided, although it's less fiercely oppositional, on both sides, than it was initially (Chrisley 2000: iii. 6–7). And Kirsh is getting strong support from some philosophical colleagues. For instance, Richard Samuels (forthcoming) has written a robust defence of the "Standard Model" in cognitive science. Unfashionably, in these largely situationist times, he argues that symbolic representations are needed to support means–end planning and much of the flexibility of human behaviour. (Often—shock! horror!—he even cites SOAR: see 7.iv.b.)

AI professionals are usually more eclectic than philosophers, even if they happen to have been philosophically trained. So McDermott included "dynamic planning" (which he attributed to the ideas of Agre, Chapman, Rosenschein, and Kaelbling) as a subclass of planning when he co-edited a special volume of *Artificial Intelligence* (McDermott and Hendler 1995: 6). And although some roboticists today rely only on situationist techniques, others also employ symbolic (deliberative) planning. Indeed, a recent volume supposedly—according to its title—focused on situated, behaviour-based, robotics devoted an entire chapter to the topic of how to combine reactive and deliberative mechanisms (Arkin 1998, ch. 6).

Probably, the future lies in systems combining the two approaches. For many such systems already exist. By the late 1980s Flakey was being driven by a combination of an improved STRIPS-based, world-modelling, planner and a more reactive, situationist, system (D. E. Wilkins 1988, ch. 12). And even before that, the mind had been informally described by Minsky as a combination not only of symbolic and connectionist representations, but also of top-down GOFAI and largely autonomous, bottom-up, subsystems (Chapter 12.iii.d).

Symbolism and situationism needn't be clumsily bolted together, as they are in many current "hybrid" systems. Alan Mackworth has recently put it like this:

> The methodologies [for building integrated perceptual agents] are evolving dialectically. The symbolic methods of Good Old-Fashioned Artificial Intelligence and Robotics [GOFAIR] constitute the original thesis. The antithesis is reactive Insect AI. *The emerging synthesis*, Situated Agents, needs formal rigor and practical tools. A robot is a hybrid intelligent dynamical system, consisting of a controller coupled to its plant . . . Even though a robotic system is, generally, a hybrid system, its [overall control should be] unitary. Most other robot design methodologies use *hybrid models of hybrid systems*, awkwardly combining off-line computational models of high-level perception, reasoning and planning with on-line models of low-level sensing and control. We have developed a [unitary] testbed for multiple, visually-controlled, cheap robot vehicles performing a variety of tasks, including playing soccer. (Mackworth 1998; italics added)

Mackworth, then, has abandoned the sensori-motor sandwich—but without abandoning planning. Instead, his "Constraint Net" model is based on, and verified by, a formal specification of a *symmetrical coupling* between robot and environment (Sahota and Mackworth 1994). He's no longer entering his ball-kicking robots in the RoboCup competition that he helped initiate (with Hiroaki Kitano) in the late 1990s (see 11.iii.b). But his constraint-satisfying robots are a significant progression from both SHAKEY and Flakey, and also from Brooks's early menagerie of Allen, Herbert, Genghis, Attila, and Hannibal.

As for what Mackworth calls "the original thesis", this hasn't stood still: post-Kraken advances in symbolic planning have been significant (McDermott and Hendler 1995; S. Russell and Norvig 2003, chs. 11–12). They're still continuing. The 1995 edition of a widely used AI textbook described algorithms generating plans with dozens of steps, but the second edition only eight years later presented algorithms that "scale up to tens of thousands of steps" (S. Russell and Norvig 2003, p. viii).

One powerful GOFAI planner, for instance, controls the operations of a spacecraft, given high-level goals specified from Space Control on earth (Jonsson *et al.* 2000). It generates structured plans and also monitors their execution, diagnosing and (often) fixing problems as they occur. It's not HAL, to be sure (A. C. Clarke 1968). But, in its own (relatively predictable) domain, it's highly effective.

Up to a point, less predictable domains can be handled too, for some recent planning systems include ways of reasoning under uncertainty. In short, planning is here to stay. But whether it can survive as a *general-purpose* topic, as the NewFAI researchers had intended, is unclear. McDermott isn't optimistic:

> [Possibly, architectures and/or formalisms for general-purpose planning may be developed.] This would allow a recoupling of theory and practice, and could lead in exciting new directions.
>
> However, we're pessimistically forced to conclude that another solution is somewhat more likely. It may be inevitable for the field of planning to split into even smaller subfields, each with its own domain of interest (manufacturing, deliberation scheduling, logistics planning, etc.). After all, there may not be much in common between designing the behavior of a robot and

designing the behavior of a military logistics system. It would be a pity to see this happen, but if what is gained is a set of elegant and powerful theories coupled with useful implementations replacing the current elegant but weak theories coupled with toy systems, then maybe it will be worth it. (McDermott and Hendler 1995: 13)

d. Agents and distributed cognition

Both Rosenschein and Agre, in the quotations given above, referred to situated *agents*. Indeed, situationism helped spark a flurry of research on "intelligent agents", or "autonomous agents". The *Artificial Intelligence* journal devoted over 800 pages to the topic, which were also published as a stand-alone book (Agre and Rosenschein 1995); and the interest continued (Wooldridge and Jennings 1995; Huhns and Singh 1997; Wooldridge 2001). Likewise, situationism encouraged work on the closely associated topic of "distributed" cognition (Bond and Gasser 1988; Demazeau and Muller 1990; G. Weiss 1999).

In distributed cognition, the overall task is achieved by numerous agents acting in concert, no one of them having access to all the relevant information or skills. The individuals may be more or less complex, in psychological terms. But they can achieve the task only by (knowingly or unknowingly) cooperating. In short, the interactions *between the many agents* are at least as important as the nature of each agent as an individual.

Examples found in the social (*sic*) insects include termite nests and ant trails, in which the phenomenon (nest or trail) emerges from the behaviour of many individual agents. Ants, of course, *are not* mindlike, and the cause of ant trails is very simple: each ant automatically drops chemicals ("pheromones") as it walks, and automatically follows pheromones dropped by others (see Chapter 15.x.a). A human example, discussed in Chapter 8.iii, is the navigational knowledge aboard a modern ship, which is distributed across many crew members. (The "ultimate" distributed workforce, it's been suggested, would be the world community of seafarers, linked by the Internet to their employers, unions, weathermen, and families: P. Collins and Hogg 2004.)

By century's end, it had become clear that the interactions *between agents and their environment* were crucial too. The situationists had stressed embodiment and environmental triggering, of course. But they'd seen "agent" and "environment" as clearly distinct, despite their causal interactions. In the late 1990s, that view was challenged by some specialists in HCI (human–computer interaction: see Section v, below).

Combining Bruner's work on cognitive technologies (6.ii.c), Edwin Hutchins's on environmentally embodied knowledge (such as shipboard instrumentation: 8.iii), and Clark's on the extended self (16.vii.d), they defined "distributed cognition" as a new theoretical approach in HCI. "One major benefit", they said, "is the explication of the complex interdependencies between people, artifacts and technological systems *that can often be overlooked when using traditional theories* of cognition" (Y. A. Rogers forthcoming; italics added). Blurring the conceptual boundaries between self and environment, individual and culture, helped them to analyse collaborative workplaces in general and computer interfaces in particular.

In the 1980s, however, those developments lay in the future. Meanwhile, distributed cognition was understood in the "traditional", more individualistic, way. Indeed, the term was used interchangeably with "multi-agent systems"—which inevitably raised the question "Just what is an agent?"

The answer wasn't clear. The term "agent" had officially entered AI long before, in Oliver Selfridge's Pandemonium paper (having originated in discussions with McCulloch). His then futuristic term had had a double meaning: (1) a self-directed task-achieving (i.e. mindlike) system, or demon; and (2) a demon performing some relatively menial (but purposeful) task on behalf of human users, who would otherwise have to do it themselves. For the 1980s situationists there was a third meaning: (3) a very simple demon, which might be program code or a situated robot.

(For the record, Selfridge himself is still working on agents, within DARPA's agent-based computing programme: see Chapter 12.iv.b. He's trying to build adaptive purposive hierarchies made up of lower-level purposive mechanisms. These multi-loop-controlled agents are much more complex than those favoured by most "situationists" today.)

These three demon-types, all implemented in the 1980s (or earlier: see Doran 1968*a*), were very different. For instance, mindlike agents had goals of their own, and ways of deciding how to achieve them, while simple demons didn't. And whereas most agents were largely dormant, waiting to be triggered by their environment, some mindlike agents were continuously active. Minsky's *Society of Mind*, widely circulated in draft from the late 1970s, had referred repeatedly to "agents" of various kinds. By an agent, Minsky meant

> a machine that accomplishes something, without your needing to know how it works. You call it an agent when you want to treat it as a black box . . . When I call my travel agent Roy, I'm less concerned with how Roy works than with having him do what I need him to do. (Minsky and Riecken 1994: 24)

It followed that one shouldn't expect to define an agent in terms of how it worked, because the whole point (according to Minsky) was that one didn't need to know this.

Even now, AI workers debate the difference between an agent and *just any* AI program (S. Franklin and Graesser 1997). They also ask whether "multi-agent systems" are better described more anthropomorphically, in terms of the interactions within "societies of agents" (Huhns and Stephens 1999, sect. 2.4). And even now, they disagree about just what an agent is:

> [There] is no universally accepted definition of the term agent, and indeed there is a good deal of ongoing debate and controversy on this very subject. Essentially, while there is a general consensus that autonomy is central to the notion of agency, there is little agreement beyond this. (Wooldridge 1999: 28)

These differences of definition reflect differences in methodology. While some post-Kraken programmers were developing societies of mini-minds, each with internal state representing their own and even others' goals, others were modelling agents of a much more minimalist kind. So Agre, in his introduction to the special double volume of *Artificial Intelligence* devoted to agent research, pointed out that it was "inspired by a great diversity of formalisms and architectures" (Agre 1995: 1).

Let's consider the minimalists first. These were the situationists in general, including some people more closely associated today with A-Life than with AI (because distributed systems are often thought of as "self-organizing" systems: Chapter 15). As we've seen, they described intelligent behaviour—whether in individuals or in groups—as emerging from a collection of independent reflexes, not directed by top-down control or abstract plans.

The most minimal examples of all were cellular automata in which the rules were (*a*) very simple and (*b*) identical for each agent, or cell (15.v). Work on cellular automata—together with Douglas Hofstadter's discussions of ant colonies in *Gödel, Escher, Bach* (12.x.a)—inspired Mitchel Resnick's development of Seymour Papert's LOGO language into the massively parallel StarLogo (Resnick 1994, pp. xvii, 31, 59).

Each agent in a StarLogo system was typically very simple, and similar to all the others. (Multi-agent systems composed of mindlike agents, by contrast, would have fewer—and more diverse—components.) As we saw in Chapter 10.vi.b, StarLogo enabled programmers to simulate not only interactions between situated agents, and agents' actions on the environment, but also the actions/interactions of the many different parts of the environment itself. Its potential was huge. Resnick's agents could represent turtles, or termites (ants), or cars and lorries in traffic jams . . . indeed, indefinitely many classes/colonies of interacting individuals.

Besides being used for professional AI research, StarLogo made distributed computation/cognition accessible to the general public. In two trade books, one of them specifically aimed at teachers, Resnick explained how StarLogo could be used to build systems simulating hundreds, even thousands, of individual agents (Resnick 1994; Colella *et al.* 2001). And he made the software available on the Web (<http://www.media.mit.edu/~starlogo/>). Using StarLogo, or the broadly similar SimAnt software, "thousands of . . . households [began to] play with ants on their computer screens". Ants, indeed, were the flavour of the day: the leading ethology volume on these little insects became "a sort of cult classic, attracting attention far outside the [biological] community" (Resnick 1994: 59).

Resnick hoped both to teach StarLogo users and to learn from them (1994: 5). The former, in helping them to understand decentralized systems in general. The latter, in discovering the "*folk* systems science" (comparable to naive physics) used when people think intuitively about distributed systems. Much as naive physics contains many mistaken assumptions, so—he expected—naive-systems science does too. Indeed, the "centralized mindset" of modernism had specifically inhibited a correct understanding of distributed systems. The illusory notions it had encouraged included the Freudian ego, creationism in biology, conspiracy theories in politics, and authoritarian views of family and pedagogy (1994: 119–23; 129). Work in distributed AI, of which StarLogo was a special case, could help to change that:

> When something happens, [most people] assume that one individual agent must be responsible.
>
> But the centralized mindset is neither unchanging nor unchangeable. As decentralized ideas infiltrate the culture—through new technologies, new organizational structures, new scientific ideas—people will undoubtedly begin to think in new ways. People will become familiar with new models and new metaphors of decentralization. They will begin to see the world through new eyes. They will gradually recraft and expand their ways of thinking about causality. (Resnick 1994: 130)

Resnick didn't claim that *all* cognition is distributed:

> In economics, an unyielding commitment to decentralized, laissez-faire strategies can be just as debilitating as an unyielding commitment to centralized planning. So too with thinking: an unyielding decentralized mindset is no better than a centralized one. Many phenomena in the

world *do* have centralized explanations. As [we] construct theories about the world, [we] should be able to draw on both centralized and decentralized ideas. (Resnick 1994: 148)

In this, he was following Papert himself. For Papert, in close cooperation with Minsky, had described the mind as a *hybrid* society of agents (12.iii.d). That is, there were GOFAI-ish agents as well as situationist ones. Indeed, there were connectionist agents too, so the society of mind was hybrid in both senses of the term (see 12.ix.b).

During the 1980s–1990s, research into GOFAI agents went on alongside work on the minimalist variety. Indeed, "alongside" sometimes meant *within the same family*: Stanley Rosenschein's brother Jeffrey outlined how to design "rational agents" that would use game theory to make "deals"—language better suited to GOFAI than to Brooks (J. S. Rosenschein and Genesereth 1985; cf. Rosenschein and Zlotkin 1994). Broadly, a mindlike agent was a robot or chunk of software (sometimes called a softbot) with three characteristics. Its action was autonomously controlled by its own internal processes, and by cues in its real/virtual world; the action was relatively complex, or purposive; and its own goals and self-generated sub-goals might, if the agent so decided, take priority over the goals of other agents or even of the system as a whole.

Sometimes, agents were *defined* as having "mental state, consisting of components such as beliefs and commitments" (Shoham and Tennenholtz 1995: 231). And sometimes, their mental state was analogous to the Theory of Mind, or ToM (7.vi). In such cases, the agent could represent not only other agents' abilities, beliefs, and intentions but also the social relations between self and other: "In order to cooperate effectively with its peers, an agent must *represent* any social structures in which it plays a part, and *reason* with these representations" (d'Inverno *et al.* 1997: 600).

These agents used their knowledge of others' capacities and intentions to generate shared plans and/or to decide whether to assist in another's plan. That decision, in turn, could rest either on monitoring the other's performance or on anticipating future performance or intentions. As for how they acquired their model of their peers' intentions, they normally used inductive techniques of "plan recognition" based on their observation of one or more interactions with the fellow agent concerned. In many cases, their "peers" were human beings, monitored and/or anticipated in much the same way.

One must hope that their ToM is realistic, for the applications include NASA's "VISTA" ground-control support system for the space shuttle, which went live in 1992 (Horvitz and Barry 1995). This program monitors the status of the five major engine subsystems, deciding *how to present the data on the screen being watched by the human operators*.

As Eric Horvitz (personal communication) remarks, VISTA was "perhaps the first exploration of the use of two rich probabilistic models running side by side". One of these is of the shuttle itself, based on a stream of telemetry; the other concerns "the beliefs of a user of a particular level of expertise, based on the displayed information". The inferences of both models are combined to make decisions about the psychological costs and benefits of revealing or highlighting different information on the screen. Besides avoiding information overload, VISTA aims to capture/shift the user's attention when something significant happens. In short, it tries—in real time—to pre-empt the problems facing machine operators that were studied long ago by Kenneth Craik (4.vi.c) and Donald Broadbent (6.i.c), and (in respect of short-term memory) by George Miller too (6.i.b).

Selfridge's second meaning (above) became especially relevant in the late 1980s. For by that time, many autonomous software systems were being built into computer interfaces, designed to handle administrative tasks of information retrieval/filtering on behalf of the human user (see v.c–d, below). The variety of these unseen agents increased with the years. When Berners-Lee's vision of the Semantic Web finally comes about, it will be thanks not only to shared ontologies but also to reliable agents working behind the scenes on behalf of the human users.

As Kay put it, these 1980s agents were "computer processes that act as guide, as coach, and as amanuensis" (1989: 130). For instance, they might devise timetables (respecting the entries already in the user's diary), book hotel rooms, or arrange for flights and car hire—perhaps without bothering the user, or perhaps making suggestions for human ratification (D. A. Norman 1994). Some could even learn how to do better in future by inferring, or being told, why their suggestion was rejected. One such agent could learn up to twenty new timetabling rules each night, by applying a version of ID3 to the information gleaned from the user on the previous day (T. M. Mitchell *et al.* 1994: 87).

By the end of the century, intelligent/autonomous agents had caught the imagination of many AI scientists. The ever-growing body of research had led (for instance) to international conferences—and journals—on 'Multi-Agent Systems', 'Autonomous Agents', and 'Adaptive Systems', and to specialist sessions in the IJCAI meetings (e.g. M. E. Pollack 1997: 578–654). Distributed AI was being used in industry as well as in interfaces (Parunak 1999; Alonso 2002). Moreover, affordable robots were now available off the shelf, so that people could study not only single home-made robots (such as FREDDY, SHAKEY, Flakey, or Cog) but also groups of interacting robots (Arkin 1998, ch. 9).

The general public was pricking up its ears, too. "Agent" had even become a buzzword in the marketplace. The Apple Newton, for example, was proudly advertised as "agent software", and General Magic trumpeted their new "messaging agents" (Riecken 1994: 18).

Agents had first achieved media popularity through Minsky's 1985 trade book *The Society of Mind*. But one didn't need to read the book to hear of the idea. Quite apart from reports by journalists, Minsky himself had been spreading the gospel among the business community for some years. At fundraising meetings in MIT's new Media Lab, he (and Kay, too) had sung the praises of agents as a way not only of evolving minds but also of developing useful and user-friendly computer technology (Section v, below).

As for distributed cognition, this idea had entered the public consciousness in 1979 through Hofstadter's extraordinary best-seller *Gödel, Escher, Bach* (Chapter 12.x.a). It had been reinforced in the mid- to late 1980s by the PDP 'bible' (12.vi.a). And—as remarked above—self-organization in "ant colonies" had become so evocative that a specialist tome on ants had become a cult book.

The popularity of both these notions was partly due to the widespread counter-cultural disaffection with centralized control and affection for the concrete and specific (see 1.iii.c–d). Indeed, Resnick said as much in lauding the fall of the Soviet Union *and* the decentralization of IBM in December 1991: "Throughout the world", he remarked, "there is an unprecedented shift toward decentralization" (Resnick 1994: 7; cf. Toulmin

1999; Turkle and Papert 1990). Systems where many autonomous individuals 'did their own thing' were felt to be even more culturally/politically appealing than committees, which in turn had been seen as more attractive than autocratic hierarchy (10.iv.a).—So much, yet again, for the Legend.

e. Social interaction and agents

Modelling collections of mindlike agents raised analogues of problems in social management that people face every day. In the absence of a top-down executive control, questions arose about how the knowledge possessed by the various components of the distributed AI system is integrated within the system as a whole. How could robots, or softbots in a virtual world, cooperate so as to achieve a goal which none could achieve alone?

The "social" behaviour of agents thus became an issue: the challenge was "to guarantee the successful coexistence of multiple program and programmers . . . [where the] agents' actions, and perhaps also goals, may be either facilitated or hindered by those of others" (Shoham and Tennenholtz 1995: 231). Increasingly, then, designers of distributed AI focused on the *interactions* between agents.

Social behaviour, in this context, included various types of communication: not just informing and questioning, but negotiating, bargaining, and voting too. The simple demons in Pandemonium had 'voted' via the loudness of their shouts (12.ii.d). But some late-century agents had to 'think' much harder before deciding which way to vote: for instance, by comparing their existing goals with the probable results of what they were being asked to do by some other agent. Negotiation and bargaining were even more complex. (In 1997 a special issue of the *Artificial Intelligence* journal was devoted to these "economic" aspects of distributed AI: Boutilier *et al.* 1997; see also J. S. Rosenschein and Genesereth 1985; Sandholm 1999.)

Various types of negotiation and bargaining were modelled, Rosenschein's "deals" being among the first. In systems based on *contract nets* (R. G. Smith 1980), for instance, the agents made "bids" that described how their abilities (including their current beliefs) were relevant to solving the overall problem. A central "manager" then decided which "contracts" to assign to each agent. One recent example of this approach was developed for NASA, to aid astronauts on long-term missions (Naghshineh-pour *et al.* 1999). The NASA contract net schedules the production and transportation of food—planting, monitoring, harvesting, recycling, and processing—in outer space.

As that example indicates, some modern agents can negotiate about several different goals, with incomplete information, and differing time deadlines (Fatima *et al.* 2004). An individual agent may even have deadlines, known only to the agent itself; if so, these deadlines affect its bargaining about which tasks it will volunteer and which it will accept (Sandholm and Vulkan 1999).

Besides communication, there was cooperation: *when? how? with whom? why?* In other words, post-Kraken agent modellers had to think about the issues raised many years earlier by the psychologist Robert Abelson, regarding the identification of plan junctures at which one particular agent might be able to help another (Chapter 7.i.c).

That's not to say that they used Abelson's work, for they didn't. But a late-century abstract analysis of "cooperation structures" dealt with the questions he'd raised, and related them to specific difficulties in the programming of distributed AI—how to determine, for instance, whether cooperation is even in principle possible, given some group of agents and a particular agent's goal (d'Inverno *et al.* 1997).

Similarly, Abelson's questions arose when people discussed how to generate collaborative plans (Grosz and Kraus 1996, 1999). And although most AI researchers ignored the fact (which Abelson had highlighted) that an agent may want to aid *or obstruct* another agent's plans, a few didn't. One team, for instance, said: "[Unlike most of those working on cooperation, we do not] assume benevolent agents" (d'Inverno *et al.* 1977: 605)—and their abstract model of cooperative structures specifically allowed for indifference or malevolence in some agents. Again, a general ontology for describing social interactions between AI agents explicitly allowed for "selfish" as well as "collaborative" behaviour (Castelfranchi 1998).

A central feature of 'mindlike' distributed AI was the communication of one agent's internal state (its beliefs, goals, and willingness to help) to others, and/or the communication of non-shared knowledge about the environment (e.g. the constraints on or goals of the problem as a whole). The same had been true of previous efforts to model cooperation—for instance, the two robots discussing how to open a bolted door (see Chapter 9.xi.f). Indeed, people usually take it for granted that communication, and a fortiori cooperative communication, *must* have evolved so that information could be transmitted to creatures currently ignorant of it.

Researchers in distributed AI typically did so too—and so did most A-Lifers. Even minimalist examples like ant trails, formed by the pheromones dropped by individual ants (15.x.a), could be shoehorned into this assumption. And A-Life models of the adaptive evolution of language usually relied on it heavily (e.g. Steels 1998*a*,*b*,*c*; Steels and Kaplan 2001; Steels and Belpaeme forthcoming). Some writers made it absolutely explicit: "A first prerequisite for communication is that some organisms have access to information (knowledge) that others do not, for if they all have access to the same information, no communication is necessary" (MacLennan and Burghardt 1994: 165).

However, some turn-of-the-century work, broadly inspired by Francisco Varela's work on autopoiesis (15.viii.b and 16.x.c), challenged it. The Sussex A-Life researcher Ezequiel Di Paolo (1970–) showed that communication, and cooperation, can in principle evolve *without* information being transmitted from one agent who has it, to another, who doesn't (Di Paolo 1999, ch. 8; 1998).

He built an intellectually rich series of evolutionary computer models, which evolved various types of social coordination between (simulated) robots. Systematic experimental variations discovered which parameters, under which conditions, were most important, and suggested implications for biological theories of communication. In some versions of the model, information wasn't equally available to all, and (sometimes) cooperative action–response strategies evolved so that the robots could benefit from each others' knowledge. In other versions, all agents possessed the same information—but even then, cooperative communication sometimes developed.

Each robot needed to replenish its energy regularly by accessing food. If it failed, it would die. And only if its energy level was above a certain threshold would it be able to reproduce. The food was finite, so the more one robot consumed the less there was for the others. In that sense, there was a conflict of interest: prima facie, not a situation in which one would expect cooperation.

In the informationally asymmetric versions of the model, more energy was made available to those robots which happened to signal the presence and type of found food (as opposed to either 'cheating' or remaining silent) and/or which happened to approach suitable food when perceiving the signal. However, no robot 'knew' that a particular action was a signal. Indeed, an action's communicative function *as* a signal, denoting a certain type of food and prompting neighbour robots to approach it, evolved as an aspect of the increasing coordination between the robots.

In the 'universal information' version, fitness didn't depend on single actions by individuals (emitting, or responding to, a signal). Rather, it depended on *a sequence of alternating actions by both agents*. *For example*, *imagine* that you and I are both gazing hungrily at a tall cherry tree. You must say "bing", then I must say "bong", then you say "tring", and I say "trong"—for *only then* will any cherries drop from the tree. Or rather, *only if you happen to say* "bing" . . . etc. will the cherries fall: whether you're aware that you "must" say this to get that result is immaterial. An apple tree would require a different four-signal sequence (perhaps tring, trong, bing, bong—with me to start, this time) before either of us could sink our teeth into the fruit.

Similarly, energy in Di Paolo's model was released "partially depending on the actions being correct at the required steps of the sequence" (Di Paolo 1999: 163). At first, there was no "sequence", only random actions. But an accidental 'correct' action would provide some energy, and a correct four-action sequence would provide even more. Ideally, the robots would select their next action depending on the food type and the previous actions—all perceptible to both robots. And evolution, due to differential reproduction, often resulted in a final generation that coordinated their actions perfectly. (This was true *even though* one and the same robot might have to perform a given action in first place or in third place, depending on the food type: apples or cherries, as it were.)

Di Paolo's robots couldn't have 'learned' to produce the right actions as lone individuals. They could achieve high energy levels only by acting cooperatively in locating the food. This type of cooperation, however, was very different from that studied by Abelson, or by AI scientists designing cooperating mindlike agents. There were no plans, no intentions, no symbolic references to food . . . no internal state at all. Accordingly, Di Paolo argued that this work cast serious doubts on orthodox cognitive science (1999, ch. 10).

One implication, he said, was that an individual's successful performance needn't imply a corresponding competence at the individual level (Chapter 7.iii.a). An agent who can get the cherries by cooperating with another agent may have *no* individual competence for getting cherries. Similarly, a robot that produces rhythmic behaviour when interacting in a particular acoustic world may show no hint of rhythm when acting on its own (Di Paolo 1999, ch. 9; 2000*a*).

Another implication—highly subversive, from the point of view of orthodox cognitive science—was that AI work on "social" agents wasn't truly social. AI agents were conceptualized as *individuals*, who happened to be interacting. Certainly, things occurred when they interacted which wouldn't have occurred otherwise. (Remove the diary-checker from the multi-agent system responsible for personal timetabling, and the human user wouldn't be happy.) But there was little or no notion that social behaviour may depend largely on *the dynamical properties of the interaction as such*.

For purely technological purposes, this might not matter. But for explaining human social behaviour (7.i.c), Di Paolo felt that it did. Even situated AI, although superior (in his view) to classical GOFAI, hadn't gone far enough:

To take situatedness seriously sometimes implies renouncing the simplicity of explanatory monism and embracing the complexity of the multiple concurrent and interdependent factors that form a historical process. This may not always be an easy task. However, once a situated process is properly understood many issues that are initially mysterious can be explained in a natural manner. Thus, cooperative coordination in games with conflict of interest can be explained by a combination of Darwinian selection and ecological situatedness [as outlined above]. (1999: 190; italics added)

From this viewpoint, my claim (in Chapter 1.ii) that cognitive science has studied social matters as well as individual cognition is misleading. To be sure, an adequate cognitive science would have to encompass social interactions, and some cognitive scientists have *attempted* to do so. If Di Paolo is right, however, they've gone about it in a fundamentally wrong-headed way. Even the respected *social* psychologist Abelson is individualistic at heart.

This dispute is an old one, although Di Paolo has put it in a new, and scientifically intriguing, way. In a nutshell, the question is whether individual selves constitute society or whether they're constituted by it. (Note: constituted by it, not just influenced by it.) Opposing answers have been defended by philosophers and social scientists for at least a century (Hollis 1977).

f. Technology swamps psychology

Inductive learning is a prime example of psychological AI's spawning, and eventually being overtaken by, technological AI.

There's no doubt that the psychologists got there first, for they were already studying concept learning by mid-century (see 6.ii.b–c and 10.iii.d). Informational analyses were published by Carl Hovland in 1952, computational strategies by Bruner in 1956, and computer models by Hovland and Earl Hunt in 1960–2.

Through the 1960s, Hunt continued his research on concept learning. No longer working with Hovland, who'd died in 1961, he now cooperated with Janet Marin and Philip Stone. They defined a new method for inductive classification: the Concept Learning System, or CLS rule (Hunt *et al.* 1966). Having only five steps, it was much simpler than the strategies discussed in Hunt's 1962 book (see Figures 10.10 and 10.12). But like them, it was a recursive algorithm which, given a training set of examples, learnt a top-down decision tree for classifying them.

CLS started by asking whether either *all* or *none* of the input cases were labelled as being examples of one concept. If so, it would stop. If not, it would divide the set into subsets and ask the same question again. At each hierarchical level, it would choose a property with more than one value (including present/absent), and partition the set accordingly. So flowers might be sorted into subsets by scarlet, blue, yellow, or white (think poppies, bluebells, daffodils, and snowdrops).

One weak spot in this procedure, at least in the early version, was that the property used to partition the set was chosen at random. This could result in a very inefficient search. So the programmers made it possible for the human user to choose the property to be considered. In other versions, simple frequency counts (successors of step 3 in Figure 10.10) would select the most useful property for partitioning the set. A property possessed by only 1 per cent of the examples, for instance, isn't a good (i.e. computationally efficient) one with which to start—even if it's a *sufficient* condition of the relevant concept.

Another weak spot was that concepts were (still) assumed to have necessary and sufficient conditions: as though all bluebells were blue, and all daffodils yellow. In fact, some bluebells are white, or pink. But most are indeed blue, which is why blueness is a very useful indicator of bluebells. CLS, on being presented with a pink bluebell, wouldn't treat it as an exception to be tolerated. Rather, it would reject blueness as a criterion of bluebells—thus throwing out the baby with the bathwater.

CLS could learn from its mistakes. If a new example (a pink bluebell, perhaps) didn't fit its current model, it would reconstruct the entire decision tree so as to include it. Because the combinatorial explosion raised its ugly head as the number of past classifications grew, Hunt's team eventually amended CLS so that it considered only a random subset of its 'memories' while revising the decision tree.

Not everyone studying GOFAI induction in the 1960s was doing similar things. For instance, other methods were devised by several members of the Edinburgh AI group, its leader Donald Michie among them. They occasionally cited Bruner (e.g. Popplestone 1969: 203), and/or defined strategies which were generalizations of his (e.g. Richard M. Young *et al.* 1977). But their work was logical, not psychological. Much of it was an attempt to widen theorem proving to cover induction too (Popplestone 1969; G. D. Plotkin 1969, 1971).

In the 1970s, as remarked in Chapter 10.iii.d, learning was seen—in the USA, at least—as "a 'bad' area to do research in" (R. S. Michalski, personal communication). Nevertheless, this period saw several advances. In the mid-1970s, meta-DENDRAL induced previously unknown rules about the points at which certain chemical molecules are likely to split (Chapter 10.iv.c). Simon's psychology student Pat Langley (1953–) started work on BACONian induction at much the same time (iv.c, below). And Ryszard Michalski used a multi-valued version of predicate logic to define a new learning algorithm, AQVAL (Michalski 1973; Michalski and Larson 1978).

When it made a mistake, AQVAL reconsidered only those previous classifications which were most relevant—not a random subset, as with CLS. And it reconstructed only that part of the decision tree which had made the mistake, not the whole tree. In those ways, it was an improvement on CLS. But that hadn't been Michalski's aim in designing it. He'd first modelled learning (of handwritten characters from several alphabets, including Roman, Greek, and Cyrillic) in 1966, in Poland. When he started work on AQVAL, soon after his arrival in the USA in 1971, he knew nothing of Hunt's research (personal communication).

Suddenly, around 1980, induction turned from being a "bad" area to a popular one. The first international workshop on machine learning was held (at CMU) in 1980, and three issues of the *International Journal of Policy Analysis and Information Systems* were given over to it. A few months later, in spring 1981, a special number of the *SIGART Newsletter* followed suit. In 1983 an authoritative collection of papers appeared, which was very widely read (Michalski *et al.* 1983). The Japanese Fifth Generation project was spreading hopes of providing expert systems with learning capabilities. The mid-1980s saw Bundy's analytical unification and critique of superficially diverse learning programs (11.iii.b). And by 1986, the new journal *Machine Learning* had been established, with Langley as its founding editor.

The methods used included connectionism as well as GOFAI, and genetic algorithms as well as fixed programs (J. H. Holland *et al.* 1986; Goldberg 1987). By the late 1980s, some machine learning was taking account of underlying causal mechanisms (Bratko *et al.* 1988, 1989). And the field was influencing the philosophy of science (Thagard 1988, 1989, 1990; P. M. Churchland 1989).

Not all of this post-Kraken literature concerned Hunt's theme (and ours): what one might term "property-list" induction. But much of it did.

Why the sudden blossoming of interest? After all, people had been working on GOFAI induction for some years. They included Michie, Robin Popplestone, and Gordon Plotkin in Edinburgh; Ivan Bratko in Prague; Langley and Simon at CMU; Michalski at the University of Illinois; and Thomas Mitchell, also at Illinois—who'd cut his AI teeth (at Stanford) on the learning aspect of meta-DENDRAL, but who became well known for his method of "version spaces" (T. M. Mitchell 1979; Mitchell *et al.* 1983). One name, however, stood out above all: J. Ross Quinlan (1943–), ensconced at the RAND Corporation by 1983.

It was Quinlan's work, from the late 1970s on, which tipped the popularity scales in favour of machine learning. Specifically, he devised the ID3 algorithm (Quinlan 1979). This was instigated in the context of chess endgames, thanks to a "challenging" question posed by Michie: could one tell, from the state of the board alone, whether a certain endgame was likely to be lost within a fixed number of moves? (Quinlan 1986: 84; cf. Quinlan 1983: 481). But Quinlan soon moved beyond chess, generalizing his algorithm a few years later (1983, 1986).

ID3 revolutionized machine learning, setting the GOFAI agenda for many years to come. It was the first inductive program specifically designed to handle "large masses of low-grade data" (1983: 463). And it was mathematically guaranteed to find the most efficient classification method for a given domain, provided that it was given a representative sample of examples (i.e. all types of example included, and the rarities suitably rare). Potentially, the commercial applications were legion.

One might argue that the *theoretical* interest of Quinlan's work on machine learning hadn't increased—had perhaps even decreased—with ID3. For his initial research, presented at the very first IJCAI meeting in 1969, had been different. Like Arthur Samuel's game-player, Sussman's HACKER, and Michie's pole-balancer (Michie and Chambers 1968), his first learning program had used adaptive self-monitoring to improve its own problem-solving ability (Quinlan 1969). By contrast, ID3 discovered already structured concepts. That's a perfectly respectable type of learning—but it's not the only one, nor the deepest.

It was, however, the one with the greatest technological promise. But if ID3 pointed towards technology, it had started out in psychology. For Quinlan had been deeply influenced by Hunt. He'd even co-published with him, on problem solving (Hunt and Quinlan 1968). That had been during his time as the first Ph.D. student in computer science at the University of Washington, where Hunt had a home in the Psychology and the Computer Science departments (E. B. Hunt, personal communication). On turning to learning as his prime topic, he benefited from Hunt's ideas. Later, he described ID3 as "a relative" and "a descendant" of the CLS classification rule (1979: 171; 1983: 465). Indeed, he acknowledged CLS as "the patriarch" of the large family of post-Kraken inductive programs (1986: 84).

In outline, ID3 was given a training set of a large number of instances of various concepts: chess endgames, perhaps, or the nineteen common diseases that affect soya beans (see below). Each instance was described in terms of a set of properties (the position of king or rook, for example), and the program learnt rules for defining each concept. It did this by a hierarchical series of binary partitions of the training space. When the space could be divided no further, the program would be tested on sets of new examples (instances and non-instances).

So far, so CLS. But ID3 was hugely more efficient than its psychological precursor. Its advantages were:

* the much greater size of the training set,
* a larger number of attributes used in defining concepts,
* greater complexity of the concepts (measured by the number of nodes on the decision tree),
* much greater speed and computational efficiency,
* the ability to accept classifications accounting only for *most* of the data, and
* the possibility of discovering some classification-relevant attributes automatically (i.e. local *patterns* of attributes, as in chess positions—1983: 477–81).

ID3, said Quinlan, was "five times as fast as the best alternative method that I could devise" (p. 463). And it surpassed all the other inductive algorithms favoured at the time, such as Michalski's AQVAL or Mitchell's version spaces. Version spaces had been designed to deal with large data sets too, by setting boundaries of maximal and minimal generality to the concepts being developed. But as Quinlan pointed out, when the number of examples was *very* large, Mitchell's method (which required the system to remember all the still-possible maximal/minimal rules) would become unmanageable. Instead, he suggested a simple iterative strategy:

** select at random a subset of the given instances (called the *window*)
** *repeat*
  * form a rule to explain the current window
  * find the exceptions to this rule in the remaining instances
  * form a new window from the current window and the exceptions to the rule generated from it *until* there are no exceptions to the rule. (Quinlan 1983: 469)

(For generating *approximate* classification rules, that final "until" had to be relaxed—1983: 474–7.)

Experimenting with two different ways of forming the window, Quinlan used this approach to classify a data set of nearly 2,000 objects, involving fourteen attributes, and requiring a decision tree with no fewer than forty-eight nodes (Quinlan 1979). The results were staggering.

Irrespective of the window-forming method used, he found that *only four iterations* were normally needed to find a correct decision tree. The final window could contain only a small fraction of the 2,000 objects, and the size of the initial window didn't matter much. Moreover, the time required increased only linearly as the task difficulty rose (measured by the number of objects, attributes, and decision tree nodes). So whereas Hunt had been restricted to very simple concepts, like the experimental examples in Bruner's *A Study of Thinking*, Quinlan's method could be used to deal with much more interesting cases.

Consider soya bean diseases, for instance—no mere triviality in America's Midwest, since soya beans are Illinois's main commercial product. The nineteen common diseases are recognized by thirty-five descriptors, covering various types of leaf spots (with/without haloes, or water-soaked margins, or . . .) and holes, seed shrivelling, and information about season and rainfall.

There's no simple one-to-one mapping of symptom to disease. Rather, there's a complex pattern of symptoms for each disease, complicated by the fact that not all the symptoms need to be present in a particular case. (Pink bluebells, again.) So even experienced soya bean farmers can't always be sure what's ailing their plants. Illinois has long provided a number of Agricultural Extensions Offices which they can phone for advice. In especially difficult cases they can also arrange for microscopical tests to be done, at the farmer's expense, by the university.

Michalski and Richard Chilausky, both working—appropriately enough—at the University of Illinois, decided to use ID3 to write an expert system that might save time and money for all concerned (Michalski and Chilausky 1980). With the help of the textbooks, augmented by forty-five hours of consultation with a local plant pathologist, they identified the probably relevant descriptors and provided them to ID3. In addition, they designed a descriptive questionnaire to be filled in by the farmers whose crops were afflicted—and the farmers' answers were then used as input to the expert system (see Figure 13.2).

It turned out that, for fifteen diseases, their ID3-based program outperformed the world expert—who'd written the textbook on which the initial data classification had been based. Having been trained on 307 different cases, it was tested on 376 new ones. (The tree was automatically converted into a coherent set of production rules, implying that IF such-and-such symptoms were present, THEN such-and-such a disease was present.) It got only two diagnoses wrong, whereas humans following the textbook rules failed in 17 per cent of cases. Indeed, the computer-generated rules were accepted for daily use by soya bean farmers and pathologists alike (Michie and Johnston 1984: 111).

Even though all the data in ID3's training set (regarding soya beans or anything else) were presented simultaneously, the algorithm made sensible decisions about which attributes to consider first. The window was chosen at random, as we've seen. But the item "form a rule to explain the current window" involved frequency counts that improved on those used by CLS. In Quinlan's words:

> The whole skill in this style of induction lies in selecting a useful attribute to test for a given collection of objects so that the final tree is in some sense minimal. *Hunt's work* used a lookahead scheme driven by a system of measurement and misclassification costs in an attempt to get minimal-cost trees. ID3 uses *an information-theoretic approach* aimed at minimizing the expected number of tests to classify an object. (Quinlan 1983: 466–7; italics added)

That was the thin end of the technological wedge. Whereas Hunt had started from experimental data, common sense, and simple logic to define thinking strategies that

Environmental descriptors
- Time of occurence = July
- Plant stand = normal
- Precipitation = above normal
- Temperature = normal
- Occurence of hail = no
- Number of years crop repeated = 4
- Damaged area = whole fields

Plant global descriptors
- Severity = potentially severe
- Seed treatment = none
- Seed germination = less than 80%
- Plant height = normal

Plant local descriptors
- Condition of leaves = abnormal
  - Leafspots–halos = without yellow halos
  - Leafspots–margin = without watersoaked margin
  - Leafspot size = greater than ⅛"
  - Leaf shredding or shot holding = present
  - Leaf malformation = absent
  - Leaf mildew growth = absent
- Condition of stem = abnormal
  - Presence of lodging = no
  - Stem cankers = above the second node
  - Canker lesion color = brown
  - Fruiting bodies on stem = present
  - External decay = absent
  - Mycelium on stem = absent
  - Internal discoloration of stem = none
  - Sclerotia-internal or external = absent
- Conditions of fruit-pods = normal
  - Fruit sports = absent
- Condition of seed = normal
  - Mould growth = absent
  - Seed discoloration = absent
  - Seed size = normal
  - Seed shrivelling = absent
- Condition of roots = normal

Diagnosis:

Diaporthe stem canker( ) *Charcoal rot*( ) *Rhizoctonia root rot*( ) *Phytophthora root rot*( ) *Brown stem root rot*( ) *Powdery mildew*( ) *Downy mildew*( ) *Brown spot(x)* *Bacterial blight*( ) *Bacterial pustule*( ) *Purpose seed stain*( ) *Anthracnose*( ) *Phyllosticta leaf spot*( ) *Alternaria leaf spot*( ) *Frog eye leaf spot*( )

FIG. 13.2. A questionnaire completed by a soybean farmer, used as input to an ID3-based expert system, with the program's diagnosis (Brown spot) shown underneath. Reprinted with permission from Michalski and Chilauski (1980: 138)

might actually go on in human heads, Quinlan was using highly abstract formulae drawn from information theory. In effect, ID3 was doing entropy calculations in order to choose which attribute to consider next (1983: 467 ff., 475 ff.). These calculations were justified *not* by psychological theory (even though some psychologists were starting to use ideas about entropy in their models: 12.vi.b), but purely by mathematical efficiency.

As the post-Kraken period progressed, the psychological roots of automatic induction grew ever more obscure. For Quinlan (e.g. 1988, 1993) and others used increasingly arcane statistical measures to enable more efficient machine learning. Much as connectionist learning, during these years, grew closer to mathematical statistics *as such* (Chapter 12.vi.f), so most of the GOFAI versions did too.

This was pointed out in the early 1990s by Michie (Michie *et al.* 1994). Indeed, most of the papers given at his 1992 Machine Intelligence workshop, which was devoted to the topic of learning, exemplified the mathematical trend (Furukawa *et al.* 1994). Despite a handful of people-centred presentations, including one by a leading developmental psychologist based in Edinburgh (C. B. Trevarthen 1994), human beings weren't much considered. Like most other 1990s work on automatic induction, this was *machine* learning: technological, not psychological, AI. (The exceptions included Michalski's theories of plausible inference and human learning; based on a model of dynamic links between conceptual hierarchies, these were developed through the 1980s with the psychologist Allan Collins: Collins and Michalski 1989; Hieb and Michalski 1993.)

Some even began to claim that this research wasn't AI at all (see vii.b, below). Statisticians and computer scientists didn't want to be labelled as doing AI. This attitude was—is—due partly to intellectual territoriality ("Get off my patch!"), and partly to a wish to avoid diversionary philosophical challenges. Hard-headed technologists and mathematicians didn't want to be saddled with provocative psychological terms such as *intelligence*, *knowledge*, or even *learning*.

As a result, the most successful type of machine learning is near-invisible today, because it's blandly named "data mining". (Two of the field's pioneers now use both names in the same breath—and the same book title: Michalski *et al.* 1998.)

By "successful", I really do mean successful. As one commentator has put it, the AI equivalent of Columbus' looking for India and finding the resource-rich America is looking for machine learning and finding data mining (Whitby 2004). Huge sums of money are now spent on partitioning enormous (and noisy) data sets into useful categories. For example, advertising agencies are commonly asked to find detailed descriptions of the people likely to be interested in buying such-and-such a product, or voting for such-and-such a policy. It's a rare client, however, who thinks of this as machine learning—still less, as AI. Yet without AI, there'd be no data mining.

The *psychological* origins of automatic induction are less visible still. (Statistics rules!) For practical purposes, that doesn't matter. For historical purposes, however, machine learning's debt to experimental psychology should be recognized.

13.iv. Explaining the Ineffable

'Explaining the Ineffable' was the title—and 'Intuition, Insight, and Inspiration' the key words in the subtitle—of the paper which Simon, near the end of the century (Simon

1995*b*), said that AAAI Fellows should read if they doubted that AI is a *science* (see vii.a, below). Clearly, he felt that AI had gone some way towards fulfilling the promise of his 1958 RAND harbinger (10.i.f). But that promise hadn't been taken up explicitly until the 1980s.

a. Creativity ignored

Creativity was an obvious challenge for AI right from the start—or even before it. In the imaginary conversation that launched the Turing Test, Turing had depicted a computer as interpreting/defending a sonnet, tacitly implying that a computer might compose poetry too. However, once people started writing AI programs, this particular challenge was parked on the sidelines.

When GOFAI was still NewFAI, creativity was a no-go area. To be sure, Donald Mackay (1951) had described a probabilistic system which he said would show "originality" in a minimal sense—but that had been an aside, not the main object of the exercise. Similarly, problem-solving programs were occasionally described as creative. And Simon, in 1957, had mentioned the "theory of creativity" he and Newell were developing—and had praised the pioneering work of Lejaren Hiller and Leonard Isaacson, whose computer-generated Illiac suite (a string quartet, first performed in 1957) was, in his estimation, "not trivial and uninteresting" (McCorduck 1979: 188). Nevertheless, creativity in the layman's sense (i.e. art, music, and science—and maybe jokes) was all but ignored by AI professionals.

Outside the field, this was less true. Zuse's vision of automatic carpet design, with deliberate weaving-errors to add 'authenticity', wasn't yet in the public domain. But visual computer art was getting started in Europe and the USA by 1963, and interactive computer art had already begun in the 1950s (see Section vi.c, below).

In the 1950s, too, Hiller—a professional chemist, but also a Master of Music—had initiated the Illiac suite (the score is given at pp. 182–97 of Hiller and Isaacson 1959). The first three movements were generated from rules defining various musical styles (sixteenth-century counterpoint, twelve-tone music, and a range of dynamics and rhythms), sometimes combined with tone-pairs chosen by chance; the fourth movement was based not on familiar styles but on Markow chains (Hiller and Isaacson 1959). Systematic experiments in computer music, including instrumentation, were done at IRCAM in Paris from the early 1960s. And a competition for computer-composed music was organized at the 1968 International Federation for Information Processing meeting in Edinburgh (and led to the founding of the Computer Arts Society).

In general, however, these projects involved the artistic avant-garde, with a few art-oriented scientists—not the leaders of GOFAI. Their references to "creativity", "invention", and "discovery" in the Dartmouth proposal weren't being echoed in AI research (McCarthy *et al.* 1955: 45, 49 ff.). Even creative problem solving was rarely described as such, despite the LT team's use of the term in their late 1950s call to arms.

That's why my AI colleagues were bemused when, in the early 1970s, I told those who asked that I'd decided to include a whole chapter on the topic in my book on the field. Several protested: "But there isn't any work on creativity!"

In a sense, they were right. Admittedly, the 1960s had produced an intriguing model of analogy (see below), and meta-DENDRAL had touched on creativity in chemistry.

Moreover, much NewFAI work was an essential preliminary for tackling creativity as such. For instance, NLP researchers had asked how memory structures are used in understanding metaphysics (Wilks 1972: see 9.x.d), metaphor (Ortony 1979), or stories (Charniak 1972, 1973, 1974; Schank and the Yale AI Project 1975; Rieger 1975*a*,*b*). One brave soul was generating story-appropriate syntax (Davey 1978: see 9.xi.c), and another studying rhetorical style (Eisenstadt 1976).

But apart from a handful of painfully crude "poets", "story writers", or "novelists", there were no models of what's normally regarded as creativity (Masterman and McKinnon Wood 1968; Masterman 1971; Meehan 1975, 1981; Klein *et al.* 1973). The renowned geometry program was only an *apparent* exception (see 10.i.c and Boden 1990*a*: 104–10).

This explains why John Haugeland (1978, sect. 7), when he questioned the plausibility of cognitivism, raised general doubts about GOFAI analyses of "human insight" but didn't explicitly criticize any specific models of it. His first worry was that GOFAI systems "preclude any radically new way of understanding things; all new developments would have to be specializations of the antecedent general conditions". But Galileo, Kepler, and Newton, he said, invented "a totally new way of talking about what happens" in the physical world, and "a new way of rendering it intelligible". Even to learn to understand the new theory would be beyond a medieval-physics GOFAI system, "unless it had it latently 'built-in' all along". (He may have chosen this particular example because he'd heard of the about-to-be-published BACON suite on the grapevine: see below.) The underlying difficulty, he suggested (following Dreyfus: 11.ii.a), was that "understanding pertains not primarily to symbols or rules for manipulating them, but [to] the world and to living in it".

Before the 1980s, then, creativity was a dirty word—or anyway, such a huge challenge that most programmers shied away from it. The most important exception, and still one of the most impressive, was due to someone from *outside* the NewFAI community.

b. Help from outside

Harold Cohen (1928–) was a highly acclaimed abstract artist of early 1960s London. (Those words "highly acclaimed" weren't empty: a few years ago, a major exhibition on 'The 1960s' was held at London's Barbican. Even though this was focused on 1960s culture as a whole, not just on the visual arts, two of Cohen's early paintings were included.) He turned towards programmed art in 1968. He spent two years in Stanford as a visiting scholar with Feigenbaum, in 1973–5, where he not only found out about AI but also learnt to program.

In the four decades that followed, while at the University of California (San Diego), he continuously improved his drawing and colouring program, called AARON (H. Cohen 1979, 1981, 1995, 2002; McCorduck 1991; Boden 2004: 150–66, 314–15). Successive versions of AARON were demonstrated at exhibitions in major galleries (and at Science Centres) around the world, and received huge publicity in the media. (An early version is now available as shareware.)

Unlike his 1960s contemporaries Roy Ascott and Ernest Edmonds (vi.c, below), Cohen wasn't using computer technology to found a new artistic genre. Rather, he was investigating the nature of representation. To some extent, he was trying to achieve a better understanding of his own creative processes. But, over the years, he came to see his early attempts to model human thought as misdirected:

> The common, unquestioned bias—which I had shared—towards a human model of cognition proved to be an insurmountable obstacle. It was only after I began to see how fundamentally different an artificial intelligence is from a human intelligence that I was able to make headway. . . . The difference is becoming increasingly clear now, as I work to make AARON continuously aware of the state of a developing image, as a determinant to how to proceed. How does a machine evaluate pizazz? (personal communication, July 2005)

Cohen asked how he made introspectively "unequivocal" and "unarbitrary" decisions about line, shading, and colour. (From the mid-1990s his main focus was on colour.) And he studied how these things were perceived—by him and others—as representing neighbouring and overlapping surfaces and solid objects. Moving towards increasingly 'three-dimensional' representations, he explored how his/AARON's internal models of foliage and landscape, and especially of the human body, could be used to generate novel artworks. (He was adamant that they *were* artworks, although some philosophers argue that no computer-generated artefact could properly be classified as art: O'Hear 1995.)

Two examples, dating from either side of 1990, are shown in Figures 13.3 and 13.4. Notice that the second, drawn by the later version of the program, has more 3D depth than the first. (Which, in turn, has more than the drawing by AARON's early 1980s 'Acrobat and Balls' period—see Boden 1990*a*/2004, frontispiece.) In particular,

Fig. 13.3. An example of AARON's 'jungle' period, late 1980s; the drawing was done by the program, but the colouring was done by hand. Untitled, 1988, oil on canvas (painted by Harold Cohen), 54″ × 77″; Robert Hendel collection. Reproduced with permission of the artist

Fig. 13.4. An example of early 1990s AARON; the drawing was done by the program, but the colouring was done by hand. *San Francisco People* (1991), oil on canvas (painted by Harold Cohen), 60″ × 84″, collection of the artist. Reproduced by his permission

'Jungle-AARON' didn't have enough real 3D data about the body to be able to draw a human figure with its arms overlapping its own body. His early 1990s city-people could have waved, if he had wanted them to; but his late 1980s jungle-dwellers couldn't have crossed their arms instead of waving.

By 1995, Cohen had at last produced a painting-machine-based version of AARON which could not only draw acceptably but also colour to his satisfaction—using water-based dyes and five brushes of varying sizes. However, his satisfaction was still limited.

By the summer of 2002, he'd made another breakthrough: a digital AARON-as-colourer, whose images could be printed at any size. The program was regularly left to run by itself overnight, offering up about sixty new works for inspection in the morning. Even the also-rans were acceptable: one gallery curator who exhibited it told Cohen that "he hasn't seen AARON make a bad one since it started several weeks ago" (Cohen, personal communication). One might even say that AARON has now surpassed Cohen as a colour artist, much as Samuel's program surpassed Samuel as a checkers (draughts) player nearly half a century before. For Cohen regards this latest incarnation of AARON as "a world-class colorist" whereas he himself is merely "a first rate colorist" (personal communication).

A comparably spectacular, though later, AI artist was "Emmy"—originally EMI: Experiments in Musical Intelligence. This program was written in 1981 by the composer

David Cope (1941–), at the University of California, Santa Cruz. (It wasn't easy for other people to run, or experiment with, the early version. For the now familiar MIDI, or Musical Instrument Digital Interface, which defines musical notes in a way that all computers can use, wasn't yet available. Indeed, its inventor, Dave Smith, first had the idea in that very year, and didn't announce the first specification until August 1983: Moynihan 2003. Today, Emmy's successors are based on MIDI, so can be run on any PC equipped with run-of-the-mill musical technology.)

This wasn't the first attempt to formalize musical creativity (and nor was the Hiller and Isaacson effort). A system of rules for do-it-yourself hymn composition was penned in the early eleventh century by Guido d'Arezzo, who also invented the basis of tonic solfa and of today's musical notation (A. Gartland-Jones, personal). But Cope, almost 1,000 years later, managed to turn "formalize" into "implement". Moreover, his program could compose pieces much more complex than hymns, whether within a general musical style (e.g. baroque fugue) or emulating a specific composer (e.g. Antonio Vivaldi or J. S. Bach). It could even mix styles or musicians, such as Thai–jazz or Bach–Joplin, much as the Swingle Singers do.

Emmy gained a wide audience, though not as wide as AARON's. Part of its notoriety was spread by scandalized gossip: Cope has remarked that "There doesn't seem to be a single group of people that the program doesn't annoy in some way" (Cope 2001: 92). But as well as relying on word of mouth, people could read about it, and examine some Emmy scores, in Cope's four books (1991, 2000, 2001, 2006). Enthusiasts could even try it out for themselves, following his technical advice, by using one of the cut-down versions (ALICE: ALgorithmically Integrated Composing Environment, and SARA: Simple Analytic Recombinant Algorithm) provided on CDs packaged inside his books.

They could listen to Emmy's compositions, too. Several stand-alone CDs were released (by Centaur Records, Baton Rouge) in the late 1990s. In addition, several live concerts of Emmy's music were staged to public audiences. (These featured human instrumentalists playing Emmy's scores, because the program didn't represent expressive performance: it laid down what notes to play, not how to play them.)

However, the concerts were mostly arranged by Cope's friends: "Since 1980, I have made extraordinary attempts to have [Emmy's] works performed. Unfortunately, my successes have been few. Performers rarely consider these works seriously" (Cope 2006: 362). The problem, said Cope, was that they (like most people) regarded Emmy's music as computer "output", whereas he had always thought of it rather as *music*. Moreover, being "output" it was infinitely extensible, a fact—he found—that made people devalue it.

In 2004 he took the drastic decision to destroy Emmy's historical database: there will be no more "Bach" fugues from the program (2006: 364). Emmy's "farewell gift" to the historical-music world was a fifty-page score for a new symphonic movement in the style of Beethoven, which required "several months of data gathering and development as well as several generations of corrections and flawed output" (2006: 366, 399–451). From now on, Emmy—or rather, Emmy's much-improved successor—will be composing in Cope's style, as "Emily Howell" (p. 374).

Hofstadter, a fine amateur musician, found Emmy impressive despite—or rather, because of—his initial confidence that "little of interest could come of [its GOFAI] architecture". On reading Cope's 1991 book, he got a shock:

> I noticed in its pages an Emmy mazurka supposedly in the Chopin style, and this really drew my attention because, having revered Chopin my whole life long, I felt certain that no one could pull the wool over my eyes in this department. Moreover, I knew all fifty or sixty of the Chopin mazurkas very well, having played them dozens of times on the piano and heard them even more often on recordings. So I went straight to my own piano and sight-read through the Emmy mazurka—once, twice, three times, and more—each time with mounting confusion and surprise. Though I felt there were a few little glitches here and there, I was impressed, for the piece seemed to *express* something ... [It] did not seem in any way plagiarized. It was *new*, it was unmistakably *Chopin-like* in spirit, and it was *not emotionally empty*. I was truly shaken. How could emotional music be coming out of a program that had never heard a note, never lived a moment of life, never had any emotions whatsoever?
>
> [...Emmy was threatening] my oldest and most deeply cherished beliefs about ... music being the ultimate inner sanctum of the human spirit, the last thing that would tumble in AI's headlong rush toward thought, insight, and creativity. (Hofstadter 2001*a*: 38–9)

Hofstadter was allowing himself to be *over*-impressed, here. For Frederic Bartlett's "effort after meaning" (5.ii.b) imbues our perception of music as well as of visual patterns and words. The human performer projects emotion into the score-defined notes, much as human readers project meaning into computer-generated haikus (9.x.c). So, given that "Chopin-like" scores had been produced, it wasn't surprising that Hofstadter interpreted them expressively.

What was surprising was the Chopin-like musicality of the compositions. Simon's 1957 prediction that a computer would write aesthetically valuable music within ten years had failed, and had been mocked accordingly (H. L. Dreyfus 1965: 3). But Cope had now achieved this, though fourteen years late.

Emmy's basic method was described by Cope as "recombinatory", and summarized by Hofstadter as "(1) chop up; (2) reassemble" (p. 44). In fact, Emmy was exploring generative structures as well as recombining motifs. It showed both combinational and exploratory creativity—but not, as Hofstadter (2001*b*) was quick to point out, transformational creativity (Boden 1990*a*/2004). A 'new' style could appear only as a result of mixing two or more existing styles.

The program's database was a set of 'signatures' (note patterns of up to ten melodic notes) exemplifying melody, harmony, metre, and ornament, all selected by Cope as being characteristic of the composer concerned. Emmy applied statistical techniques to identify the core features of these snippets, and then—guided by general musicological principles—used them to generate new structures. (Some results worked less well than others—e.g. Cope 2001: 182–3, 385–90.)

Strictly, Emmy wasn't an exercise in "explaining" the ineffable. For Cope's motivation differed from Simon's (and Hofstadter's: see below). His aim wasn't to understand creative thought, but to generate musical structures like those produced by human composers. Initially, he'd intended EMI to produce new music in *his* style, but soon realized that he was "too close to [his] own music to define its style in meaningful ways", so switched to the well-studied classical composers instead (2001: 93). (A quarter-century later, having destroyed the historical database, he switched back to computer compositions in his own style—2005: 372 ff. and pt. III *passim*.)

In short, he was modelling music, not mind. (The task wouldn't necessarily have been easier had he known the psychological details; for instance, limits on short-term memory rule out the use of powerful generative grammars for jazz improvisation: Johnson-Laird 1989/1993.)

Nevertheless, the implication of Cope's writings was that all composers follow some stylistic rules, or algorithms. Sonata Form, for example, was supposed to be a formal structure rigidly adhered to by everyone composing in that style. This assumption has been questioned. It's known that Haydn, Mozart, and Beethoven (for instance) worked diligently through the exercises given in various musical textbooks. But whether they stuck rigidly to those rules in their more original, creative, music is quite another matter. Peter Copley and Drew Gartland-Jones (2005) argue that they did not.

On their view, the formal rules of style are extracted and agreed *post hoc*, and are then followed to the letter only by musical students and mediocrities. Once sonata form, or any other musical structure, has been explicitly stated, it tends to lose its creative potential. (This explains the "paradox" of sonatas in the romantic period being *far less* free than in the classical times: p. 229.) But the rules are flexible enough to evolve in use:

> It would be tempting to view this process as *generally agreed* forms, evolving. But . . . [it] would be more useful to see the general acceptances of common practice as *present to provide a frame for musical differences, changes, developments etc.* (Footnote: This is the basis for Boden's transformational creativity). If there is a constraint it comes organically from within a complex network of practitioners rather than [a] set of stated constraints that are accepted until someone decides they need breaking. This is a complex mechanism indeed, and even if we argue that algorithms might explain certain emergent patterns, it is not at all sure that such patterns stem from a simple, if enormously lengthy, set of rules. (Copley and Gartland-Jones 2005: 229; final italics added)

Cope's Emmy, they admit, can indeed compose many acceptable pieces. But even if it could generate fully "convincing" examples, "without a model of how [the abstracted rules] change we are capturing an incomplete snapshot of musical practice" (p. 229). In other words, Cope is modelling musical creations—not yet musical creativity.

c. In focus at last

It's no accident that those two highly successful programs, AARON and Emmy, were written by non-AI professionals. For they depended on a reliable sense of how to generate and appreciate structures within the conceptual space concerned (Boden 1990*a*/2004, chs. 3–4). In general, a plausible computer artist stands in need of an expert in art. Even if (like Hiller) the person isn't a professional artist, they need (again, like Hiller) to be a very highly knowledgeable amateur.

Often, artist and programmer are different people (e.g. William Latham and Stephen Todd, respectively: Todd and Latham 1992). But some artists are sufficiently computer-literate to design their own systems. Edmonds was a professional computer scientist in the 1960s, as well as being an influential artist. (Although he's always used his programs to help him understand creative thinking in general, he was less concerned than Cohen or Cope to talk about *the program as such*: if his viewers needed to realize that there was a program involved, they didn't need to think about just how it worked: see vi.c, below.) Today, forty years later, many young artists are computer-literate even if they're not computing professionals.

If artist programs need experts in art, much the same is true of programs focused on literature, maths, and science. A competent programmer is the sine qua non, but domain expertise is needed too. Since most AI researchers were reasonably proficient in those areas, one and the same person could be both programmer and expert. That's why AI work on creativity, once it got started, usually focused on them (rather than on music or, still less, visual art).

The everyday skill of analogy, which features in both literature and science, had been modelled as early as 1963 by Thomas Evans (1934–) at MIT. His program was a huge advance (T. G. Evans 1968). Implementing the ideas briefly intimated by Minsky in 'Steps' (see Figure 10.3), it not only discovered analogies of varying strength but also identified the best.

It could do this because it described the analogies on hierarchical levels of varying generality. Using geometrical diagrams like those featured in IQ tests (see Figure 13.5), Evans's program achieved a success rate comparable to that of a 15-year-old child. But it wasn't followed up. (This was an example of the lack of direction in AI research that so infuriated McDermott: 11.iii.a.)

By the early 1980s, analogy had returned as a research topic in AI. For instance, an international workshop held in 1983 included five papers explicitly devoted to it, plus several more that could be seen as relevant (Michalski 1983, esp. 2–40).

Evidently, the AI scientists concerned didn't read Fodor's *Modularity of Mind* (1983), or anyway didn't accept its pessimism about explaining the higher mental processes. Fodor despaired of any attempt to understand analogy in scientific terms. Despite its undeniable importance, he said,

> nobody knows anything about how it works; not even in the dim, in-a-glass-darkly sort of way in which there are some ideas about how [scientific] confirmation works. (Fodor 1983: 107)

And, according to him, they never would: "Fodor's First Law of the Nonexistence of Cognitive Science [states that] the more global . . . a cognitive process is, the less

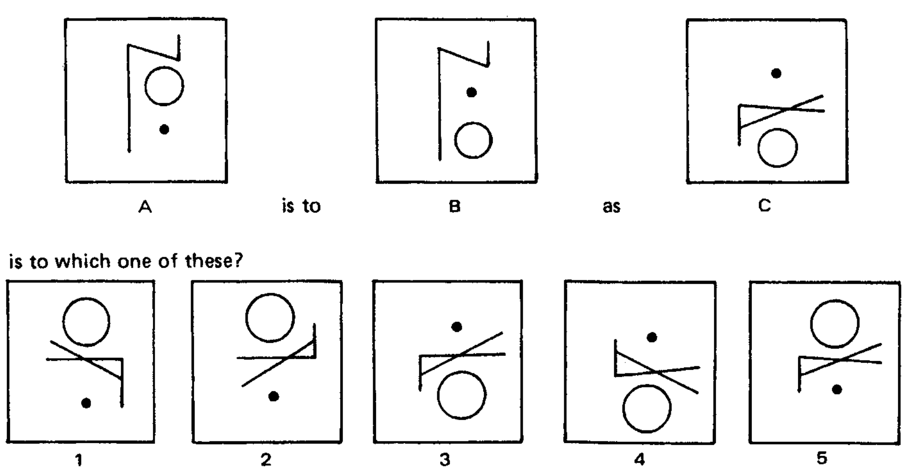

FIG. 13.5. Analogy problem tackled by Evans's program. Reprinted with permission from (Minsky 1968: 332)

anybody understands it." (As we saw in Chapter 7.vi.h, he was right in arguing that we'll never be able to predict/explain every case of analogy in detail, but wrong in concluding that nothing of scientific interest can therefore be said about it.)

Fodor's scepticism notwithstanding, several GOFAI scientists in the 1980s tried to model how conceptual analogies are generated, interpreted, and used (Gentner 1983; Holyoak and Thagard 1989; Thagard *et al.* 1988; Gentner *et al.* 1997). Like Newell and Simon before them, they sometimes went back to the Gestalt psychologists' 1930s work on problem solving (Chapter 5.ii.b). For instance, they asked (taking Karl Duncker's example) how the notion of a besieging army could help in discovering how to irradiate a tumour without killing the surrounding tissues.

In general, they wanted to know just how an analogous idea could be identified, and fruitfully mapped onto the problem at hand. The answer usually given was to show how distinct conceptual structures could be compared, and—if necessary—adapted so as to match each other more closely. Sometimes, the problem-solver's goal was allowed to influence the comparison. But the basic process was like that used long before by Patrick Winston's concept-learner (10.iii.d): comparing abstractly defined, and pre-assigned, structures.

A blistering critique of these "inflexible" and "semantically empty" approaches was mounted by Hofstadter (Hofstadter and FARG 1995: 55–193). He complained that they were less interesting than Evans's work of twenty years before, and radically unlike human thinking. (Although both these charges were fair, his stinging critique wasn't entirely justified; for 'structuralist' replies, see Forbus *et al.* 1998; Gentner *et al.* 1997.)

But Hofstadter didn't share Fodor's gloom about the impossibility of *any* scientific understanding of analogy. To the contrary, he'd already spent many years studying it, using a basically connectionist approach. He'd been thinking—and writing—along these lines since the early 1970s (Chapter 12.x.a).

By the mid-1980s, he and his student Melanie Mitchell had implemented the Copycat program (Hofstadter 1985*a*, chs. 13 and 24, 2002; M. Mitchell 1990/1993; Hofstadter and Mitchell 1993/1995; Hofstadter and FARG 1995, chs. 5–7). This was described in several seminars at MIT in 1984, although without attracting much attention at the time (personal communication).

Intended as a simulation of human thinking, it modelled the fluid perception of analogies between letter strings. So it would respond to questions like these: "If *abc* goes to *pqr*, what does *efg* go to?", or (much trickier) "If *abc* goes to *abd*, what does *xyz* go to?" (Lacking a 'circular' alphabet, it couldn't map *xyz* onto *xya*; instead, it suggested *xyd*, *xyzz*, *xyy* . . . and the especially elegant *wyz*.) Its descriptors were features such as *leftmost*, *rightmost*, *middle*, *successor*, *same*, *group*, and *alphabetic predecessor/successor*. Like Evans's program, Copycat could generate a range of analogies, and compare their strength. Unlike Evans's program, it was probabilistic rather than deterministic, and could be 'primed' to favour comparisons of one type rather than another.

Whereas Copycat worked on letter strings, Hofstadter's Letter Spirit project focused on complex visual analogies. Specifically, it concerned the letter-likenesses and letter-contrasts involved in distinct alphabetic fonts. An *a* must be recognizable as an *a*, no matter what the font; but seeing other letters in the same font may help one to realize that it is indeed an *a*. At the same time, all twenty-six letters within any one font must share certain broad similarities, all being members of *that* font (see Figures 13.6 and 13.7).

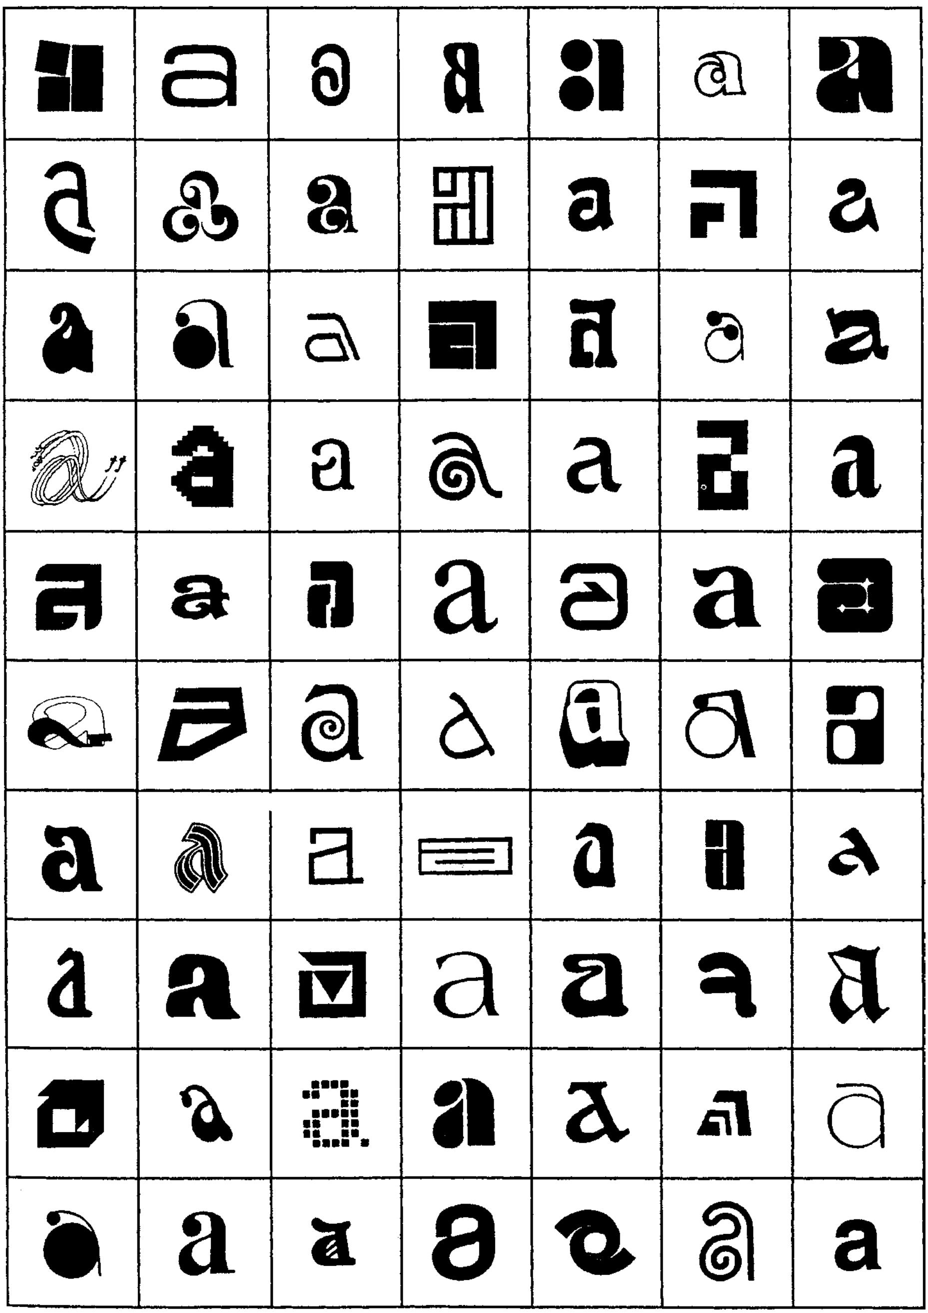

FIG. 13.6. The letter 'a' written in different fonts. Reprinted with permission from Hofstadter and FARG (1995: 413)

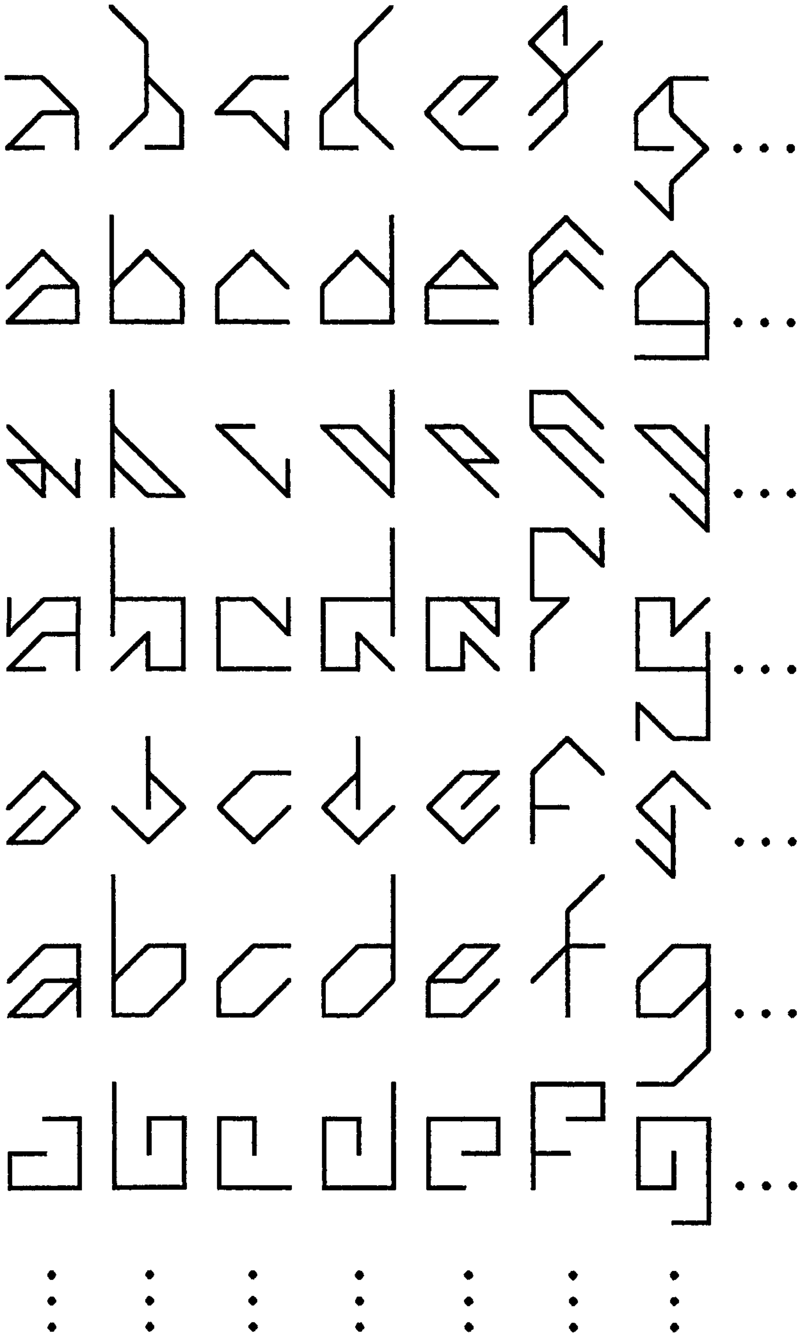

Fig. 13.7. Different fonts based on the Letter Spirit matrix. Reprinted with permission from Hofstadter and FARG (1995: 418)

Hofstadter's early writings on Letter Spirit had outlined a host of intriguing problems involved in interpreting and designing fonts (e.g. Hofstadter 1985*b*). And in the mid-1990s he described a program capable of recognizing letters in a variety of styles (Hofstadter and FARG 1995: 407–96; McGraw 1995; Hofstadter and McGraw 1995). By the new millennium, the design aspect of Letter Spirit had been part-implemented too (Rehling 2001, 2002). The new program could design an entire alphabet, given five 'seed' letters (*b, c, e, f, g*) as a guide. Today, the group's aim is to generate an alphabet from only a single seed.

Letter Spirit is the most ambitious AI analogy project, and in my view the most interesting. Whether it can readily be applied to other domains, however, is unclear. Even the much simpler Copycat would be difficult to generalize. However, if what one is interested in is how it's possible for human beings to engage in subtle and systematic analogical thinking, then it's a significant contribution. It's no simple matter to generate or appreciate an alphabetic font. So much so, indeed, that hardly anyone other than Hofstadter would have dreamt that anything cogent could be said about the computational processes that may be involved.

Turning from analogy to story writing, the best AI story-writer was authored not by a novelist or literary critic but by a computer scientist, now a professional games designer: Scott Turner (1994). (He's not to be confused with Mark Turner, a teacher of English at the University of Maryland who turned to cognitive science to illuminate the interpretation and creation of literature: M. Turner 1991; Fauconnier and Turner 2002.)

This program didn't produce high-quality literature. Its plots were simplistic tales about knights, princesses, and dragons, and its use of English left a great deal to be desired. But it had three interesting features.

First, it used case-based reasoning (ii.c, above) to create new story plots on the basis of old ones. For example, it generated a concept/episode of *suicide* (derived from *killing*) when the story's plot couldn't be furthered by third-party fighting. Second, it relied on the latest version of the Yale analysis of motivational and planning schemata to decide what might plausibly be done, and how (cf. 7.i.c and 9.xi.d). And third, Turner had realized—what previous AI programmers had not (e.g. Meehan 1975)—that a story needs not only goals and plans for each character involved in the plot, but also *rhetorical* goals and plans for the storyteller. Accordingly, a character's goals were sometimes rejected by the program, or their expression suppressed in the final narrative, for reasons of story interest or consistency. (For a sustained critique of Turner's approach, see Bringsjord and Ferrucci 2000.)

By the mid-1990s, AI had even made good on Babbage's suggestion that puns follow "principles" including double meanings and similar pronunciation of differently spelt words (Chapter 3.iv.a). Kim Binsted, at the University of Edinburgh, wrote a program—JAPE—that originated punning riddles fitting nine familiar templates, such as *What do you get when you cross an X with a Y?*, *What kind of X has Y?*, *What kind of X can Y?*, and *What's the difference between an X and a Y?* (Binsted 1996; Binsted and Ritchie 1997; Binsted *et al.* 1997; Ritchie 2003*a*). JAPE used a semantic network of over 30,000 items, marked for syllables, spelling, sound, and syntax as well as for semantics and synonymy. The program would consult the templates (no simple matter) to generate results including these: *What do you call a depressed train? A low-comotive; What do you call a strange market? A bizarre bazaar*; and *What kind of murderer has* *fibre? A cereal killer*. Babbage's "triple pun" (cane/Cain, a bell/a belle/Abel) couldn't have been created by JAPE, but its puns were no more "detestable" than most. (In fact, it's the most successful of today's AI jokers—Ritchie 2001; 2003*b*, ch. 10.)

As for creative mathematics, great excitement (within AI, if not outside it) was caused in the late 1970s by Lenat's program AM, or Automated Mathematician (Lenat 1977). This was his doctoral thesis at Stanford. Starting from a few simple concepts of set theory, it used 300 heuristics for modifying concepts, and criteria of mathematical "interestingness" (occasionally supplemented by specific nudges from the programmer) to generate many concepts of number theory. These included *integer*, *addition*, *multiplication*, *square root*, and *prime number*. It even generated a historically novel concept, which was later proved as a (minor) theorem, concerning *maximally divisible numbers*—a class which Lenat himself hadn't heard of. Later, he recalled how he found out about them:

> [I wondered whether any mathematician had thought of such a thing. Polya seemed to be the only one who knew.] He said, "This looks very much like something the student of a friend of mine once did." Polya was about 92 at the time. It turned out the friend was [Godfrey] Hardy and the student was Ramanujan. (D. B. Lenat, interviewed in Shasha and Lazere 1995: 231)

Coming up with something that had been discovered by such a giant as Srinivasa Ramanujan (1887–1920), people felt, was no mean feat.

Whether the excitement was fully justified was another matter. Critics pointed out that Lenat hadn't made clear just how the interesting concepts were generated, and suggested that a heuristic that was crucial for generating the notion of primes had been included, whether consciously or not, so as to make this discovery possible (Ritchie and Hanna 1984). What's more, they said, it may have been used only the once. (No detailed trace of the program was available.)

Lenat replied that AM's heuristics were fairly general ones, not special-purpose tricks, and that (on average) each heuristic contributed to two dozen different discoveries and each discovery involved two dozen heuristics (Lenat and Seely Brown 1984). He admitted, however, that writing AM in LISP had given him a tacit advantage. For minor changes to LISP syntax were relatively likely to result in expressions that were mathematically interpretable.

A few years later, yet more excitement was caused by Lenat's EURISKO, which—satisfying McDermott's plea for program development (11.iii.a)—incorporated heuristics for modifying *heuristics* (Lenat 1983). Besides being used to help plan experiments in genetic engineering, it came up with one idea (a battle-fleet design) that won a war-game competition against human players, and another (a VLSI chip design) that won a US patent—which are awarded only for ideas not "obvious to a person skilled in the art". Lenat himself then switched to research on CYC. But his AM program led others to focus on how mathematical "interestingness" could be used in automating creative mathematics (for a review, see Colton *et al*. 2000).

What of Simon himself? His late-century programming efforts were devoted to explaining creativity in science, although he gestured towards the humanities from time to time (Simon 1994*b*). With Langley and others at CMU, he wrote a suite of increasingly powerful programs intended to model the thought processes of creative scientists such as Francis Bacon, Joseph Black, Johann Glauber, Georg Stahl, and John

Dalton. These were initiated in the late 1970s, and continually improved thereafter (Langley 1978, 1979, 1981; Langley *et al.* 1981, 1987).

These inductive systems generated many crucial scientific principles—quantitative, qualitative, and componential. They came up with Archimedes' principle of volume measurement by liquid displacement, the very origin of *Eureka!* And they rediscovered Ohm's law of electrical resistance, Snell's law of refraction, Black's law of the conservation of heat, Boyle's law relating the pressure/volume of a gas, Galileo's law of uniform acceleration, and Kepler's third law of planetary motion. Occasionally (e.g. with Snell's law), they used a symmetry heuristic to choose between more and less elegant, though mathematically equivalent, expressions. Some could produce hypotheses to explain the observed data patterns, whether mathematical (e.g. Black's law) or qualitative (the chemical patterns observed by Glauber, and componentially explained by Stahl and Dalton). And the later versions could use the real (i.e. messy, imperfect) historical data, not just data doctored to make the sums come out exactly right.

Simon wanted to *explain* the ineffable, not just—as in meta-DENDRAL, or Emmy—to mimic it. So his group aimed to keep faith with human psychology.

Their programs, accordingly, respected the details recorded in the laboratory notebooks of the scientists concerned. For example, they used the same data that the long-dead authors had used. (Or rather, they used the same verbal/mathematical data: they couldn't accept visual/auditory/haptic input from the real world, nor recognize similarities between sensory patterns—cf. Chapter 12.v–vi.) And as well as generating the same scientific laws, they tried to match the heuristics that had been used by the human scientists, and the temporal order of their hunches and discoveries—and mistakes. Later work by the CMU group focused, for instance, on the general principles of how to suggest and plan experiments (Kulkarni and Simon 1988), and on the use of diagrams in scientific discovery (Cheng and Simon 1995).

At one level, the BACON program and its siblings (BLACK, GLAUBER, STAHL, and DALTON) were highly impressive. They offered successful models of induction, and illuminated certain aspects of how many human scientists go about their work. (Despite the common propaganda, some science is *not* concerned with numbers, nor with componential structure: Chapter 7.iii.d.) But the creativity involved was exploratory rather than transformational.

In other words, these programs were spoon-fed with the relevant questions, even though they found the answers for themselves. What their human namesakes had done was different, for they'd viewed the data in new ways. Indeed, they'd treated new features as data. To identify *mathematical* patterns in the visual input from earth or sky had been a hugely creative act when Galileo Galilei first did it. To look for numerical constants was another, and to seek simple linear relationships *before* ratios or products (search priorities that were built into the heuristics used by the BACON suite), yet another. The CMU programs were deliberately provided with the ways of reasoning which Bacon, Glauber, Stahl, and Dalton had pioneered for themselves. They were roundly criticized by Hofstadter as a result (Hofstadter and FARG 1995: 177–9; see also H. M. Collins 1989).

(This, of course, recalls Haugeland's principled objection to GOFAI-based models of "insight". It also relates to the worries about "open-ended" evolution mentioned below and discussed in Chapter 15.vi.d. We'll see there that *totally new types* of sensor have been evolved in artificial systems, but only by unexpectedly taking advantage of the contingencies of the physical environment and/or hardware. Compare these 'biological' examples with Haugeland's psychological claim that understanding pertains to "the world and to living in it".)

In short, Saul Amarel's (1968) hope that an automated system might come up with a radically new problem representation remained unfulfilled. And not only Amarel's, for Simon himself had expressed much the same hope in the 1950s. The LT team's harbinger memo had listed four characteristics of "creative" thought, of which the last was this: "The problem as initially posed was vague and ill-defined, so that part of the task [is] to formulate the problem itself."

That's *still* beyond the state of the art. Langley (1998) recently reviewed seven cases of AI-aided discovery that were sufficiently novel, and interesting, to be published in the relevant scientific journals. He pointed out that, in every case, the programmers had been crucial in formulating the problem and/or manipulating the data and/or interpreting the results. So Ada Lovelace's futuristic vision of science-by-machine has been realized: many new answers have been found automatically, and some new questions too (e.g. new experiments). But *fundamental reformulations of old problems*, still less *radically new* ones, have not. (As we saw in Chapter 3.iv.b, Lovelace wouldn't have been at all surprised by that. On the contrary, it's just what she expected.)

In one sense, it's what Simon himself expected, too. For machines, at present, lie outside the cooperative loop (Chapter 2.ii.b–c). Simon described scientific discovery as a matter of "social psychology, or even sociology" (1997*a*: 171). His main reason was that open scientific publication provides a "blackboard" that hugely extends the individual scientist's memory (p. 172). At present, machine discovery systems "are still relatively marginal participants in the social system of science". We might be able to hook them up to data-mining programs, to reduce their reliance on human beings for providing their data and problems. However, "Even this is a far cry from giving machines access to the papers, written in a combination of natural, formal and diagrammatic language, that constitute a large part of the blackboard contents" (p. 173).

As for negotiations about the value of supposed "discoveries" (Chapter 1.iii.f and Boden 1997), Simon's view was that "the machine (augmented now by the computer) has already, for perhaps a hundred years, been a member of the society of negotiators" (Simon 1997*b*: 226). (Here, he cited the prescient Henry Adams, who'd been so deeply troubled by his visit to the dynamo hall in an industrial exhibition: H. Adams 1900.) Future AI programs, said Simon, might persuade us to value their discoveries above our own previous judgements (1997*b*: 225). He added that this was already happening in the area of mathematical proof (but that's not straightforward: see MacKenzie 1995).

Disputes about what counts as a discovery are especially likely in cases of transformational creativity, in which previously valued criteria are challenged. This type of creativity *was* eventually modelled, up to a point, by evolutionary programs. Some were focused on art (Sims 1991; Todd and Latham 1992), some on music (Gartland-Jones and Copley 2003; P. W. Hodgson 2002, 2005), and some on science or engineering (Goldberg 1987; Sims 1994; Ijspeert *et al*. 1997).

To some extent, genetic algorithms (Chapter 15.vi) could transform the conceptual space being explored by the program. For example, Paul Hodgson, an accomplished jazz saxophonist, wrote several programs designed to improvise Charlie Parker-style jazz in real time. The first two, IMPROVISER and VIRTUAL BIRD, used brief melodic motifs as primitives (these weren't statistically culled, as in Cope's work, but were based on a systematic theoretical analysis of music: Narmour 1989, 1992). VIRTUAL BIRD played well enough, early in the new century, that the world-famous Courtney Pine was willing to perform alongside it. Another, an evolutionary version called EARLY BIRD, used only dyadic (two-note) primitives (P. W. Hodgson 2005). It explored 'Bird-space' even more adventurously than its predecessor, partly because of the transformations it generated and partly because its primitives were less highly structured. Even so, it wasn't 'transformational' in the sense of generating a recognizably different musical style. Hodgson felt that this would be possible, but only if he himself added a great deal more musical information to constrain the changes allowed (personal communication).

That's hardly surprising, for in all such evolutionary programs the fitness function was due to the human being, whether built into the program or provided interactively. Peter Cariani (1997) has criticized current GAs accordingly, arguing that they're incapable of the sort of "open-ended" creativity seen in biological evolution. We'll see in Chapter 15.vi.d, however, that wholly new sensory organs *have* been evolved in artificial systems, by a combination of GAs and environmental/hardware contingencies. Perhaps future research on psychological creativity will take a leaf out of this biological book?

Biological evolution is not only open-ended, but unpredictable. And most creative ideas are unpredictable, too. There are various reasons why that's so (Boden 1990*a*/2004, ch. 9; see also Chapter 17, below). But that doesn't mean that AI creativity researchers were wasting their time. One may be able to explain something—to show *how it is possible*—without also being able to predict it (7.iii.d). Much as a theoretical psychology could never predict every passing fancy or every suicidal thought within Jo Bloggs's mind, so it could never predict every creative idea. It might be able to say a great deal, however, about the general types of ideas that were likely or unlikely, and why. That, you'll remember, had been Cohen's aim when he embarked on AARON in the first place; and it was Simon's aim, too.

By the turn of the millennium, then, AI research on creativity had at last become respectable. Several books on the topic had appeared, written or edited by long-standing members of the community (Michie and Johnston 1984; Boden 1990*a*; Shrager and Langley 1990; Partridge and Rowe 1994; Hofstadter and FARG 1995). The interest was spreading way beyond a few enthusiasts. The *Stanford Humanities Review* published two book-length special numbers on AI and creativity, especially in relation to literature (Guzeldere and Franchi 1994; Franchi and Guzeldere 1995).

The respectability suddenly snowballed into a range of professional meetings. IJCAI-1997 commissioned a keynote presentation on the topic (Boden 1998*a*). And a flurry of creativity conferences and workshops were mounted by AI and A-Life researchers. These included a continuing series on 'Discovery Science', which complemented the 'Creativity and Cognition' meetings on computer art that had been organized in the UK for many years past by Edmonds (vi.c, below).

If the ineffable hadn't yet been fully explained, *that it was truly ineffable* was now highly doubtful.

13.v. Outreach to Everyman

You may remember Babbage's lady visitor, who asked: "Now, Mr. Babbage, there is only one thing that I want to know. If you put the question in wrong, will the answer come out right?" (Chapter 3.i.a). Harriet Martineau was outraged, seeing this as a waste of the great man's time.

In 1960 many might have shared her outrage, especially if they'd never read Vannevar Bush (10.i.h). After all, most people hadn't ever touched a computer, and it wasn't at all clear that they ever would. The easy assumption, at that time, was that anyone who used a computer would be a computer expert so the issue of "putting the question in wrong" simply wouldn't arise.

What a mistake that was! Even by then it was clear that programming languages were needed, both to prevent *the computer experts themselves* from putting the questions in wrong and to enable them to ask the right questions in the first place (10.v.a–c). And error-detecting compilers were soon devised to alert the computer buffs to some of their mistakes. (In the mid-1970s, IBM's PL/1 tried to help programmers to remove bugs: Des Watson, personal communication. But even today, 'silent' automatic error correction is used only for very simple/common cases; instead, diagnostic error messages help the human to correct what's been put in wrong.)

Above all, it was a mistake to assume that *ordinary people*—from doctors and lawyers to the man on the Clapham omnibus—wouldn't be interacting with computers. Indeed, a few privileged doctors were interacting fruitfully with MYCIN by about 1970. But the man on the Clapham omnibus would have to wait until the mid-1980s, when user-friendly home computers became available.

Today, computer scientists take it for granted that users will often be ignorant, careless, impatient . . . in a word, human. So anticipating their mistakes, and enabling human–computer interaction (HCI) to be so intuitively natural that mistakes are minimized, is a thriving research area (D. A. Norman and Draper 1986; Sharples 1996; Rheingold 2000). The softbots, or intelligent agents, mentioned in Section iii.d are an example: human users who can rely on a softbot's doing something not only save time and effort, but avoid the mistakes they might make if they tried to do it for themselves.

This section (and the next) describes how GOFAI helped to bring user-friendly computing about. As we'll see, GOFAI itself benefited from the exercise. In making Bush's "memex" a reality, AI scientists would devise ways of interacting with computers without which today's AI simply couldn't exist. Computer graphics and object-oriented programming languages, for instance, were initially developed to help fulfil Bush's prophetic vision.

a. Papert and the media lab

In a sense, "user-friendly home computers" had been available ever since the late 1960s. For Papert had provided a programming language, LOGO, that was intelligible to very young children (10.vi). He'd designed homely forms of implementation too: push-buttons instead of keyboards, for use by clumsy-fingered infants, and line-drawing "turtles" moving on the CDU screen or on the floor. Much of LOGO's success lay in the fact that it resulted in (real or virtual) drawings, rather than text. For visual imagery is more basic, more intuitive, than writing.

Someone might object that LOGO turtles weren't really computers, just programmable toys. But that would be too quick, and too dismissive. For Papert had always aimed to make computing in general more accessible to non-specialists. What's more, his vision and example played a large part in inspiring others to develop the home computers we know today.

Papert's role in encouraging user-friendly computing grew even more prominent in the 1980s than it had been before. Besides developing StarLogo, which made distributed computing possible even for children, he intensified his activities in public education. For instance, in 1985 he started an educational/experimental programme in Boston's James E. Hennigan School, offering the LOGO experience to children drawn from a deprived area of the city (Brand 1988, ch. 7).

Still more to the point, he moved sideways within MIT: having begun in the young AI Lab, in 1986 he joined Nicholas Negroponte's (1943–) newly founded Media Lab. In other words, he was a key player in the Media Lab's activities from the start. Indeed, he'd been a player even *before* the start. For the Media Lab's real beginnings were twenty years earlier: it was the successor of Negroponte's late 1960s Architecture Machine Group, or AMG (Brand 1988: 137–54). Papert had been closely involved with AMG. (So had his close collaborator Minsky, who is now the Toshiba Professor of Media Arts and Sciences, as well as being an MIT Professor of Electrical Engineering and Computer Science.)

The Media Lab would turn out to be crucial in developing various futuristic technologies, especially VR. Whereas the AI Lab itself had grown more technological and less psychological (and so less to Papert's taste), the Media Lab took the two dimensions of AI equally seriously. That's because their prime focus was on human–computer *interaction*. (A secondary focus was on what's now called A-Life—see Chapter 15, and Brand 1988, ch. 6. Selfridge, currently working on adaptive agents, is now yet another of the Media Lab's pioneer stars: Selfridge and Feurzeig 2002.)

The AMG had pioneered 'exploratory' computer graphics of the type foreseen by Douglas Engelbart (10.i.h). They made sure that even architectural designers—and even architects' clients—with no prime interest in computers would be able to use their software. Besides experimenting with the computer-aided design (CAD) of individual buildings, they also explored Negroponte's (1970, 1975) interests in cityscapes. In general, they aimed to achieve Joseph Licklider's (1960) "symbiosis" between human and computerized visual designers, whether in architecture or beyond.

For example, AMG produced the first detailed VR simulation of an actual town (Aspen, Colorado) in 1978–9. Its users could explore the simulated streets as they wished, see the buildings from varied perspectives, and even enter some of them—and all this in any one of the four seasons.

The "Aspen Movie-Map" had been funded by DARPA, because of the Pentagon's interest in the use by Israeli commandos of a (physical) mock-up of Entebbe airport for practising the freeing of the hostages held in 1973 (Brand 1988: 141). Not quite everyone was impressed: the Movie-Map was one of the visionary research projects ridiculed by Senator William Proxmire (see 6.iv.f). But as so often happened, the Senator's scorned targets eventually had the last laugh—and everyone playing video games today should be laughing with them. (Although the US Army's current VR training environment and children's game are no laughing matter: see <http://www.ict.usc.edu> and <http://www.americasarmy.com>.)

Also funded by DARPA, and also a seed of today's technology for VR 'telepresence', was the Talking Heads project (Brand 1988: 91–3). This was intended to enable the US's five top leaders to run the country together while sheltering from a nuclear attack in five different locations. Among other things, it initiated attempts to model realistic lip–sound synchronization for speech (9.xi.g).

The Media Lab, then, was highly interdisciplinary. Architects mingled with biologists, psychologists, linguists, acousticians, musicians, and educationists—and everyone mingled with AI scientists. Indeed, as befits genuine interdisciplinarity, much of the mingling went on *inside* individuals' heads.

One of the key interdisciplinary heads in this enterprise was Papert. On joining the Media Lab, he set up the Epistemology and Learning Research Group (Harel and Papert 1991). This was no ivory-tower containment. Besides many educational consultancies, he founded a successful commercial venture (LOGO Systems Inc.) in 1981, and the non-profit Logo Foundation ten years later (<http://el.media.mit.edu/logo-foundation>). These provided a wide range of software, books, and advice on educational methods inspired by Piagetian ideas in general and LOGO in particular.

Papert is well known today for various reasons. His fame within the AI community—and with most cognitive scientists—rests primarily in his cooperation with Minsky on *Perceptrons* and *The Society of Mind* (Chapters 12.iii.d and 7.i.e), and secondarily in his trenchant rebuttal of Dreyfus (11.ii.b). In addition, these people remember his pioneering work on LOGO.

The general public, and educational psychologists, know of him through LOGO and also through his wider interests in pedagogy. He's been a highly visible gadfly on the back of the educational establishment for nearly forty years. Like the counter-cultural Ivan Illich (1971), but with a much stronger theoretical base, he was a fierce critic of orthodox practices in the 1970s. Many years later, he's still pursuing radical reform of the school system (Papert 1993).

There's a third reason why Papert *should* be remembered. It's unknown to most people, even among his professional peers. But it's the one which is especially important here. Namely: his AI work has influenced every computerized desktop, and almost every multimedia application, of the twenty-first century.

For it was Papert's Piagetian approach, and his child-friendly LOGO language and display, which inspired Kay to design computer interfaces for use by Everyman (see subsection d, below). Without those, today's world of widespread personal computing would be impossible. And he encouraged Negroponte to try to simulate architectural spaces (in AMG), and to set up the Media Lab to explore the possibilities of realistic simulation in general (including A-Life). That too was an exercise in the design of novel, and relatively intuitive, interfaces. It was guided, according to Negroponte's initial proposal, by studies in "epistemology [and] experimental psychology" (Brand 1988: 11)—code words meaning Papert.

Minsky and Jerome Wiesner were also hugely important influences. Indeed, the well-connected Wiesner—just retired, in 1980, as President of MIT and previously science adviser to the Kennedy and Johnson administrations—was able to be even more supportive of the Media Lab than he had been of the infant AI Lab, a quarter-century before (10.ii.a). He and Negroponte "toured and lectured and demoed and bargained for seven years, and raised the requisite millions" (Brand 1988: 11; cf. 131–7).

In short, Papert helped to develop virtual *machines* into virtual *reality*. His help was largely indirect, but crucial nevertheless. The user-friendly LOGO was eventually surpassed by SMALLTALK, the push-button boxes by menus and icons. And the on-screen LOGO turtles made way for on-screen Aspen . . . and for the host of VR applications we know today.

b. The H in HCI

HCI is a special case of what Donald Norman (1986*a*) called "cognitive engineering": the area of "applied cognitive science" which deals with how we use tools—from bath taps to computers. Since *Home sapiens* is above all a tool-using species, cognitive engineering has ramifications in many areas. Indeed, if—with Bruner (and Engelbart: 10.i.h)—one regards even language and drawing as cognitive *technologies*, then cognitive engineering is potentially relevant to virtually every aspect of human life.

As Norman pointed out, any adequate study of tool use is going to need not only an analysis of task complexity, but also "a theory of action". It's no accident, then, that he's helped to develop a general psychological theory of action. Besides influencing HCI (and tool design in general: D. A. Norman 1988), this is now influential in clinical neuroscience (Chapters 12.ix.b and 14.x.b). It's also no accident that two early papers on the general principles of HCI were largely due to him (D. A. Norman 1986*a*; W. J. Hutchins *et al.* 1986).

HCI work falls broadly into two groups. On the one hand, it involves writing user-friendly programs *to be run on a computer*. These may concern education and professional training, for instance—a huge area today, with several dedicated conferences/journals. On the other hand, it involves designing user-friendly interfaces *to be part of the computer itself*. As this section will indicate, these concerns may overlap. A successful interactive VR program, for example, needs to be easily usable by people who aren't AI experts.

One aspect of a successful interactive program is that it makes the computer, and the program running it, invisible. That is, it gives users

> the qualitative feeling that we are *directly* engaged with control of the objects [of interest to us]—not with the program, not with the computer, but with the semantic objects of our goals and intentions. (E. L. Hutchins *et al.* 1986: 95; italics added)

The writer using a word processor, for example, has the illusion that they're dealing directly with words, lines, or paragraphs—none of which exist as such inside the physical machine. Rather, they are structures in the virtual machine. Likewise, someone playing a computer game feels that they're zapping the goblin itself, or negotiating a real ski jump. It should be no surprise, then, that early HCI involved the development of 'direct' image manipulation on the one hand, and of object-oriented programming on the other.

The invisibility of the tool, to the tool-user, is a very old idea. René Descartes pointed out that the blind man's stick is, in effect, an extension of his body. More recently, phenomenologists such as Merleau-Ponty have written at length on this theme; and David Sudnow (1978/2001) has described the simultaneous growth of power and invisibility in learning to play the piano. So HCI is a special case of the study of "in-dwelling" in one's tools.

HCI has both technological and psychological aims, for it seeks to expand *the mind* as well as the computer. (This, of course, is just what Engelbart predicted nearly half a century ago.) It's also an aspect of cognitive science. To write easily usable software, one has to know something about how the "H" in HCI functions—and how that mental functioning enables, or prevents, the I between the H and the C. Kay, perhaps the most famous of all interface designers, put it like this:

> [The] actual dawn of user interface design first happened when computer designers finally noticed, not just that end users had functioning minds, but that *a better understanding of how those minds worked* would completely shift the paradigm of interaction. (A. C. Kay 1990: 123; italics added)

Kay dated this realization as happening "to many computerists in the late sixties". And, as noted above, it was the guiding principle of MIT's Media Lab. However, both Bush and Gordon Pask had achieved it much earlier. Bush, indeed, was the first person to realize the need for HCI (Bush 1945, sects. 6–8). His memex was intended to achieve a man–machine fit by exploiting associative processing—and visual imagery—in both (10.i.h).

The memex was purely imaginary. Twenty years later, Pask looked more closely at *just how* people make what Bush had called associations. And he used what he found to pioneer human-friendly AI teaching machines. Pask's mid-1960s machines were designed for use by learners with three fundamentally different cognitive styles (Chapter 4.v.e). If he didn't allow for the questions being put in "wrong", he did allow for them being put in three contrasting ways. However, his ideas didn't catch on. In part, this was because they'd need to be reapplied in each subject domain. For Pask's HCI concern wasn't how to improve the computer itself, but how to write helpful educational programs for it.

Papert, too, was developing teaching machines in the mid-1960s. He wasn't allowing for human users' individual differences, as Pask was. But he was allowing for differences in age: his machines were designed to be accessible even to very young children, as we've seen.

Partly because of the child-friendly interface, Papert's ideas did catch on. During the 1970s, LOGO systems spread like wildfire (or like successful memes: Chapter 8.v.c). By the end of the decade, others were applying his Piagetian ideas about self-critical learning (as opposed to the LOGO language) in AI teaching machines. So they were used, for instance, to improve children's arithmetic, or university students' programming skills (Brown and Burton 1978; O'Shea and Young 1978; Brown and VanLehn 1980; Burton 1982; Sleeman and Brown 1982; O'Shea and Self 1984).

Babbage's lady visitor certainly wouldn't have outraged Papert, for his key point was that "putting the question in wrong" can be highly instructive. In other words, *bug* is a "powerful idea", and bug correction helps one think at a meta-level about one's own thinking (see 10.vi). But if that aspect of his psychological theory was widely taken up by others, his turtles weren't. They were restricted to simple drawing and/or locomotion.

What was required to go further was an interface that could be used for many different purposes. The 'universal' digital computer needed a 'universal' interface.

c. Good ideas in hibernation

The most important interface designers, besides Engelbart, were Sutherland and Kay. (For others, see: Laurel 1990; Rheingold 2000.) They wouldn't have been outraged by Babbage's visitor either. But besides hoping to minimize the non-specialist user's mistakes, they aimed to enable users—including AI scientists—to do things 'naturally' on computers which couldn't be done at all before.

To do that, they designed fundamentally new kinds of interface, for inclusion within the computer itself (i.e. the second type of HCI distinguished above). But their work took many years to be put into effect, because their ideas when first mooted were far ahead of their time.

Sutherland (1938–) was a wunderkind. While at high school in the early 1950s, he not only programmed simple computer calculators but also—with his elder brother Bert, and under the direction of Edmund Berkeley (1909–88)—built an electro-mechanical "squirrel" called Squee (D. G. Bobrow, personal communication).

Berkeley was an apt teacher for two machine-minded youngsters. He'd already designed a very early computer for personal use, called "Simon" (Berkeley 1949, 1956). It had 129 relays and a five-hole paper-tape feed. Given numbers of up to 255 binary digits, with coded instructions for up to nine different arithmetical operations, it displayed its answers in lights. The prototype was completed in 1950, and by the end of the decade he'd sold over 400 plans or kits for the machine (J. M. Norman 2004: 73).

In addition, he'd written the first popular book on electronic computers: *Giant Brains or Machines that Think* (Berkeley 1949). After describing various existing (and planned) machines, such as the Mark 1 and the ENIAC, he devoted the final chapters to speculations on how computers would affect society. In a sense, that was what it was all about. Indeed, the book's original title, cited in the contract he signed in 1946, had been *Machines to Help Us Think* (J. M. Norman 2004: 73). In other words, he was closer to Bush, Licklider, and Engelbart than to Minsky, McCarthy, and Newell-and-Simon. Possibly, the young Sutherland may have absorbed some of Berkeley's interest in the practical uses of computers.

For the time being, however, he and his brother were concentrating on their robot squirrel. Squee, which made the front cover of Berkeley's *Radio Electronics* magazine and was also featured in *Life* (19 March 1956), looked like a slightly more complex Grey Walter tortoise. It had two phototubes ("eyes") at the top of the steering post, two switches for sensing contact, and a scoop ("hands") at the front; guided by light, it searched for a "nut" (a torchlit tennis ball), which it picked up and took back to its "nest" (Berkeley 1956). Having exhibited this delight across the USA (New York, Pittsburgh, and Minneapolis) by 1956, Sutherland published a description soon afterwards (Sutherland *et al*. 1958).

Like the tortoises (4.viii.a–b), Squee was meant to draw a general moral—one which applied to human intelligence too. And many readers were persuaded. When he was still only 20 (in March 1959), Sutherland won a prize from the American Institute of Electrical Engineers for a paper on 'Parallels—Men and Machines'.

In later life, he deepened this early interest in mechanical creatures, writing about walking robots for the *Scientific American* (Raibert and Sutherland 1983) and patenting a robot arm in 1990. And his IT skills were recognized when, still only 26 years old (in 1964), he followed Licklider as head of ARPA's office for information processing technology.

But his fame arose from two achievements of his early to mid-twenties that had nothing to do with squirrels, artificial or otherwise, and which were decades before their time in terms of technology. For that reason, they had to go into hibernation until it was technically possible to put them into effect. These were his Ph.D. thesis on Sketchpad (1963), which initiated interactive computer graphics; and his 1965 vision of virtual reality, or VR.

Given that Sketchpad was described as early as 1962, why didn't I include Sutherland as a "harbinger" in Chapter 10.i? Well, that research—like Kay's, which was based on it (from 1966 on)—couldn't come to fruition until the late 1980s. Indeed, Kay said in 1989 that user-interface design was *still* hardly accepted as "a real subject" (A. C. Kay 1989: 123). Similarly, Sutherland's mid-1960s ideas on VR couldn't be fulfilled until the 1990s. Because both men had to wait twenty years or more for computer technology to catch up with them, their legacy to AI has a very modern, post-Kraken, feel.

Their CVs feel pretty modern too. Kay's includes appointments at Xerox, Apple, Disney, and Hewlett-Packard. As for Sutherland, his first job was as ARPA's Director of Information Processing in 1962–4 (supporting Project MAC, for instance). He's now Vice-President at Sun Microsystems. And, having co-founded a company doing VR simulations for aerospace and defence applications, he's now a billionaire.

Beginning life as a Ph.D. thesis, Sketchpad eventually became "one of the most influential computer programs ever written by an individual" (according to the citation for Sutherland's 1988 Turing Award). The thesis itself was published only as an MIT Technical Report, accessible to relatively few people until it was made available on the Web (Blackwell and Rodden 2003). But it was summarized in a conference publication (I. E. Sutherland 1963).

As it turned out, that was enough. For the details were far less important than the overall picture. Considered as a program, Sketchpad was highly limited. (Hardly surprising, given its date.) It couldn't even be shared, for it could be run only on the TX-2 at MIT's Lincoln Laboratory. But considered as a vision, it was dynamite.

For one thing, it was the first program which enabled the user to change the content of a computer's memory interactively, without reprogramming. (The SAGE operators in the 1950s had used lightpens to alter graphic displays by touching the screen; but they were changing *which stored memories were shown*, not *the memories that were stored*; see 11.i.) For another, it provided a suite of facilities for drawing and transforming pictures systematically. It wasn't the first graphics program: Spacewar, for example, had preceded it (10.i.i). But it was the first where the user could manipulate images *as such*.

The human could produce multiple instances of various image schemas ("master drawings"), and alter them at will in several ways. For example, the user could change the size of an existing drawing. Or if one had drawn a line on the screen that wasn't quite vertical, one could tell Sketchpad to make it vertical, maintaining the continuity of the whole object as it did so. Similarly, a carelessly drawn corner could be automatically transformed into a 'proper' corner. Physics could play a role too. So a truss in an engineering drawing, described as having a particular mass, could be made to bend as if it were governed by Newton's laws—that is, 'realistically'. In addition, Sketchpad allowed individual instances to be moved around the screen (with a lightpen) as whole objects, rather than remapping a collection of individual pixels.

Changing the master drawing would immediately change all its daughter images in the relevant way: so adding a third ear to a rabbit schema would magically add an extra ear to all the "copied" rabbits. What's more, images could be superimposed: "You could make a picture of a rabbit and a picture of a rocket, and then put little rabbits all over a large rocket. Or, little rockets all over a large rabbit" (Nelson 1977).

The details would disappear from view if the picture were made small enough, but would reappear when it was enlarged again. And the superpositions were recursive: you could have rabbits on rockets, on rabbits, on rockets. . . . Describing Sketchpad in a chapter with the title 'The Most Important Computer Program Ever Written', Ted Nelson (1977) admitted that "the rabbits and rockets are a frivolous example". But he pointed out many "obvious" applications: "blueprints, or electronic diagrams, or all the other areas where large and precise drafting is needed. . . . [A] new way of working and seeing was possible."

As for the still-untapped potential, Sutherland suggested (for instance) that facial characteristics in a drawing could in future be altered by the user. What's more,

> if the almost identical but slightly different frames that are required for making a motion picture cartoon could be produced semi-automatically, the entire Sketchpad system could justify itself economically in another way. (Blackwell and Rodden 2003: 4–5)

Yes indeed!

d. The human face of the interface

Sutherland had intended his program to be used by artists and engineering draughtsmen, as a tool for CAD. In other words, 'interface' HCI had begun. But it would be Kay who saw how the ideas in Sketchpad could be exploited in designing interfaces for an even wider range of users.

Kay first encountered Sketchpad in 1966, as a very new graduate student at the University of Utah. This was one of the first few locations to be put on the ARPAnet, and it was to be Sutherland's home for many years. As Kay remembered it:

> At Utah before you got a desk you got a stack of manuscripts and you had to read the stack. It described Sketchpad. Basically, you had to understand that before you were a real person at Utah.
>
> They also had a tradition there that the latest graduate student got the latest dirty task to do. Mine happened to be on my desk—a pile of tapes and a note which said "This is the Algol for the UNIVAC 108; if it doesn't work, make it work." It turned out to be the first Simula. (interview in Shasha and Lazere 1995: 42)

SIMULA, which had been developed in Norway just one year earlier, is now seen as a primitive object-oriented programming language. The first person to see it that way was Kay—whose "dirty task" would change not only his life, but (eventually) millions of other lives too. Like Sketchpad, SIMULA distinguished general classes from specific instances, which shared core properties with the master. Kay, who'd studied biology (and maths) as an undergraduate, felt that he was encountering something vaguely familiar in both cases: "The big flash was to see this as biological cells" (interview in Shasha and Lazere 1995: 43).

If the images/objects in Sketchpad and SIMULA were truly analogous to living cells, they'd have autonomy (as whole-object individuals), property inheritance, communication (passing and receiving messages), and the capacity to congregate in many-levelled hierarchies. Kay, then, sensed the possibility of a powerful object-oriented programming language (his term). Six years later, he'd designed one: SMALLTALK (Chapter 10.v.d). (And by 1991, an article about object-oriented programming, optimistically called 'Software Made Simple', was emblazoned on the cover of *Business Week* magazine—Resnick 1994: 42.)

But that was for the future. Meanwhile, on leaving Utah in the late 1960s, Kay—enthused by Licklider's concern for man–machine symbiosis (a near-synonym for HCI)—helped to design the ARPAnet. In 1970 he moved to Stanford's AI Lab, and in 1972 to Xerox PARC, where he headed the interdisciplinary Learning Research Group.

During the late 1960s, he worked on the FLEX machine, intended for use by doctors, lawyers, and the like (Shasha and Lazere 1995: 43–4). This experience—at a time when most people had hardly heard of computers, never mind seen one—led Kay to speculate about future interfaces which Everyman would find easy to use.

To address the H in HCI, Kay drew on Marshall McLuhan's *Understanding Media* (1964) and also on computationally informed theoretical psychology. As for the first, he recalled later:

> Though much of what McLuhan wrote was obscure and arguable, the sum total to me was a shock that reverberates even now. The computer is a medium! I had always thought of it as a tool, perhaps a vehicle—a much weaker conception. What McLuhan was saying [when he talked about the printing press and television having changed the thought patterns of those who learned to read, or view TV] is that if the personal computer is a truly new medium then *the very use of it would actually change the thought patterns* of an entire civilization. (A. C. Kay 1989: 124; italics added)

(Bush had said much the same about the memex: remember that medieval historian, researching the Crusades? 10.i.h.) Kay was struck, too, by McLuhan's idea that "anyone who wishes to receive a message embedded in a medium *must first have internalized the medium* so it can be 'subtracted' out to leave the message behind" (p. 124; italics added).

Clearly, the closer the medium was to the already existing mind, the more chance that it would be "internalized" effectively. Hence Kay's interest in the psychology of thought, creativity, and learning. This interest was deepened by his conversations with Papert from the late 1960s on, including his visit to "one of the earliest LOGO tests within a school" (A. C. Kay 1989: 125). Indeed, he was "greatly encouraged" by Papert's work (A. C. Kay and Goldberg 1977: 171), and "*possessed* by the analogy between print literacy and LOGO" (A. C. Kay 1989: 125; italics added).

On reading "many" books in theoretical psychology, he soon turned (at Papert's suggestion) to Jean Piaget. Piaget had pointed out that the child's ways of thinking, as compared with the adult's, aren't just 'less of the same' but *different*. Clearly, this had implications for how one should best design interfaces for use by children. But Piaget's writing was too like McLuhan's—intriguing, but obscure—to be really useful. What was useful was Bruner's new interpretation of Piaget's results, especially as described in his book *Towards a Theory of Instruction* (Bruner 1966*b*).

In particular, Kay was inspired by Bruner's notion of cognitive technologies (Chapter 6.ii.c). These were different systems of mental representation: enactive, iconic, and verbal–symbolic. Kay saw them as "multiple separate mentalities with very different characteristics" (1989: 126), and aimed to exploit all three. In his words:

> Now, if we agree with the evidence that the human cognitive facilities are made up of a *doing* mentality, an *image* mentality, and a *symbolic* mentality, then *any user interface we construct should at least cater to the mechanisms that seem to be there*. But how? One approach is to realize that no single mentality offers a complete answer to the entire range of thinking and problem solving. *User interface designs should integrate them* at least as well as Bruner did in his spiral curriculum ideas. (1989: 127; last two italics added)

Accordingly, he invented—initially, for FLEX—HCI facilities including a computer mouse (enactive); screen icons (visual); and overlapping windows of text (verbal–symbolic).

As is usual (see 1.iii.g), his highly original ideas didn't come out of thin air. Early versions of Kay's interface items had been available since the 1960s (10.i.h). But Kay's were more powerful, and easier to use—and, as we've seen, more directly connected with current psychological theory. They were also better grounded empirically:

> [It] took our group [at Xerox PARC] about five years and experiments with hundreds of users to come up with the first practical design that was in accord with Bruner's model and really worked. (A. C. Kay 1989: 128–9)

For example, his windows *overlapped* because there was psychological evidence—from a best-selling book on tennis coaching, believe it or not (Gallwey 1974, ch. 7)—that people think/learn better if they're concentrating on only one thing at a time. (Later, and probably thanks to Kay, the tennis author—Tim Gallwey—would become a consultant at the Media Lab—Brand 1988: 100.) So having one window almost completely obscuring another was a Good Thing, provided that the other/s could be made the centre of attention at the click of a mouse. (Gallwey's book had included advice on how to learn to focus on one aspect of performance at a time; where Kay generalized this to computer interfaces, Gallwey later published best-sellers on other sports, and on "work" . . . etc.)

These technical advances were made possible by means of object-oriented programming. Today, this is hugely important across GOFAI as a whole. But it was developed by Kay to build flexible interfaces.

The SMALLTALK programming language (completed in 1972) was also driven by psychological criteria. It matched people's natural tendency to think in terms of concepts, and to 'place' a concept in a new context without worrying about just how it will be able to fit in. This made it easier to design computer interfaces where the user simply has to press a button or click on an icon, instead of knowing—and telling the machine—just what computations have to be performed. It also made it easier to include graphics in the interface, which—following Bruner and Papert—Kay saw as especially helpful to children.

He didn't stop there. He predicted personal computers much more convenient than the 350 lb FLEX machine: "This note speculates about the emergence of personal, *portable* information manipulators . . . " (A. C. Kay 1972; italics added). He went on to design the Dynabook, a notebook-sized gadget "as small and portable as possible" combining pictures, animation, music, speech, and text (words and musical notation). The Dynabook was intended as "a dynamic medium for creative thought" of many different kinds, in which—for instance—maths could become "a living language in which children could cause exciting things to happen" (A. C. Kay and Goldberg 1977: 170, 177; see also Kay 1977, 1989; Ryan 1991).

Although this multimedia system was never fully built, its core ideas were implemented in the Xerox Alto computer by 1974 and it was the ancestor of today's laptops and palmtops. And as if all that weren't enough, he also instigated desktop publishing (thanks to multi-font word-processing), and helped develop the Ethernet, laser printing, and client–server architectures.

I say "he", but of course others at Xerox PARC were involved too. One of these was Kay's assistant Adele Goldberg. Another was David Canfield Smith, who coined the term "icons", and whose 1975 Stanford thesis—based on SMALLTALK—eventually fed into the Xerox Star machine (D. C. Smith 1977). This programming environment enabled the user to select, and hop about among, different visual presentations of the interface by choosing from a menu. In Smith's mind, his Pygmalion program was not only assisting creative thought, but—in a sense—modelling it too. The same had been true, of course, of Bush's "associative" memex.

Kay's success in HCI eventually helped foster the success of Apple Computers—and, indirectly, of Microsoft too. Xerox PARC had refused to manufacture machines or to market software based on his work, rejecting his visionary prediction of huge technological applications. They wanted to develop the paperless office, not home computers for Everyman. As for the multitude of visitors to PARC, most realized that Kay's team were making "spectacular advances", but "very few understood either in depth or in scope the applications of what they were seeing" (L. Tesler, interviewed in Brand 1988: 173). Steve Jobs, by contrast, saw the point:

> When I went to PARC [in November 1979], I thought it would be an interesting afternoon, but I had no concept of what I'd see. Larry Tesler was my guide for an hour, to show me around. My mind was just totally blown. The minute I saw an Alto (PARC's personal computer) and the mouse and the multiple fonts, I *knew* that we had to have it. I came back to Apple a raving maniac about this stuff and I grabbed a bunch of people . . . and dragged them over there. (Steve Jobs, interviewed in Brand 1988: 172–3)

After this "mind-blowing" visit to Kay's lab, Jobs tried to buy the SMALLTALK software, but Xerox refused to sell it—despite being a minor shareholder in Apple (Shasha and Lazere 1995: 49). Apple used ideas inspired by Kay in developing the AppleMac (and appointed Kay as an Apple Fellow in 1984). The rest, as they say, is history. (A chequered history, to be sure: because of IBM PC marketing patterns, Microsoft's "Windows" software is much more widespread than the AppleMac version, on which it's based.)

Over the years, Kay has become increasingly interested in children's education—partly as a result of a 1968 visit to Papert's lab (Shasha and Lazere 1995: 45, 47 ff.).

Following Papert's example, he regularly tested the accessibility of his HCI ideas by trying them out on children, both at a Palo Alto junior school and—via Papert—at Boston's Hennigan School. A second reason for working with children was that, being used to having coloured paints and musical instruments, they "really needed" computing facilities that were pushing the state of the art in the 1970s (A. C. Kay and Goldberg 1977: 171).

Having worked for Apple in the mid-1980s, and for Disney Imagineering in the 1990s, Kay is now a Hewlett-Packard Fellow. He was—and still is—an important presence/visitor for the Media Lab, where he's advised on projects ranging from Hollywood animation to A-Life (Brand 1988, ch. 6). And he's involved in various educational ventures, such as the non-profit Viewpoints Research Institute (founded in 2001). But despite his journey through the highest hills of high tech, he retains his interest in psychology. Indeed, he still calls Bruner on the phone about once a fortnight (Shore 2004: 87).

Bruner's ideas on cognitive technology are enthusing a new generation of HCI enthusiasts, too. For instance, Mike Scaife (who died suddenly in 2003) and Yvonne Rogers at Sussex have instituted a research programme called Interact. Explicitly inspired by Bruner (Y. A. Rogers *et al.* 2002*b*), this is centred on children's (often collaborative) use of external representations of various kinds: words, diagrams, pictures, toys . . . and so on.

These include 'tangibles', which are physical objects (bricks, balls, puppets, clothing . . .) electronically augmented so as to trigger events in other electronic artefacts. For instance, the children's play activities with a tangible interface can cause changes in a screen interface. The VDU may show a virtual animal, which engages the children's attention: as they do this or that with their electronically enhanced toys, the screen animal shows this or that aspect of its form or behaviour (Price *et al.* 2003). And those changes are recorded by the computer, to be used later by the children for discussion and self-reflection of many kinds.

The Interact programme is essentially interdisciplinary, for it has two closely related aims. One is to devise new technologies—in this case, for use by young children. The team's new designs go way beyond Papert's turtles, for they involve recent advances such as "pervasive" computing (i.e. the use of tangibles) and multimedia VR. (For examples, see Scaife and Rogers 2001; Rogers and Muller forthcoming; Marshall *et al.* 2004.) The second aim is to augment, as well as to exploit, our understanding of how children play, learn, collaborate, and represent (e.g. Scaife and Rogers 1996; Scaife 2005; Rogers *et al.* 2002*a*).

Of the many advances in these areas of psychology since Bruner's seminal 1960s work, some were initiated in the 1970s by Scaife himself (see 6.ii.c). Moreover, Rogers—whose expertise is strongly technological—was initially trained as a psychologist, as were several others in their group. In short, Interact is just one example illustrating the fact that in HCI research, psychology and GOFAI (and sometimes connectionism too) walk hand in hand.

Increasingly, they walk unnoticed—indeed, invisibly. In a futuristic article in the *Scientific American*, Xerox PARC's chief scientist Marc Weiser (1952–99) predicted the advent of what he called "ubiquitous" computing, or ubicom (Weiser 1991). This, he said, would be the "third wave in computing", following on time-shared mainframes and the personal computers foreseen long ago by Bush. What even Bush hadn't foreseen was the use of miniaturization and telecommunications (e.g. wireless technology, offering local links and/or entry onto the Internet) to embed tiny adaptive computers into almost every niche in our environment: offices, houses, cookers, cars, toys . . . even jewellery and clothes. The human–computer interface, traditionally understood, has largely disappeared: as Weiser (1994) put it, "the world is not a desktop".

There's now an international conference series on ubiquitous computing (Ubicomp), dedicated to putting his vision into effect. IBM preferred their own terminology: pervasive computing, or "percom". But whether driven by Xerox or by IBM, or by the many start-up companies at the turn of the millennium, the third wave of computing is gaining strength. The closer it gets to human lives, the more important the psychological issues become. And as we've seen, much of it was seeded by psychology in the first place.

13.vi. Virtual Reality

Virtual reality is the epitome of current high tech in IT. But it's not of interest only to 'techies'. It raises some deep philosophical issues (see 16.vii.d and viii.c), many intriguing psychological questions (e.g. 14.viii.b and 15.xi.a), and various social-psychological worries too (subsections d–e, below). Nor is it really new. The idea, and even the pioneering technology, dates back to the late 1950s.

One might argue that the general idea dates back even further than that, if one counts E. M. Forster's dark sci-fi story 'The Machine Stops' (1909). The characters are a mother, Vashti, and her son Kuno. Vashti, like most of the civilized human race, lives underground in a wholly machine-tended capsule. She communicates with her son (and "several thousand" others: "in certain directions human intercourse had advanced enormously") only by a videophone, never face to face. The videophone—"rightly", she thinks—doesn't "transmit nuances of expression": it conveys instead "a general idea of people . . . good enough for all practical purposes". Kuno prefers the despised real world, and eventually stops the machine—to his mother's desperation, who prays for it to restart some day.

Kuno's (Forster's) horror at the human isolation and machine dependence suffered/enjoyed by Vashti parallels some of today's worries about computer companions and avatars (see below). But even Forster's imagination didn't stretch to wholly machine-generated images, still less to the ambition and detail of VR as we know it a century later. (Nevertheless, a quotation from his story opens a recent paper on the philosophical implications of VR: H. L. Dreyfus 2000.)

The term "virtual reality" was coined in 1989 by Jaron Lanier, to denote "three-dimensional realities implemented with stereo viewing goggles and reality gloves" (M. W. Krueger 1991, p. xiii). Lanier, a computer scientist and musician, had already founded the first commercial VR company (in the early 1980s). So he wasn't announcing a new vision. On the contrary, his new label (like the term "artificial life": 15.x.a) was intended to pull together pre-existing work of diverse kinds.

VR has since been redefined in several ways (Steuer 1992). These vary on both technological and philosophical dimensions. We don't need to consider those variations here, but it's worth noting that "VR" means different things to different writers.

It also means different things to different writers in the sense that it's ethically approved by some and roundly condemned by others. By the mid-1980s, various commentators were raising worries about VR.

Some were sociopolitical. Donna Haraway (1944–) was especially influential, here (Haraway 1986/1991). (For recent examples, concerning multi-user VR and the BodyNet, see Rheingold 2002.) I'll ignore those, however. There will be plenty of psychological worries (and some philosophical implications) to discuss. That's only to be expected, given that VR is such an intimate form of cognitive engineering.

a. Intimations of VR

Among the pre-existing work gathered under Lanier's label was Sutherland's. Indeed, Sutherland's second claim to fame is as the prophet of VR.

Besides being its prophet, he was an early pioneer. His revolutionary VR headset, announced in the 1960s and completed by 1970, superimposed a transparent TV image over the real-world perception (I. E. Sutherland 1968). (Previous efforts had *substituted* a TV display for the real image: Comeau and Bryan 1961.) It provided a full-colour, three-dimensional, visual display that filled the user's entire field of view. (Moreover, Sketchpad-derived techniques enabled the wearer to manipulate the virtual images with various input devices.) The experience of 'total visual immersion' was new—and, even though it lacked stereovision, remarkably compelling.

Filmgoers, of course, had long got drawn into Bambi's hand-drawn virtual world. But while watching him they could see the walls, and the seats and people and popcorn too. The conventional movie screen took up a mere 5 per cent of the spectator's field of vision. Even Cinerama and Cinemascope, still novelties at the time, didn't get anywhere near 100 per cent visual immersion (Heilig 1955: 283–4).

One of the first cinematographers to be enthused by that "100 per cent" idea was Hollywood's Morton Heilig (1955). His description of 'The Cinema of the Future' saw the viewers near-inhabiting the film, being wholly immersed in a virtual world even more all-encompassing than Cinerama. Besides all-round visual experience and stereo sound, it would offer taste, touch, and smell—each sense to "dominate the scene in roughly the same proportion we found them to have in man: sight, 70%; sound, 20%; smell, 5%; touch, 4%; and taste, 1%" (Heilig 1955: 292). (Unappreciated in Hollywood, Heilig moved to Mexico, where he invented two early virtual reality devices that later inspired more powerful versions from others—Packer and Jordan 2001: 220.)

However it was Sutherland's prophecies, not his technical achievements, which caused the stir in the 1960s. For what he had in mind was a very high degree of reality attribution. Visual immersion was just part of it.

Even before announcing the VR goggles, he'd already urged his NewFAI colleagues to produce computer-generated pictures (and sounds, and forces) that would be experienced by the viewer as 'real'—and which might represent unreal "Wonderland" worlds too. So in his speech to a large IFIPS meeting in 1965, he'd said:

> We live in a physical world whose properties we have come to know well through long familiarity . . . A display connected to a digital computer gives us a chance to gain familiarity with concepts not realizable in the physical world [such as non-realistic geometries, or negative mass]. *It is a looking-glass into a mathematical wonderland.* (I. E. Sutherland 1965: 506; italics added)

To be convincingly realistic, he continued, the display "should serve as many senses as possible". Excellent sound generation was already achievable, although speech generation wasn't (nor would it be, until much later: see 9.xi.g). And computer-generated "kinesthetic displays" were well within reach, by extending the controls of flight simulators—which gave trainee pilots of the 1960s "the feel of a real airplane".

Besides providing joysticks with force-feedback capability (already available), future VR computers—he said—would "easily sense the positions of almost any of our body muscles". Because they'd be able to monitor not only hands and arms but eye movements too, we might use "a language of glances" to control a computer: "For instance, imagine a triangle [in the VR display] so built that whichever corner of it you look at becomes rounded."

The futuristic speech ended with a flourish:

> *The ultimate display* would, of course, be a room within which the computer could control the existence of matter. A chair displayed in such a room would be good enough to sit in. Handcuffs displayed in such a room would be confining, and a bullet displayed in such a room would be fatal. *With appropriate programming such a display could literally be the Wonderland into which Alice walked.* (p. 508; italics added)

One of the people in the audience for Sutherland's lecture was Frederick Brooks (1931–), who'd headed the team designing IBM's System/360 computers in the late 1950s. For him, it was an epiphany:

> [Sutherland] said, "Think of the screen as a window into a virtual world. The task of computer graphics research is to make the picture in the window look real, sound real, interact real, feel real." And I said, "That's where it's at." I've been working on that challenge ever since. (interview in Shasha and Lazere 1995: 170)

Brooks wasn't the only one. And once the technology had caught up with Sutherland's vision, VR found many industrial applications.

Vibrating seats, fan-generated winds, and chemical 'smell banks' arrived relatively early. By the late 1980s, thanks largely to work done at NASA-Ames and the Media Lab, and funded by Hollywood as well as by government grants, VR had added stereovision, headphones, microphones, gesture interaction, and fibre-optic data gloves that could measure the ever-changing bend of each finger joint and the distance between the fingers (Fisher 1990; Brand 1988). (An early pressure-sensitive glove, the "Teletact", was invented by Robert Stone and Jim Hennequin, but wasn't taken up by other VR workers: R. Stone, personal communication.)

Brooks ended his reminiscence by saying "Any year we'll get there." For already "by 1994", on his view, "one could honestly say that VR 'almost works' " (Brooks 1999: 16). This means that "any year" is roughly *now*. Presumably, he's disappointed. For despite all the hype, a near-fully realistic experience is only slightly nearer.

Complete sensory immersion still isn't possible. (Even if it were, it's not clear that it could ever be phenomenologically equivalent to having a bodily presence in a real situation—H. L. Dreyfus 2001: 59–72; Dreyfus 2003.) In research laboratories today, and even in artists' studios, VR goggles and gloves—and body suits—can be fed with signals from afar, or from simulated worlds instead of the real one. And entire virtual environments can be built, obviating the need for goggles or gloves. But the VR dreamt of by Sutherland, where the simulated world is wholly imaginary and yet utterly convincing, is still a very long way off.

Indeed, some multimedia experts are already claiming that VR, as originally understood, has not only "failed" to live up to its promises but has no chance of doing so in the future. More success, in Stone's (2005) view, has been achieved within what's called "serious gaming"—whether intended purely for entertainment or for training purposes. This is partly a matter of accessibility and affordability: unlike VR installations confined to specialist high-tech laboratories, these systems are already available to, and easily usable by, Everyman. But it's also a matter of verisimilitude in the characters and avatars depicted. As of January 2006, perhaps the best example of 'realistic' human movements and facial expressions in such a game is the "G-man" character in Half Life 2, which has "40 facial muscles and a skin texture that beggars belief" (R. J. Stone, personal communication). Indeed, this technology has inspired an eerily plausible simulation of the court room scene in the Jack Nicholson film *A Few Good Men*—called, as you might expect, *A Few Good G-Men* (see <http://www.machinima.com/films.php?id=1154>).

Partly because of the huge difficulties—and expense—involved (how many dollars per simulated muscle?), by the late 1990s much of the research emphasis had switched from the interface itself to the human's *interaction* with it. The 'reality' was largely projected onto the interface by that interaction (effort after meaning, again).

Accordingly, some current definitions of VR don't specify particular technologies (e.g. gloves, graphics, or headsets) but focus rather on the interactive experience. For instance, when the UK's Department of Trade and Industry launched their VR Awareness Initiative in 1996, they adopted Stone's definition: "Virtual Reality refers to a suite of technologies supporting intuitive, real-time interaction with multi-dimensional databases" (R. J. Stone, personal communication).

The omission of any reference to immersion, as envisaged by Sutherland and Brooks, was deliberate. For excessive hype had led to widespread scepticism. (The same old AI story!: see 11.ii–iii and 12.ii.f.)

b. VR as a practical aid

To illustrate the (limited) degree to which VR has already "got there", let's consider four practical applications: one for information access, one for doing surgery, one for surgical training, and one for training in hands-on mechanics. (Then, in subsection c, we'll look briefly at VR in contemporary art and entertainment.)

The first is an example of "wearable computing", intended for (literally) everyday use. This is a "Personal Information Architecture" gadget (for belt, briefcase, or handbag) called BodyNet (because the components communicate by low-powered radio waves extending no more than six feet from the body). The aim is to combine a person's radio, TV, video/CD-player, laptop, diary, and mobile phone. Like a waterproof wristwatch, this is "an intimate interface: always there, always on" (Shivers 1993: 7).

BodyNet is based on "magic goggles": clear-glass goggles which, besides enabling the wearer to see the real world, present small inset colour displays to each eye. These may carry information about the current state of the stock market, or they may present a TV newscast or chat show, or the wholly imaginary VR world of a computer game. Miniature earphones and microphone enable the wearer to hear and deliver speech within the virtual world. The focus of the (stereoscopic) goggle display was initially identical, irrespective of where the person was looking. But by the mid-1990s the system could monitor the wearer's eye movements to discover what they were looking at. If this is something in the virtual world, the next image sequence and/or audio input could be generated accordingly.

Wearing/carrying BodyNet, one could be walking through a simulated VR fantasy while also walking down the High Street. For the virtual images accompany the person's real perception rather than replacing it. Partial immersion, such as this, raises interesting HCI questions about how people manage to focus on physical and virtual worlds simultaneously, and how they can be induced by the VR engineer to attend to what's 'relevant' (Ohta and Tamura 1999). In other words, psychology and computing in a close embrace, again.

The second practical application concerns 'distance surgery', still in the experimental stage. The thinking and planning is done by the human surgeon. But he/she is immersed in a virtual world. This represents the real world at a distance, where the real patient is really located. In other words, this is a form of *telepresence*, as opposed to a wholly fictitious VR construction.

The surgeon receives camera input and force-feedback (haptic) data from the real-world site, thanks to VR goggles and gloves, and sends body-movement signals to the robot 'surgeon' at the other end of the line. If miniature robots are involved, the surgeon's movements are scaled down during transmission. In short, distance surgery combines sensory (visual, touch, and kinaesthetic) VR with sophisticated robotics.

One leading centre for this research is Oussama Khatib's laboratory at Stanford. Khatib, currently co-editor of the *Robotics Review*, directs a wide range of research in robotics. This includes "human-centred" robotics, in which the robot interacts and/or cooperates with a human being in real time (Khatib *et al.* 1999, 2002).

Human-centred robotics in general raises a number of problems which traditional robotics didn't have to face. Some concern the 'psychological' interlock between the person and the (largely) autonomous artefact: just how can their plans/perceptions be integrated? A mismatch between surgeon and robot could have horrendous consequences. Others concern their physical interlock: if they're sharing the same space, the robot must (usually) have no sharp edges, no sudden movements, and no excessive forces (Zinn *et al.* 2002).

Excessive force can be avoided, whether the robot is human-centred or not, by deliberately limiting its mechanical strength and/or by building in haptic sensors. These provide force feedback to control the power of its autonomously generated movements. In other words, the robot 'knows' by touch not only *that there's something there* but also *how resistant it is*, and therefore *how strongly the robot should push at it*. (Compare the feel of flesh with that of bone; and imagine pressing on a cushion, a balloon, or a bottle of wine.) In addition, 'kinaesthetic' feedback tells the robot how much force it needs to exert to lift the object, and/or carry it.

Yet other new problems concern the VR aspects—if any. In distance surgery, the surgeon doesn't share the robot's physical space but the patient does. There's an exception to the "no sharp edges" rule, since the robot manipulates a scalpel. It's especially important, then, to ensure that haptic information is conveyed to the surgeon effectively. If the robot responds autonomously to its own sensors, it must do so immediately and delicately. (In many distance-robotics applications the haptics don't need to be quite so delicate.)

One might argue that, in a very real—i.e. phenomenological—sense, the surgeon *does* share the robot's space. For as the surgeon becomes more familiar with the robotic tool, the tool (much like a blind man's cane) comes to be experienced as part of his/her own body. To put it another way, the boundary of his/her body seems to extend to the region of the robot. This is a special case of the sort of action-led adaptability in body image that was first studied by George Stratton over 100 years ago (see Chapter 14.viii.b). (Many other Strattonesque reorientations based on VR and/or telepresence are described in A. J. Clark 2003*a*.)

In principle, the same equipment can be used to convey 'sensory' information from a *virtual* world. The better the VR design, the greater the person's sense of immersion in a "genuine" reality will be. (I can vouch for that, having experienced Khatib's experimental visual/haptic system when visiting his lab in autumn 2003.) In one sense, this isn't new: as Sutherland pointed out in his 1965 talk, flight simulators have existed for years. But they've got steadily more convincing.

Distance surgery isn't the only use of VR by surgeons: our third example concerns the use of 3D simulations of bodily organs for surgical *training*. For instance, consider a VR brain being developed at the University of Nottingham under the direction of the neurosurgeon Michael Vloeberghs (Wang *et al.* forthcoming).

Not only does this VR brain have the appropriate 3D anatomy, but it's realistically squashed/deformed (in real time) when the trainee's virtualized surgical tool touches it. As well as *looking* different, it *feels* different too. Given that brains are very soft (compared with hearts, for example), the visual/haptic information at issue here is highly complex. For instance, the "touching" may be prodding, pinching, or cutting—each of which has its own distinctive material and perceptual effects.

The mathematical techniques being used by the Nottingham team have already been applied to other parts of the body too. And organs that aren't surrounded by a bony skull may be easier to simulate. For in listing their VR tasks in order of difficulty, these authors identify the deformations caused by "the contact of the tissue with itself and with its surroundings" as the most challenging of all (Wang *et al.* forthcoming, sect. 3).

The last illustration of practical VR is a recently developed system for training mechanical skills. A number of "embodied conversational agents" are already being developed for HCI-based training in a wide range of domains (Andre 1999; Cassell *et al.* 2000). That word "embodied" is misleading for these agents aren't robots. Rather, they're VR creatures existing in cyberspace—and interacting there with real people.

One of a variety of AI training systems developed by Jeff Rickel and Lewis Johnson, at the University of Southern California's School of Engineering, is called Steve (Rickel and Johnson 1998, 1999, 2000). The acronym stands for SOAR Training Expert for Virtual Environments. As that "S" indicates, this computer tutor is grounded in GOFAI work. It builds not only on SOAR (which itself is highly complex: Chapter 7.iv.b), but also on GOFAI agents, teaching machines, computer graphics, and NLP (e.g. B. G. Deutsch 1974; Grosz 1977; Grosz and Sidner 1979; Rickel *et al.* 2002). And, true to the interdisciplinary nature of HCI in general, it also uses psychological research—such as Paul Ekman's work on the facial expression of emotion (cf. Chapter 7.i.d).

Steve's designers describe him (*sic*) as "a new breed of computer tutor", since he's "a human-like agent that can interact with students in a virtual world to help them learn". (One of the first of the old breed of computer tutor was the programmed mechanic CBC, mentioned in Chapter 10.iii.c.)

The human pupil, in order to share the VR world with Steve, wears VR-display goggles and VR gloves, and carries a 3D mouse. And Steve—visually presented to the learner as a 3D humanoid (disturbingly, lacking hips and legs)—is able to watch and monitor the pupil's actions, and to give spoken advice, accompanied by gestures, when difficulties arise. (The "-oid" in "humanoid" is only too apt, for Steve also lacks realistic skin texture and facial expressions: he's hugely inferior in these respects to the Half Life 2 example mentioned above.)

Despite the lack of nether regions, Steve is a 'believable' agent. This is largely because he/it integrates perception, cognition, and motor control:

> The perceptual module monitors the state of the virtual world, maintains a coherent representation of it, and provides this information to the cognition and motor control modules. The cognition module interprets its perceptual input, chooses appropriate goals, constructs and executes plans to achieve those goals, and sends out motor commands. The motor control module implements these motor commands, controlling Steve's voice, locomotion, gaze, and gestures, and allowing Steve to manipulate objects in the virtual world. (Rickel and Johnson 1999: 343)

Specifically, what Steve teaches his students is how to perform *physical* tasks, where bodily demonstrations, as well as verbal instructions, may be helpful. Examples mentioned by his designers include the operation and maintenance of complex—and often dangerous—equipment in ships, factories, power stations, and the like. (In principle, other physical tasks, from cooking to surgery, might be demonstrated by Steve too. But this would require detailed simulation of the relevant physical objects in the VR world.)

Steve's tasks can involve more than spanners and knobs. They have a social dimension as well:

> In addition to training students on individual tasks, he can also help them learn to perform multi-person team tasks: he can serve as a tutor for a student learning a particular role in a team, and *he can play the role of a teammate when a human teammate is unavailable.* (Rickel and Johnson 1998: 30; italics added)

(In subsection d, we'll consider some worrying implications of the use of the words *teammate* and *he* in that quotation.)

c. VR in art and play

Sutherland's talk of Wonderland had carried associations of play, and of art. And indeed, artists were inspired by AI/VR to develop new artistic genres (Brand 1988; Stiles and Selz 1996; Packer and Jordan 2001).

Some of these could be seen as versions of performance art, in that the prime interest wasn't in the sensory qualities of the product (images, music . . .) but in the mental processes and physical skills that produced it. Arguably, *all* art, even including the *Mona Lisa*, is performance art in that sense (D. Davies 2004, esp. chs. 7–10). If so, then the new VR art wasn't as marginal as a conventional aesthetics would imply. In any event, the art world of the late twentieth century was greatly influenced by experiments in AI and VR (Stiles and Selz 1996: 384–498; Packer and Jordan 2001).

Sometimes, computers were used merely as "rather complicated tools, extending the range of painting and sculpture, performed music, or published literature". But in the more interesting cases, they made possible "*a whole new field of creative endeavor* that is as radically unlike each of those established genres as they are unlike each other" (Ascott 1990: 245; italics added). A key feature of *interactive* computer art was that the viewer wasn't just a viewer, but a playful participant—even a co-creator.

Computer art began in the mid-1960s (Klutsch 2005; Nake 2005). One of the first recognized computer scientists to support this new activity was Berkeley, who'd encouraged the young Sutherland brothers in their Squee project shortly before (and who'd written the first popular book on electronic computers: Berkeley 1949). The February 1963 issue of Berkeley's magazine, recently renamed *Computers and Automation*, announced a competition for "examples of visual creativity in which a computer plays a dominant role".

At much the same time, the first examples were already being produced. Some in New York, by Michael Noll (aided by the cognitive psychologist Bela Julesz), and some in Stuttgart, by Frieder Nake (1938–). Nake even used a new flatbed drawing machine constructed by Konrad Zuse himself (Nake 2005: 55; cf. Chapter 3.v.a).

As for interactive art, the first highly visible instance was *SAM* (Sound Activated Mobile), built by the cybernetic sculptor Edward Ihnatowicz (1926–88). Exhibited to public delight at the 1968 exhibition in London (and ending up in the Exploratorium in San Francisco), this looked like a large fibre-glass flower on a flexible stalk, with four petals and four stamens. But the stamens were radio sensors. They picked up noises made by the viewers, and caused the hydraulic pistons in the stalk to move the flower left or right, up or down, towards the source of the sound (Zivanovic 2005: 103).

That was the principle, too, of Ihnatowicz's even more famous interactive sculpture, *The Senster*. This eerie creature, built in the laboratories of University College London, had been commissioned by Philips, Eindhoven, and was exhibited by them from 1970. Looking like a 15 foot tall Meccano giraffe, it was equipped with sound and movement sensors attached to hydraulic motors that moved its head and neck towards the person making the sound/movement. It was even more compelling than Grey Walter's Festival of Britain tortoises (4.viii.a), because it seemed to engage with *you*, as an individual. In addition, it seemed to have feelings of its own: it would shy away from loud noises, and if the noise became overwhelming it would raise its head and "disdainfully ignore further sounds until the volume subsided" (Zivanovic 2005: 104–5).

(Philips eventually dismantled it, without informing Ihnatowicz, because they had problems in keeping it working properly. The visitors to their site, many of whom had come there only to view *The Senster*, had been complaining that it was malfunctioning—and Philips had had enough. Today, the reassembled and slowly rusting mechanical structure sits, *sans* electronics, on the premises of an engineering firm who'd done some work on it in its heyday.)

Other original applications were due to the Greek Australian performance artist Stelarc (1946–). His exceptionally imaginative performances included experiments linking/integrating his own muscles with robots, and with random or human-originated messages from the Internet (Stelarc 1986, 1994, 2002*a*,*b*; M. Smith 2005). They weren't mere physical exploits to be gawped at, but activities that raised questions about the limits of body and self (see Chapter 16.vii.d). Stelarc's artistic journey wasn't initiated by VR. He'd started out, in the late 1960s, with non-electronic man–machine linkages: meat hooks inserted into his skin, and attached to pulleys (Paffrath 1984). But as soon as it was possible to exploit robotics/telepresence/VR, he began to do so.

Most artists, however, were engaged in less intimate interactions, and with VR rather than robotics. Moreover, they weren't necessarily playing with different *realities* so much as a different *medium*: the computer-generated sensory image. That image might be shown on the machine's VDU, or projected onto a wall, or (occasionally) transferred onto canvas. And it might or might not be presented as an alternative world.

One of the first to produce "cybernetic" artworks, and explicitly to define a new aesthetic relating to them, was the British painter Roy Ascott (1934–), later described by the art historian Frank Popper as "the outstanding artist in the field of telematics" (Popper 1993: 124). While working at the Ealing School of Art in the 1960s, he helped initiate an artistic revolution. This was done partly through his own work, and partly by inviting like-minded pioneers such as Pask to lecture to his students.

His first interactive art didn't involve computers, but consisted of canvases with items/images on them that could be continually moved around by the viewer. So the "viewer" of the resulting collages was their *maker* too. This aspect was retained, and strengthened, in the computerized art that followed. The value of AI-based interactive art, for Ascott, was its ability to engage the viewer–participant *as creator* (Ascott 1964, 1966/1967; cf. 2003). By the same token, he held that its aesthetic crux was the nature of the interaction itself, not the (visual and/or musical) end result.

Inevitably, the authority of the single artistic signature was undermined, for crucial creative choices were now being made by the viewer. A quarter-century later, with the advent of the Internet and the Web, authorship of the "telematic" artwork might be very widely dispersed:

> [The] status of the art object changes. The culturally dominant objet d'art as the sole focus (the uncommon carrier of uncommon content) is replaced by the interface. Instead of the artwork as a window into a composed, resolved, and ordered reality, we have at the interface a doorway to undecidability, a dataspace of semantic and material potentiality. (Ascott 1990: 237)

> Telematic culture means, in short, that we do not think, see, or feel in isolation. Creativity is shared, authorship is distributed, but not in a way that denies the individual her authenticity or power of self-creation, as rather crude models of collectivity might have done in the past. On the contrary, telematic culture amplifies the individual's capacity for creative thought and action . . . *Networking supports endless redescription and recontextualization such that no language or visual code is final and no reality is ultimate*. (Ascott 1990: 238; italics added)

In brief: Ascott's telematic art is VR as a buttress of postmodernism. That particular philosophical interpretation is relatively recent. But right from the start Ascott was always more interested in the conceptual implications of cybernetic technology than in the technology itself. That's why, when the art critic Jasia Reichardt organized the now famous Cybernetic Serendipity exhibition in 1968, she didn't include him (J. Reichardt, personal communication).

Another early AI art experimenter was the artist–computer-scientist Edmonds (1942–), of the University of Loughborough—now, director of the Creativity and Cognition group at Sydney's University of Technology. In contrast with Ascott, he *was* primarily concerned with how the new technology could be used to create novel forms of art.

His inkjet print *Nineteen* (a static array of twenty coloured oblong patches on a near-white background) was first exhibited in 1968–9 and, having been accidentally destroyed, was reconstructed for a historical exhibition in the late 1990s. It was generated by a FORTRAN program designed to find the best of all possible placements of the twenty patches (each of which had already been designed by Edmonds), subject to a few constraints—e.g. that two particular pieces shouldn't be on the same row or column (because this would dominate the canvas).

Edmonds's aesthetic aim, here, wasn't merely to produce a visually interesting composition, but to focus the viewer's mind on the structural possibilities:

> It was intended that the assembly in the array be such that a feeling of finality be avoided. The variety of possible relationships between the elements is left for the viewer to sense without actually being able to move them about as he would in an assemblage. (Cornock and Edmonds 1970/1973)

In other words, Edmonds had used the computer "as a problem solver", to tackle an aesthetic problem which was "very hard to solve by hand or analysis" (Edmonds 2002). (In fact, in the three hours allocated, the computer didn't manage to find a solution satisfying all of Edmonds's constraints. But it got very near to doing so, and Edmonds himself was able to modify its solution slightly so as to get what he felt was the best arrangement. His Notes on how he did this were sometimes exhibited alongside the piece.)

His work in later years showed how to use computers as essential aspects of new creative styles, as well as aids in stylistic exploration. For example, he exhibited the world's first generative time-based artwork: *Fragments 1984/5* (a special case of what he named Video Constructs). Here, viewers could sense "the variety of possible relationships" by watching an ever-changing series of abstract compositions generated by a PROLOG program. *Time* was part of the artwork, as well as geometry and colour: variations in the order of images, and in the pace of change, provided different aesthetic effects. Even before Video Constructs, Edmonds had pioneered *interactive* art (e.g. Edmonds and Lee 1974). His novel HCI designs often involved threefold dependencies between action, graphics, and music. By the mid-1980s, he was developing complex VR technology too, for exploring 3D (or 4D, if one includes time) instead of 2D, as before (Wernald and Edmonds 1985).

In all these artistic endeavours, the underlying generative structure, not the individual images/sounds, was the focus of interest. So Edmonds opened a retrospective statement of his general approach by quoting Paul Cézanne's remark that "The technique of any art consists of a language and a logic", and Kasimir Malevich's that art-making involves "a law for the constructional inter-relationships of forms" (Edmonds 2003). (He also cited serialist composers, such as Pierre Boulez.) His very earliest art had been figurative. However, he was already tending towards abstractionism when computers came on the scene, and this technology led him (enabled him) to commit even more fully to abstract, formal, work.

The development of interactive art in the UK was strongly influenced, from the 1960s on, by Edmonds and Ascott. (Strictly, they weren't the ultimate pioneers, for Pask had placed his adaptive "Musicolour" in UK dance halls in 1953: see Preface, ii, and 4.v.e.) Across the Atlantic, the Bell Labs engineer Billy Kluver (1927–) cooperated in the 1960s with several New York artists—Jasper Johns, Andy Warhol, Robert Rauschenberg, and the composer John Cage—to produce electronic art of various kinds (Kluver 1966). By the end of the decade, the avant-garde interest was enough to prompt a seminal international meeting on "cybernetic" art at London's Institute of Contemporary Arts (J. Reichardt 1968). (Avant-garde, but not counter-culture: as remarked in Chapter 1.iii.d, this August 1968 exhibition couldn't have happened in Paris, given the political *événements* in July.)

In the 1970s the interest grew, and widened (Brown and Lambert in preparation). For example, the University of Wisconsin's Myron Krueger (1942–), trained as a computer scientist, was inspired by Cage's work on randomness to design interactive environments as artworks. In some of these, images of people located in different places were projected into a single virtual space—enabling the real individuals to experience the telepresence of their fellows, and to communicate accordingly. Like Ascott and Edmonds, he defined a new aesthetic, suggesting how "responsive environments" were best appreciated (M. W. Krueger 1977). (Krueger envisioned his interactive system spreading way beyond the art world, for use in education, psychology, and psychotherapy; the examples of surgery and training, above, wouldn't have surprised him.)

Today, computer-generated and/or interactive art is still cutting-edge, if no longer avant-garde (e.g. Krueger 1991; Candy and Edmonds 2002; Ascott 2003; Whitelaw 2004). It exploits VR, multimedia, the Internet, the Web, and A-Life evolutionary programming—all of which are dependent on AI research.

Both Ascott and Krueger had explicitly defined their new aesthetic in terms of the gallery visitor's *interaction* with the electronic object/environment. The beauty or interest of the product (the visual display, the music . . .) was much less important to them than the nature of the interaction. (This left open many questions about just what sort of interaction was to be valued, and why: Boden forthcoming.) At the turn of the century, a similar concern was taking over in VR research more generally—for education, certainly, but also for entertainment.

Now, in 2006, entertainment rules the VR roost. There are a number of massively multi-player online simulation games, such as Everquest. These may have hundreds of thousands, even millions, of human players, all continually building and extending online virtual worlds, and online relationships for play, trading, or debate. While most are fantasy worlds, in which players build imaginary cities and forge imaginary alliances, some are based on actual places and/or events—such as the Battle of Britain. The computer game based on this Second World War conflict provides detailed simulations of English airfields, towns, and cities (Bradbury 2003). The players create (or re-create) air crews, and engage in virtual bombing missions or Spitfire–Messerschmitt dogfights that may mimic specific events from August 1940. Clearly, AI/VR has come a long way since Spacewar (see 10.i.i).

Occasionally, the human–VR interaction spills intriguingly from simulation to reality in unprecedented ways:

> Some people are making their (real) living from playing virtual online games—by building up powerful characters or buildings, amassing virtual wealth, and then selling it for real money through eBay. (M. Sharples, personal communication)

And not only eBay: several dedicated web sites specialize in auctioning virtual characters and attributes for decidedly *non-virtual* money. Large sums of money may be spent on a single item, whether a carefully crafted VR person or a VR magic sword, and the overall spend is huge. Indeed, one US economist has estimated that the VR gaming world has a GDP per capita roughly the same as Namibia's (Mueller 2004: 13).

'Crazy', perhaps—but innocent enough. Indeed, less harmful than the quest for the black tulip in seventeenth-century Holland, in which livelihoods were lost as well as fortunes made. But whether all merging of the virtual and the real is as benign as this is questionable, as we'll now see.

d. Computerized companions

VR applications prompt the human subject to have 'reality experiences' to differing degrees. But they all foster experience as opposed to imagination. In other words, the willing suspension of disbelief with which one approaches films and theatre (and novels) differs radically from the *spontaneous experience* of reality that's brought about by successful VR.

For example, the world of a 1990s MUD (Multi-User Dungeon) chat room makes possible a set of shared experiences which simply weren't available before (Curtis 1992; Turkle 1995: 180–209, 248 ff.). It may generate a very strong sense of reality, leading MIT's Sherry Turkle (1948–) to say: "Our experiences [in cyberspace] are serious play. We belittle them at our risk" (Turkle 1995: 269). Some philosophers have even claimed that virtual worlds have *a new kind of reality*, rather than being simulations of something else (Graham 1999: 158–66; see also Haraway 1986/1991 and Turkle 1995).

These facts underlie some common misgivings about VR. For instance, the quotation above, referring to the virtual mechanic Steve as "he" and as a "teammate", raises some tricky questions. So besides asking whether VR (as Brooks predicted) has "got there", one might also ask *whether we'd really want it to*.

That question was addressed in the 1980s–1990s by many people. Some were professional VR technologists, such as Pavel Curtis (1960–) of Xerox PARC, creator of the popular MUD LambdaMOO (Lambda from LISP, MOO for MUD, Object-Oriented). LambdaMOO is an ever-growing multi-user virtual environment, with thousands of different rooms and outside spaces, described in words by its players (see Rex 2005). Besides creating LambdaMOO (in 1990), Curtis described his experience of maintaining it, which had shown him how people were using—and misusing—it (Curtis 1992). Some were social scientists: the sociologist Turkle (1995), for instance, or the social psychologist Neil Frude (1983). And some, such as Ascott (1990, 2003) and Haraway (1986/1991), were artists, littérateurs, or philosophers. The items represented by their various worry beads ranged widely over human experience, both actual and potential.

Concerns were raised, for instance, by VR applications that weren't just intellectually engaging, but emotionally engaging too. One example was Creatures, a computer game or (better) a computer world based on evolutionary programming (Grand *et al.* 1997; Grand and Cliff 1998; cf. Chapters 15.vi and 16.x.b).

Creatures caused considerable interest and experimentation on the Internet when it was commercially released in 1996–7, and swiftly led to several hundreds of dedicated web sites—and to improved versions in subsequent years (Cliff and Grand 1999). Indeed, it has aroused attention from cultural commentators, who see it as a paradigm of the technology of autonomy that underpins "the posthuman cyborg" (see Kember 2003: 83–109, and Chapter 1.iii.d). Here, however, what's relevant is that it turned out to be surprisingly addictive in a personal/emotional sense.

The user could hatch, teach, and evolve up to ten virtual animals ("norns") at a time. Each norn had an individual (genetically specified) outward appearance, a neural-network "brain", a particular temperament, and an underlying metabolism. And each learnt to behave in different ways, depending on its environmental history—including the situations devised, and the rewards and punishments administered, by the user. The properties that could be selected for breeding the next generation included temperament and bodily (i.e. computer-graphic) appearance.

The effect on users was compelling. Some youngsters became so emotionally attached to their carefully nurtured creatures that they would grieve if one was wiped from the disk—even though new norns could be hatched on command (M. Sharples, personal communication). Frustration and annoyance would have been appropriate, since the individual norns had been evolved and taught through many hours of highly concentrated interaction with the system. But grief, however fleeting, is another matter. It showed that the norns were being experienced as analogous to real people, or anyway pets (see 7.i.f).

Similarly emotion-ridden effects were often seen in the craze for Tamagotchis in the mid-1990s. (The Japanese word means 'egg-friends'.) These virtual beasties were even less real-looking than norns, having a near-minimal interface (only 10×10 pixels). The attraction, and the addiction, was in the need (if the beast was not to "die") for the user to nurture, feed, and even entertain it—all in real time. Norns and Tamagotchis were thus heralds of the end-of-century switch of VR emphasis from *interface* to *interaction*.

If even pixie-like norns and 100-pixel Tamagotchis can engage some people's emotions to this extent, what of more humanoid creatures? Pask's CASTE teaching machine had led some early 1960s users to experience "a sense of participating in a competition (some say a conversation) with a not dissimilar entity" (see 4.v.e). And Rodney Brooks's Cog robot could induce even a *technically knowledgeable and philosophically hostile* visitor to engage with it "as though in the presence of another being" (see 15.viii.a).

But those examples were merely tasters. Cog's long-eyelashed stablemate Kismet, built and nurtured (*sic*) by Brooks's students Cynthia Breazeal and Brian Scassellati, apparently expressed emotions as well as eliciting them (Breazeal and Scassellati 1999, 2000, 2002*a*,*b*). Like its predecessor *The Senster*, it seemed not only to pay attention but also to have its attention captured appropriately by the human's actions. Visitors to the MIT lab found it much more effective in eliciting emotional reactions than *The Senster*, and even more seductive than Cog (Fox Keller forthcoming). That's hardly surprising, given that its HCI was deliberately modelled on that of human infants/mothers (e.g. C. Trevarthen 1993).

Indeed, psychological research figures increasingly prominently in today's efforts to produce humanoid robots, and even "robot companions". For example, there have been systematic studies of how children's expectations of and interactions with robots compare with those of adults (e.g. Dautenhahn 1999, 2002; S. Woods *et al.* 2004, 2005).

Physical robots, such as Kismet, are limited by their creators' skills as mechanical engineers. With the potential of today's VR, the human's experience of "presence" can be made yet stronger.

Many years ago, the social psychologist Frude (1983) predicted personal GOFAI companions, in the form of talking sex dolls or screen displays. These would go far beyond Descartes's ill-fated (and probably apocryphal) automaton Francine (2.iii.f). They'd engage in intelligent and sympathetic conversations, speaking in friendly/sexy synthesized voices. And they'd learn what interested their human partner—so they wouldn't bore my son by talking about jewellery, or me by talking about cars. Moreover, they'd cater for a wider range of "interests" than one might think: cuddly/furry robots "would extend the range of potential activities and permutations to present a whole new realm of challenges to the sexually inventive" (Frude 1983: 174).

Frude's prediction hasn't come to pass. However, plenty of AI/VR work has been commenced which might help in moving towards it. (Some, indeed, is already being exploited for that purpose: see below.) For instance:

* The synthesized voices could now be given appropriate local accents (Chapter 9.xi.g).

* They could be given emotional intonations, too (Chan 1990; Cassell *et al.* 1994). In principle, they might one day include 'realistic' emotional features like those in John Clippinger's 'neurotic' NLP program (7.ii.c).

* The lip–sound synchronization for VR speech can be based on photographs of the lip movements of a specific person (9.xi.g).

* VR systems may also be able to 'lip-read' to aid their understanding (only sixteen lip positions are needed to represent English speech: Lucena *et al.* 2002).

* Animators are applying David Perrett's data on computer-simulated facial attractiveness (see 14.iv.d), and in principle could adjust their VR faces to exploit the female user's time of the month (Penton-Voak *et al.* 1999).

* Work's going on around the world on enabling AI systems to recognize people's facial expressions of emotion. (Steve is one example, mentioned above; others include robots developed by Fumio Hara's group at the Tokyo University of Science.)

* If the human user were to wear suitable VR gloves (as Steve's interlocutors already do), the AI companion could also use electrical signals from the skin to gauge the person's emotional state.

* Conceivably, the system might even be able to tell when the human is telling lies. For besides acting—through the gloves—as a conventional lie-detector, it might pick up facial cues to lying (7.i.d gives references to Ekman's work on lying).

* The companion's own 'face' might express emotions too, even if it were a doll (as opposed to a VDU screen). Roboticists in Japan and the USA have been modelling our detailed facial musculature, to enable their robot's rubberized 'face' to change its shape

according to one basic emotion or another—e.g. Hara's group, again. (Advances in materials science might provide more realistic 'skin' and 'flesh'.)

* Rod Brooks's Kismet robot—carrying floppy pink ears, huge blue eyes, and ultra-long eyelashes—engages people's interaction (and "caring" responses) despite its limited range of behaviour (15.viii.a);

* mutual gaze and joint attention are so convincingly modelled in Brooks's humanoid robots that even people who are in the know seem to sense an animate "presence" (15.viii.a);

* Negroponte's Media Lab have been aiming at highly personalized conversational computers since the 1970s, their ultimate test case being the intriguing all-anaphors interchange quoted in 9.xi.g.

* Finally, teledildonics (the mind boggles!) already offers a wide range of sex at a distance, sometimes involving wearable VR gear such as the "cybersex suit" or the "Virtual Sex Machine" (*Teledildonics* 2003). Future advances in haptics will probably be adapted for these purposes.

Frude saw convivial computerized companions as inevitable (1983: 58). The AI technology will be developed, and the businessmen (and the pornographers: p. 174) will then take over. The huge consumer demand, he said, will be driven by the universal human tendency to animism (which can now be understood as drawing on the concepts and inferential processes of Theory of Mind), in which intentional agency is ascribed to non-human beings (see 7.vi.f and 8.vi.d).

One must agree about the animism, and about the businessmen: just think of Tamagotchis, again. Although it's relevant to note, here, that robots are already being used for interacting with people who *lack* the normal tendency to animism. As we saw in Chapter 7.vi.f, autistic children lack Theory of Mind. Some people working in social robotics have tried to use robots to help mediate social interaction *between the autistic child and other humans* (Robins *et al.* 2005; cf. Robins *et al.* 2004). They've had some success, but they've also noticed that the robots can reinforce the autistic's tendency to fall into repetitive stereotyped behaviour. The use of non-human, and therefore non-threatening, robots in teaching autistic children isn't new: see the LOGO-based approach described in Weir and Emanuel (1976). What Weizenbaum would think about these projects probably doesn't bear repeating in polite company; but, as with Colby's automated psychiatric interviews, perhaps the key question is whether or not the child is actually helped (cf. 7.i.a).

But if one agrees with Frude about the animism, one may disagree about the full-blown technological prediction. Intellectually stimulating, and even emotionally engaging, robots and/or (Interneted) VR interfaces, yes. And pseudo-satisfying 'sexual' encounters, too. After all, both of these exist already. But the arguments elsewhere in this book suggest that the fully "intimate" machines envisaged by Frude are unattainable. NLP will never be up to it (Chapter 9.x–xi). Nor will our computational theories of motivation and emotion (7.i.e–f), nor of reasoning, relevance, and common sense (7.iv and iii.d, 10.i.f and iii.e, and i–ii, above).

Some AI professionals, however, might take Frude's side here. Attendees at the IEEE's latest international "Ro-man" symposium, whose theme was 'Getting to know Socially Intelligent Robots', probably would (see <http://ro-man2006.feis.herts.ac.uk>). And when I asked one of Steve's authors whether he shared my scepticism about this, he didn't say that I was obviously wrong—as some AI enthusiasts would have done. More cautiously, he said:

> Well, ever is a long time. I'm leery of speculating about what will ever happen in the future, not without some convincing argument that such a computerized companion is altogether impossible.
>
> I see rapid advances these days on computational models of emotion. I am not sure how far progress will go, but I don't see obvious barriers at the present time.
>
> And corpus-based NLP techniques are also making rapid advances. They make broad-based question–answer systems much more feasible than was the case in the past.
>
> Still, there are many barriers to creating a general conversational companion. Even if there is progress in some areas the overall goal still seems very far off. (W. L. Johnson, personal communication; quoted by permission)

As for whether such technical advances would be *ethically* welcome, Frude sat on the fence. He granted "the danger that contact with an artificial intimate [*sic*] might prove so fascinating and so satisfying that natural inter-human friendships would be overshadowed" (p. 174). But he pointed out that old people in Western cultures are often neglected, and suggested that—in the absence of real human interactions—this futuristic HCI would be better than nothing: "Such a machine promises freedom from loneliness and boredom and could end for ever the blight of social isolation with all its attendant evils."

You may find this suggestion chilling, a prime case of what Weizenbaum called "obscenity": substituting computers for humans in quintessentially personal contexts (7.i.a and 11.ii.d). If so, I agree with you. Nevertheless, at least one AI colleague—whom I shan't name—disagrees. Moreover, pushed by the demographics of an ageing population, Japan's Ministry of International Trade and Industry has recently launched a major research programme into humanoid robots, intended as helpers *and companions* for the elderly (Fox Keller forthcoming, n. 18). Presumably, these politicians have no ethical quibbles either.

Chilling or not, we don't need to worry too much about computerized companions—at least, not yet. VR avatars are another matter. People not at all worried by Frude's intimate machines, because they doubt that they'll ever exist, may already be very worried by these.

e. Psychology and avatars

In Hinduism, an avatar is an animal incarnation or representative of a god. In VR, it's a screen name/image that represents a particular human user (Damer 1998; Wilcox 1998). When someone uses the same avatar over a period of time, it grows a database for future use. (Steve isn't an avatar: he/it doesn't represent a specific person, merely a generalized human tutor.)

In general, an avatar prompts the psychological processes that enable us to interpret other people's behaviour. In other words, it taps into the user's Theory of Mind—as screen-borne or robotic companions would, too (7.vi.f).

Today's avatars include printed names/initials or abstract icons; 2D cartoons or photos of humans or animals; and 3D images of a person with face, body, and fingers—and bodily movements as well. The range of humanoid avatars is huge, not least because a company in Iceland sells software enabling you to design your own (Wilcox 1998, ch. 8). Already, several recent simulation games, such as The Simms, involve the DIY design of avatars.

Tomorrow's screen stand-ins will be even more realistic. Naturalistic gestures and facial expressions (remember Steve), and suitable voices, will be designable (Cassell *et al.* 1994). The more detailed the avatar's face, the more important that its lip movements match its voice plausibly. So special synchronizing algorithms will doubtless be employed too (Waters and Levergood 1995; Lucena *et al.* 2002).

An avatar converses either by writing text messages or by audible/visible speech. And it may walk to different locations in the virtual world displayed, taking up different points of view (affording different information) accordingly. It may soon be able to recognize emotions in the interlocutor's voice or written text, and *automatically* simulate them in its own facial expression (Olveres *et al.* 1998). (It's already possible for the avatar-holder to key certain facial expressions in by hand.) As ever in HCI, for the avatar to be realistic the psychologists must previously have found out just how *people* behave in comparable contexts (Cassell *et al.* 1994, again).

We don't have to look to the future to be worried by avatars, for they've already aroused social and psychological anxieties. The prime reason is that they enable a person to hide their identity, including their age and gender, and even to pretend that they're someone else. (Significantly, the chapter on avatar design that reports on the Icelandic company mentioned above is subtitled 'Who Would You Like To Be Today?'—Wilcox 1998: 187.)

Now, in the new millennium, several million people may be continually presenting (misrepresenting?) themselves as avatars within a single MUD. It's worth noting that these MUDs are often called MMORPGs: Massively Multi-Player Online *Role-Playing* Games.

The social psychologist Irving Goffman (1959) long ago pointed out the potential for deception and confabulation in role playing, and in the everyday "presentation of self". But VR is Goffman in spades. So one MUD enthusiast, for instance, said to Turkle:

> You can be whoever you want to be. You can completely redefine yourself if you want. You can be the opposite sex. You can be more talkative. You can be less talkative. Whatever. You can just be whoever you want, really, whoever you have the capacity to be. You don't have to worry about the slots other people put you in as much. It's easier to change the way people perceive you, because all they've got is what you show them. They don't look at your body and make assumptions. They don't hear your accent and make assumptions. All they see is your words. (quoted in Turkle 1995: 184–5)

This threatens not only to deceive other people, but also to confuse—and perhaps to destabilize—oneself. Just what might follow from a new realization of "whoever you have the capacity to be"?

Sometimes, the illusory avatars are harmless enough. For one thing, people only rarely adopt "a coherent character with features distinct from their real-life personalities" (Curtis 1992: 327). For another, their MUD avatars—according to Curtis—are driven by wish-fulfilment of a fairly innocent kind: "I cannot count the number of 'mysterious but unmistakably powerful' figures I have seen wandering about in LambdaMOO." The virtual world, he said, seemed to be enabling people to emulate various attractive characters from fiction. (How many Mr Darcys, I wonder? And how many James Bonds?)

But less attractive characters could be emulated too. This was illustrated by another of Turkle's interviewees, a male student whose avatars are often highly violent. He acknowledged that the violence is "something in me", and defended himself thus: "but quite frankly I'd rather rape on MUDs where no harm is done" (p. 185).

Well, perhaps. No woman is harmed (yet??). But the user himself may be harmed by repeatedly acting out such behaviour. "Perhaps", and "may be", because this is of course an empirical question. Given the ambiguous results of the massive research done on the psychological effects of watching violence on TV, it's a question that's not likely to be easily answered.

Again, a MUD user can sometimes take control of *someone else's avatar*, forcing it to do things which the genuine owner wouldn't want it to do. This allows for an especially 'realistic' version of virtual rape (Turkle 1995: 250–4). Here, the perpetrator doesn't merely act out the rape of a specially created (wholly imaginary) VR character, but forces cooperation (and 'signed' messages expressing satisfaction, and pleading that he should continue . . .) from a pre-existing avatar victim. Not surprisingly, the hidden humans violated in this way—who may or may not be female—don't like it. The common defence is: "This is a GAME, nothing more. [People need] to chill out and stop being so serious. MUDs are supposed to be fun, not uptight" (Turkle 1995: 253). I'm not persuaded.

In short, it's not at all clear that "no harm is done" by engaging in these unsavoury activities. But neither is it clear that simply *avoiding* unsavoury activities would neutralize all the potential problems.

Specifically, a number of VR critics have argued that merely adopting different personae at different times, whether unsavoury or not, may unsettle someone's psychological equilibrium. As Dreyfus put it, quoting Søren Kierkegaard, "the self requires not 'variableness and brilliancy' but 'firmness, balance, and steadiness' " (H. L. Dreyfus 2001: 82). You may feel that cognitive scientists shouldn't be troubled by this. For cognitive science sees the "self" as a narrative construction rather than an encapsulated essence (Chapters 7.i.e–f and 16.vii.d). But as a virtual machine (*sic*) that underpins the purposive coherence of the person's life, it had better have "firmness, balance, and steadiness". VR experiments in "multiple personality" are all very well, but in some cases they're playing with fire (Turkle 1995: 206 ff.; cf. 7.h).

Postmodernists, however, may not agree. For example, Kenneth Gergen, one of the first counter-culturalists to attack 'scientific' social psychology in the 1970s (see 6.i.d), has recently welcomed the relativizing effects of what McLuhan (1964: 3) called the global village:

> [We] exist in a state of continuous construction and reconstruction; it is a world where anything goes that can be negotiated. Each reality of self gives way to *reflexive questioning, irony, and ultimately the playful probing of yet another reality*. The center fails to hold. (Gergen 1991: 6; italics added)

He was talking primarily about the multiplication of real (i.e. geographical/cultural) environments in our experience, but he later included VR too (Gergen 1994).

The italicized phrases, above, express attitudes typical of VR users. So it's not surprising that other postmodernists, who already favoured the deconstruction of the self for independent philosophical reasons, welcomed the variation of self afforded by avatars in cyberspace. The leading proponent of that view was Haraway (1986/1991). But the influential artist Ascott, too, promulgated the notion of "Cyberself":

> We are each made up of many selves: de-centred, distributed, and constructively schizophrenic. We are the embodiment of technoetic relativity . . . [where a "technoetic" aesthetics focuses not on the surface image of the world but on] creative consciousness and artificial life. (Ascott 1998/2003: 375, 381)

And Turkle remarked approvingly that

> The rethinking of human . . . identity is not taking place just among philosophers [she meant postmodernists, but some philosophers of cognitive science are included too: Chapter 16.vii.d] but "on the ground," through a philosophy in everyday life that is in some measure both proved and carried by the computer presence. (Turkle 1995: 26)

Raising the question whether MUDs offer "psychotherapy" or "addiction", Turkle cited cases—including herself—where someone's experience of acting within a particular (real or VR) communicative world helped them achieve a more satisfactory personal balance (1995: 196–209, 262–3). And she endorsed postmodern relativism, "humor" and "irony" about these matters: "We do not feel compelled to rank or judge the elements of our multiplicity. We do not feel impelled to exclude what does not fit" (p. 262).

She also pointed out, however, that avatar experimentation has its limits. For instance, a man pretending to be a woman on the Internet *must* miss out on many aspects of the experience of being a woman, from the fear of pregnancy to worries about how much make-up to wear to a job interview (p. 238). And despite her postmodernist sympathies, she said: "Virtual environments are valuable as places where we can acknowledge our inner diversity. *But we still want an authentic experience of self*" (p. 254; italics added). She saw VR as offering us "a multiple but integrated identity whose flexibility, resilience, and capacity for joy comes from having access to our many selves" (p. 268). However, she added that "if we have lost reality in the process, we shall have struck a poor bargain".

In a nutshell, nothing here is straightforward. The evidence shows that avatars can be psychologically liberating as well as oppressive. They enable social experimentation and self-exploration that may be advantageous, up to a point. Possibly, they may even display 'the real person' for almost the first time. That was suggested by Turkle's interviewee Thomas, who told her: "MUDS make me more what I really am. Off the MUD, I am not as much me" (p. 240). (Of course, this isn't conclusive: he may have seen himself as much closer to Darcy or Bond than he really is.) It was suggested by a Texan muscular dystrophy sufferer featured in the Alter Ego photographic exhibition in London of MUD/MMORPG players and their online avatars (Mueller 2004: 13). And it was suggested, too, by William Horwood's (1987) haunting novel *Skallagrigg*.

That word "haunting" reminds us that novels, plays, films . . . provide forms of VR which may seem very real indeed. Kenneth Walton (1990) has argued that such arts depend on "make-believe"—in which we experience what it would *really* be like to be shipwrecked on a desert island, or to consider killing one's stepfather the king, but without experiencing the nastier aspects of those realities. (It's not clear that he's right:

if you know you can't drown, where's the "real" horror of shipwreck?—Graham 1999: 155–8; cf. Turkle 1995, ch. 9.) Walton's view implies that VR is just 'more of the same'.

If so, we should worry about it no more—though also no less—than we do about the violence in Quentin Tarantino's movies, or the pornography filmed on the other side of those Hollywood hills. There's a difference, however. VR worlds/avatars can offer an experience of 'immersion' stronger than that involved in reading a book or watching a film, and can even be individually crafted. As a result, they may be both more haunting and, in their practical consequences, more nasty.

Over and above the personal practicalities that have been the focus of this subsection, and the one before it, philosophical issues concerning self and embodiment are highlighted by VR, and especially by telepresence. These issues were raised long ago, for instance in a hugely intriguing thought experiment described by Daniel Dennett (1978*e*). The core question concerns the location, and/or the boundaries of the self. Does it stop at the skull? Or at the skin? Or does it encompass the cultural artefacts without which we couldn't function as we do—and wouldn't be the people that we are? If the latter, as argued for instance by Andy Clark (1997), then VR technology adds further opportunities, further complications . . . and further questions (A. J. Clark 2003*a*: 90–8). (The philosophy of self and embodiment is discussed in Chapter 16.vii.d; and the VR ideas that inform *The Matrix Trilogy* are related to philosophical arguments about realism in Chapter 16.viii.c.)

Much more could be said about this new cognitive technology, the realization of Bush's and Engelbart's dreams. There's already a huge literature on the virtues, and the dangers, of VR and the Internet. (Extensive bibliographies are given in Turkle 1995, Shields 1996, C. H. Gray 1995, and Haraway 1986/1991; for a strongly hostile approach, see the references cited in Kroker and Kroker 1997.) However, much of it is either technically ill-informed or philosophically naive—and some is both. My advice is to read Turkle's fascinating interviews and subtle psychological insights, and to look out for an informative and thought-provoking book being written by Yorick Wilks: a long-time aficionado of NLP (see 9.x.d), originally trained in philosophy, and currently a Fellow at the Oxford Internet Institute (Y. A. Wilks in preparation).

13.vii. Coda

Two hostile questions, one old-and-continuing, the other more recent, are often raised about AI. The first is whether it's a 'proper' discipline. In other words, is there a well-defined subject matter which AI is *about*? The second is whether AI—in particular, GOFAI—has failed.

Many critics answer "No" to the first and "Yes" to the second. I'll argue that the "No" is justified, up to a point, but that—again, up to a point—the "Yes" isn't.

a. Is AI a discipline?

In 1968 Michie and his co-editor Ella Dale opened *Machine Intelligence 2* with these questions:

> What is Machine Intelligence? Is it a theory, a discipline, an engineering objective? Or is it a pretentious name for the more peculiar parts of computer science? (Dale and Michie 1968, p. ix)

They weren't asking purely on their own account. Indeed, they answered immediately that

> In our view the matter is quite clear. Since the objective is to bring into existence an intelligent machine, those engaged in the attempt must look on themselves as engineers. (ibid.)

Rather, they were reflecting the puzzlement, not to say scepticism, being expressed by others.

There was a lot of that about. Even Lord Bowden, the leading computer scientist who agreed to write the Preface to one of Michie's *Machine Intelligence* volumes, asked, "is this enterprise of yours part of the main stream development of computers, or is it merely an interesting, but irrelevant, side line?" (Bowden 1972, p. v). Michie may have regretted inviting him to contribute the Preface, for he went on to say:

> How far can computers be used to solve the apparently insoluble intellectual problems of the day? I have probably misunderstood your work, but I have been disheartened by some of the research in which your members are engaged. It is pressing against the limits of knowledge and this is splendid, but are you right to be so worried about problems which appear to me to be semantically significant rather than technically important, and philosophically interesting rather than economically useful? (Bowden 1972, p. viii)

As for using AI to help us understand the workings of the human mind/brain, such as the recognition of gestalts, he despaired: "Heaven knows these problems defy solution—why therefore should one expect that they can be studied or solved or practised by computers?" (p. ix).

Bowden wasn't complaining that NewFAI was doing its job badly, rather that it had chosen the wrong job to do. Psychology (or the imitation thereof), he believed, was beyond the remit of AI as an intellectual discipline. But many other computer scientists at that time were asking not so much whether AI was a discipline as whether AI workers were disciplined. That is, the doubts about hype and lack of self-criticism which Drew McDermott would later discuss (see 11.iii.a), and which would soon land Michie himself in very hot water (11.iv.a), were already bubbling beneath the surface.

Those doubts were still bubbling in the late 1970s, when a historian of AI was told by orthodox computer scientists that it's "a 'freaky', rather dubious fringe activity" (Fleck 1982: 207). And they're still bubbling now.

In 1996, for instance, the AAAI Fellows had an email debate about whether AI is "engineering" or "science". Some voted for the former, as Michie had done long ago. Simon's contribution was brief, and to the point. He referred his fellow Fellows to two very recent papers, including a "case-study" on creativity (Simon 1995*b*,*c*), and to his classic *Sciences of the Artificial* (1969; see especially chs. 1, 3, and 4). He insisted that—alongside its engineering aspects—"artificial intelligence is science". And he added testily, "I do think that members of the community who wish to discuss these matters have some responsibility for familiarity with the serious literature on the topic" (AAAI Fellows' email list, 22 May 1996).

Two years later, the editors of the 100th volume of *Artificial Intelligence* exulted that it had been firmly established as "a discipline" (Bobrow and Brady 1998*a*). It was now respected even by engineers, they said—adding that Sir James Lighthill had got his come-uppance at last (cf. 11.iv).

But this upbeat editorial carried a whiff of Hamlet's "Methinks the lady doth protest too much". Other remarks in their essay bemoaned the specialist splintering that was preventing NLP or vision research, for example, from being submitted to the core journal. This splintering soon brought complaints also from two presidents of the core society, AAAI. Ronald Brachman's Presidential Address in 2004 complained about the centrifugal tendencies of AI, and his successor, Mackworth, declared that "The way to overcome these centrifugal tendencies is to develop better theories of cognitive architecture and to work in integrated applications [i.e. GOFAIR: see Section iii.c above, and 11.iii.b]"—adding that AAAI was "needed more than ever", being "the premier venue for bringing together the subdisciplines" (Hedberg 2005: 12). (However, he's optimistic: "There was a lot of evidence [at the AAAI and IAAI meetings in 2005] that AI is in a healthy state, [with many] exciting new ideas and applications. Our field is reaching out to many related disciplines in a new way. That to me is a sign of maturity: we are no longer insecure as a discipline"—Hedberg 2005: 15.)

Besides their complaints about subdisciplinary splintering (and the profusion of subdisciplinary journals), the *Artificial Intelligence* journal editors even complained that too many papers were now purely mathematical, rather than implementational. In short, they were implying that some of their own colleagues didn't have a good sense of AI *as a discipline*. (Soon afterwards, they underlined the wide scope of current AI by reprinting the fourteen invited lectures from IJCAI-1997—ranging from Bayesian analysis and non-monotonic logic, through NLP, planning, and visual identification, to social robotics and creativity: Bobrow and Brady 1998*b*.)

Further evidence of continued bubbling comes from the delightful Father Hacker, who's still a regular contributor to the *AISB Newsletter/Quarterly*. A key item of advice in his recent 'Guide for the Young AI-Researcher' is this:

> The basis for your reputation is a notable piece of science or engineering, with which you are associated worldwide. But in this environmentally aware world, recycling will avoid unnecessary effort on your part. The recent history of AI is replete with the revival of old techniques (neural nets, genetic algorithms), rejected as unfeasibly inefficient in the Mid-Twentieth Century [see Chapters 12.iii and 15.vi.b], but given new life by Moore's Law [i.e. the inexorable growth of affordable computing power] in the Twenty First. A bit of historical research, plus some judicious renaming to place the old ideas in a modern context, will pay dividends. (*AISB Quarterly* 2003: 12)

If today's AI researchers aren't deliberately stealing and renaming old ideas, as Father Hacker advises, they are sometimes reinventing the wheel—and lack of historical knowledge doesn't help. For instance, 1980s–1990s work in machine learning often replayed insights available in traditional statistics (see 12.vi.f, and iii.f above); and the NewFAI researchers Michie and Gregory both said that the best model of the real world is the real world itself, long before the situated roboticists did (iii.b, above).

A related failing is AI's vulnerability to fashion—and to the uncollegial scorn that comes with it. Dissension, if not active scorn, has characterized AI almost since the beginning.

(AI isn't alone. Professional psychology, too, has long been subject to fashion and unpleasantness: see 7.vii.b and e. Anthropology has suffered dreadfully from professional dissent: see 8.i.d and ii.a–c. As for philosophy, that's not all sweetness and light either. Just look at Bertrand Russell's comments on Ludwig Wittgenstein's mature work, or at some of the epithets hurled at Heidegger by Anglophone philosophers: see Chapter 16.vii.a.)

Much of the rivalry within AI was due to the explanatory/methodological schism that developed in the 1950s (4.ix). The late 1960s scandal over perceptrons was just one high-visibility example (Chapter 12.iii).

One might have expected the dissension to have settled down by the mid-1980s. But when AI was already some 30 years old, Newell identified no fewer than thirty-six issues on which AI researchers had been divided, and in many cases still were (Newell 1983: 191). Worse, the division was often unscientific, not to say ungentlemanly. Newell lamented the "sloganeering character" of these disagreements (p. 189). And he complained bitterly about the disputatious tone of an anti-GOFAI paper published in the same volume, "written to accomplish science entirely by means of commentary" (p. 292).

Today, things are scarcely much better. As remarked in Chapter 4.ix.a, a recent AISB editor complained: "The lack of tolerance [between different research programmes in AI] is rarely positive, often absurd, and sometimes fanatical" (Whitby 2002*b*). The charge of *being ill-disciplined*, then, still has some force.

But the scepticism that Michie was seeking to counter may have been caused also by AI's use of two very different methodologies, symbolic and connectionist. Lee Cronbach, had he seen Michie's questions, might have replied that AI wasn't a "discipline" for that reason (see Chapter 7, preamble). Were he alive today, Cronbach would have been even more puzzled, for AI now involves evolutionary computing too—not to mention the so-called nouvelle AI of situated robotics and enactive perception (15.vii–viii and 7.v.e–f). Even though all of these are in principle compatible, individual AI scientists tend to choose one rather than another.

There was another worry, too. That reference to "the more peculiar parts of computer science" could be interpreted as referring to peculiar *topics*, not just peculiar (even ill-disciplined) *methods*. If AI was truly a discipline, what was it studying which wasn't better studied by some other part of computer science?

Nearly twenty years after Dale and Michie, on the occasion of the *Artificial Intelligence* journal's fifteenth birthday, a different editorial duo addressed much the same doubts. Bobrow and Hayes (1985) invited about twenty people to answer ten questions about the achievements of AI, including both GOFAI and connectionism. One of their ten queries asked whether it was a single discipline or just a miscellaneous collection of ideas about non-numerical computing. The unspoken implication was that these ideas were perhaps not only disparate, but largely half-baked and/or "pretentious" too.

In answer to the editors' questions, a number of leading AI experts said it *wasn't* a single discipline. For example:

> AI, broadly conceived, is just too large to be a single discipline—mainly because intelligent perception and behavior touch so many aspects of computer science, control theory, and signal processing theory. (Nils Nilsson, quoted in Bobrow and Hayes 1985: 376)

> If AI is a single discipline, it is more like Biology than Neuro-biology. It is inherently multi-disciplinary, and the more AI is applied the more disciplines will be involved. (Aaron Sloman, quoted in Bobrow and Hayes 1985: 377)

At the same time, some of the very same people said that there *was* a core discipline there. But this was identified in very different ways, sometimes as "declarative" GOFAI, sometimes much more broadly—as the intellectual core of cognitive science in general:

> [That] part of AI based on reasoning with declaratively represented knowledge (e.g. logical formulas) with semantic attachment to specialized procedures and data structures is a coherent field. I think it will inherit the name AI and continue to develop as the core discipline underlying intelligent mechanisms. (Nilsson, quoted in Bobrow and Hayes 1985: 377)

> There is a central coherent core of AI/Cognitive Science [*sic*] which is the systematic study of actual and possible intelligent systems. This seeks general principles, not just successful designs. (Sloman, quoted in Bobrow and Hayes 1985: 377)

Very few people, Sloman added, were working on that—"partly because it is the hardest part of AI, and has least short-term pay-off". (His own work, however, had already been focused on it for some years: Chapters 7.i.f and 16.ix.c.)

My own answer said, in part:

> AI suffers from some of the same problems as philosophy: it tackles the unanswered, or even the unanswerable, questions. As soon as it manages to find a fruitful way to answer one of them, the question gets hived off as a specialist sub-field. The special sciences started emerging from philosophy in the Renaissance. Specialist areas of study have been emerging from AI for only thirty years. But already we have distinctive sub-fields—such as pattern-recognition, image-processing, and rule-based systems. Their executors often speak of AI (if they speak of it at all) as something not quite respectable, something nasty in the woodshed that was once glimpsed but is better forgotten. What should not be forgotten is that the respectable topics were excluded from what people are prepared to call "AI" as soon as they became "respectable". (M. A. Boden, quoted in Bobrow and Hayes 1985: 376)

Today, some twenty years later still, I stand firm by that reply—except that I should have made it clearer that the "sub-fields" (and the discoveries) are often attributed to *computer science*, or to *software engineering*, not to AI itself. Time sharing, for instance, was developed by McCarthy, and so were fast-prototyping and data mining. But they're not usually thought of as having hailed from AI.

A proliferation of specialist journals has appeared since *Artificial Intelligence* first came off the press. New ones are founded with relentless regularity, accompanied by specialist (and sub-specialist . . .) conferences whose papers, and even whose CFPs (Calls for Papers), are nigh-unintelligible to all but dedicated experts. Computational methods are there being perfected, details added to answers, new questions raised—and, often, new applications made possible. It ought to be acknowledged, however, that the pioneering methods, questions, and answers came largely from AI.

Those questions for which reliable methods and answers haven't yet been found still lie within AI itself. Since they aren't yet well defined, it follows that—in a sense—AI *isn't* a proper discipline. But it doesn't follow that it's not worth pursuing. The very existence of so many specialist offshoots, in areas which initially would have been regarded as "peculiar", "pretentious", or even "freaky", shows the contrary.

Some philosophers, of course, argue that the central goals and assumptions of AI, and especially of strong AI (16.v.c), are fundamentally incoherent. If so, then strong AI certainly isn't a proper discipline—much as fairyology isn't, and couldn't be. On their view, it's *philosophically* pretentious, since it pretends to possess an explanatory potential which, in principle, it lacks. Whether that's true is explored throughout Chapter 16. But even if it is, it doesn't apply to most AI work—for most AI researchers avoid making claims about explaining or constituting "real" intelligence.

b. Has GOFAI failed?

The second hostile question often heard today is sometimes expressed in terms of "AI", but is often intended primarily for GOFAI. The charge is that AI has *failed*.

This charge was made by Dreyfus (hardly a disinterested witness), in his 1998 Houston University lecture on 'Why Symbolic AI Failed'. And a few years earlier, he'd said:

> Like the dissolution of the Soviet Union, the speed of *collapse* of the GOFAI research program has taken everyone, even those of us who expected it to happen sooner or later, by surprise. (H. L. Dreyfus 1992, p. xiv; italics added)

> The rationalist tradition [in philosophy] had finally been put to an empirical test, and it had *failed*. (H. L. Dreyfus and Dreyfus 1988: 34; italics added)

The connectionist Robert Hecht-Nielsen might not agree with Dreyfus about the philosophical "why", but he does agree with him about the practical verdict:

> [As] it turned out, this approach [GOFAI] *never amounted to much*—a realization which it took two decades and billions of dollars to establish and which did yield *a handful of valuable accidental discoveries*. (in J. A. Anderson and Rosenfeld 1998: 303; italics added)

A negative verdict is strongly implied, too, by Brooks—another non-disinterested witness—in his 1991 paper 'Intelligence Without Representation', which argued that GOFAI was/is fundamentally wrong-headed (Section iii.b, above, and Chapter 15.viii.a). Indeed, given the huge media publicity which Brooks's work attracted, his habit of using the term Artificial Intelligence to cover *only* GOFAI was partly responsible for the general belief today that AI has failed (see 1.iii.g).

Two of those three men have a numerous following, among the public as well as in cognitive science itself. The feminist Sarah Kember, for instance, cites Dreyfus with approval (though adds that he's "exceeded by Donna Haraway's formulation of situated knowledge"—Kember 2003: 9). She has sympathy for Brooks's approach, even though she accuses him of working "without any real regard to human implications, social and scientific applications or philosophy" (p. 69). Indeed, she devotes many pages of cultural commentary to celebrating the successes and potential of A-Life. In her mind, however, "AI" (i.e. GOFAI) is different: her opening page proclaims "the failure of AI as a project" as an apparently self-evident proposition.

So an opinion poll on the matter of AI's failure would have depressing results for GOFAI pollsters. However, people—even *most* people—can be wrong. Are they wrong, in this case?

If the measure of failure is whether AI has lived up to its most extravagant promises, then they're right: it's failed. The "world chess-champion by 1967" didn't happen (although a world-beater had emerged by 1997). And much of the connectionist hype that irritated Bernard Widrow (12.vii.b) hasn't been fulfilled either.

To be sure, if something hasn't happened yet it may happen tomorrow, or the day after. Undated promises must be treated with care. However, my own view—some AI colleagues would disagree—is that some promises won't be fulfilled for hundreds of years, if ever. Perfect, or anyway human-level excellent, translation is one example (9.iv.b and x.e).

Further 'failures' are doubtless in store—especially if we listen to the futurologists. One such, British Telecom's Ian Pearson, recently hit the headlines (see BBC Online, 18 January 2002: Sci Tech News). He predicted that by 2010 the first robot will have passed its GCSE exams, which British children take at age 16; A Levels (age 18) will follow a few years later, and the robot will be ready for its degree a few years after that.

This fantasy makes RoboCup's predictions of a world soccer champion by 2050 seem cautious by comparison (11.iii.b). The AISB journal editor judged it extraordinary that a professional within a high-tech company like BT should believe such nonsense, and I agree with him:

> It could be that BT has something very special in a secret lab somewhere. Then again, it could be that Mr. Pearson has based this prediction on observation of tealeaves rather than of robots. (Whitby 2002*a*)

(In Britain, reading the tea leaves left in someone's cup is the equivalent of Roman augurers' reading chicken bones. Unfortunately, this charming practice is dying out, because of the widespread use of teabags.)

But fulfilment of hyped-up promises isn't a reasonable criterion of success-or-failure. That's especially true, given that many (most?) people in the field didn't subscribe to them in the first place.

By the same token, 'passing the Turing Test' has never been an appropriate criterion of success in AI (see Chapter 16.ii.c). So the fact that—with a handful of (arguable) exceptions—it hasn't been passed is neither here nor there. Nevertheless, many people still assume that it's highly relevant. Dreyfus's 'Failure' lecture, for example, opened with a reference to Turing's remarks about human–computer indistinguishability by 2000.

Rather, we should ask whether AI—symbolic, connectionist, evolutionary, or situationist—has made significant progress towards the goals expressed in less careless moments. In Naudé's terminology (see Preface, preamble), we should credit AI researchers with a concern not for Magick but for Mathematicks, and ask how effective their Mathematicks has been.

To answer that question, we must recall the distinction between technological and psychological AI. The goal of the former was/is to build useful computer systems—doing or, as Minsky forecast in 'Steps' (10.i.g), *assisting with* tasks which humans want done. (One can't say "tasks which humans would otherwise have done", for some tasks can be performed only by means of huge computer power.) The goal of the latter is to develop explanatory theories of mind, and perhaps also (according to strong AI) to build computer systems that are genuinely intelligent in themselves.

As regards technological AI, the response to "Has AI failed?" must be a resounding "No!" Even though this book virtually ignores applications, a few are briefly mentioned. Examples include:

* software for translation (Chapter 9.ix.f) and speech generation (9.xi.g);
* computer vision techniques (7.v.c) and 'retinal' VLSI chips (12.v.f);

* expert systems in many different areas (10.iv.c and ii.b–c, above);
* Hollywood animation (15.ii.a and x.a);
* interface design (v, above);
* virtual reality systems (vi, above);
* computer-assisted and/or interactive art (iv and vi.c, above);
* robotic surgery (vi.b, above);
* and, regrettably, battlefield management and missile guidance (3.v.a, 4.vii.a, and 11.i).

A volume even longer than this one could be written about technological AI as a whole. Besides the many high-profile examples, it would have to mention the host of *invisible* AI applications, of which the general public aren't even aware. Sometimes they're invisible because the businesses that commissioned/built them regard them as trade secrets. More often, they're invisible because miniaturization, and sometimes wireless communication too, have made them so. Weiser, in his *Scientific American* article of 1991, spoke of "calm technology, when technology recedes into the background of our lives".

Even before the arrival of literally "ubiquitous" computing, AI already pervades our lives to an unrecognized degree. Everyone in industrial societies is surrounded by it: in the street, the office, the supermarket, the factory, the bank, the car, the airport, the home . . . and so on, ad nauseam. Try to launder money for the Mob, for example, and you may be caught out not by a detective but by a machine (Senator *et al.* 1995). Some of these AI systems are neural networks, like those used (unseen by their customers) by financial institutions of various kinds. Others are GOFAI programs, like those used (again, unseen) by insurance salesmen in telephone call centres.

Even when the public are aware that such programs are being used, they may not think of them as *examples of AI*:

> Knowledge-based systems have permeated almost all areas of modern life. Indeed this area of AI has been so successful that many people no longer associate it with AI. They simply see advice-giving as yet another thing that computers can do. That is, I suppose, the ultimate success for any branch of science. (Whitby 2004: 36)

We've seen, for instance, that the longed-for Semantic Web—typically regarded as a futuristic project *for computer science*—will require advances in ontology research (Section i.c, above). But work on computerized ontologies was pioneered by NewFAI, both for AI planning and for NLP. Indeed, this was a key theme of the seminal paper on 'Some Philosophical Problems' (Chapter 10.iii.e).

Besides specific application programs (many of which outperform human beings in their particular specialized task), a host of widely used computer technologies, not normally thought of as AI, actually originated in AI research:

> Work in AI has pioneered many ideas that have made their way back to mainstream computer science, including time sharing, interactive interpreters, personal computers with windows and mice, rapid development environments, the linked list data type, automatic storage management, and key concepts of symbolic, functional, dynamic, and object-oriented programming. (S. Russell and Norvig 2003: 15)

AI technologies underlie many Internet tools, such as search engines, recommender systems, and Web site construction systems. (S. Russell and Norvig 2003: 27)

[There are many] examples of AI technology that are now so pervasive that few people even realize they involve AI concepts. These include spreadsheets, speech recognizers, digital maps, and even the World Wide Web, which is just a large semantic network. (Pat Langley, email to AAAI Fellows, 14 August 1998; quoted by permission)

Video games and animated movies are using techniques developed in robotics. For example, path planning algorithms are used to move soldiers around in video games. [Added May 2004: Bodily control and perception algorithms are also being used to produce plausible characters in visual reality.] Machine vision techniques are also in use to search and index images in large databases such as the world wide web. (Matt Mason, email to AAAI Fellows, 17 August 1998; quoted by permission)

[User-friendly AI-based systems include] programs which can detect the presence of known or new viruses in computer programs; checkout scanners which can identify fruit and vegetables through the use of scent sensors; car navigation systems which can guide a driver to a desired destination; password authentication systems employing biometric typing information; ATM eyeprint machines for identity verification; and molecular breath analyzers which are capable of diagnosing lung cancer, stomach ulcers and other diseases. (Lofti Zadeh, email to AAAI Fellows, 17 August 1998; quoted by permission)

As two of those quotations point out, many of these things are thought of as "mainstream" computer science, not as AI at all. (This is yet another illustration of AI's successes being relabelled as belonging to some *other* discipline.) Sometimes, such relabellings are truly bizarre: an AI colleague of mine was recently astonished, and outraged, to be told by a professional computer scientist that "NLP isn't AI, it's computer science" (Sharon Wood, personal communication).

Sometimes, to be sure, there are disasters. The newspapers abound with horror stories about hugely expensive government software failing to do what it was intended to do. Nevertheless, the notion that AI, or even GOFAI, has failed as a *technological* enterprise is absurd. So also—IMHO, as they say on the emails—is Hecht-Nielsen's reference to "a handful of valuable accidental [GOFAI] discoveries".

More to the point, for our purposes, is the question whether *psychological* AI has failed. This can be posed with respect to both weak and strong AI. The success/failure of strong AI will be discussed in Chapter 16, so let's concentrate on weak AI here.

People often say that whereas connectionist AI has succeeded in helping theoretical psychologists, GOFAI hasn't. At best, they'll allow that GOFAI was historically significant, in encouraging psychologists of the 1960s–1970s to think computationally and to build computer models (Chapters 6.iii–iv and 7). Considered as psychology, they say, GOFAI has failed.

The Dreyfus brothers, for instance, declared in 1978 that "classical, symbol-based, AI appears more and more to be a perfect example of what Imre Lakatos [1970] has called a degenerating research-programme". And fourteen years later, Hubert Dreyfus repeated that charge almost word for word (1992, p. ix).

It's true that some psychological topics haven't been, and perhaps never can be, adequately addressed by hands-on GOFAI modelling or even by detailed computational theorizing. The identification of relevance (7.iii.d and 8.vi.c) is an example. Such topics are intractable because of the frame problem (10.iii.e and i–ii, above); the fuzziness of concepts (8.i.b, 9.x.d, and 12.x); cultural variations in language and custom (8.i and 9.iv.b); the highly idiosyncratic experience and world-knowledge of human individuals; and, not least, human *embodiment* (16.vii, and iii.b–c above).

Nevertheless, GOFAI modelling is still being used—sometimes alone, sometimes in hybrid systems—to develop theories of hypnosis (1.i.g); of absent-mindedness and pathological disturbances of everyday action (12.ix.b); of artistic and scientific creativity (iv, above); and of anxiety (7.i.f). And GOFAI ideas are helping us to explore the mental architecture of the mind as a whole (7.i.e–f and 12.iii.d). The people engaged in this work include clinical neurologists and psychologists as well as AI scientists, so it can't be dismissed as merely a fantasy of the nerds, nor even as pure (impractical) theory.

Indeed, we saw in Section iii.b and 12.viii–ix (and shall see again in 14.ix.b) that symbolic AI's methodological rivals—connectionism, situated AI/A-Life, and dynamical systems—can't cope with some phenomena that are crucial features of human psychology. Means–end planning, deliberate reasoning, and flexible thought using objective concepts are the prime examples. Philosophers such as Fodor, Kirsh, and more recently Samuels, despite the disagreements between them (over modularity for instance: 7.vi.d–e), have spelt out some of the reasons. Plenty of puzzles remain: SOAR, or the GOFAI aspects of ACT* (7.iv.b–c), haven't solved all the problems. But the point is that, *in principle*, some sort of GOFAI approach will be needed (as well as connectionist and situationist ideas) to understand the human mind. Clearly, then, the charge that GOFAI is "a degenerative research programme" is mistaken.

Blay Whitby has put it in a nutshell:

> A myth has developed that AI has failed as a research programme. This myth is prevalent *both inside and outside* AI and related scientific enterprises. In fact AI is a remarkably successful research programme which has delivered not only scientific insight but a great deal of useful technology. (Whitby 2004: 1; italics added)

He points out that GOFAI and connectionism alike have been—and are—useful, in both academia and the marketplace. Indeed, one very widely used commercial application, the UK's prizewinning Clementine data-mining system, relies on an amalgam of both methodologies—with evolutionary computing (15.vi) thrown in for good measure (Khabaza and Shearer 1995).

In sum, GOFAI hasn't "failed", and it hasn't ceased either. Today's AI champions can still produce defensive rhetoric that makes one wince:

> Researchers in AI have traditionally met problems of formulation joyfully, courageously, and proudly, accepting the severe risks ensuing from such exploratory work ... (Doyle and Dean 1997: 88)

(Entire boxfuls of medals couldn't do justice to such heroes!) But the same writers aren't going over the top when they say:

> As a field, AI embarks on the next fifty years excited about the prospects for progress, eager to work with other disciplines, and confident of its contributions, relevance, and centrality to computing research. (p. 99)

As Mark Twain might have said, the rumours of its death are greatly exaggerated.

14

FROM NEUROPHYSIOLOGY TO COMPUTATIONAL NEUROSCIENCE

In his peppery *Dictionary of Psychology* (1995), N. Stuart Sutherland said that cognitive science and neuroscience are ''almost mutually exclusive'' (see Chapter 1.ii.c). This was more than a little naughty. As an expert in vision and a friend and admirer of David Marr, and as a colleague of Albert Uttley, Sutherland knew very well how necessary that ''almost'' was. They'd long pointed out that a theory of the brain needs a theory of what it is that the brain is doing.

Alan Turing had said this long ago (in 1951), in a letter to the anatomist J. Z. Young:

> I am afraid I am very far from the stage where I feel inclined to start asking any anatomical questions. According to my notions of how to set about it, that will not occur until quite a late stage when I have a fairly definite theory about *how* things are done. (quoted in S. S. Turing 1959: 146; italics added)

That ''how'', of course, was a computational how. And the principle hadn't changed since 1951. By the time Sutherland made his remark, many psychologists had said the same thing (e.g. Mehler *et al.* 1984), and so had Chomsky, in 1965 (Chapter 7.iii.a). What's more, many neuroscientists agreed. Michael Gazzaniga (1939–), for instance, had recently insisted that ''neuroscience needed cognitive science . . . to attack the central integrative questions of mind–brain research'' (1988: 241).

This is a very general point. Even in GOFAI, as we saw in Chapter 10.v, what's usually of interest is the *virtual* machine defined by the programming language and/or the program, not the manufactured tin can which—in *physical* terms—is doing the work.

Sutherland's claim (in the same dictionary entry) that cognitive science concerns the brain's *software* and neuroscience its *hardware* also needed qualification. He himself had long rejected Hubert Dreyfus's view that ''we must leave the physical world to the physicists and neurophysiologists'', to the exclusion of AI (see Chapter 16.vii.a). On the contrary, he'd said, we need high-level (software) concepts to understand brains as well as computers:

> Understanding the workings of the brain also involves us in developing the appropriate concepts to summarise blocks of similar operations conducted by it and an appropriate language in which

such concepts can be embedded and manipulated . . . e.g. negative feedback, receptive field, iconic store, and so on . . . (N. S. Sutherland 1974: 265)

In short, it's not true that computation is irrelevant if we have the neuroscience (a claim made also by Dreyfus's Berkeley colleague John Searle—1992, ch. 10). For, so Sutherland was saying, the one is integral to the other.

If neuroscience looks at the brain (and the rest of the nervous system) and asks "What does this bit do?", *computational* neuroscience asks "How does it manage to do it?" And that "How?" is computational. As John Mayhew, another vision expert (and a follower of Marr: see Chapter 7.v.e), has put it:

Finding a cell that recognizes one's grandmother does not tell you very much more than you started with; after all, you know you can recognize your grandmother. What is needed is an answer to how you, or a cell, *or anything at all*, does it. The discovery of the cell tells one what does it, but not how it can be done. (Mayhew 1983: 214; italics added)

Even if the detailed wiring diagram is available, as it was for the cerebellum by the early 1960s (see Section iv.c), *what the wires are doing* may be unknown. The key questions concern what information is received and/or passed on by the cell or cell group, and how it's computed by them. Put another way, they concern "how electrical and chemical signals are used in the brain to represent and process information" (C. Koch and Segev 1989: 1).

The differences between the systems discussed in Chapter 12 and those described here are outlined in Section ii. Then, we'll look at some early examples of neuroscientific work driven by computational questions, though rarely aimed at implementation. Section iv explains how computational ideas helped inspire the discovery of feature-detectors. Section v outlines early models of specific parts of the brain (such as the reticular formation and the cerebellum), while Section vi considers some especially 'realistic' system-level simulations. The whole-animal approach of computational neuro-ethology is considered in Section vii.

Various examples and definitions of "representation" are discussed in Section viii, followed (in Section ix) by some common sources of scepticism about AI neuroscience. Lastly, in Sections x and xi, we'll ask whether cognitive neuroscience has moved us—or ever could move us—closer to an understanding of consciousness.

Before embarking on the substantive issues, however, let's look very briefly at the history of two labels.

14.i. Notes on Nomenclature

In one sense, the story told in this chapter is anachronistic. For I often use vocabulary that's relatively recent to describe work done many decades ago. That's deliberate, for I'm seeking to show the links, indeed the continuity, between that older work and what went on later.

Specifically, if you go back to read the neuroscientific literature published before the early 1960s, you won't find the word "neuroscience". And you won't find the phrase "computational neuroscience" until a quarter-century after that. (As for "cognitive neuroscience", those words first left the presses after the one and before the other: see Section x.b, below.)

a. The naming of neuroscience

Neurophysiology became computational before it became (i.e. before it was called) an aspect of neuroscience. When I was a medical student at Cambridge in the 1950s, some of our supervisors (notably Horace Barlow) were already starting to talk about neurones in informational terms. But the word "neuroscience" was never used. We spoke rather of neurophysiology and neuro-anatomy (hardly, yet, of neurochemistry) . . . and of clinical neurology, psychopathology, and psychiatry. Moreover, we thought of these as largely *distinct*, in practice if not in principle.

The new term was coined at MIT in the early 1960s by the neurochemist Francis Schmitt. (He also coined the term "information substances" twenty years later, to cover "a variety of transmitters, hormones, factors, and protein ligands": S. Beer 1999. That is, even at the level of the neurochemicals themselves, *messages* were deemed to be as important as molecules.)

Schmitt needed the new name for a nationwide project specifically aimed at uniting several sociologically distinct camps. He was bringing together at least half a dozen experimental scientific disciplines (ranging from molecules to behaviour), and clinical expertise too. As he recalls:

> [Now] in the 1990s such a program seems entirely reasonable, *but in the 1950s and 1960s it was not so*. The boundaries between the various biomedical disciplines . . . were clearly defined, particularly for didactic purposes in medical school curricula. Professionals in individual fields looked somewhat askance at experts in other fields who presumed to be knowledgeable also in theirs, as would certainly be the case in the new field I then had in mind. (Schmitt 1992: 1; italics added)

He took care to involve the US funding agencies right from the start—a wise move, given their crucial role as René Descartes's wealthy philanthropists enabling research to be done (2.ii.b–c). Soon, the new label gained international respectability, when the editor of *Nature* invited him to write a piece explaining just what "neuroscience" was (Schmitt 1992: 10).

The date of this multidisciplinary foundation was perhaps no accident, being determined not only on intellectual grounds (e.g. the recent advances in biochemistry and molecular genetics) but also by sociological factors. We saw in Chapter 1.iii.c–d that the general cultural challenge to formalist modernism in the 1960s involved an increased respect for concrete, situated, studies, including what had previously been sidelined as mere "applied" sciences (Toulmin 1999: 165). So perhaps Schmitt had sensed that the "pure" scientists were now more willing to listen to what the medics had to say, and to think of *their own* problems in practical, clinically oriented, terms.

The Society for Neuroscience was founded a few years later, when (according to its web site) "neuroscience barely existed as a separate discipline". Today, the SFN still makes a point of describing itself as a group of "basic scientists *and physicians*". Now, SFN has over 36,000 members. But when it began in 1970 there were only 200. And it was almost ten years after that before cognitive psychologists, as opposed to brain scientists, started to take *clinical* data really seriously (see Section xi.b, below).

Here as elsewhere, McCulloch had been an ambiguous figure. On the one hand, he was (for cognitive science) *the* seminal formalist. On the other hand, he'd always valued practical/therapeutic relevance as much as rigour, and many-methods rather than just one (see Chapter 4.ii–v). Some of the more orthodox, more modernist, scientists had been wary of him accordingly.

Perhaps encouraged by *Nature*'s interest, the new word caught on. The journal *Neuroscience* was founded in the mid-1970s. Twenty years later Sutherland (1995), acerbic as ever, defined the term as "a fashionable catch-all phrase that includes all disciplines that directly study the nervous system . . . and all that attempt to relate behaviour to the nervous system (e.g. physiological psychology)".

He explicitly contrasted it with cognitive science: "an equally fashionable term, comprising a set of disciplines that barely overlap with neuroscience". But this was misleading. The overlap, though admittedly limited (and viewed with suspicion by some: see Section viii.d, below), was by then significant. Indeed, it had been growing steadily for fifty years.

b. The computational species

Computational neuroscience, focusing on information processing, was pioneered at mid-century, as we'll see. But the name dates only from the early to mid-1980s.

Its first high-visibility usage was in a paper in *Science*, written by three leading cognitive scientists—drawn from neuroscience, connectionism, and philosophy (Sejnowski *et al.* 1988). They used it to cover any research on the brain and nervous system which asked computational questions and/or used computational modelling.

For example, it would cover research that asked *just how* cells in a monkey's temporal cortex could detect—i.e. compute—another monkey's face looking in a particular direction (see Section iv.d, below). Merely finding those cells (by experiments with micro-electrodes), without ever considering such questions, would be interesting. But, as Mayhew would be quick to point out, it wouldn't count as *computational* neuroscience.

But there are stricter definitions. Three years earlier, in 1985, Eric Schwartz wrote to a number of authors inviting them "to contribute to a book whose purpose was to define the term *computational neuroscience*" (E. L. Schwartz 1990, p. ix). The result was a 1987 symposium in California, followed by the promised book in 1990.

In explaining why he'd bothered to do this, Schwartz reported "violent turbulence over the past four decades" in the fortunes, and even the name, of the area he'd been working in. All the names he listed (*cybernetics*, *neural networks*, *brain theory*, *artificial intelligence*, *neural modelling*), he said, had been "abused, and none felt untainted for the present purpose" (p. ix). His preference, *computational neuroscience*, was described as "that area of overlap between neuroscience and computer science which required sufficient specialized expertise to justify a new subdiscipline". More particularly:

> computational neuroscience, then, is the problem area in which *difficult algorithmic or implementational questions are intimately related to the data of the nervous system*. The interplay of neural data and of computation and applied mathematics define the scope of this term. (E. L. Schwartz 1990, p. x)

Since Schwartz's definition specifically mentions difficult applied mathematics, it doesn't cover all of the work discussed in this chapter. Of course, what's difficult for one person may not be difficult for another. Nevertheless, the seminal research described in Sections iii–v below, even including Marr's early models of the cerebellum and hippocampus, doesn't fall under Schwartz's rubric. Nor does the early work in computational neuro-ethology (Section vii).

To refuse to regard any of that research as computational neuroscience, however, would be to lose sight of two key points. First, it would jettison Mayhew's important distinction between what-questions and how-questions. Second, it would obscure the historical connections between the relatively straightforward discussions of the 1950s–1960s and the (often fearsome) mathematics of neuroscientific research in the 1980s–1990s.

Accordingly, I'll rely on the more catholic definition given above. What's more, I'll interpret it so as to include approaches inspired by cybernetics and/or information theory (cf. 1.ii.a).

This chapter, then, narrates how purely biological neurophysiology and neuro-anatomy were joined by computational neuroscience. The plot of the story is concerned less with the specific discoveries that were made, fascinating though these are, than with the changes in *the sorts of question being asked*. Over the past sixty years, the central nervous system came to be appreciated not only as a biological organ but also as an informational/computational machine. Besides enriching neuroscience as such, this change made possible its growing rapprochement with psychology. Without it, neurophysiology would have remained outside cognitive science.

14.ii. Very Non-Neural Nets

The computational properties of neurones and cell assemblies were studied in very general terms by the connectionist AI/psychology described in Chapter 12. From the neuroscientist's point of view, that research had four major deficiencies: too neat, too simple, too few—and too dry.

a. Too neat

Connectionist AI tried to be neat, whereas the brain is likely to be messy. Connectionist learning rules, as we saw in Chapter 12, were valued for their increasing mathematical power and elegance. But this is largely irrelevant, from the neuroscientist's perspective.

Francis Crick (1916–2004) put it like this:

> [I] suspect that within most [connectionist] modellers a frustrated mathematician is trying to unfold his wings. It is not enough to make something that works. How much better if it can be shown to embody some powerful general principle for handling information, expressible in a deep mathematical form, if only to give an air of intellectual responsibility to an otherwise rather low-brow enterprise? (Crick 1989*a*: 132)

All very well, he continued, but evolution is a tinkerer, employing a ragbag of "slick tricks" rather than purist mathematical principles. And those tricks are what biologists want to identify:

> Why not look inside the brain, both to get new ideas and to test existing ones? The usual answer given by psychologists is that the details of the brain are so horrendously complicated that no

good will come of cramming one's head with that sort of information. To which the obvious reply is, "If it's as complicated as that, how do you hope to unscramble its workings by a purely black-box approach, by merely looking at its inputs and outputs?" (Crick 1989*a*: 132)

Crick himself was oversimplifying. Many neuroscientists value the mathematical elegance of computer models, if only in providing 'existence' proofs. Sometimes, they show that something broadly similar to a real neural network, *but even simpler*, can do very surprising things. For instance, an utterly random network—which the embryo brain is not—can self-organize into structures very like those found in real brains (see Sections vi.b, ix.a, and ix.c).

One can't deny, however, that over-fierce mathematics may put neuroscientists off. The history of the field would have been rather different if that weren't so (see Sections v.d, vi.a, viii.b, and ix.b). Nor can one deny that the more 'lifelike' a neural model gets, the less formally intelligible it may be. Large 'evolutionary' networks, for example, may embody clear rules (even Type-I theories *à la* Marr: see Chapter 7.iii.b), but their final state may be nearer to a Type-II theory—which is almost to say, no *theory* at all (see Section ix.d).

But Crick was right about the slick tricks. Various ecologically relevant feature-detectors found in crabs, frogs, and mammals are mentioned in Section iv, and other special-purpose mechanisms (in frogs and insects) are described in Section vii and Chapter 15.vii. Significantly, Walter Pitts—a mathematician—was *disappointed*, even *a little appalled*, by his seminal co-discovery of bug-detectors, because they weren't formally tractable (see Section iv.a).

b. Too simple

The second deficiency of connectionism was its unrealistic 'neurophysiology'. A connectionist unit—of whatever type—is a mythical beast, as elusive in the biological world as the gryphon. The computational power of a real neurone is closer to that of a complex artificial network, or even a small computer, than to a single network-element.

Real neurones aren't (or aren't just) components of logic gates: one cell may have thousands of possible outputs. As Crick (1989a) has remarked, there may be many glutamate receptors on a single neurone, whose number and locations are surely relevant but which are simply ignored by connectionists. And it was discovered in the mid-1980s that dendrites, of which a neurone can have many thousands, aren't passive conduits but dynamical transmitters (with varying conductance). It's even been suggested, on the basis of a simulation (McKenna 1994: 83), that *an individual dendrite* may be able to compute exclusive-or—which Frank Rosenblatt's perceptron couldn't do (Chapter 12.iii.b).

What counts as a 'plausible' model, of course, changes as our knowledge grows. Implausibility can vanish overnight. For instance, multiplication rules were included in artificial networks (12.v.e) to provide mathematical neatness, certainly not biological credibility. But in the mid-1990s, "multiplication synapses" were discovered in the brain (Elman *et al.* 1996: 105).

In addition, *time* matters in real brains. For example, there's a wide range of 'windows' (measured in milliseconds) during which two inputs can have a joint effect; and spiking frequencies may be more relevant than single spikes. Yet connectionist networks are typically time-less. (Some exceptions are discussed in Section ix.g.)

Furthermore, the most widely used connectionist learning rule—back propagation—is unrealistic. Synapses don't transmit in two directions.

c. Too few

The third drawback of connectionist AI concerned its less than generous 'anatomy'. Judged by the numbers of units, artificial neural networks were tiny by biological standards.

True, some biological species have only 302 neurones (see v.b, below). And some have specific networks with only thirty neurones or fewer, whose connections and patterns of excitability can be individually modelled. For instance, there are alternative simulations of the network that enables a sea slug (*Aplysia*) to swim away from danger (Getting 1989; Kleinfeld and Sompolinsky 1989).

But even insect brains are enormously larger than that (M. O'Shea, personal communication). The bee brain is estimated to have about 1 million neurones (plus perhaps 100 million glial cells). And some molluscs, namely octopodes, have insect-like numbers of neurones: hundreds of thousands, if not millions. This is due to their very advanced visual systems: lower molluscs, such as sea slugs, have only about 20,000–30,000. As for the human cerebral cortex, this has about 20,000 million neurones (i.e. 20 US billions), and the number of dendrites and synapses is orders of magnitude greater. The largest of today's artificial networks is puny, indeed microscopic, by comparison.

Admittedly, network models soon started growing. In the late 1960s, for example, a Hungarian researcher simulating the cerebellum achieved a huge jump in scale: from a network of 1,296 units to one of over 64,000 (see Section viii.b). By the mid-1970s, he was coping with more than 1,700,000 components. But even that number, impressive though it is, was niggardly alongside the cerebellum itself.

Moreover, these numbers *matter*. It's not good enough to say there are "many" neurones, each one with "many" synapses. To understand the functioning of a particular part of the brain, one often needs to know *just how many* (see Section v.c).

Even more to the point, the brain isn't a formless mass of identical cells. So building a super-duper-computer that matched the huge *numbers* wouldn't help much. The networks described in Chapter 12 were very rarely assigned to specific parts of the brain. The assumption seemed to be that a neurone is a neurone, is a neurone . . . But there are many (perhaps twenty-five) distinct types of neurone, with different locations and physiological—and computational—properties.

(The even more numerous glial cells, which outnumber the neurones by about 100:1, seem to have mainly structural/guiding and nutritive functions, not informational ones. For instance, some of them form the myelin that coats mature axons. However, there's recent evidence that they can modulate the responses of the neurones, so in that sense they play a computational role: M. O'Shea, personal communication. For more on neuromodulation, see Section ix.f, below.)

This anatomical diversity of the neuronal cells was already being noted at the beginning of the century (2.viii.c). Santiago Ramón y Cajal identified five types of cerebellar neurone (the Purkinje, basket, stellate, Golgi, and granule cells), and distinguished some of their interconnections (the mossy, climbing, and parallel fibres)—see Figures 2.1–2.3. That was the beginning of the anatomical work used to ground the modelling of the cerebellum seventy years later (Section v.c, below). Ramón y Cajal also showed that the retina contains several types of unit: rods, cones, bipolars, horizontals, amacrines, and ganglion cells (whose axons form the optic nerve).

Later, John Eccles and others combined microscopy with single-unit recording, making the anatomical complexity even clearer (2.viii.e). Under the microscope, the cortex has six layers. And single-cell recordings showed functional distinctions, too. Visual cortex, for instance, contains over fifty distinct areas or neurone groups, simultaneously processing many different features, such as colour, lightness, texture, depth, and shape (Zeki 1993). Today's functional map of the striate cortex is more complex than that of the London Underground.

Most AI connectionists ignored such facts. Even Carver Mead's VLSI chips (12.v.f) only *approximated* the real retina, cochlea, and cortex. So when connectionists boasted that their models were more biologically plausible than GOFAI, they should rather have said they were *less implausible*.

To be fair, some did. Warren McCulloch and Pitts themselves, in 1943, had admitted that their formal units and "temporal" expressions, or TPEs, were idealizations (4.iii.e). This was confirmed in the 1950s by work on stochastic firing, grounded in continuous synaptic variation that's independent of the input from other neurones. By the 1980s, the idealization had become even more evident (Perkel 1988). Indeed, the PDP bible included a chapter on how PDP units differ from real neurones (Crick and Asanuma 1986).

But most of the connectionists featured in Chapter 12 paid little or no attention to the brain *as such*. Here, we'll consider research using computational theories and/or computer modelling *to cast light on the nervous system itself*.

d. Too dry

Computational neuroscience aims to match the details of the software to specific aspects of the biological hardware—or, as it's sometimes called, the wetware. And "wetware" is often interpreted as *wireware*. Certainly, the computational neuroscientists discussed in this chapter concentrated on the detailed anatomical connections within the nervous system. They weren't concerned with chemical/biophysical properties. The "wetness" of real neurones was ignored: linkage was all. In that sense, they're 'connectionists' too.

Strictly, however, wetware includes more than wireware. For neuroscientists study not only the networks of neurones but also what they are made of, how they actually work. The Hodgkin–Huxley equations for the nervous impulse were an early example (2.viii.e).

Accordingly, some computational neuroscience looks *below* the neuronal level. (For some examples, see C. Koch and Segev 1989, chs. 2–5; Feng 2004, chs. 2–7.) This is a relatively recent development: wireware models came first, as we'll see.

By the 1990s, however, a few researchers were simulating the computational functions of membranes and dendritic spines, and the action of the calcium ion and neurotransmitters (e.g. C. Koch 1990, 1999; Gazzaniga 1995, pt. i). A specific Hebbian learning rule was modelled in terms of biophysically realistic data on the strength, and temporal properties, of synaptic currents and membrane potentials (Rao and Sejnowski 2001). And some computer models included the effects of neuromodulators, which can temporarily change a neurone's properties (Philippides *et al.* 1998).

Two interesting wetware examples are described in Section ix.f, below. One concerns the computer simulation of neurochemical modulation; the other seeks to produce non-linear computation by harnessing real chemicals and/or neurones to electronic circuits. With those exceptions, I'll consider only models of the wireware: theories at the level of neurones or large neurone groups. This is partly because wetware models are state of the art rather than historical, and partly because they are less relevant for cognitive science in general than wireware models are.

I'll also ignore 'neuro-informatics'. This deals with the wireware too. It applies computerized statistical analysis to huge data-banks of results, so as to discover possible structure–function relations in the brain. It's increasingly necessary, given the flood of neurological data. Over 14,000 reports of connections in the rat's brain, in over 900 separate papers, appeared between 1980 and 2000, since when there will have been many more (M. P. Young 2000: 3, 56). And then there's cats, and monkeys . . . Neuro-informatics may help inspire computational theories, by leading people to ask what the anatomical data *mean* in functional terms. But it's still in its infancy. The theories I'll discuss here weren't based on statistical data analysis, but on individual experiments and observations.

An objection often heard from the more traditional neuroscientists is that computer models are (to put it politely) of dubious value, because they hugely oversimplify the neurophysiology *even if* they attempt to take it on board. Indeed, we'll see that it took many years before such models were seriously regarded by professional brain scientists (v.d and vi.c, below). However, two leading computationalists, namely Christoph Koch and Idan Segev, have given this scepticism a suitable reply:

> One frequently hears the criticism that simplifying brain models lack this or the other physiological feature and are thus unbiological and irrelevant for understanding the nervous system. . . . This argument, taken to its extreme, implies that we will not be able to understand the brain until we have simulated it at the detailed biophysical level! . . . [But] such a simulation with a vast number of parameters will be as poorly understood as the brain itself. Furthermore, if modeling is a strategy developed precisely because the brain's complexity is an obstacle to understanding the principles governing brain function, then an argument insisting on complete biological fidelity is self-defeating. (C. Koch and Segev 1989: 2)

It's only recently that books have started to appear which try to take both low-level neurophysiology and high-level psychology seriously. Among the first, in the 1980s, were two by Stephen Grossberg, whose pioneering work is described in Section v. And in the 1990s, Arnold Trehub of UMass Amherst published a monograph describing computational theories (and models) of *planning* and *narrative comprehension* (Trehub 1991).

Trehub's theories of these higher mental processes are based on Hebbian learning constrained by detailed neural structures, and even by neurochemicals. The biophysical facts involved concern the mechanisms of long-term/short-term memory (e.g. ATF and DTF: axon and dendrite transfer factors), and the key neural structures are the "synaptic matrix" and the "retinoid". Trehub's claim is that these wetware matters mustn't be ignored, because they enable us to rule out a wide range of alternative cognitive hypotheses.

As for textbooks integrating connectionist modelling with real neuroscience, the first example came off the press at the turn of the century. Randall O'Reilly and Yuko Munakata, both ex-students of James McClelland (and now based at the University of Colorado), hoped to follow in their tutor's footsteps in more ways than one. For in their Preface, they said:

> Our objective in writing this text was to replicate the scope (and excitement) of the original PDP volumes in a more modern, integrated, and unified manner that more tightly related biology and cognition . . . (O'Reilly and Munakata 2000, p. xxv)

They didn't entirely succeed, for the "excitement" that had been aroused by the original PDP volumes had been so great that probably no one could have matched it (see 12.vi.a). For one thing, the new textbook wasn't aimed at the still-uncommitted student, as the PDP bible was. (Still less would it enthuse the journalists and the general public, as its predecessor did.) For another, O'Reilly and Munakata were doing something which very obviously needed to be done, whereas the PDP volumes had struck most readers as a bolt from the blue.

Nevertheless, their book was important, for it did—as they hoped—relate biology and cognition much more tightly together. O'Reilly and Munakata, and many of the computational researchers discussed by them, showed a healthy respect for the wetware. Neuroscientific findings, which in any case had ballooned since the mid-1980s, were taken on board wherever possible.

Their hope of replicating the "scope" of the PDP books was also fulfilled. For their discussions (and models) ranged psychologically from language, memory, and attention to specific learning rules, and biologically from large-scale brain anatomy to axons, ion channels, and membrane potentials. In short, their volume was not merely a textbook, but an interdisciplinary tour de force.

One way in which their text surpassed the first edition of the PDP equivalent was that they made available (on the Web) a powerful software tool with a detailed manual, and gave tutorial appendices in the printed text. In addition, they discussed many examples of psychological simulations developed by using this system.

They called it "Leabra": Local, Error-driven and Associative, Biologically Realistic Algorithm. The phrase "Error-driven and Associative" was code for the fact that Leabra combined both reinforcement and Hebbian "ft/wt" learning.

Like Allen Newell's SOAR and John R. Anderson's ACT* (see 7.iv.b–c), this was intended as a "unified" model of cognition. They shared Newell's view that a coherent unified model is much more difficult to produce, and therefore much more informative, than specialized theories of specific phenomena (p. 11). All areas of experimental/clinical psychology were supposed to be covered, in an integrated fashion.

Leabra drew on core theoretical insights from connectionist AI. But relevant aspects of neuroscience were included too—and given greater prominence. For example, the activation function controlling the spiking of the simulated neurones was only "occasionally" drawn from mathematical connectionism (p. 42). Usually, it was based on facts about the biological machinery for producing a spike (the sodium pump: see 2.viii.e). These included detailed data on ion channels, membrane potentials, conductance, leakages, and other electrical properties of nerve cells (pp. 32–48).

One might think that *from the psychologist's point of view* this was over-egging the pudding: surely such details can't be relevant for understanding high-level phenomena such as reading, word meaning, or memory?

O'Reilly and Munakata readily admitted that "higher levels of analysis . . . provide a more useful language for describing cognition" (p. 40). They pointed out, however, that the basic equations governing the activity of Leabra when it was simulating reading, or memory, or . . . weren't (except occasionally) picked out of an abstract connectionist mathematics. Rather, they were painstakingly drawn from detailed biophysical data. This was true, for instance, of the equation used in Leabra for integrating all the inputs into a neurone (see their explanation of equation 2.8 on pp. 37 ff.).

They drew the line at applying this equation "at every point along the dendrites and cell body of the neuron, along with additional equations that specify how the membrane potential spreads along neighbouring points of the neuron" (p. 38). They had no wish "to implement hundreds or thousands of equations to implement a single neuron", so used an approximating equation instead. But, characteristically, they provided references to other books which did explain how to implement such detailed single-neurone simulations (including the delightfully named *Book of GENESIS*: J. M. Bower and Beeman 1994).

In general, the psychological models developed by O'Reilly and Munakata would have been different had the neuroscientific data been different. Their discussion of dyslexia, for instance, built not only on previous connectionist work (e.g. Plaut and Shallice 1993; Plaut *et al.* 1996: see Chapter 12.ix.b), but also on recent clinical and neurological information (2000: 331–41).

As our knowledge of the brain advances (thanks to brain scanning, for example), future psychological models—they believe—will, or anyway should, be different again. They see their book as "a 'first draft' of a coherent framework for computational cognitive neuroscience" (p. 11). In short, the functionalist philosophers' "multiple realizability" is now under strong attack (16.iii). (It's under attack not only in 'human' neuroscience, but in neuro-ethology, too; indeed, the electric fish studied long ago by Lord Cavendish have prompted some strong arguments against it: Keeley 2000*a*.)

Even so, the computational level of theorizing is still crucial. Future researchers who follow O'Reilly and Munakata's lead—or who use Michael Arbib's NSL language to model macroscopic brain structures (see Section vii.c, below)—will *not* be fulfilling Wittgensteinian philosophers' hopes for "the disappearance of psychology as a discipline distinct from neurology" (Rorty 1979: 121). Or rather, they'll be doing so only if one interprets that word "distinct" to mean something like "paying no attention whatsoever to . . .". Indeed, the main theme of this chapter is that neurology itself has become more computational, more psychological.

This fact, combined with the demise of multiple realizability in its strong form, makes the demarcation between "psychology" and "neurology" more fuzzy than it used to be. But that's not to report, nor even to predict, the "disappearance" of psychology.

14.iii. In the Beginning

Detailed computational questions first arose in neurophysiology at around mid-century. McCulloch and Pitts, and Kenneth Craik too, had considered such questions in general terms in the 1940s. What was different in the early 1950s was that some people started using ideas from information theory and computing to help them study the neurophysiological nitty-gritty.

a. Computational questions

Even in the late 1940s and 1950s, when 'neuroscience' was still unheard of, people had already started to ask computational questions about specific aspects of the nervous system.

Their answers were rarely put in terms of implemented models, because computers were still primitive. But the notion that the brain (with the sense organs) is an information-processing machine, whether digital or analogue, was being taken seriously by a diverse group of people:

* by neurophysiologists such as McCulloch, Barlow, and Jerome Lettvin;
* by cyberneticians such as William Ross Ashby;
* by physiological psychologists such as Uttley;
* by psychologists with a strong engineering bent, such as Craik and Richard Gregory;
* and by computer scientists such as Turing and Oliver Selfridge.

Moreover, these people were now talking to each other. This was new. Before the Second World War, and excepting the leaders of the cybernetics community discussed in Chapter 4 (including Nicholas Rashevsky's group for mathematical biophysics), there hadn't been much interchange between psychologists and physiologists.

Admittedly, Charles Sherrington himself had joined the British Psychological Society on its foundation, and contributed a paper (on binocular flicker) to the first issue of its journal in 1904. But this was more an expression of hope and encouragement than a mark of central research activity. Behaviourism treated the brain as a black box, and Gestalt psychologists had little constructive to say about it. Freudians and Piagetians, even less. Only William McDougall had made a concerted effort to bring the two disciplines together, and he didn't get very far.

What brought brain and behaviour—and computers—closer together was the challenge set by the war (see 4.vi–viii and 11.i). Craik and Frederic Bartlett, for example, were closely involved (even before war was officially declared) in applying psychology to various tasks undertaken by servicemen. And most members of the interdisciplinary Ratio Club of the 1950s (4.viii and 12.ii.c) had been involved in the war effort as very young men, cooperating across disciplines to study not only radar, sonar, and radio, but also a wide range of machines *and* their human operators.

Turing's war work had nothing to do with physiology, or psychology either (3.v.d). But we saw in Chapter 12.i.b that he was thinking about neural networks by the mid-1940s and gave a brief description of "cortex" in his NPL report of 1947. However, his account of the brain, and of the "pleasure–pain systems" that might "organize" the cortex, was brief—and very general:

Many parts of a man's brain are definite nerve circuits required for quite definite purposes. Examples of these are the "centres" which control respiration, sneezing, following moving objects with the eyes, etc.: all the reflexes proper (not "conditioned") are due to the activities of these definite structures in the brain. Likewise the apparatus for the more elementary analysis of shapes and sounds probably comes into this category. But the more intellectual activities of the brain [such as speaking English or French] are too varied to be managed on this basis . . . We believe then that there are large parts of the brain, chiefly in the cortex, whose function is largely indeterminate. (A. M. Turing 1947*b*: 16)

Turing's notional neuroscience had little or no influence. The 1947 report remained unpublished until 1969, and Turing himself soon turned from cortex to embryology (Chapter 15.iv). When invited to give a talk to the Ratio Club he spoke first on AI and later on morphogenesis, not on brains (H. B. Barlow, personal communication).

While Turing was writing his NPL report, Pitts and McCulloch (1947) were thinking about the brain in much more detail. Their earlier, 'logical', paper of 1943 is accepted by neuroscientists today as "one of the great boosters of modern brain science" (Braitenberg 1984: 108). It had been based on the recent discoveries about synaptic activity, which would soon be confirmed by work on cell membranes and neurotransmitters (Hodgkin and Huxley 1952; Eccles 1953, 1964).

But it had ignored both the 'noise' in the nervous system and its neuro-anatomy. The computational/statistical aspects of their 1947 theory dealt with the noise, and were outlined in Chapter 12.i.b. Here, our interest is in what they said about the anatomy.

The first point to note is that they said anything about it at all. Their opening sentences put the goal and justification of computational neuroscience in a nutshell:

To demonstrate existential consequences of known characters of neurons, any theoretically conceivable net embodying the possibility will serve. It is equally legitimate to have every net accompanied by anatomical directions as to where to record the action of its supposed components, for experiment will serve to eliminate those which do not fit the facts. (Pitts and McCulloch 1947: 46)

In other words, abstract networks such as those discussed in Chapter 12 are worth discussing, but one can also try to map them onto real brains—in which case one is generating empirical hypotheses that can help brain science to advance.

Ashby, to be sure, had said the same sort of thing (4.vii.c–d). But Pitts and McCulloch were more specific than Ashby in their suggestions about *just which* cells might be doing *just what*. In their words: "We endeavor particularly to find those [net designs] which fit the histology and physiology of the actual structure" (p. 47).

They dismissed Gestalt theories of brain–world isomorphism, seeing them as hand-waving. The Gestaltists relied on some mysterious pre-established harmony (which they *did not* explain in evolutionary terms), and didn't seriously consider how the brain can identify and represent percepts/concepts. That was what Pitts and McCulloch wanted to explain.

They rejected what was later termed the grandmother cell theory, because (for example) a square could conceivably be represented by spatio-temporal averaging over a "mosaic" of cells:

[For this reason, we disagree with] the neurologists of the school of Hughlings Jackson, who must have it fed to some specialized neuron whose business is, say, the reading of squares. That language in which information is communicated to the homunculus who sits always beyond any incomplete analysis of sensory mechanisms and before any analysis of motor ones neither needs to be nor is apt to be built on the plan of those languages men use toward one another. (p. 56)

In short, *one concept*, *one cell* is both unnecessary and implausible (see Section ix.e).

Their hypothetical representation of a square, they said, might be thought to arise in a brain area one level up from Area 17. But in fact, it didn't:

A square in the visual field, as it moved in and out in successive constrictions and dilatations in Area 17, would trace out four spokes radiating from a common center *upon the recipient mosaic*. This four-spoked form, not at all like a square, would then be the size-invariant figure of square. *In fact, Area 18 does not act like this*, for during stimulation of a single spot in the parastriate cortex, human patients report perceiving complete and well-defined objects, but without definite size or position, much as in ordinary visual mental imagery. *This is why we have situated the [computational] mechanism . . . in Area 17, instead of later in the visual system*. (pp. 55–6; italics added)

Other neural hypotheses attributed temporal "scanning"—supposedly involving the alpha waves—to a specific brain area (the stripe of Gennari), and even to particular types of neurone within that layer. Similarly, they described the gaze reflex as a "servo-mechanism" (*sic*) wherein the superior colliculus "computes by double integration the lateral and vertical coordinates of the 'center of gravity of the distribution of brightness' ", and sends impulses to the eye muscles so that the eyes turn towards the centre of gravity, gradually slow down, and stop when it's fixated. Claiming "considerable support for this conjecture in the profuse anatomical and physiological literature", they related the computations supposedly involved (expressed as mathematical equations) to particular laminae within the colliculus.

The issue, here, is not whether their suggestions were correct. Indeed, their more specific hypotheses were highly provisional: "It is evident that many details of [the] hypothetical nets of this paper might be chosen in several ways with equal reason; we have only taken the most likely in the light of present knowledge" (p. 54). But the general potential was clear:

We have focussed our attention on particular hypothetical mechanisms in order to reach explicit notions about them which guide *both histological studies and experiment*. If mistaken, they still present the possible kinds of hypothetical mechanisms and the general character of circuits which recognize universals, and give practical methods for their design. (p. 65; italics added)

And, quite apart from the contingent neuro-anatomy, they claimed to have established a mathematical principle covering the design of neural networks in general:

These procedures are a systematic development of the conception of reverberating neuronal chains, which themselves, in preserving the sequence of events while forgetting their time of happening, are abstracted universals of a kind. Our circuits extend the abstraction to a wide range of properties. By systematic use of the principle of the exchangeability of time and space [see Chapter 12.i.c], we have enlarged the realm enormously. (p. 65)

By implication, biologists would do well to remember that natural selection might have discovered this principle too, exploiting it in various ways within real nervous systems.

As for whether 'the facts' confirmed Pitts and McCulloch's theories, the jury is still out. Intracerebral EEG scanning is no longer accepted, but some of the processes they ascribed to visual cortex may actually go on there.

(In the Introduction to his *Cybernetics*, Norbert Wiener reported, with no little satisfaction, that the leading neurophysiologist Gerhardt von Bonin, on catching sight of the Pitts–McCulloch paper lying on his desk, had immediately asked him: "Is this a diagram of the fourth layer of the visual cortex of the brain?"—Wiener 1948: 22. In truth, it was a diagram of the abstract architecture of their computational theory, not of the brain as such. But the similarities were hardly surprising, and Wiener's satisfaction scantly justified, since their theory had been inspired by the neuro-anatomy in the first place.)

Current biologically informed models of "how we see universals" are hugely more subtle and complex (see Sections vi–vii, below). Nevertheless, Pitts and McCulloch had made the first serious attempt to locate specific computational functions in particular cell groups in the brain. As Christopher Longuet-Higgins said in a different context (12.v.c), "a demonstration of how something could possibly happen . . . may be almost as welcome as the discovery of how it actually does happen".

McCulloch, neuroscientist though he was, would have agreed. According to his close colleague Lettvin, he himself had little desire to test his new theories by the traditional methods. To be sure, he and Lettvin would co-author an experimental report ten years later that ruled out one of the mechanisms he'd posited in 1947 (Lettvin *et al.* 1959: 253). But McCulloch's general attitude to experimental neuroscience had turned to disappointment. He now preferred an unconfirmed but mathematically coherent theory to a ragbag of empirical facts:

> [By the mid-1950s] he was dedicated to knowing how the brain works in the way that the creator of any machine knows its workings. The key to such knowledge is not to analyze observation but to create a model and then compare it with observation by mapping. But the poiesis must come first, and McCulloch would rather have failed in trying to create a brain than to have succeeded in describing an existing one more fully. (J. Y. Lettvin, in Dupuy 2000: 137)

Another person newly critical of the traditional methods of neuroscience was Gregory, who'd worked on the development of radar in the war. At Uttley's NPL meeting on 'The Mechanization of Thought Processes', and in a discussion in Cambridge a few years later, he caused no little consternation by giving an engineer's perspective on brain ablation studies (Gregory 1959, 1961).

His critique was based in his understanding of complex systems—such as a radio set:

> Suppose that when [a] condenser breaks down, the set emits howls. Do we argue that the normal function of the condenser is to inhibit howling? Surely not. The condenser's abnormally low resistance has changed the system as a whole, and the system may exhibit new behaviour, in this case howling. (Gregory 1959: 678)

What's needed instead is a theoretical model of how the brain is working (and what it's doing), in terms of which the data can be interpreted. This applied also, he said, to experiments based on electrical stimulation; but ablation studies had led to especially shaky inferences.

Gregory was—and still is—sometimes accused of having "made clear [that] neuroanatomical investigations would have to be abandoned in favour of the electrical models pioneered by Craik and Ashby" (Hayward 2001*b*: 304). This is nonsense. He didn't rule out neuro-anatomical investigations, nor even ablation experiments. Rather, he used a cybernetic argument to warn against simplistic interpretations of them.

Even in the twenty-first century, such warnings are sometimes necessary. Several have been issued recently, applying to "double dissociations" in clinical cases, to animal experiments, and to studies of deficits in vision, face recognition, and dyslexia (M. P. Young *et al.* 2000; Shallice 1988*a*, chs. 10–11; McClelland 2000, pp. xxi–xxii). McClelland, for instance, puts it like this:

> [An] explicit computational perspective often leads to new ways of understanding observed [neuropsychological] phenomena that are apparently not always accessible to *those who seek to identify subsystems without giving detailed consideration to the mechanisms involved*. . . . [Several examples illustrate that] the inference from data to the modular architecture of the mind is not at all straightforward, and that explicit computational models can provide alternatives to what in some cases appears to be *a fairly simplistic reification of task or item differences into cognitive modules*, and in other cases manifests as *a reification of types of errors (semantic, visual) into lesion [sites]*. (McClelland 2000, pp. xxi, xxii; italics added)

So Gregory shouldn't be accused either of saying that brain ablation is a waste of time, or of issuing unnecessary warnings about reification. As a historical point, however, his strictures may have helped fuel the resentment of those brain scientists who later criticized the hype attending AI models in general, and simplistic 'brainlike' networks in particular (see Section vi.c).

b. Computations in the brain

By the early 1950s, and partly because of McCulloch and Pitts' two papers, more neurophysiologists were thinking about neural functions in informational/computational terms. One of these was Uttley (who *did* combine them with traditional experimental methods, as we'll see).

As explained in Chapter 12.ii.c, he was already using Claude Shannon's theory of information to describe neuronal function, and to design computer models. His "informon theory", developed through the 1960s and 1970s, represented synapses as calculating and communicating information—and also made various suggestions about the neurophysiology involved (Uttley 1975, 1979).

Uttley defined synaptic conductivity in terms of average impulse (spiking) frequencies, changes in which were the physical basis of learning. And he argued that synapses must contain three distinct counters, probably implemented as three neurochemicals of varying concentrations, in order to estimate the probability of co-occurrence of pre- and post-synaptic impulses. It is because these counters have to sample over time, and are imperfect ("leaky") anyway, that learning takes many minutes or even hours. (Long-term memory, he suggested, requires a second mechanism, involving some near-irreversible chemical process that fixes the short-term memory.)

He argued, too, that negative feedback from inhibitory neurones is needed to stabilize conductivities. Synapses are essentially variable, nevertheless, so learning is complemented by forgetting (extinction):

> The reinforcing signal to an informon corresponds to the unconditioned stimulus which reinforces a conditioned stimulus in animal learning experiments; without such a reinforcing signal synaptic conductivity decays; correspondingly an animal forgets what it has learned. (Uttley 1982: 30)

Remembering, on this theory, isn't threatened only by confusion, where one and the same neurone group is asked to store too many different representations (cf. Chapter 12.v.c–f). Even a single memory would decay in the absence of continual reinforcement.

Uttley actually designed a dynamic computer memory based on this principle. A photocell looked at a cathode-ray tube screen displaying the output, and its signal went through a mercury delay line to the CRT input. This feedback loop continually refreshed the CRT image, maintaining the dots on the screen (R. L. Gregory, personal communication).

He even tried to provide new data, collaborating on various experimental studies of synaptic conductivity. Some of these were done with Benedict Delisle Burns, who'd argued (in the 1950s) that some synapses must have more complex properties than current models of learning allowed (Delisle Burns 1958: 96 ff.). Part of Delisle Burns's reasoning was based on the recent discovery of noise in the nervous system, which moved neurophysiology from deterministic ('telephone exchange') to stochastic theories (see 2.viii.f).

Uttley's work reflected this new approach. He tried to explain why (as he put it) "the brain ticks by itself", and to clarify the functional implications. And he offered accounts—and simulations—of the action of specific cells, such as the basket and granule cells of the hippocampus and the orientation detectors in visual cortex (discovered in the late 1950s: see Section iv.b). For instance, he modelled the newborn kitten's (fairly poor) 'innate' orientation detectors, and the learning processes that improve these networks as the kitten encounters straight lines and boundaries. (As for whether these detectors really were *innate*, see Section x.a and c, below.)

In short, Uttley made a serious attempt to take account of the neurophysiological data, in considering the different *types* of synapse that might exist in the brain. His early work was described as "an invaluable contribution to the study of learning in animals" (Delisle Burns 1968: 151).

One young neurophysiologist strongly influenced in the 1950s by Uttley's use of information theory was his fellow Ratio member Barlow (1921–), a great-grandson of Charles Darwin. Indeed, Barlow now says, "I was very fortunate to have belonged to [the Ratio Club], for when I come to think about it I can see that much of what I've been interested in since has stemmed from those evenings" (personal communication). Others included Patrick Merton, also a Ratio member (see Chapter 12.ii.c), and Jack Cowan. Cowan went from Imperial College to spend a year with Uttley at NPL before moving to Chicago to direct Rashevsky's group (12.ii.b).

Barlow was then a researcher at the University of Cambridge (and a Royal Society Research Professor there, years later). He first outlined his hugely influential "coding" theory of perception at the same two meetings where Gregory had ridiculed howl-inhibitors (Barlow 1959, 1961).

He cited Craik (see Chapter 4.vi), saying that the brain must build a "model" of the external world, which can be used to guide appropriate behaviour (1959: 542). He wanted to show what such an internal model must be like, and how it might actually be built. So, borrowing Shannon's idea of optimal coding, he asked how a machine might be designed to reduce redundancy when recording sensory information. In other words, how can a machine—or a nervous system—find simplicity in complexity?

Low-level perceptual systems (such as the retina), said Barlow, appear to possess *built-in* mechanisms for doing this with respect to types of redundancy that are always present in the environment. But high-level perception—of one's grandmother, for instance (though Barlow didn't mention that example)—requires that the nervous system be able to *learn* to reduce the relevant redundancies. This, he argued, must involve changes in nerve signalling rather than neurone numbers:

> In the nervous system the number of nerve fibres available for a specific task must, to a large extent, be determined genetically. One may expect evolutionary adaptation to have performed part of the [communication] engineer's job in selecting codes for the sensory signals, but such inherited codes obviously cannot be adapted to the redundancy of sensory input which is peculiar to each individual. Now although the number of nerve cells available is probably determined genetically, the number of impulses in the nerve cells is not, and some of the advantages of optimal coding would apply if the incoming information were coded—not onto the smallest possible number of nerve fibres each working at its optimal mean frequency—but into the smallest possible number of impulses in a relatively fixed number of nerves. This type of coding can be epitomized as *economy of impulses*. (Barlow 1959: 550)

Barlow was more interested in how perceptual redundancies, or patterns, could be recognized than in how they might be learnt. So he offered no learning rules. Nor did he claim that optimal coding had been 'proved' to happen. But he did give neurophysiological evidence for it, including experiments on adaptation and lateral inhibition—in vision, hearing, and touch. These showed that spiking frequencies can depend on specific neuronal mechanisms—such as the ON–OFF/movement receptors he himself had recently found in the frog's retina (Barlow 1953).

(A few years later, he would discover *directional* detectors in the rabbit's retina—Barlow *et al.* 1964; Barlow and Levick 1965. Again, he asked just what information was being computed, and how. And he showed how inhibition of one cell by another functions in the discrimination of direction of motion.)

As for intelligence, a word that "was added to the title in an incautious moment", Barlow saw this as largely continuous with perception. Concepts are relatively high-level input redundancies, and reasoning is based in redundancies too:

> [When] one considers the two main operations required for optimal coding there is a striking parallel with the two types of reasoning which underlie intelligence.
>
> The outputs of a code can be thought of as logical statements about the input, and, if the code is reversible [in a sense explained in his paper], these logical statements, taken together, are sufficient to determine the exact input. Forming these statements and ensuring that they fulfil this condition are straightforward problems of deductive logic . . . [As for inductive reasoning, this depends] on counting frequencies of occurrence of events. Having been presented with 1000

white swans and no black ones, the relevant parts of a code would say "henceforth regard all swans as white unless told otherwise". Inductively one would say "All swans are white." *The tools of logical reasoning appear to be the same as those needed for optimal coding*, so perhaps they can be regarded as the verbal expression of rules for handling facts which our nervous system uses *constantly and automatically* to reduce the barrage of sensory impulses to useable proportions. (1959: 555; italics added)

The emphasis in Barlow's coding theory, as in Uttley's work, was on the brain's measurement and comparison of the *probabilities* of stimuli. This approach, Barlow has recently recalled, fell into the background for many years while people focused instead on how the brain generates *transformations* of physical stimuli (Barlow 2001*b*). But the original emphasis, he now thinks, was sound. Although earlier theories of perception were "wrong in over-emphasizing the role of compressive coding and economy in neuron numbers", they were "right in drawing attention to the importance of redundancy" (see Section ix.e, below).

In short, "Think probabilities":

In any [perceptual] representation probabilities are key elements, because they are the fuel for accurate decision making. *So the take-home message for the neuroscientist should be: "Think probabilities*: What probabilities are needed? How are they represented? How are they estimated? How are they modified? How are they transmitted to other places in the brain? And how are they combined for making the moderately rational decisions that we observe brains making[?]" (Barlow 2001*b*: 251; italics added)

(As we saw in Chapter 12.vi.f and ix.d, "thinking probabilities" is just what the mathematical connectionists had been doing.) Barlow still recognizes his fifty-year debt to Uttley, whose name is one of nine mentioned in the Acknowledgments of his 2001*b* paper.

c. Formal synapses

One of Barlow's colleagues at Cambridge—and at the Ratio Club—was the physiologist Giles Brindley, who worked there until moving to London in 1968. In the 1960s, Brindley developed a formal theory of "modifiable" synapses. And Mayhew would have been happy, for Brindley was asking *just how* learning can be achieved by the brain.

Specifically, he was asking—as Uttley (also a Ratio member) had done before him—(1) what different types of synapse might exist, and (2) how their computational properties compared.

Brindley started from Donald Hebb's (1949) hypothesis about learning (5.iv.b). But Hebb's ideas had been expressed verbally, not mathematically, and Brindley (1967) pointed out that they could cover many distinct types of synaptic change. For instance, the neurones involved might be excitatory or inhibitory, and the modification might affect the pre-synaptic and/or post-synaptic cells. So several "Hebbian" learning rules were conceivable. Indeed, four had been described already (though only one had been defined formally).

Brindley suggested that different types of observable behaviour—such as classical and operant conditioning—might involve different learning rules. And if forgetting was to be explained, then extinction rules were needed too. Rashevsky's journal had reported a model of Pavlovian conditioning as early as 1950, but it hadn't allowed for extinction.

By exploring the possible combinations, Brindley defined ten types of synaptic modification. He showed that their logical input–output relations fell into three classes: A, B, and C. (The crucial question was whether the set-theoretic intersection of the two inputs was equal to one of them, or zero, or neither.) Six of the ten synapses were class A, three B, and one C. And these classes were systematically related:

> [Any] two members of the same class can, with the aid of non-remembering elements that perform simple logical operations [i.e. McCulloch–Pitts neurones combined as *and*, *or*, and *and-not* logic gates], replace one another in any net; but a member of class A cannot replace one of class B or C. A member of class B can replace one of class A or C only if non-logical elements, for example noise generators, are included in the net. (Brindley 1967: 361)

In effect, Brindley was giving a computational justification for the newly discovered noise in the nervous system (Delisle Burns 1968).

A mathematical Appendix described a wider range of modifiable synapses. These involved multiple inputs, closed (re-excitatory) loops, and temporal summation. They, too, could be formally classified in terms of their input–output relations.

Using this classification, Brindley designed (pencil-and-paper) models supporting different types of learning—such as classical and operant conditioning, both with and without extinction. His network for *classical conditioning with extinction*, for instance, used two modifiable synapses, the first of class B and the second of class A (p. 367). This was no accident, for he proved that if extinction was to be modelled at all then "classical conditioning *requires* modifiable synapses of classes A and B or of class C, and operant conditioning of class B or C" (p. 361; italics added). It followed that if Hebbian synapses are indeed involved in storing learnt information, then some of the nervous system's modifiable synapses *must* be of class B or C.

One methodological moral was that computational arguments based on the behaviour of the whole nervous system can't tell us just which synapses are present. For there are "a number of quite different but roughly equally plausible kinds of modifiable synapses that will do the same things (i.e. perform the same computations) in networks of nearly the same complexity" (p. 365).

But such arguments can suggest hypotheses about which *classes* of synapse are present, in what proportions. They prove, for example, that it is "uneconomical to use class B synapses to produce a class-A input–output relation, and infinitely uneconomical to do the reverse". And since the nervous system as a whole can exhibit class B input–output relations, it must (as noted above) involve synapses of class B or C.

In a follow-up paper, Brindley (1969) discussed the construction of much larger networks, in which only a few simple details need to be accurately specified and which can learn indefinitely many different things. (All previous models had been devoted to a single learning task.) And the *numbers* of neurones now entered the picture:

> The number of cells required for performing tasks of the kind considered [e.g. verbal rote learning] as well as the human brain can perform them, is only a small fraction of the number of cells in the brain.
>
> [The] models proposed [here] are likely to be the most economical possible for their tasks, components and constructional constraints, and . . . any others that approach them in economy

must share with them certain observable features, in particular an abundance of cells with many independent inputs and low thresholds. (Brindley 1969: 173)

Various experimentally testable predictions about synapses and cell numbers could be generated accordingly. In other words, this computational approach not only 'made sense' of the brain, but promised to help illuminate its detailed structure.

Among those whom Brindley acknowledged at the end of his 1969 paper were Barlow (already widely respected) and two unknowns: his students Stephen Blomfield and Marr. As we'll see in Section v.c, Marr was soon to publish the first formal theory of the brain *as such*. Eventually, because of his later research (on vision), he would become a household name for cognitive scientists in general. Brindley, by contrast, remained largely unknown.

But his work had been crucial. It confirmed what McCulloch, Uttley, Barlow, and Gregory had already argued: that *traditional neuro-anatomy must be combined with computational analysis*, if the nervous system is to be understood.

14.iv. A Fistful of Feature-Detectors

If Barlow's theory of perceptual coding was important for the rise of computational neuroscience, so was his practical work. Indeed, some of his early experiments led indirectly to perhaps the most famous paper (and certainly the best title) in the field.

Neurophysiologists had known since the late 1930s, thanks to Keffer Hartline at Rockefeller University, that some retinal cells in frogs aren't mere passive receptors of points of light. Rather, they respond to simple patterns of illumination: ON, OFF, or ON–OFF (Hartline 1938). In the early 1950s, Barlow reported in the *Journal of Physiology* that such cells are more sensitive to edges (light contours) than to unstructured light, and that the ON–OFF variety are especially sensitive to movement (Barlow 1953). Half-jokingly, he even called these cells "bug detectors".

In 1959 that term would start to ring still-resounding bells.

a. Bug-detectors

Most people today associate bug-detectors not with Barlow, but with the four authors of 'What the Frog's Eye Tells the Frog's Brain': Lettvin, Humberto Maturana, McCulloch, and Pitts (1959).

McCulloch had been a founder of the cybernetics movement (4.v–vi), and the 'Frog's Eye' work was done at the hub of cybernetics: MIT. So it's prima facie not surprising that although three of the four authors were neuroscientists, the paper appeared—like many 'cognitive' pieces at that time—in a journal officially aimed not at biologists but at radio engineers. However, this didn't happen by choice. Lettvin remarked in a lecture, years later, that they'd tried to get the paper published in several biological journals but were "laughed off the stage". The reason was that they saw coding not as all-or-none but as implemented by variable *bursts* of nerve signals (John Collier, personal communication).

The paper's message was as memorable as its title. For it showed that the frog's eye has a great deal to tell its brain, over and above the presence of light—or even of Barlow's edges and movement.

As Lettvin's group put it: "the eye speaks to the brain in a language already highly organized and interpreted, instead of transmitting some more or less accurate copy of the distribution of light on the receptors" (Lettvin *et al.* 1959: 251). Specifically, they had found single cells in the frog's retina that were sensitive to one of four different light patterns:

> (1) local sharp edges and contrast; (2) the curvature [within specific limits] of edge of a dark object; (3) the movement of edges; and (4) the local dimmings produced by movement or rapid general darkening. (p. 253)

These results were observed even when the stimulus, instead of being artificially isolated (as in Barlow's experiments), was surrounded by a *naturalistic* image of the countryside as presented to a frog.

The 'Frog's Eye' authors also found that the four cell-types mapped onto four distinct cell sheets in the frog's brain (the optic tectum, or colliculus). And these were precisely co-registered: neighbouring points in the retina were connected to neighbouring points in sheet 1 . . . and sheet 4. What's more, the nerve fibres would grow back to the right place if they were cut. The idea of *some sort of* point-to-point mapping had been suggested by Julia Apter, and by Pitts and McCulloch in their 1947 paper (see 12.i.c). Now, there was detailed experimental evidence. (The explanation for *how* this mapping is established was then unknown: see ix.a, below.) And there were various subtleties. For instance, some class 3 cells fired only if the movement was in a certain, very broadly defined, direction.

In fact, there were some subtleties so surprising that they weren't even mentioned in the published paper. Lettvin recalls:

> What we did not report, and what to me is still [in 1994] the most astonishing thing about the bug detectors, is the following property . . . You bring one spot in, move it into the [receptive] field, and as long as you move it around, wonderful response.
>
> You bring in two spots; if they're rigidly coupled in their motion by a fixed distance between them and are moved around, you get a good response almost as if they are only one spot.
>
> You bring three rigidly coupled spots in, and it doesn't matter their size or their disposition or their distances from each other: move them around as a rigidly coupled triad and there's no response at all.
>
> . . . If you have a white background and two black spots, OK; three spots, forget it. You connect any two spots of the three by a barely visible black line, and all of a sudden it's a two-spot system. It becomes visible. Or else you move any one spot with respect to the other two, now there's a response. (J. A. Anderson and Rosenfeld 1998: 18)

How, Lettvin asked himself, could a mere retina possibly compute such distinctions? He still has no answer—so still hasn't officially published the finding. In his judgement, then, this discovery wasn't really a discovery (see Chapter 1.iii.f). Putting it in Mayhew's terms, he'd discovered the cells, and what they were computing—but not *how* they were computing it.

What's more, it seemed that the eye might be telling the brain very interesting things—interesting, that is, *to the frog*. These concerned the approach of predators (casting a shadow over the scene: see class 4 above), and the whereabouts of food:

> The operations thus have much more the flavor of perception than of sensation if that distinction has any meaning now. That is to say that the language in which they are best described is the language of complex abstractions from the visual image. We have been tempted, for example, to call the convexity detectors "bug perceivers". Such a fiber responds best when a dark object, smaller than a receptive field, enters that field, stops, and moves about intermittently thereafter. The response is not affected if the lighting changes or if the background (say a picture of grass and flowers) is moving, and is not there if only the background, moving or still, is in the field. Could one better describe a system for detecting an accessible bug? (Lettvin *et al.* 1959: 253–4)

Indeed, the retinal cells seemed to guarantee the frog a healthy diet of fresh food. They responded only to stimuli that were moving, so—in its normal environment—probably *alive*. This tallied with previous observations of the whole animal's behaviour:

> The frog does not seem to see or, at any rate, is not concerned with the detail of stationary parts of the world around him. He will starve to death surrounded by food if it is not moving. His choice of food is determined only by size and movement. He will leap to capture any object the size of an insect or worm providing it moves like one. He can be fooled easily not only by a bit of dangled meat but by any moving small object. (p. 231)

Remarkably, the radius of curvature that strongly triggered the convexity detectors corresponded to bug size. In short, the frog's eye was seeing only what the frog needed to know.

Later, Lettvin would complain about the use of such "anthropomorphic" language even in talk about human brains, adding that "people have screwed up the frog because they're taking bachtriomorphic views of the frog. If you really want to understand the frog, you must learn to be objective and scientific" (J. A. Anderson and Rosenfeld 1998: 344). The 'Frog's Eye' paper itself, however, had initiated this perspective.

The 'Newtonian' assumption inherited from the associationists, and dating back to John Locke's distinction between "sensation" and "reflection" (Chapter 2.x.a), had been that the sense organs—and by extension, the peripheral parts of the brain—are both passive and atomistic. Sensitivity to points of light, *yes*; to complex patterns of light, *no*. To perceive (infer, compute) a light–dark gradient with a specific radius of curvature, it had been tacitly assumed, was a matter for the cerebral cortex—present only in mammals and birds—and must involve a large number of cells. Now, that assumption was shattered.

But the surprise, though great, wasn't unqualified. Recent work in both neurophysiology and cybernetics/AI had implied that some such results might be found. Barlow's experiments a few years before had modified the assumption already. Indeed, others besides the MIT team were looking for feature-detectors of some sort (see below). And Pitts and McCulloch (1947) themselves had posited several layers of visual computation in the brain, going from simple features to increasingly complex concepts.

(Admittedly, they'd assumed that the features would be relatively simple, and formally tractable. Pitts was therefore, so Lettvin recalls, "a little appalled by the results, which were very different from what he expected", and "while he accepted the work enthusiastically, at the same time it disappointed him"—J. A. Anderson and Rosenfeld 1998: 10.)

Moreover, many cyberneticians—though not the orthodox neurophysiologists—had encouraged attention to what *the animal* needs to know, given what it wants to do. In particular, Lettvin's mentor McCulloch had taught him to think of sensory neurophysiology as "experimental epistemology". (I remember being startled to find these words written on the door, on my first visit to Lettvin's lab.) He meant that one should ask not merely how perception tells animals about the world, but also how it makes appropriate action possible (Chapter 4.iii.b).

A visual neurophysiologist who became close to the MIT team a few years later was told by Lettvin that "Pitts and McCulloch actually were on the eye/brain paper as a friendly courtesy. They had no role in the planning or execution or anything of the eye/brain thing" (C. G. Gross, personal communication). However, McCulloch's lack of hands-on contributions doesn't rule out his having had a background influence on Lettvin's thinking.

Similarly, Selfridge had argued—on computational grounds, and partly influenced by Pitts and McCulloch—that complex perceptions *must* be based on many distinct feature-detectors (or "data demons"), where the "features" have survival value for the animal. And he'd illustrated part of what he meant by the Pandemonium program. (Only "part", because the program didn't need to survive, so didn't *want* anything: see Chapter 12.ii.d and iv.b.)

Lettvin was a very close friend of Selfridge, and of McCulloch and Pitts. Their mutual friendship had led to the 'Frog's Eye' work in the first place. The paper described itself as "an outgrowth" of the 1947 study of universals, which—in effect—had postulated layers of feature-detectors. In addition, it carried this acknowledgement: "We are particularly grateful to O. G. Selfridge, whose experiments with mechanical recognizers of pattern helped drive us to this work and whose criticism in part shaped its course" (Lettvin *et al.* 1959: 253, 254). In short, although the authors were doing "wet" neuroscience, not describing a computer model, they were plainly inspired by computational ideas.

What actually happened, according to Maturana (personal communication), began with Maturana's accidental discovery (in November 1958) of movement-sensitive cells in the frog's retina. He found these interesting because they confirmed his hunch that such cells might exist, a hunch based on purely anatomical grounds (microscopic evidence of asymmetries in the connection patterns of some of the retinal cells). But Lettvin's familiarity with Selfridge's ideas enabled him to see the wider importance of Maturana's finding. He immediately switched the laboratory's main research programme to a hunt for other specialized, and ecologically significant, cells—and they found them.

A further surprise was in store. Within a few years, Maturana rejected the computational interpretation of these experiments. He developed their whole-animal emphasis into a neo-Kantian philosophy of biology, in which the concepts of computation and information had no place (see 15.vii.b and 16.x.c). Orthodox neuroscientists, however, knew little or nothing of this—and cared less. Even with Maturana's blessing, neo-Kantianism was out of fashion.

b. And more, and more . . .

The whole-animal emphasis was unusual in the 1950s: most people looking for feature-detectors at the time weren't guided by it. David Hubel and Torstein Wiesel, for instance, were not.

They'd arrived at Stephen Kuffler's lab at Johns Hopkins (where Barlow was also working) in 1958, and were searching not in the frog's eye but in the cat's brain. Their discovery of feature-detectors in the striate cortex in effect confirmed Turing's hunch, that "the apparatus for the more elementary analysis of shapes and sounds probably comes into this category [i.e. definite structures in the brain]".

Their results, which revolutionized the study of visual cortex, were even more surprising than the MIT group's were. In the late 1950s they identified brain cells responsive to very highly specific patterns on the retina: lines/edges of many different orientations (Hubel and Wiesel 1959). More accurately, they found cells that responded to small line *segments*. Anything we'd normally regard as a 'line' would be represented by a *set* of 'line-detectors'. (Twenty years on, Hubel confessed that how the fragmentary information from such cells is assembled to build a percept of a line "is still a complete mystery" Hubel 1982: 519.)

Later (at Harvard), they would find even more types of feature-detector, at various levels in visual cortex. (Right from the start, they produced putative circuit diagrams for their various cell-types.) The levels seemed to be functional as well as anatomical, for some neurones, the "hypercomplex" cells, were fired by particular *combinations* of lower-level features. Moreover, the orientation detectors were arranged in regular columns, perpendicular to the brain's surface: same orientation, same column; and cells responding to similar orientations inhabited neighbouring columns (Hubel and Wiesel 1962, 1968, 1974).

They also found that many cells in visual cortex were binocular, whereas those in the first way-stage (the LGN, or lateral geniculate nucleus) were 'wired' to only one eye. The binocular cells were evidently wired with remarkable precision, each having two receptive fields closely similar in size, complexity, orientation, and position. However, most of them responded more strongly to one eye than to the other: Hubel and Wiesel called this effect "ocular dominance".

Their initial discovery had amazed them as much as anyone else, for they hadn't been expecting "features" quite like that. A year after receiving the Nobel Prize for their work, Hubel recalled:

> We had been doing experiments for about a month . . . and were not getting very far; the cells [in the cat's cortex] simply would not respond to our [two stimulus-classes, namely] spots and annuli. One day we made an especially stable recording . . . The cell in question lasted 9 hours, and by the end we had a very different feeling about what the cortex might be doing. For 3 or 4 hours we got absolutely nowhere. Then gradually we began to elicit some vague and inconsistent responses by stimulating somewhere in the midperiphery of the retina. We were inserting the glass slide with its black spot into the slot of the ophthalmoscope when suddenly over the audiomonitor the cell went off like a machine gun. After some fussing and fiddling we found out what was happening. The response had nothing to do with the black dot. As the glass slide was inserted its edge was casting onto the retina a faint but sharp shadow, a straight dark line on a light background. That was what the cell wanted, and it wanted it, moreover, in just one narrow range of orientations.

This was unheard of. *It is hard, now, to think back and realize just how free we were from any idea of what cortical cells might be doing in an animal's daily life . . .*

It took us months to convince ourselves that we were not at the mercy of some optical artefact . . . We did not want to make fools of ourselves so early in our careers. (Hubel 1982: 516; italics added)

Orientation detectors, bizarre though they seemed, were just the beginning. Hubel and Wiesel themselves soon discovered detectors for directional movement, for instance. And then, *mirabile dictu*, other researchers found cells higher up in the visual system (in inferotemporal cortex) that were responsive to hands, or to faces. These discoveries were amazing—indeed, apparently incredible (see below). But they weren't totally unexpected, and nor were they accidental.

The Warsaw neurophysiologist Jerzy Konorski (1903–73) had been the first to suggest, in 1960, that highly complex features such as these (which he called "unitary perceptions") might be coded by single neurones, or "gnostic units". In his book a few years later, he'd argued that these units might be grouped in separate places in the inferior temporal cortex. What's more, he speculated that there were different units coding for faces, limbs, animals, handwritten letters, or emotional expressions, and so on (Konorski 1967).

Konorski's ideas were still maverick in the early 1960s, when "most visual psychologists had never heard of this area [inferotemporal cortex]" and thought of the striate cortex alone as the ground of vision (C. G. Gross 2002: 86). But they hadn't come out of nowhere. He'd been inspired not only by Hubel and Wiesel's findings but also by Karl Pribram's work on the visual effects of lesioning monkey temporal cortex, and by the descriptions of highly specific clinical agnosias then coming from Luria in the Soviet Union (Pribram and Mishkin 1955; Luria 1968).

Maverick or not, Konorski was largely right: we can now see that he "anticipated subsequent discoveries to an amazing degree" (C. G. Gross 2002: 85). Even so, and despite a highly complimentary review in *Science* (C. G. Gross 1968), Konorski's book was largely ignored by visual psychologists and neurophysiologists:

For at least the next decade virtually all the many citations to the book were to the parts concerned with learning rather than with perception; learning theory [aka behaviourism] still dominated American psychology. (C. G. Gross 2002: 87)

One American who didn't ignore the parts concerned with perception (and who wrote the glowing *Science* review) was Charles Gross (1936–). While still based at Cambridge University as a graduate student (see Preface, ii), he'd visited Konorski's Warsaw lab in 1961 to learn about his strange new ideas.

Gross was as excited as anyone else by Hubel and Wiesel's recent discoveries. And he knew (from lesion studies like Pribram's, being carried out at Cambridge by his supervisor Larry Weiskrantz) that inferotemporal (as well as striate) cortex was crucial for vision (personal communication). So on moving to MIT a few years later, he decided to try to find further feature-detectors and/or gnostic units in that part of the brain—which he did.

But he could hardly believe his own eyes. He found a cell fitting one of Konorski's speculations: well, not for a limb—but for a hand. When Gross first drafted his research paper, he "did not have the nerve" to mention the cell that coded for the monkey's hand (C. G. Gross 1998: 199). He was as wary as any seventeenth-century gentleman of witnessing to the astonishing (see Chapter 2.ii.b). Like Hubel and Wiesel before him, he didn't want his career to be over before it started because of being seen as either sensationalist or gullible. A senior colleague—Hans-Lukas Teuber, a member of the cybernetics group—encouraged him to be brave. As a result, the hand-detector was duly announced (C. G. Gross *et al.* 1969).

However, it evidently beggared belief. People didn't even *try* to replicate it. No one else reported any follow-up experiments for over a decade. And Gross himself, "perhaps because of the general skepticism", waited just as long before fully describing the face-detectors (Bruce *et al.* 1981). Yet they, too, had shown up in his initial experiments.

By then, the scepticism had lessened. A flood of papers soon appeared on visual (and auditory) single-cell detectors in various parts of the monkey's cortex. They included many from David Perrett's lab at the University of St Andrews, Scotland (Perrett *et al.* 1982, 1985, 1990, 1992).

By the mid-1990s, cells had been found which discriminated (for instance) hands; faces; facial expressions; humans walking towards or away from the monkey subject; and anyone—human, monkey, or robot—picking up a raisin or performing some other action salient to monkeys. In addition, 'bimodal' detectors had been discovered, which responded to *visual and tactile* stimuli from the same body area, such as the arm and the space near to it (Graziano and Gross 1993).

Even the humble (humble?) retina had offered up further riches. Today, neuroscientists can distinguish "over 70 retinal neurons, well-differentiated in terms of morphology, connections, and transmitters and therefore presumably function too" (C. G. Gross, personal communication).

As that word "presumably" implies, not all of these retinal cells can be classified—yet—as detectors, for we don't know what they detect. But the fact remains that neural detectors of many different kinds, including the recently discovered mirror neurones (Section vii.c, below), are still being found in the nervous system.

c. But how?

As Mayhew's remark reminds us, however, the discovery of a single-cell detector doesn't tell one *how* that detection is achieved.

Of course, systematic experiments were done right from the start to identify the relevant stimulus classes. Lettvin's team, for example, studied many different stimuli, including diverse radii of curvature and various types of (smooth/jerky, fast/slow) movement. Similarly, Gross used a range of stimulus classes in testing the monkey's hand-detector (see Figure 14.1). Such experiments indicated which aspects of the stimulus are important. But they didn't show how they are computed. (Even now, the precise circuitry isn't known.)

By the mid-1980s, the biological experiments were being compared with specific computational theories. So, for example, when the St Andrews group discovered a wide variety of face-detector cells in the brain, they discussed them in the light of Marr's theory of vision (Chapter 7.v.b–d), Marvin Minsky's ideas about visual frames (10.iii.a), and Robert Baron's (1981) computational model of face recognition.

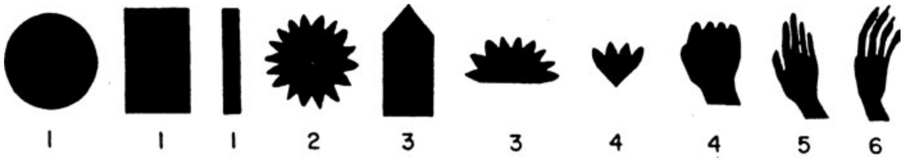

Fig. 14.1. Examples of shapes used to stimulate an inferior temporal cortex neuron "apparently having very complex trigger features. The stimuli are arranged from left to right in order of increasing ability to drive the neuron from none (1) or little (2 and 3) to maximum (6) . . . The use of [these] stimuli was begun one day when, having failed to drive a unit with any light stimulus, we waved a hand at the stimulus screen and elicited a very vigorous response from the previously unresponsive neuron . . . We then spent the next 12 hrs testing various paper cutouts in an attempt to find the trigger feature for this unit. When the entire set of stimuli used were ranked according to the strength of the response that they produced, we could not find a simple physical dimension that correlated with this rank order. However, the rank order of adequate stimuli did correlate with similarity (for us) to the shadow of a monkey hand" (C. G. Gross *et al.* 1972). Reprinted with permission from C. G. Gross (1998: 199)

Baron, a neurophysiologist at the University of Iowa, had worked on formal models of the nervous system since the early 1970s. In his account of face recognition, he'd posited various viewer-centred templates, such as distinct views of the head as it would appear at different stages of rotation. A face can be recognized (by brain or computer), he said, only if such templates are present, and "In every case, recognition is determined by correlating the processed input patterns against all stored templates" (Baron 1981: 145).

Before template comparison could get started, the system had to fixate on the relevant face features (if possible, the eyes first), and to standardize the image size. Since the relevant features were fixed (eyes, nose, chin, etc.), the program's task wasn't to distinguish between faces and other objects, but between this face and that one: Janet or Jill. Each face was represented in memory by up to five features, with up to four distinctly different templates for that feature—hence up to twenty templates in all. And, in accordance with experimental data on human eye movements, recognition was sometimes "Gestalt" (immediate), sometimes sequential (feature by feature).

Baron suggested that the various types of abnormal face recognition observed in clinical patients, such as prosopagnosia (where even one's spouse may not be recognized), are caused by breakdowns at different points within the system (pp. 171–5). He assigned specific computational roles to cells in the retina, lateral geniculate bodies, primary visual cortex, and cortex.

When discussing the types of feature-detector involved in locating a face in the first place, he said:

> It is perhaps no accident that the eye responds so readily to patterns having a dark center and light surround. The iris of the eye, eye-ball, eye socket, eyebrow, face, and hairline form a series of light and dark concentric circular regions that can easily be detected in the visual field. (p. 168 n.)

As this remark implies, he generalized his theory to visual recognition in general. And he stressed that in outlining the brain's "logical architecture", one must "carefully distinguish between the information and control processes involved" (p. 138). In short, Baron was addressing Mayhew's question about *how* a given cell computes what it does.

d. Monkey business

Perrett's group in Scotland, part-inspired by Gross and Baron, made some remarkable discoveries (Perrett *et al.* 1985). Although some cells were responsive to faces as such, others responded only to faces in particular orientations: full-face, profile, looking upwards, or looking downwards. Moreover, many of these were sensitive also to the direction of gaze, coding full-face-with-eye-contact, full-face-with-averted-gaze, or profile-with-averted-gaze.

The team suggested that these are monkeys' business. In other words, they are important social signals for monkeys, as they are for humans.

(With respect to humans, these researchers would later do hugely influential work on universal/cultural facial recognition, including a study of the attractiveness of facial symmetry—a topic discussed in Chapter 8.iv.b: Perrett *et al.* 1999; Penton-Voak *et al.* 1999; Keysers and Perrett 2004. The results of their experiments in presenting subjects with systematically varied computer simulations have been widely applied in Hollywood animation, and for VR faces too (see 13.vi): Burt and Perrett 1995; Calder *et al.* 2000.)

They observed, in separate experiments, that young monkeys "give appeasement gestures at an increased frequency for faces making eye contact compared with faces where the eyes are averted" (Perrett *et al.* 1985: 309). But, for social purposes, it presumably doesn't matter (to monkeys) whether the eyes are averted by 20, 50, 60, or 70 degrees. And indeed, the experimenters *didn't* discover a continuous range of eye-aversion detectors, analogous to Hubel and Wiesel's line-orientation cells:

> It is important to note that in the present study no cells were found that were maximally active to the face positioned at some intermediate angle between face and profile. *Only a small number of distinct views of the head seem to be receiving independent analysis in [this part of the brain]* but for each view there is considerable generalization over size and isomorphic rotation. (p. 315; italics added)

In general, they said, one might expect to find cells sensitive to features relevant to the animal's lifestyle:

> To avoid jumping into the lion's mouth one has to know which direction to jump. The importance of such information might have encouraged the evolution of neural mechanisms capable of direct and independent computation of the orientation of the head and body with respect to the observer and hence a viewer-centred analysis of these objects. (p. 315)

One must remember, here, that Perrett was studying monkeys. Most animals wouldn't be able to see *the lion*, even if they were able to avoid its mouth. In other words, very few animals—only birds and mammals—can do pattern recognition, or see whole objects such as lions or faces. All the others use "slick tricks" instead, including many species-specific feature-detectors.

For a crab, for example, if something is above the horizon it's dangerous and if it's below the horizon it's a crab. Or rather, the action that the visual stimulus evokes in the crab—either freezing/escape or claw-waving—is appropriate as a response to seagulls or crabs, respectively. The size and shape of the object involved don't matter, because they can't be perceived.

Moreover, the crab doesn't need any "neural 'software' image" to code the horizon. Instead, it's coded in such a way that "an object will be treated as a threat *if it appears* *on a particular part of the retina*, and thus the behaviour can be 'hard-wired' " (Layne *et al*. 1997: 52; italics added). That is, the crab has an appropriate slick trick. (Compare the crickets discussed in Chapter 15.vii.c.)

In relation to Marr's theory of object recognition, Perrett's group pointed out that whereas some cells were responding to faces as objects independent of the viewer, others were coding viewer-centred information. Because the oriented-face-detectors weren't representing ("making explicit") all the information available in the $2\frac{1}{2}$D sketch, their functioning was described as "a stage beyond two-and-a-half-dimensional sketches" (Perrett *et al*. 1985: 315).

Independent analysis of distinct views of the same object was necessary, they said. (*Computationally* necessary, that is.) But only relatively few distinct views may be needed (here they cited Minsky 1975). And, as remarked above, they'd found only very few views of eye gaze to be independently coded. Accordingly, they criticized Baron's model for requiring a distinct template for every 20 degrees of head rotation.

Their general conclusion was that "the recognition of one type of object may proceed via the independent high level analysis of several restricted views of the object (viewer-centred descriptions)" (p. 293). This, they said, challenged Marr's theory, which did *not* predict cells sensitive to certain views of faces. Partly, this was because viewer-centred representations were supposed to exist only at the level of the $2\frac{1}{2}$D sketch. Also, Marr had favoured distributed representations, considered as emergent properties of large groups of neurones (Chapter 12.v–vi). But Perrett's group had seemingly discovered paradigm cases of grandmother cells (individual neurones coding crucial information).

For our purposes, the important point is not whether Perrett's specific claims were right or wrong. What's important is their general nature. In a word, they were *computational* claims.

Such analysis simply couldn't have appeared in the early 1960s, when feature-detectors were both new and few. At that time, Marr and Minsky hadn't published on vision. There were no computer models of face recognition. And Barlow's theory of grandmother cells hadn't been formulated (see Section ix.e).

To be sure, by 1961 there was already a computer model of feature detection that was seen, by some, as biologically relevant. I'm thinking of Leonard Uhr and Charles Vossler's version of Pandemonium, which learnt its own basic operators (Chapter 12.ii.d). Citing Hubel and Wiesel, Uhr and Vossler described their work as embodying "relatively weak, [biologically] plausible, and 'natural-looking' assumptions" (1961*a*/1963: 265). The young Marr apparently agreed, for he would soon describe the model's operators as near-equivalents to what he termed "codons" in the brain (D. C. Marr 1969: 469)—see Section v.c, below.

Most neuroscientists at that time, however, would have disagreed. The general view—based on studies of newborn kittens—was that feature-detectors, and their anatomical organization within the brain, aren't learnt but innate. They might be fairly crude in the newborn animal, to be perfected in the critical period; and they might be lost through lack of use. (There was evidence for both of these claims.) But in essence, they seemed to be built in.

MIT's experimental epistemologists, following McCulloch, had expressed this in explicitly Kantian terms (Chapter 12.ii.c). Describing the organization of eye–brain connections, they said:

> The way that the retina projects to the tectum [to the four co-registered sheets: see above] suggests a nineteenth-century view of visual space . . . By transforming the image from a space of simple discrete points to a congruent space where each equivalent point is described by the intersection of particular qualities in its neighborhood . . . every point is seen in definite contexts. *The character of these contexts, generally built in, is the physiological synthetic 'a priori.'* [. . . If] there is any randomness in the connection of this [retina–tectum] system, it must be at a very fine level indeed. (Lettvin *et al.* 1959: 252–3; italics added)

Such views fitted well with Barlow's seminal arguments about low-level coding mechanisms (see Section iii.b), if not with behaviourist psychology. And they would endure for some years. For they cohered with the newly fashionable nativism of the late 1960s (Chapter 7.vi.d–e), including the growing evidence for a host of anatomical specializations related to language (see Chapter 9.vii and Lenneberg 1967).

In sum, feature-detectors were unexpected examples of what Turing had called "definite structures" in the cortex. They were initially assumed—by Hubel and Wiesel (1962) as well as the MIT Kantians—to be genetically determined.

By the mid-1970s, this assumption would be overturned. For computer models would show that the structure of visual cortex might arise spontaneously (see Sections vi.b and ix.a).

14.v. Modelling the Brain

The Pitts–McCulloch paper of 1947 had presented a computational theory of (part of) the nervous system, but not a computer model. Twenty years later, McCulloch would help to design such a model. It was still impossible in the 1960s, however, to simulate the brain in any detail.

Nevertheless, this decade saw the beginnings of four ambitious—and interestingly different—research programmes in computational neuroscience. Each eventually involved computer simulation, and each grew closer to the biological data over the years. They focused on brain modelling (discussed here and in Sections vii and viii.b); neuro-ethology (Section vii); and psychological realism (Section vi).

They were pioneered by Marr, Arbib, Andras Pellionisz, and Grossberg. All four men were highly interdisciplinary. The first three turned to neuroscience (and in Arbib's and Marr's case, to psychology too) after being trained in mathematics and/or physics and engineering. Grossberg's initial training was in psychology and, despite his voracious reading in neurophysiology and mathematics, he always regarded himself (and still does) as a theoretical psychologist (personal communication).

In addition, the equally interdisciplinary McCulloch initiated a brain model in the 1960s that was perhaps the first computer simulation to be constrained by specific details of neuro-anatomy and neurophysiology. After lying largely forgotten for many years, it has very recently been resuscitated. Let's start with that.

a. The Mars robot

One of the earliest—and most perceptive—working simulations of a specific brain region was produced by an engineer, a neuroscientist, and a programmer: William Kilmer, McCulloch (the senior partner), and Jay Blum (Kilmer *et al.* 1969).

This program—named RETIC—was a model of the reticular formation (RTF), a structure in the vertebrate brainstem that was attracting much interest at the time. The received wisdom was that the RTF switched the animal between sleep and waking. But some had suggested that it might also switch between different modes of activity, or instinctive behaviours.

Under the microscope, it appeared to be a stack of tissue slices (likened to poker chips: cf. Ito 1984). There were visible interconnections within each slice and also between slices—and sensori-motor connections, too. But what the microscope couldn't show was *just what* pattern of connections would be capable of activity switching of the type proposed. That was the biological question driving the project.

There was a technological aspect too, for the program was intended as a controller for a Mars robot. Indeed, it was an early example of situated robotics (see Chapter 15.vii.a), although it was a simulation rather than an actual robot. The situatedness was a technological necessity, because of physics. Because radio signals between Earth and Mars travel slowly, neither new sensory information (picked up by the robot) nor new goals (suggested by the humans back home) can be swiftly communicated between the two planets. So a Mars robot must be largely autonomous, switching automatically from one activity to another as the local circumstances require.

GOFAI planning (then in its infancy: see Chapter 10.iii.b), used for NewFAI robots such as SHAKEY, was eschewed partly because it was too slow. In addition, however, the anatomical evidence didn't favour a central controller.

Many vertebrate species have an RTF but no cortex, which suggests that their behavioural 'decisions' aren't made top-down. For the same reason, a hierarchical program like Pandemonium, with its autocratic master demon, seemed biologically implausible. Rather, the lower-level units should somehow decide the outcome themselves, "shouting" not to some higher-level demon but to each other.

What was needed, then, was distributed, cooperative, computation. McCulloch had already described this in his 1947 paper (12.i.c). But he called it "redundancy of potential command". This terminology—and the idea itself—was a legacy from McCulloch's Navy days (4.iii.a). He'd learnt then that, in battle conditions, control can shift continually from one ship to another, according to the information they're receiving. Even the Admiral's flagship isn't all-powerful—nor, unfortunately, ever-present (Arbib 2000: 194).

The Mars robot was designed accordingly. Each RTF slice was modelled by a small network, or module, which estimated how likely (how appropriate) a particular type of activity was, given the current sensory input. These within-slice estimations were tentative, in that they could be influenced by between-slice connections. The final selection was distributed over the whole system. That is, the overall network would identify the maximum inter-module consensus, so choosing the most appropriate activity as its motor output.

In principle, one might have expected occasional confusion and/or paralysis, with no *one* activity being a clear winner. (Remember Buridan's ass: placed exactly halfway between two identical bundles of hay, and lacking 'freewill', the creature would supposedly starve to death.) In fact, this very rarely happened. Irrespective of the input, RETIC almost always converged to a majority-based choice of a single mode of action.

McCulloch's team (let's call them KMB) were making a crucial assumption, here. Namely, that distinct bodily activities have distinct neural mechanisms driving them, plus a 'switch' to activate one rather than another.

Peter Greene at Chicago, building on the ideas of Beurle and Belmont Farley (Chapter 12.ii.b), had already shown that in principle this needn't be so (P. H. Greene 1962). He'd sketched a hypothetical horse whose gaits—walking, trotting, cantering, galloping—were all generated by a single system of four interconnected 'neurones'. Gait selection involved tipping *the whole system* into one of four modes, each with its "natural" or "resonant" frequency. If the brain was anything like this mathematical model, he said, single-unit analysis and/or theories of separate neural circuitry could never provide the true explanation.

In modern parlance, Greene was talking about attractors in dynamical systems (see Section ix.b, below). But for most neuroscientists at that time, McCulloch included, specific neural circuitry was more attractive than attractors.

Attractive or not, RETIC was only very superficially related to the brain. This was partly due to the fact that it was a functioning program, designed when computing power was still very limited.

The early model has recently been updated by Kilmer (1997), one of the original authors. Incorporating a heterarchical 'committee' of up to thirty interconnected modules, the new network converges to a single output (action pattern) in less than thirty cycles of computation. It's still described by Kilmer as being inspired by the brain (the RTF). But it's more strongly oriented to practical robotics than to neuroscience.

Some other models of action selection are grounded in hypotheses about different areas of the brain. For instance, in a simulation built at the University of Sheffield, specific behavioural gating is done by mechanisms based on the anatomy of the basal ganglia (e.g. Prescott *et al.* 1999; Gurney *et al.* 1998). The RTF wasn't represented in the model. At that stage, Tony Prescott (personal communication) allowed that the RTF affects the general arousal state (sleep/wakefulness), but believed that its sensory innervation is too primitive to change the organism appropriately from one behaviour to another.

Besides their basal-ganglia simulation, Prescott's team have built a robot embodying the same principles. It switches cleanly between actions of wall following, search, food pickup, corner finding, and food depositing (Gonzalez *et al.* 2000). The overall behaviour appears coherent nevertheless—indeed, this integration was a prime constraint guiding the research (Prescott 2001). It's achieved partly because competing (potential) actions don't distort the chosen action, and also because the winning action persists even when the strength of the salient input falls somewhat below the level that was required to initiate it.

At least, that's true when the simulated dopamine level is "normal". But varying the dopamine level results in behavioural changes analogous to those seen in humans. Low dopamine leads to difficulty in approaching and picking up "food" objects, and/or in slower movements (compare Parkinson's disease). High dopamine may lead to inappropriate behaviour, such as repeated lifting/lowering of the robot's arm, caused by two action systems being selected simultaneously (compare Tourette's syndrome).

Yet more recently, Prescott's team have returned to the 1960s RTF Mars robot (Humphries *et al.* forthcoming). They now acknowledge that the basal ganglia can't be the only action selection system operating in vertebrates. For both helpless neonates and decerebrate cats "have a limited behavioral repertoire that can be expressed in the absence of basal ganglia (in [helpless] neonates [the basal ganglia are] not connected; in decerebrates [they] have been lesioned)" (sect. 2.2). For instance, these animals can switch between grooming, feeding, locomoting, escaping, and self-defence. It follows that "some neural structure *within the intact brainstem* must also be capable of functioning as a limited action selection system" (italics added). And the prime candidate for that structure, as McCulloch suggested long ago, is the RTF.

The Sheffield group tested the KMB model (and Kilmer's updated version of it) in three ways:

* by simulating it,
* by implementing it as a control architecture for a robot,
* and by comparing its performance with various other controllers.

They found that the original KMB version often worked, but not always. For some input sets, it didn't converge in the simulation (although it did when embodied as a robot). And in the simple task they set to it, it did no better *for the robot* than a random-choice controller, and less well than a winner-takes-all controller. In other words, the sequence of action selections didn't reliably lead to behaviour enabling the robot to "survive". However, when they "fixed" the KMB model by preventing random reassignments of connections, performance improved dramatically.

In addition, they used GAs (genetic algorithms; see 15.vi) to test various controllers of the same general type but which *weren't* constrained by the facts of neuro-anatomy. Among the huge number of configurations available in KMB space, they found many that could function as robot controllers. Some of these outperformed the winner-takes-all strategy that had beaten KMB's original design. Moreover, some could function even with very noisy input sets—alias relatively primitive sensors.

Their paper ended with some speculations about how the RTF and basal ganglia may interact in vertebrate action selection (sect. 6.2), and how KMB models might be useful—even advantageous—in robotics (sect. 6.3).

In a nutshell, then, the Sheffield team had been able "to fulfill McCulloch's original hope for the model for the first time" (sect. 2.3).

b. The musician in the spare room

While the early RTF program was being designed in one Cambridge, a much more ambitious formal theory of the brain was being developed in the other—but without a computer program.

The location was a spare room provided by Crick and Sydney Brenner at the Molecular Biology Unit, sponsored by the Medical Research Council in 1963 (the successor of Max Perutz's 1950s Cavendish Laboratory group). Crick, with James Watson and Brenner, had recently discovered the nature of the genetic code—and before that, in 1953, the structure of DNA. As for Brenner, he was initiating a long-term study on the development of every single cell (under the electron microscope) of the nervous system of the 1 mm-long nematode worm *C. elegans* (Brenner 2001: 125–36). With only a few hundred cells (it turned out to be 302), always interconnected in the same way, *C. elegans* was destined to become hugely important for neurobiology and genetics. (Both Crick and Brenner received Nobel Prizes: in 1962 and 2002, respectively.)

The focus of the new theory that's of interest here, however, wasn't biochemistry or genetics. Rather, it was computation.

The occupant of the spare room was Marr, who'd been given a job in the lab "simply because he was working on something interesting" (Brenner 2001: 136). (Those were the days!) He turned out to be a wizard in dealing with the Unit's first computer—acquired only after much wrangling with the MRC funders, who didn't see the point of biologists having their own machine (Brenner 2001: 140–1). But that was more of a hobby than a serious research interest. Although Marr—persuaded by Brenner, persuaded in turn by his childhood friend Seymour Papert—saw the scientific potential in computing, the Unit's hard-won machine wasn't suitable for the ambitious work he wanted to do. Specifically, his ambition was to understand the brain.

After completing a degree in mathematics at Cambridge, Marr had done a year's intensive study of neuroscience and biochemistry—when he wasn't playing the clarinet, at which he was a master. He'd been selected for the National Youth Orchestra, had played various types of music at Rugby public school, and had been a member of a flourishing jazz group, the J. L. Dixie 7. His musical interests were an added bond with his neuroscience supervisor, Brindley—who is a respected amateur composer, some of whose works have been performed by the London Sinfonietta (P. Husbands, personal communication).

But music wasn't Marr's only passion. Like McCulloch and the 12-year-old Pitts before him (4.iii), Marr had been seduced in his youth by Bertrand Russell and Alfred North Whitehead's *Principia Mathematica*. One of his schoolfellows, also a Dixie player, remembers him—as a teenager in the early 1960s—reading this with "fascination and vast admiration", alongside the work of William Grey Walter on robots and John Dunne on time (P. M. Williams, personal communication). By the late 1960s, Marr's intellectual gurus also included Hebb—and therefore McCulloch too (see Chapter 5.iv.b). It was their concern with network-logic and learning which inspired his postgraduate studies.

His dissertation for his Trinity College Fellowship of 1968 had considered associative memory in the brain. It asked not only (qualitatively) how this is possible, but (quantitatively) how large the memory storage could be, given a certain network size. Others, notably David Willshaw and Longuet-Higgins, were addressing similar topics at that time (see Chapter 12.v.c). But Marr combined his abstract mathematical argument with a profusion of neuroscientific detail.

Soon, he converted his Trinity dissertation into three closely related theoretical papers (Marr 1969, 1970, 1971), plus a fourth co-authored with Blomfield (Blomfield and Marr 1970). All four appeared in leading scientific journals. One of these—the *Journal of Physiology*—had never published a non-experimental text before. In short, Marr was engaged in a fundamentally new *type* of neuroscientific research.

His four papers discussed the cerebellum, cerebrum (neocortex), and hippocampus (archicortex). They aimed to explain how the cerebellum learns and perfects movement in bodily skills, and to show that the neocortex and hippocampus are the sites of long-term and temporary memory respectively, with many memory-relevant interconnections. And they did this in terms of specific hypotheses about *what*, *where*, and—Mayhew's question (directly inherited from Marr)—*how*. These hypotheses covered many different things:

* input–output relations;
* neural connectivities, numbers, and activity levels;
* and the ways in which different classes of synapse,
* assigned to specific types of neurone,
* can be modified during learning
* and later used for retrieval.

In other words, Marr was following in Brindley's footsteps. Indeed, Brindley was acknowledged in each of Marr's papers. And "Brindley synapses" were repeatedly mentioned in the text—for instance, in the discussion of (Marr's equivalent of) feature-detectors (D. C. Marr 1970: 205–6, 215; 1971: 32–3, 78–9). But besides his classification of learning rules, Brindley had also inspired Marr to think about the cerebellum.

c. Secrets of the cerebellum

The cerebellum doesn't initiate skilled (for Marr: "voluntary") movements: that's done by motor cortex. Rather, it coordinates and controls them. More accurately, it coordinates skilled, learnt, or voluntary movements. (Reflex movements, including integrated patterns involving all four limbs, are controlled by the spinal cord and/or brain stem; they can occur even in decerebrate animals: Chapter 2.viii.d.)

In 1964 Brindley had published a brief paper on how the cerebellum uses sensory information. He'd suggested that the task of the cerebellum is to learn motor skills in such a way that when a simple or incomplete message (compare: an intention to pick up a glass, without knowing exactly how) is sent to it from the cerebral cortex, the required movement is performed automatically. That is, the cerebellum functions as an associative memory.

Marr agreed (1969: 438). But his discussion was very much fuller than Brindley's, and included a host of predictions about synaptic functions, connections, and numbers.

Even that fact, however, was partly due to his supervisor. Many years later, Brindley modestly said he'd given Marr no more than "a few" ideas—plus "one or two pep talks". The purpose of those pep talks was "to persuade him that unless his work led to experimentally testable predictions whose prior probability was neither almost zero nor almost unity, no experimenter would read his work" (Vaina 1991: 308).

Marr's view of what the cerebellum was doing reflected the several different 'languages' found even in the early digital computers. For instance, he said:

> Where it is possible to *translate* the combined activity of many cerebral fibres rather simply in *directives*, doing so in the cerebellum would free the cerebrum from an essentially tedious task. In these circumstances, the cerebellum becomes rather more than a slave which copies things originally organized by the cerebrum: it becomes an organ in which the cerebrum can set up *a sophisticated and interpretive buffer language* between itself and muscle. . . . The automatic cerebellar *translation* into movements or gestures will reflect in a concrete way what may in the cerebrum be diffuse and *specifically unformulated*, while the analysis leading to that diffuse and unformulated state can proceed *in its appropriate language*. (Marr 1969: 468; italics added)

So, where Craik had talked of "translation" from sensory to cerebral to motor languages (Chapter 4.vi.b), Marr implied several (many?) cerebral languages suited to modelling different things. One brain level may pass messages to another, which translates them into some other internal language . . . and ultimately into muscle movements.

Besides this general notion of computer 'languages', Marr would employ many specific computational arguments. His thinking started, however, from the neuroscientific data.

This is clear from the rhetorical structure of his first paper. Its opening sentence was "The cortex of the vertebrate cerebellum has a simple and extremely regular fine structure."

He cited the recent (1967) book by Eccles and two younger colleagues (one of whom was a Hungarian expert on control-engineering), with the telling title *The Cerebellum as a Neuronal Machine* (Eccles *et al.* 1967). (These authors had suggested that learning takes place in the cerebellum, perhaps by the growth of dendritic spines on the Purkinje cells.) And he immediately went on to summarize what was known of the (cat's) neuro-anatomy:

> The axons of the Purkinje cells form the only output from the cortex of the cerebellum; and these cells are driven by two essentially different kinds of input, one direct, the other indirect. The first is the climbing fibre input, and the second the mossy fibres, *whose influence on the Purkinje cells may be complicated.*
>
> The inferior olive is the only known source of climbing fibres . . . Each [olivary cell] sends out an axon which terminates in one climbing fibre on just one Purkinje cell; there are very few exceptions. The climbing fibre completely dominates the dendritic tree of the Purkinje cell, and its action has been shown to be powerfully excitatory . . . (Marr 1969: 438–9; italics added)

(It's now known that there are more than a "very few" exceptions: although each Purkinje cell has only one climbing fibre, each climbing fibre connects with ten to fifteen Purkinje cells—Rolls and Treves 1998: 191.)

Bearing these biological constraints in mind, he then outlined his solution. What the cerebellum was doing, and *how*, could be understood in terms of associative memory. And, unlike the writers discussed in Chapter 12, Marr ascribed this memory to distinct structures in the brain:

> [I suggest] that each olivary cell corresponds to a "piece of output" [an *elemental movement*] which it is necessary to have under control during movements.
>
> . . . Every action therefore has a defining representation as a sequence of firing patterns in the olive.
>
> The final assumption . . . is that the nervous system has a way of converting the (inhibitory) output of a Purkinje cell into an instruction which provokes the precise movement to which its uniquely related olivary cell responds.
>
> [I shall argue that] the Purkinje cell can learn all the "situations" in which the olive cell movement is required, and later, when such a situation occurs again, can implement the movement itself . . . [So] the cerebellum could learn to carry out any previously rehearsed action which the cerebrum chose to initiate, for as that action progressed, the context for the next part of it would form, would be recognized by the appropriate Purkinje cells, and these would turn on the next set of muscles, allowing further development of the action. In this way, each muscle would be turned on and off at the correct moment, and the action would be automatically performed. (Marr 1969: 439)

As for the mossy fibres ("whose influence on the Purkinje cells may be complicated"), they provide the information that defines the "context" for each Purkinje cell. And how could that be done? This was his suggestion:

[It] is necessary to demonstrate that the mossy fibre–granule cell–Purkinje cell arrangement could operate as a pattern recognition device. The notion fundamental to this is that the mossy fibre–granule cell articulation is essentially a pattern separator. That is, it amplifies discrepancies between patterns that are rather similar . . .

[A] mossy fibre input has been learnt by a given Purkinje cell if, and only if, the input is transformed into impulses in a bundle of parallel fibres all of whose synapses with that Purkinje cell have been facilitated. (p. 440)

But there were two crucial complications:

First, the number of parallel fibres into which a mossy fibre input is translated increases very sharply with the number of active mossy fibres unless the threshold of the granule cells also increases . . . [Economy] arguments suggest that the granule cell threshold should be controlled in a suitable way. An inhibitory interneurone could achieve this, and the Golgi cells are interpreted as fulfilling this role.

The second point is that [variation in parallel fibre activity] will still exist. Whether or not a Purkinje cell should respond to a given mossy fibre input cannot therefore be decided by a fixed threshold mechanism. . . . The natural way to implement [the necessary threshold-setting mechanism] is to allow the parallel fibres to drive an interneurone which inhibits the Purkinje cell: and it will be shown that the various stellate inhibitory cells can be associated with this function, *although their dendritic and axonal distributions are at first sight unsuitable*. (p. 440; italics added)

The theory offered many surprises. These included functional interpretations for previously mysterious structures, and various counter-intuitive claims too (cf. "although their dendritic and axonal distributions are at first sight unsuitable").

One such claim was that a single pair of olivary and Purkinje cells might perform in two different ways at different times. In other words, its input–output relations depend on the type of learning involved—for maintaining posture or for active movement (pp. 466–9).

Another was that the *only* modifiable synapses in the cerebellum are those between the parallel fibres and the Purkinje cells. This was pure theory: these synapses weren't experimentally shown to be modifiable until very much later (Ito 1982, 1984: 115–30). Similarly, Marr's claims that the synapses between the Golgi cells and the mossy and parallel fibres are *not* modifiable were argued on purely computational grounds (p. 454).

At the core of the theory was a new Hebbian learning rule, not included in Brindley's classification:

[If] a parallel fibre is active at about the same time as the climbing fibre to a Purkinje cell with which that parallel fibre makes synaptic contact, then the efficacy of that synapse is increased towards some fixed maximum value. ("At about the same time" is an intentionally inexact phrase: the period of sensitivity needs to be something like 50–100 msec.) (pp. 455–6)

This rule was "Hebbian" in the broad sense. Whereas Hebb had posited learning when a pre-synaptic and a post-synaptic cell are co-active, Marr demanded two co-active pre-synaptic cells, irrespective of activity in the post-synaptic cell. Moreover, only one of the two synapses involved was modifiable.

The function of the climbing fibres, on this theory, was to carry feedback (about the intended movement) from the olivary nucleus to the Purkinje cells. In other words, the cerebellum was being described as a system for 'supervised' learning (see Chapter 12.ii.d).

Perhaps even more surprising, Marr's interpretations often involved precise numbers: of cells, synapses, and excitation levels. Right at the beginning of the paper, he pointed out that "Behind this general structure lie some relatively fixed numerical relations." For example:

> Each Purkinje cell has about 200,000 (spine) synapses with the parallel fibres crossing its dendritic tree, and almost every such parallel fibre makes a synaptic contact. The length of each parallel fibre is 2–3 mm . . . Each basket cell axon runs for about 1 mm transversely, which is about the distance of 10 Purkinje cells . . . There is one Golgi cell per 9 or 10 Purkinje cells, and its axon synapses (in glomeruli) with all the granule cells in that region, i.e. around 4500. (pp. 442–3)

The list continued, on and on . . . and on. But why? Who cares?

Marr cared, because he assumed that these numbers, being "relatively fixed", must have some functional (computational) significance. Eccles and his fellow neuro-anatomists, who had helped discover these numbers in the first place, had doubtless made the same assumption. But Marr tried to show, in detail, just what the functional significance is.

He even *predicted* many as yet unknown numbers. Some of these quantitative predictions suggested minimum–maximum limits between which the thresholds of the modifiable synapses must vary, or time periods during which 'simultaneous' events must happen (see above). Others concerned activity levels within cell populations; or the number of synapses on a single cell; or overall cell numbers; or numbers of simultaneously active cells. For instance:

* "The number of granule cells active at any one time (say in any 50 msec period) is a small fraction (less than $\frac{1}{20}$) of all granule cells" (p. 469).
* "[Given that there are 200,000 parallel fibres for each Purkinje cell], the maximum desirable number of facilitated synapses on any one Purkinje cell [is] 140,000, and
* the minimum number of parallel fibres active in any learned event [is] 500" (p. 457).
* "Calculations based on slightly tenuous assumptions suggest that each Purkinje cell receives connections from about 7000 mossy fibres" (p. 443).

Similarly, in defining his crucial concept of a *codon* (a subset of a collection of active mossy fibres, feeding into a granular *codon cell*), Marr committed himself to specific quantities. He gave mathematical equations for the exact number of codons of a given size that are associated with a given number of active mossy fibres, and for the number of mossy fibres that may influence a single Purkinje cell (pp. 444–5). These numbers were needed, he said, in order to understand "the codon sampling statistics" that enabled the cerebellum to distinguish similar patterns.

These hypotheses were presented as being based solely on neurophysiology and mathematics. But AI had apparently been an inspiration too. For towards the end of the paper, he pointed out that a codon is "closely related to the feature analysis ideas current in the machine intelligence literature" (p. 469)—and he cited Uhr and Vossler (see Section iv.d).

In making his numerical predictions, Marr relied on the general principle of computational "economy", or "efficiency". For instance:

> It is [evident] that the maximum codon size used depends critically on the number of claws to each [granule] cell. Given this, the factor that will determine the number of claws to each cell will be *economy of structure*; and the relevant question is what is *the least number* of claws such that [the system has the properties required]. (p. 447; italics added)

> The number of patterns a Purkinje cell can learn decreases sharply as the number of active parallel fibres involved in each increases. It is therefore essential to the *efficient* functioning of the system that the codon size should depend on the amount of mossy fibre activity . . . The codon size must be maximal, subject to conditions [previously specified]. This ensures that the number of modifiable synapses used for each learned event is minimal, *and hence that the capacity is maximal*. (pp. 449–50; italics added)

Throughout the paper, Marr assumed that evolution must have found the mathematically optimal way of doing things.

Bearing in mind Crick's contrast (Section ii.a) between biology's "slick tricks" and the mathematician's "powerful general principles", it wasn't obvious that Marr's optimality assumption was warranted (cf. Boden 1988: 60–3). Indeed, it's still not obvious, despite an intriguing attempt by a computer scientist in the late 1980s to defend an information-maximizing role for the brain (see Section ix.a, below). But that's just to say that Marr's quantitative predictions might have been wrong. What's more important is that he made them at all.

The paper bristled with testable hypotheses, as well as novel explanations of known facts. Some were so central that "If this is not true, the theory collapses", while the disproof of others would be "embarrassing but not catastrophic" (p. 468). In the two companion papers, Marr elevated such distinctions to a fine art, marking each prediction by up to three asterisks. Unasterisked predictions were those which lay "strictly outside the range of the theory, but about which the theory provides a strong hint" (D. C. Marr 1970: 231; cf. 1971: 77).

Evidently, Brindley's "pep talks" had worked. Marr offered many hostages to experimental fortune. But did the experimenters respond, as Brindley had hoped?

d. Audience reaction

A few did. Rashevsky's intellectual successors—computationally inclined and mathematically competent neuroscientists—found Marr's ideas hugely exciting. Cowan remembers that "the 1969 cerebellum paper created a sensation", and that all three papers generated "a tremendous amount of interest among neurobiologists" (J. A. Anderson and Rosenfeld 1998: 114).

These people, of course, were already familiar with mathematical theories of associative memory. Indeed, Cowan saw Marr's core cerebellar learning rule as a development of Wilfred Taylor's pioneering research in the 1950s (Chapter 12.ii.b), and essentially similar to his colleague Greene's (1965) theory of retrieval, published in Rashevsky's journal four years earlier (see Chapter 12.v.c). According to Cowan: "It requires only inhibitory neurons to control thresholds, and intrinsic climbing fibers to train synapses (both suggested but not implemented by Greene), to complete the picture" (Vaina 1991: 204).

It's not clear whether Marr knew of Greene's paper. In general, he cited others less often than he should have done. I've been persuaded of this by several private conversations over the years, and it's now been remarked in print more than once—by Cowan and Arbib, for instance (J. A. Anderson and Rosenfeld 1998: 110, 231–2). But Cowan also allows that "David had a very original mind, so it's easily credible that David just invented the whole thing himself" (J. A. Anderson and Rosenfeld 1998: 111). However that may be, Marr had added ample neuroscientific flesh onto Greene's mathematical core. (Greene hadn't even mentioned the cerebellum.)

One might have expected neurobiologists *in general* to appreciate that fact. The Rashevsky school did. But many others didn't. As remarked above, no purely theoretical paper had appeared in the *Journal of Physiology* before—and not all of the readers welcomed the novelty. Cowan, again: "a lot of the theoretical biologists felt that [Marr's first paper] was so speculative that it couldn't possibly be right and weren't impressed with it" (J. A. Anderson and Rosenfeld 1998: 115).

Marr's theory of the cerebellum was indeed speculative, for it couldn't (yet) be directly confirmed by single-unit recording or neurochemistry, nor tested as a functioning computer model. And, as Brindley had shown (see Section iii.c), *behavioural* tests were inadequate in principle.

Even some people already working on the abstract mathematics of memory saw it as premature. For instance, Longuet-Higgins described Marr's work as "excellent"—not a term he ever used lightly—but said (in his reply to the Lighthill Report) that "for some time to come" it would be less valuable for the cognitive sciences than GOFAI theories of cognition (Longuet-Higgins 1973: 36–7). (By the end of Marr's short life, Longuet-Higgins believed that that time *had* now come: see subsection f, below.)

Furthermore, Marr's work was difficult to read. Even highly sympathetic critics have remarked on the numbing profusion of neuro-anatomical detail, the "pedantry" of the style, and the "over-elaborate" mathematics (Willshaw and Buckingham 1990).

The mathematics was indeed taxing. In the neocortex paper, Marr defensively said, "The results [of these technical preliminaries] are mainly of an abstract or statistical nature, and despite the length of the formulae, are essentially simple," and "The reader who is not familiar with this notation should not be put off by it. All the important arguments of the paper have been written out in full" (Marr 1970: 193, 167). Many readers were put off, nonetheless. And those who weren't, didn't always master what they were reading. So Willshaw has recently complained that more people have cited Marr than have understood him (Willshaw and Buckingham 1990).

Eventually, however, Marr's early work set a theoretical and experimental agenda that's still driving some neuroscientific research today. Masao Ito, in his now classic book on the cerebellum, recalls that Marr's theory assumed a special type of synaptic plasticity in cerebellar cortex, and says: "[Being] impressed by the close conformity of this assumption to the neuronal circuitry [worked out in our laboratory in the early 1970s], I was prompted to verify [it] experimentally" (Ito 1984, p. ix). (Ito also praises Marr for his three-level account of explanation, outlined in Chapter 7.iii.b—Ito 1984: 2.)

Bruce McNaughten (of the University of Arizona) sees Marr's papers as "guiding lights" for himself and various other neuroscientists. In his judgement, they showed "astounding prescience", given the sparsity of experimental evidence available at the time. Their insights, he says, have been largely substantiated, and "have brought order to a number of otherwise disconnected data on the anatomy, biophysics and information transmission of [the brain]" (Vaina 1991: 121, 126).

Marr's theory of supervised learning in the cerebellum was especially influential, and—although some doubts remain (Vaina 1991: 47–8)—is still widely regarded as essentially sound. That's not to say that every current model of the cerebellum is like his. We'll see in Section ix.b–c, for instance, that Pellionisz's account relies on a very different formal analysis. And Grossberg's model is different again (see Section vi). But Marr's central insights are now accepted—with two qualifications.

One of these concerns the precise mathematical form of his learning rule. It was later proved that the algorithm as he defined it would eventually lead to a state in which all the weights are at a maximum value (Sejnowski 1977). (Nevertheless, it was an ancestor of some now current connectionist learning rules.) The other concerns his neurological interpretation of it.

Marr proposed that the parallel-to-Purkinje synapse is strengthened by co-activity in the parallel and climbing fibres (see above). James Albus had been developing a similar idea—which he likened to a perceptron (Albus 1971). Soon afterwards, he implemented it as the "CMAC" mechanism (Cerebellar Model Arithmetic Computer); this was initially developed to control a robot arm, but is today used by others for various purposes (Albus 1975; van der Smagt 1998). But if Albus shared Marr's commitment to computational explanations, he differed on the neurophysiology.

In Albus's account of the cerebellum, joint activation of the climbing and parallel fibres would *decrease* the efficiency of the parallel-to-Purkinje synapse. Moreover, he saw the learning as driven (via the feedback in the climbing fibres) by *error*, where Marr had seen it as driven by *intention*—that is, by the "context" alerted by the cerebrum. At that time, it seemed that Marr was right; now it's known that they both were. So people speak today of the "Marr–Albus" model.

As with back propagation (Chapter 12.vi.d), there are several priority disputes here. Quite apart from Brindley's and Eccles's vague suggestions about cerebellar learning, formal equivalents of Marr's learning rule had already been defined.

One example was Greene's (1965) work, mentioned above, which Cowan describes as "virtually identical with David Marr's cerebellum model, except it's not applied to the cerebellum". What's more, Grossberg had formulated the same rule in 1964—and he *had* applied it to the cerebellum (Grossberg 1969). He'd even made the same prediction, that learning would occur at the synapses of the parallel fibres and Purkinje cells. However, because of the difficulties in getting his work accepted by journals of psychology or neurophysiology, his cerebellum paper was published in *Studies in Applied Mathematics*—not something which neuroscientists were likely to see.

e. Beyond the cerebellum

Because of the cerebellum's relatively simple histological structure (one climbing fibre to each Purkinje cell, for example), Marr had been able to represent all the neuronal pathways involved. But that wasn't possible for the cerebrum or hippocampus. His theories about these were even more "speculative" as a result.

The paper on neocortex, Marr later told Terrence Sejnowski, was the one he was "most proud of" (Vaina 1991: 297). It focused on the unsupervised learning of high-level concepts: sophisticated examples of Pitts and McCulloch's "universals" and Konorski's "gnostic units" (see Sections iii–iv).

Marr described neocortex as "classifying cortex", in contrast with the "memorizing cortex" of the hippocampus. He claimed that whereas the hippocampus stores patterns in the "language" in which they were input to it, the cerebrum can also generate "a new language" in which to describe (classify) them (1971: 73–4).

The vocabulary of both these languages consisted of codons. Whereas his cerebellar theory had assumed the existence of preformed codons, Marr suggested that the neocortex can learn codons as a result of environmental input (compare Taylor's machine, described in Chapter 12.ii.b). He defined a method whereby certain synapses could calculate conditional probabilities. Uttley had discussed such synaptic calculations too (see Section iii.b), but whereas he'd focused on the *frequency* of events, Marr focused on their *similarities*. He described this learning method as a form of "numerical taxonomy", in which the differences between objects are computed, and then clusters are formed which minimize these differences (1970: 175).

The neocortex paper was full of intriguing ideas—not least, that sleep is necessary for the formation of new codons (Marr 1970: 215). But most of its intellectual cheques still can't be cashed—nor even presented to the cashier. As Sejnowski has pointed out, increased computer power will be needed to evaluate Marr's theory of neocortex properly (Vaina 1991: 298). (Cowan believes that the central learning method will work if the outside world is reasonably coherent, and likens it to classification techniques recently developed by Grossberg and by Teuvo Kohonen—Vaina 1991: 208.)

As for the hippocampus, a huge amount of computational work has been done in the last quarter-century, including much based on 1970s research on cognitive maps (Gluck 1996; Burgess *et al.* 1998). Nevertheless, a very recent review states that "Models of the hippocampal system and episodic memory still have many elements in common with Marr's basic view of hippocampal function, [even though] recent efforts have added considerable elaboration and refinement" (Gluck *et al.* 2003: 274). And Willshaw's judgement (around 1990) was that "Even 20 years after publication, Marr's theory remains the most complete computational model of the hippocampus" (Vaina 1991: 120).

"Complete" doesn't mean "correct", however, and Willshaw himself rejects a number of Marr's claims (Willshaw and Buckingham 1990). The fundamental problem, he remarks, is that the hippocampus is very difficult to analyse, because—unlike the cerebellum—it's not completely connected. In general, Marr's computational arguments didn't sufficiently constrain his theory of hippocampus: other models are possible too.

Moreover, neurones may have computational properties that Marr didn't fully consider, which undermine some of his key arguments. For example, he suggested (giving no algorithm) that some neurones may have a *dual* threshold, in which activation requires inputs from both a minimal number and a minimal proportion of the cell's many synapses. He even discussed what types of local circuitry could do the relevant arithmetic. But whereas he said his model would be "impaired" if only one threshold-type were available, Willshaw sees dual threshold-setting strategies as *essential* for incompletely connected nets. Such units will behave differently from 'classical' neurones, and a particular cell's activity will depend on the specific numbers involved.

With this in mind, Willshaw argues—and has confirmed, by extensive simulation—that Marr's reasons for positing a third neurone layer in the hippocampus were mistaken. These reasons concerned storage capacity in associative memories (a long-standing interest of Willshaw's: Chapter 12.v.c).

Willshaw showed that, in principle, if the dual thresholds and connectivities are set appropriately then two layers will suffice. Not only that: in most conditions, his own two-layer simulation (based on Grossberg's "competitive" nets: see Section vi) performed as well—stored as many memories, with similar recall—as the three-layer version, even though it contained many fewer synapses. Willshaw has also compared the behaviour of various types of dual-threshold mechanism. But he has the advantage of considerable computer power. Marr, when he wrote and 'published' his Fellowship dissertation in the late 1960s, didn't.

Both Marr and Willshaw, of course, were committed to computational theorizing about the brain. But (as remarked already) by no means all neuroscientists are. In the 1960s, that was only to be expected. Brenner, for instance, recalls:

> [In] those days biologists were in general very antagonistic to computers. They thought that anybody interested in computing was choosing an easy way out of a responsible job. In other words, if you didn't work at the bench you weren't worth anything! (Brenner 2001: 139–40)

However, many people who specialize in hands-on brain research still, in the twenty-first century, have scant regard for the computational approach. Gross, for example, who is more knowledgeable than most about the history of his field, says this:

> I'm a bit dubious about the role of theory *or at least of theoreticians* in biology. So far, I'd suggest, no pure theoretician ever made any contribution to biology at all, and indeed they disappeared so quickly that we have all but lost their names.... [The] great theoreticians in biology were above all empiricists who steeped their waking days and nights in observing, collecting, experimenting—such as Aristotle, Darwin, Bernard, Mendel, Freud, Sherrington and in our day Sperry and Hubel and Wiesel. So far, theory without empirical slogging in the same head has yielded nothing. Maybe biology is changing. Maybe one can be a pure computational biologist and never touch a plant and animals but only a computer... we'll see. Crick and Watson are the only exceptions I can think of. Maybe they herald a new way in biology. But Crick in neuroscience makes the rule. He is very smart, very well read in neuroscience, gets all the latest data fed to him and for decades has produced zilch but an absurd idea about dreams and a silly localization of consciousness. (C. G. Gross, personal communication; italics added; quoted by permission)

On this view, Marr's work on cerebellum was influential largely because it was so dependent on Hebb and Brindley—both of whom were empiricists first and theoreticians second. (Their books cite many empirical papers with themselves as sole/first author, plus others written with others.) Marr's later work on the brain is much less widely known by neuroscientists (he's not mentioned, for example, in the widely used textbook by Kandel *et al.* 1995). In Gross's opinion, that's as it should be.

This is a special case of a general type of cross-disciplinary complaint. Similar criticisms have been made by biologists of the "pure computational biologist" Stuart Kauffman, as we'll see in Chapter 15.ix.c. And professional psychologists commonly rebuke—and even more commonly ignore—AI modellers for their lack of attention to the experimental data. AI researchers, in turn, often lament others' blithe ignorance of computational concepts and constraints. As for philosophers, they're more than ready to point out philosophical naivety on the part of scientists of all stripes. (Maybe this is because the scientists so often express contempt for philosophy: see ix.d below, and 16, preamble.)

In general, one needs to decide to what extent such attacks are mere defensive territoriality, and to what extent they have real substance. Such decisions are especially relevant if one claims that interdisciplinarity is crucial—which is a large part of the message of this book.

f. A change of tack

The lack of computer power was partly responsible for Marr's unexpected change of direction in the early 1970s. Instead of following up his seminal papers on the brain, he turned to consider the retina and primary visual cortex instead. He studied these until his premature death (aged 35), from leukaemia, in 1980.

His computational theory of vision was outlined in Chapter 7.v.b–d. Here, what's of interest is how he related it to neuroscience.

His first paper on vision, in 1974, aimed to explain how the primate retina computes subjective lightness—which is almost independent of the objective illumination. His Abstract stated that "The operation of the midget bipolar–midget ganglion channel is analysed in detail, and a functional interpretation of various retinal structures is given" (D. C. Marr 1974*a*: 1377). And his paper ascribed distinct computational functions to (for instance) the small stratified amacrine cells (unistratified and bistratified); the diffuse amacrine cells (narrow-field and wide-field); the amacrine/bipolar synapses . . . and so on.

So far, so familiar: this is just what one would expect from the author of the papers discussed above. And here too, Brindley had part-inspired him (D. C. Marr 1974*a*: 1379). But Marr's intellectual strategy was already changing.

Instead of starting with a description of the retina *as such* (compare: cerebellum), he started with a lengthy mathematical discussion of the abstract problem of computing lightness. Next, he asked, "Is this method relevant to retinal function?" Only then did he offer a section on 'The Anatomy of the Retina', before making various predictions about the functions of the retinal circuitry. Possibly, this 'mathematical' strategy put the experimenters off: not one contemporary reference to Marr's lightness paper is recorded in the Science Citation Index (Vaina 1991: 226).

From then on, the abstract definition of visual computation increasingly took precedence in Marr's work. The neuro-anatomy, by contrast, almost faded into the background.

Marr explicitly defended his new approach. He did this first (at a vision meeting in December 1973) in terms of two 'Levels of Understanding', and later (in a 1976 grant proposal and in his book of 1982) in terms of his three-level theory of psychological explanation *in general*: see Chapter 7.iii.b. (Perhaps it wasn't a totally new approach: Willshaw points out that the hippocampus paper had havered between *Any such theory must be like this* and *It must be like this, because the hippocampus is like this*—Willshaw and Buckingham 1990.)

Marr's final verdict on the lightness paper was that the neuroscience was mistaken (it turns out that lightness is computed in visual cortex: Zeki 1993), but that the methodology was sound. As he put it: "[It] showed the possible style of a correct analysis. Present is *a clear understanding of what is to be computed, how it is to be done*" (D. C. Marr 1982; italics added)—where the "how" was computational, not neurological.

The turning point—away from neuro-anatomy, towards abstract computational analysis of the task—dated from May 1972. That was when Marr first met Minsky and Papert, an engineer and mathematician then doing pioneering work in GOFAI in MIT's AI Laboratory (see Chapter 10.i.g, ii.a, and v.f).

The occasion was a small interdisciplinary workshop on Marr's theory of cortex, organized at Boston University's School of Medicine by the physiologist Benjamin Kaminer. The participants included many biological luminaries, such as Barlow, Hubel, Wiesel, Kuffler, Crick, and Brenner (and Blomfield, too). But Kaminer remembers that Marr spent much of his time with Minsky and Papert (Vaina 1991: 312).

Their research was very different from his, and they had scant respect for connectionism in general (see Chapters 10.iv.b and 12.iii). The latter point was perhaps a 'plus' for Marr (see below). But, by his standards, they knew next to nothing about the brain. Nor could they outdo him in mathematics, despite their mathematical expertise. So what could they possibly teach him?

The pivotal moment, according to Tomaso Poggio (personal communication), occurred when Marr took a few hours off to give a seminar on the cerebellum at MIT. Minsky remarked from the floor that we have to think about "the [abstract] problem of motor control" before we can ask the right questions about the cerebellar hardware. Marr later described this to Poggio as a crucial insight. For it would underlie his definition of the "computational" level of explanation as psychologically basic (Chapter 7.iii.b).

In addition, Minsky and Papert together persuaded him that computer simulation could help develop and test computational theories. This persuasion was a classic case of business mixed with pleasure. Crick recalls that "The boat trip after [Kaminer's] meeting was David's Road to Damascus . . . He became converted to AI and before long moved to MIT" (Vaina 1991: 314).

Just as Saul already knew of Jesus before his Damascene conversion, so Marr already knew of AI—indeed, Uhr and Vossler's work had been one of only ten citations in his cerebellum paper (see above). Moreover, machine translation and other aspects of NLP had long been established in Cambridge, England (Chapter 9.x.a–d). But AI simulation in general was much more advanced in Cambridge, Massachusetts.

So, in 1973, Marr left the one Cambridge for the other. Initially, he'd intended no more than a three-month visit. In the event, he never left: in 1976 he was officially appointed to the Department of Brain and Cognitive Sciences. (While at MIT, he soon added a passion for flying to his long-standing passion for the clarinet.)

Minsky's remark about "the problem of motor control" had prompted Marr to reassess his own earlier work. In December 1973, he wrote to Brindley:

> I do not expect to write any more papers in theoretical neurophysiology—at least not for a long time; but I do not regard the achievements of your 1969, or my papers as negligible. At the very least, they contain techniques that anyone concerned with biological computer architecture should be aware of, and I shall be very surprised if my 1969 or 1971 papers turn out to be very wrong. (quoted in Vaina 1991: 2)

Why had he given up on "papers in theoretical neurophysiology"? Writing to a potential translator at much the same time, he said:

> It would be fun to have some of [my early papers] translated into Russian. My present opinion of my earlier work is, however, that even if it is correct it does not take one much further in the study of how the brain works than, for example, the study of more obviously physical phenomena like . . . the conduction of nervous impulses. The reason why I believe this is that this part of my work has to do more with computer architecture than with biological computer *programs*! I have studied how some basic "machine-code" instructions can be implemented in nervous tissue; but these studies tell you rather little about how the brain uses these facilities—e.g., what is the overall structure of a particular motor program for picking an object up, or for throwing a ball. *It is the second kind of question that I am now interested in.* (quoted in Vaina 1991: 3)

Having moved to MIT's AI Laboratory, Marr soon abandoned the problem of motor control for the problem of *vision* instead. Another letter to Brindley (in October 1973) declared:

> I turned to vision when I arrived here, hoping that insight into the functions you had to perform to recognize something, together with the detailed neurophysiological knowledge and an unexcitable disposition, would be capable of illuminating many questions that are surely not yet vulnerable to the microelectrode. (quoted in Vaina 1991: 2)

The switch to vision was influenced by his MIT colleague Berthold Horn, who was then working on the (mathematical) computation of lightness. Marr's transitional paper (1974*a*) opened with a discussion of Horn's algorithm, and the claim that if it were implemented in the retina that would "make sense" of many of the known biological facts.

That paper was "transitional" not only in (still) saying a good deal about the neuroanatomy, but also in preceding Marr's second switch: from lightness to stereopsis. This interest was grounded in recent neurophysiological work by Barlow, and in Bela Julesz's studies of random-dot stereograms (Barlow *et al.* 1967; Julesz 1971). It owes something also to Parvati Dev, although her model of stereopsis was—dismissively—cited only in a footnote at the end of the paper (J. A. Anderson and Rosenfeld 1998: 231).

Even at MIT, however, Marr was initially frustrated by lack of computer power. In an early lab report on stereopsis, he said:

> [complex parallel algorithms] are very expensive to simulate, and it is extremely difficult to derive analytically, from a system with complex non-linear components, quantities that could be measured experimentally. (D. C. Marr 1974*b*: 232)

He discussed various ways in which different 'families' of theories based on stereo disparity might be implemented. But he couldn't actually implement them. (Computer models of scene analysis, by contrast, had been up and running in the AI Lab for some time: Chapter 10.iv.b.)

A few years later, that changed. Now, he was able—with Poggio, then based in Tübingen—to implement two powerful theories of stereopsis (D. C. Marr and Poggio 1976, 1979). And these papers, unlike the one on lightness, received enormous attention from experimentalists. They formed the core of an influential research programme on vision that continued up to—and after—his death, and which spread around the world (see Chapter 7.v.f).

Although Marr did relate his final theory of stereopsis to visual neuroscience, it hadn't been *driven by* the biology, as his cerebellar theory had been. On the contrary:

> We feel that an important feature of this theory is that *it grew from an analysis of the computational problems* that underlie stereopsis, and is devoted to a characterization of the processes capable of solving it *without* specific reference to the [neural] machinery in which they run. (D. C. Marr and Poggio 1979: 324; italics added)

Previous theories of depth vision, said Marr, for all their ingenuity in dreaming up algorithms, were fundamentally wrong-headed: "not one of them computed *the right thing*" (D. C. Marr 1982: 122; italics added). As for connectionism in general, much of it was useless for psychological purposes:

> Again, the primary unresolved issue is *what* functions you want to implement, and *why*. In the absence of this knowledge, a neural net theory, unless it is closely tied to the known anatomy and physiology of some part of the brain and makes some unexpected predictions [like his own early work], is of no value. (D. C. Marr 1975*c*: 876)

Evidently, Minsky's lessons—in the boat and the seminar room—had been well learnt. Neuroscience needed cognitive science, not just the other way around.

And people listened. It was Marr above all who made this point clear—both in his work on vision and in his models of the brain. In a glowing obituary of his younger friend, Longuet-Higgins put it like this:

> If neurophysiology was *a theoretical vacuum* when he entered it, it is now seething with lively controversy about the validity of his ideas on the visual system . . . Even if no single one of Marr's detailed hypotheses ultimately survives, which is unlikely, the questions he raises can no longer be ignored and the methodology he proposes seems to be *the only one that has any hope of illuminating the bewildering circuitry of the central nervous system*. (Longuet-Higgins 1982: 992)

14.vi. Realism Rampant

While Marr was formulating his theory of associative memory in the 1960s, an even more data-driven approach was already being developed by Grossberg. He combined neuroscience with an extraordinarily wide range of findings from experimental psychology. Indeed, he started from the behavioural data and brought in the neuroscience to explain it.

(Grossberg's technical work isn't easy to read. His neologisms don't help: for instance, he speaks of "syncytia" and "subsyncytia" where others would speak of networks, neurone pools, or cell assemblies. For an especially accessible summary, see his *American Scientist* article: 1995.)

a. A voice in the wilderness

Grossberg had first written about his project in 1957, as a freshman at Dartmouth—only one year after the famous Dartmouth summer gathering (see Chapter 6.iv.b). As a graduate student at Stanford in the late 1950s, he'd circulated manuscripts containing many detailed hypotheses about integrated brain processes. These even contained an equivalent of the Marr–Albus rule—and also, in what Grossberg termed his Generalized Additive Model, a near-equivalent of what were later named "Hopfield" nets (12.v.f).

Unlike Marr, however, Grossberg had to wait a long time for recognition. By the late 1980s, he was being described as "one of the most visible scientists working in neural networks for nearly twenty years"—that is, from about 1970 (J. A. Anderson and Rosenfeld 1988: 243). But he'd been doing important work since the late 1950s. Between then and the early 1970s he was treated as an eccentric, though brilliant, outsider. Hence Paul Werbos's remark (quoted in Chapter 12.v.g): "We were not people they trusted, neither Steve nor I."

He had great difficulty in getting his early papers published. Although a 500-page monograph appeared from the Rockefeller Institute for Medical Research, where he was a newly arrived graduate student (Grossberg 1964), journal editors proved less amenable. For instance, it wasn't until 1980 that a paper appeared in *Psychological Review*. Before then, they'd been sent back to him without review, as not being the sort of thing the journal published.

One problem was the relentless interdisciplinarity. The bristling mix of psychology, mathematics, neurophysiology, and neuro-anatomy—though not, yet, computing: see below—would have daunted all but the most eclectic cybernetician (see 1.iii.h). Another was the very richness of Grossberg's fare. He provided so many novel ideas in a single paper that any one risked being obscured by the others.

Another hurdle, Grossberg recalls, was the low value that psychologists in the 1950s–1960s gave to abstract mathematical argument:

> One had to function primarily as an experimentalist. Even Bill Estes, I was told, had a lot of trouble getting his modelling papers published at first, even though he was already a distinguished experimentalist. (J. A. Anderson and Rosenfeld 1998: 174)

Much as Marr's early brain models seemed merely "speculative" to empirically minded biologists, so Grossberg's early theories of mental processing—despite being grounded in behaviour—failed to impress the psychologists.

It didn't help that the mathematics was taxing. ("The problem is that, although I would often have an idea first . . . I would develop it too mathematically for most readers"—J. A. Anderson and Rosenfeld 1998: 179.) In any one paper, Grossberg would offer many interacting non-linear differential equations—with no way, at that time, of leaving a computer to do the sums.

He provided proofs, to be sure. But some of these were even more difficult than Rosenblatt's proof of the convergence theorem (see Chapter 12.ii.f). Many readers simply didn't believe them. And his qualitative predictions of the system dynamics and observable behaviour which, he said, would result from his equations were far from obvious to most people. Often, they were counter-intuitive.

Even Stanislaw Ulam and his fellow physicists at Los Alamos, who implemented the equations on their huge computer in 1966, had been sceptical initially. Grossberg, again: "At first they didn't believe the theorems either, but then they ran the networks on the computer, and the simulations did exactly what the theorems said they should" (J. A. Anderson and Rosenfeld 1998: 179).

(Two decades earlier, machine demonstration wouldn't have convinced Los Alamos. In 1944 the newfangled IBM punched-card machines weren't trusted by the scientists designing the implosion atom bomb, and their wives were asked to do the relevant sums using mechanical hand calculators: MacKenzie and Spinardi 1995. Even the EDSAC, a few years later, made numerous errors because of overheated valves, so calculations had to be repeated several times.)

It wasn't only the mathematically inept who wilted. As we saw in Chapter 12.v.g, Grossberg's undergraduate dissertation—which he'd sent, unsolicited, to numerous renowned researchers in 1965–6—"perplexed" the leading mathematical psychologists at Stanford. They realized that there was a good mind there, and invited him to join them as a graduate student accordingly. But they recognized the work's true quality only much later.

The key difficulty was that *the general nature* of Grossberg's mathematics was unfamiliar, quite unlike what was typically used by psychologists or neurophysiologists at the time. Specifically, it was "nonlinear, nonlocal, and nonstationary" (1980: 351).

Put another way, he was discussing complex dynamical systems, adapting from moment to moment—not chains of atomistically conceptualized events (Markov processes, for instance). Dynamical approaches in cognitive science came to prominence from the late 1980s on (see viii–ix below; 15.viii.c, ix, and xi.b; and 16.vii.c). In the late 1950s, when Grossberg circulated his first work, dynamical systems theory was distinctly outré in psychological circles. So the researchers who'd invited him to Stanford didn't actually take up his ideas about additive networks. Instead, they continued working on stimulus sampling and Markov chains, the preferred intellectual approach at that time (Chapter 6.i.a).

Even as an undergraduate, Grossberg addressed virtually every problem area in psychology. The breadth of his ambition would be evident in the subtitle of his 1982 book: *Neural Principles of Learning, Perception, Development, Cognition, and Motor Control*. In his eyes, these are not utterly different phenomena, grounded in independent modules somehow bolted together in the brain. Rather, they are emergent characteristics of a shared body of fundamental processing principles, which generate and stabilize a hierarchically structured connectionist network. This didn't make things easy for academics trained in narrowly defined specialist areas.

In effect, then, he was trying to keep Rosenblatt's promises (see Chapter 12.ii.e–f). But this was controversial, as well as ambitious. For Rosenblatt had made many of those who *did* value mathematical analysis distinctly wary of any sort of connectionism (12.iii).

Even broadly sympathetic brain scientists such as Cowan were deeply doubtful about Rosenblatt's ambitious claims. And in the computational psychology of the 1960s–1970s GOFAI was the preferred approach. Grossberg attracted scepticism accordingly. Today, he's lauded as one of "a few hardy researchers" who persevered with neural-network models (O'Reilly and Munakata 2000: 9). Then, he was seen as a maverick.

Even so, MIT appointed him Assistant Professor of Applied Mathematics in 1967 (when he still hadn't completed his Ph.D.), and Associate Professor in 1969. He was on the conventional tenure track . . . until the unexpected recession of the early 1970s put MIT into financial difficulty. Because of OPEC's sudden hike in the oil prices in 1973, plus political influence from the counter-culture, there was less R & D money available in the USA than before (see 11.i.b).

Since MIT was hugely dependent on R & D funding, it was hit harder than most universities were. Berthold Horn recalls it as a time when "There was almost no funding for a while" (quoted in Crevier 1993: 117). One result was that almost all of the untenured junior faculty were unexpectedly let go, as the euphemism has it.

In this context, a knight on a white charger—or anyway, a knight—championed Grossberg in 1973. Sir James Lighthill, whose recent critique of GOFAI had set back AI research in the UK and cast a shadow also in the USA (11.iv.a–b), was asked by MIT for his opinion on Grossberg's work. As the Lucasian Professor of Applied Mathematics at Cambridge, he would understand the material if anyone could—and it was clear that many couldn't.

MIT had approached Lighthill because they were bemused by the extraordinarily mixed response to their first call for references. As Grossberg remembers it:

> [When asked whom to approach for recommendations] I naively gave them a list of about fifty names of distinguished people across the fields of psychology, neuroscience, and mathematics. I got a very wide range of letters. A number of letters said I deserved a Nobel prize and I am a genius. I also had other letters that said, in effect: "Who the hell does he think he is trying to model the mind?" (J. A. Anderson and Rosenfeld 1998: 182)

Lighthill's answer to the query, says Grossberg, was "a glowing three- or four-page letter which basically said that I was doing exactly what AI should have done".

But to champion isn't necessarily to rescue. Despite this encomium from MIT's chosen court of appeal, they still didn't offer him tenure. His work was felt to be too controversial, given the unhappy financial climate, and he was warned that he'd soon have to leave. However, he was rescued—not by another knight but by Boston University, who offered him a full professorship. He left MIT for Boston in 1975.

Soon after Grossberg's arrival there, he founded the interdisciplinary Center for Adaptive Systems (CAS)—where he remains today (2006). The Boston group covered a wide spectrum, for he insisted that every CAS member be trained in at least three of four disciplines: computer science, mathematics, psychology, and neurobiology.

Much of his later work was done in collaboration with his wife, Gail Carpenter, a leading researcher in her own right. Her first work had involved mathematical analyses of single cells, using the Hodgkin–Huxley equations (J. A. Anderson and Rosenfeld 1998: 200 ff.), but her interests soon broadened. Like him, she was invited as one of only fourteen opening speakers at DARPA's crucial workshop on connectionism in 1987 (12.vii.b).

By that time, clearly, he was accepted as a leader in the field. Indeed, he'd just become the first President, and co-founder, of the International Neural Network Society (12.vii.a). The wilderness had been left far behind.

b. Adaptation—and feature-detectors

What Grossberg was doing from the start, and what Lighthill thought AI should have been doing, was explaining mind and behaviour by bringing in the brain. Starting from behavioural data, he looked for neurophysiological explanations. And he tried to do this as *realistically* as possible. Toy problems were avoided: the focus was on "problems requiring *real-time adaptive* responses of individuals to *unexpected* changes in *complex* environments" (Grossberg 1988, p. viii; italics added). Blocks world, this was not.

He also tried to do it as *parsimoniously* as possible. He spoke of "minimal anatomies", meaning the simplest neurological model that could account for the observed behavioural constraints. A few general principles—i.e. mathematical theorems, some of which he saw as "particularly simple and lucid" (1976*a*: 253)—were used to explain a profusion of empirical facts. Many superficially diverse (and seemingly unrelated) aspects of behaviour were unified, as unexpected emergent properties of an underlying dynamical system.

The data were drawn from psychology, Grossberg's first love as an undergraduate at Dartmouth, and from various levels of neuroscience. Besides explaining various *psychological functions* in terms of common processing principles, he aimed to show how a variety of *neural structures* can emerge from the same underlying neurological source. That is, he wasn't merely looking to current neuroscience for ideas that would explain behaviour. He was also looking to behaviour—in particular, to the way in which the organism adapts moment by moment to a changing world—to suggest hypotheses about as yet unknown neural mechanisms.

With hindsight, one can list many experimental confirmations of biological predictions made by his ART computer model (see below). For example, since 1988 there have been at least a dozen confirmations of his claim that attention and concept matching involve a top-down modulatory on-centre/off-surround network. Some of these, though not all, were experiments done by his Boston team. So he can surely escape Gross's charge (above) about "theoreticians" having contributed nothing to biology.

Consider, for instance, what he said about feature-detectors. By the mid-1970s, neurophysiologists—including Barlow (Barlow and Pettigrew 1971)—had discovered that even if cortical orientation detectors are in some sense innate, they aren't genetically *determined*. (People didn't yet realize that the fact that newborn kittens already possess vertical/horizontal detectors *does not* prove that these must be coded in the genes: see Section ix.a.)

Recent experiments had shown not only that normal experience fine-tunes the detectors already present at birth, but also that unusual visual input after birth can produce corresponding types of detector or, through disuse, destroy them. The relevant differences in *behaviour* had been noted in the 1960s, but now people were studying the neurology. If a newborn kitten wears goggles that present it with only vertical lines in the right eye and only horizontal lines in the left, the orientation cells in its brain will develop/atrophy accordingly. In a word, even low-level feature-detectors can be *learnt*—and unlearnt.

Grossberg asked how this is possible, and why the visual cortex has the columnar structure that it does. Tellingly, his answers were published, soon after his arrival at Boston, in a journal of cybernetics, not neuroscience (Grossberg 1976*a*,*b*). He described a form of Hebbian learning, or synaptic modification, justified by proofs of mathematical theorems. This two-part paper was built on the account of brain processing he'd been developing for almost twenty years—and it graduated from "additive" to "adaptive resonance" theory (see below).

The first part of the paper concentrated on feature-detectors, and offered a functional classification of the different types. Grossberg defined equations that would enable single cells in the cortex to learn different patterns, having compensated for various types of real-world noise. They might do this by enhancing contrast in the input, for instance, or by computing relative rather than absolute light intensities.

He added that the equations implied that cortical cells learning similar patterns would become grouped together. He indicated how the range, or degree of resolution, of coded similarities would depend on the numbers of neurones involved (Chapter 12.v.c). And he argued that pattern-discriminators can be hierarchically organized—as in Hubel and Wiesel's hypercomplex cells (which he mentioned specifically—1976*a*: 250), Gross's monkey's-hand-detectors, and perceptual concepts in general. In addition, he offered some testable hypotheses about the role of the retinal amacrine cells.

Characteristically, the paper used powerful mathematics inspired by specific findings in neuroscience. For example, it relied on S-shaped (sigmoid) learning rules, which modelled the cells' responses at high/low extremes of stimulation. In thus avoiding over(under)shoots, this mimicked some properties of biological neurones—and other cells, too.

Grossberg used sigmoids for a reason. He'd published a theorem in 1968 which proved that sigmoid learning enables cells both to suppress noise and to enhance contrast sensitivity, thus avoiding what he called the "noise-saturation dilemma". The idea was later used by the PDP connectionists in two famous papers (McClelland and Rumelhart 1981; Rumelhart *et al.* 1986*a*,*b*).

The proof concerning sigmoid cells wasn't a stand-alone result, but part of an analysis of *all* the ways in which cells could signal one another. That analysis also showed that *on-centre/off-surround interactions* (between cells that obey the membrane equations describing neurones) are *essential* to avoid the noise-saturation dilemma. In other words, it's no accident that the nervous system contains so many on-centre/off-surround units, and so much lateral inhibition (so Hartline had discovered cells whose existence was largely explained by the mathematics of system dynamics: see iii.c, above). Accordingly, Grossberg's model of pattern learning simulated centre–surround cells and lateral inhibition to increase the contrast in the input.

Third, the information that modified the simulated synapses wasn't carried by single responses, as in the networks of Chapter 12. Instead, it was coded by changes in a cell's rate of firing, averaged over small amounts of time. This reflected the neuroscientists' long-held conviction that the *frequency* of neuronal firing is crucial for coding (see Sections iii.b and ix.g). Again, Grossberg's learning rules—which defined recurrent networks (12.viii.b)—distinguished between short-term and long-term memory.

Fifth, some of his equations presupposed facts about local connection structures in the retina and the brain. And last, but by no means least, the model showed how a pattern can be *distributed* over a large number of individual neurones.

All very intriguing—at least, if one could understand it. But as we've seen, at first many couldn't. So why should they believe him? ("Who the hell does he think he is . . . ?") How could they be persuaded that his theory really did imply what he said it did? Perhaps it was just hot air?

Well, no. For another computer model, besides the Los Alamos experiment, had already suggested there was gold in the Grossberg hills. This model, which Grossberg commented on in his 1976 paper, was focused on feature-detectors. It was inspired by additive theory, and in particular by some equations that Grossberg had published, and criticized, early in the decade (Grossberg 1972). Its designer was Christoph von der Malsburg (1942–), who'd implemented it a few years earlier (von der Malsburg 1973).

Von der Malsburg adapted Grossberg's equations in building a two-layer connectionist network that modelled the development of striate cortex from a partly random starting point. Only "partly" random, because the system started off with more local structure than the networks discussed in Chapter 12: as remarked above, Grossberg's theory presupposed certain facts about brain connectivities. The results were startling.

When the 162-unit "retinal" layer was repeatedly presented with lines in various orientations, the 338-unit "cortical" layer gradually organized itself into a two-dimensional structure that matched Hubel and Wiesel's descriptions of visual cortex to a remarkable degree. Units that responded to the same orientation were grouped together in clusters. In addition, neighbouring units responded to similar orientations, so that the clusters were systematically arranged across the "cortex": see the seventh line down in Figure 14.2.

These results ensued even though the input had contained significant amounts, and interacting types, of noise. (This model *illustrated* the emergence of ocular columns rather than *explaining* it: a few years later, von der Malsburg (1979) gave an explicit analysis.)

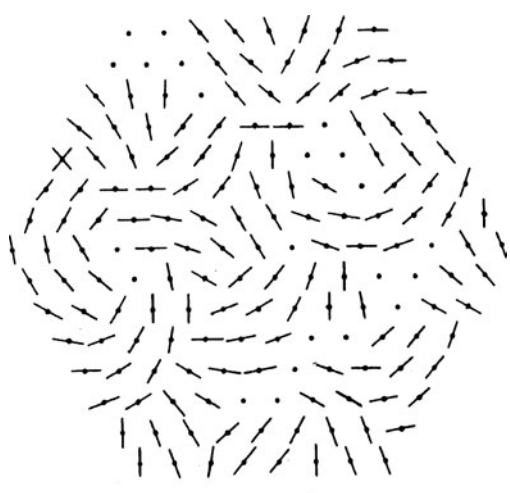

Fig. 14.2. View onto the [simulated] cortex after 100 steps of learning. [Each small line shows the orientation to which the relevant unit responds most strongly.] Reprinted with permission from von der Malsburg (1973, fig. 13)

Moreover, von der Malsburg found that non-standard stimulation had 'neuro-anatomical' effects comparable to those which occur in real animals. It's evident from Figure 14.1 that the input for the standard learning history depicted there had ranged across many different orientations. When the network's input was restricted to only vertical or only horizontal stimuli, the resulting orientation detectors were skewed and/or absent accordingly. And this skewing became irreversible after a certain "critical" period. Both these results had recently been observed in newborn kittens (C. Blakemore and Cooper 1970).

(As we'll see in Section viii.a, Von der Malsburg was also working on a model of neural self-organization *in the embryo*, prior to any perceptual experience: Willshaw and von der Malsburg 1976.)

This simulation proved that Grossberg's account, at least in its modified form, wasn't merely hot air. However, it didn't model every aspect of additive theory—never mind its later substitute (Grossberg 1976*b*). For instance, von der Malsburg used only very simple stimuli, namely motionless straight lines, whereas Grossberg had also discussed more complex cases.

Indeed, Grossberg was arguing—as always—in highly general (i.e. theoretically parsimonious) terms. His equations, he said, fitted many different parts of the brain, including olfactory, auditory, and cerebellar cortex, and also the hippocampus. They were part of a general psychophysiological theory he applied also to attention, arousal (including consciousness), analgesia, motor action, communication, reasoning, and psychopathology.

Even an outline simulation of that would require a much more ambitious computer model.

c. ARTful simulations

Together with his wife, Grossberg eventually produced one. They called it ART-2 (Carpenter and Grossberg 1987).

This system learnt to recognize input patterns, both binary and analogue, in real time and despite noise. The categories involved could be familiar, near-familiar, or novel, and they could self-organize on several hierarchical levels. Where GOFAI systems at that time were testing pre-set perceptual hypotheses (see Chapter 10.iv.b), ART-2 formed, learned, and stabilized its own. Moreover, it did this in real time, even after having learnt many different categories, because learnt categories could be accessed *directly*.

ART-2 was based on adaptive resonance theory, introduced in Grossberg's 1976*b* paper. The core idea was this:

> The functional unit of cognitive coding [is] an adaptive resonance, or amplification and prolongation of neural activity, that occurs when afferent data and efferent expectancies reach consensus through a matching process. The resonant state embodies the perceptual event, or attentional focus . . . (Grossberg 1980: 1)

The "expectancies" concerned included not only what we'd normally call expectations, but also predictions, questions, goals (intentions), and even learnt or 'instinctive' motor patterns such as those modelled by Kilmer (see Section iv.a).

On this theory, activity patterns are passed between two networks until they match. At that point, they stabilize. Inputs are held in STM, and compared with previously learnt categories (“codes”) in LTM. Near-matches lead to refinement of the pre-existing codes. If there’s no match, previously uncommitted LTM (if any) is used to encode the pattern currently held in STM.

This way of putting it may suggest that the patterns are passed *to and fro* between the networks, which could take a long time. But ART-2’s activity patterns oscillated at most once, and self-stabilization was mathematically guaranteed. Unlike the networks described in Chapter 12, it didn’t require repeated presentations of the input pattern, but “quickly learned to group fifty inputs into thirty-four stable recognition categories after a single presentation of each input” (Carpenter and Grossberg 1987: 151). It did this by using fast parallel search, the nature of which changed adaptively during learning.

ART-2’s predecessor, ART-1 (now there’s a surprise!), could handle only binary input patterns. Ideas from ART-1 had been borrowed by a number of fellow connectionists for use in their own work. ART-2 was less borrowable, because its many-levelled analogue-friendly representations were much more complex.

Nevertheless, patents were taken out on both systems, and on their successors ART-3 and ARTMAP. By the late 1990s “a lot of people” were using them for industrial R & D (J. A. Anderson and Rosenfeld 1998: 190). Whereas ART-1 and ART-2 dealt with perceptual categories, the later systems went beyond these to include aspects of attention, goal seeking, and motor action.

One might describe ART theory as an updated, and enormously complexified, version of TOTE units (Chapter 6.iv.c), in the sense that the core idea was *testing*:

> [Within] an ART system, adaptive pattern recognition is a special case of the more general cognitive process of discovering, testing, searching, learning, and recognizing hypotheses. Applications of ART systems to problems concerning the adaptive processing of large abstract knowledge bases are thus a key goal for future research. (Carpenter and Grossberg 1987: 152)

In other words, Barlow’s “incautious” suggestion about intelligence was being deliberately taken up (see Section ii.b).

Strictly speaking, ART-2 wasn’t “one” model, but a general class of models. So were ART-1, ART-3, etc. For the neuropsychological theory was expressed as a set of differential equations, whose variables could be instantiated in different ways and where one or more could be experimentally dropped, or “ablated” (pp. 154–5).

Grossberg’s theory had initially been developed without any reference to computers, as we’ve seen. When he arrived at Stanford in 1961, the leading simulator there tried to model his theory, but failed (personal communication). Later, when suitable technology became available, Grossberg turned to simulation himself. Indeed, he not only used that methodology, but proselytized about it.

Besides helping to clarify one’s theory, he said, it can help advance it. For it prompts thinking about how the data could arise as “emergent properties of a real-time process engaged moment-by-moment by the external environment” (1988, p. viii). One-off simulations, however, are irrelevant. (Compare Drew McDermott’s critique of one-off programs in GOFAI: 11.iii.a.) Copious, and systematic, modelling is required:

Only through the sustained analysis of many hundreds or even thousands of such experiments can one accumulate enough data constraints to discard superficial modelling ideas and to discern a small number of fundamental design principles and circuits. (Grossberg 1988, p. viii)

Through this approach, "a series of design paradoxes, or trade-offs, come into view which balance many data and computational requirements against one another".

Neuroscience in particular, he insisted, needs computer simulation:

The dynamics of large ensembles of neurons are as yet difficult to observe directly. Even if direct observation were possible, it would not explain *how* the interactions among neurons generate the emergent properties that subserve intelligent behavior. Additional methodologies are needed to investigate *how* the collective properties of a neural network are related to its components. Computer simulations of neural networks are crucial tools in the current explosion of work in brain science.

... Once a mathematical model of neural functioning is formulated, [it may be possible to prove] theorems concerning [its] stability or convergence behavior ... [However, neural processes] involving large and hierarchically organized systems of nonlinear ordinary differential equations are characteristically difficult to analyse through purely formal procedures. For these systems there may be no way to determine the output of the model when given a certain input short of "running" the model in a numerical computer simulation. Thus "experiments" can be run on a model, in ways that are similar in some respects to experiments run on human or animal subjects. (Grossberg and Mingolla 1986: 195; italics added)

This method enables neuroscientists to do things they simply couldn't do before:

Simulations can be cheaper and faster [than experiments on organisms], but more importantly they permit a much more precise level of control of many variables than could ever be realized in physiological or behavioral experimental paradigms. [They can even lead to] general design insights which can at times be formalized into mathematical proofs that would otherwise have been difficult to discover. (Grossberg and Mingolla 1986: 196)

In short, computer modelling can promise significant results that wetware experiments can't achieve.

Why did he spell this out at such length, as late as 1986? After all, cognitive scientists had been saying this sort of thing for years. The essential point had even been made, with respect to *mechanical* simulation, by some early 1930s behaviourists (see Chapter 5.iii.c).

The reason was that, even in the late 1980s, many *neuroscientists* were still suspicious of computer-based methods.—Computational (information-processing) questions, yes; computer models of the brain, *No!*—James Anderson recalls that at Rockefeller University in the early 1970s, "psychologists were far more open and responsive to new ideas [i.e. connectionism] than were neuroscientists" (J. A. Anderson and Rosenfeld 1998: 254). Similarly, Arbib found in the mid-1980s—when Grossberg was writing the words just quoted—that "the experimentalists in neuroscience, instead of being excited at having a distinguished program of brain modelling on campus [UMass, Amherst: see Section vi.b–c], saw it as either irrelevant or threatening" (J. A. Anderson and Rosenfeld 1998: 229).

Most brain scientists today are less suspicious (although Gross's comment on Marr smacks of the old school: v.e, above). They're increasingly using computer models in their work. Indeed, virtually all neuroscience—excepting nitty-gritty neurochemistry and theoretically unmotivated brain scanning (see Section x.b)—now involves computational questions about brain function, whether or not simulation is involved. This applies to work on feature detection, cognitive maps, motor control, action selection, language, schizophrenia . . . and consciousness.

As Arbib has remarked, his computationally oriented *Brain Theory Newsletter*, which attracted only a few hundred subscribers in 1980, would be selling in the tens of thousands were it still running today (J. A. Anderson and Rosenfeld 1988: 231). (In fact, it was incorporated into the journal *Cognition and Brain Theory* in 1982: see Chapter 6.v.c.)

d. Avoiding the black box

Inevitably, neuroscientists' computer models will become increasingly realistic. But there's a danger here. Lighthill commended the young Grossberg to MIT for doing what he thought AI should have done: taking account of the brain. The message of his notorious Report (Lighthill 1973) was that biological realism is a Good Thing—and, by implication, the more of it the better. But that implication was questionable.

Even in the 1940s, Ashby (1948: 383) foresaw that advanced versions of the Homeostat might behave in ways "too complex and subtle for the designer's understanding" (see Chapter 4.vii.d). Similarly, von Neumann predicted at the Hixon Symposium that complex automata would be almost as mysterious to their builders as animals are to biologists (Jeffress 1951: 109–10). And a widespread worry in the late 1980s, as we saw in Chapter 12.vi.f, was that large connectionist systems, once they became available, would be unintelligible.

Given enough computer power, one can stuff extra data parameters into one's simulations indefinitely. But if the result is in effect a black box, the exercise has scant scientific value. In the mid-1980s, one British computer scientist put the worry like this:

> Connectionism and its second coming is the next unavoidable issue [for AI] . . . [If] subsymbolic networks are necessary to support intelligent systems, then the conceptual transparency of the resulting AI systems is likely to be *on a par with that of the brain—i.e. somewhere close to zero*. Homogeneous networks of subsymbolic elements will severely test our abilities to understand our models. So if subsymbolic network architectures are in some sense necessary then that might be bad news for AI. (Partridge 1986–7: 16; italics added)

Similarly, Willshaw, in defending early Marr against charges of oversimplification, has pointed out "the danger that any completely specified model will become just as difficult to analyse as the brain itself" (Willshaw and Buckingham 1990: 116).

How does Grossberg's research stand up to the charge of black-boxery? It must be said at once that his work appears forbiddingly complex to non-specialists. Consider this statement of his commitment to realistic modelling, for instance:

> We [at CAS] typically begin by analysing a huge interdisciplinary data-base within a prescribed problem area. In our work on preattentive vision, for example, we have studied data from many parts of the vision literature—data about boundary competition, texture segmentation, surface perception, depth perception, motion perception, illusory figures, stabilized images, hyperacuity, brightness and color paradoxes, multiple scale filtering, and neurophysiology and anatomy from retina to prestriate cortex. (Grossberg 1988, p. viii)

All these data from visual psychology feature in a single paper on the perception of colour and 3D form (Grossberg 1987*b*). The same paper also draws on hypotheses about the cortical and retinal cells involved—and the neurotransmitters, too.

But the paper—like other CAS publications—isn't a mere ragbag of empirical facts. On the one hand, it draws many theoretical morals. For example, it argues that "the popular hypothesis of independent modules in visual perception is both wrong and misleading. Specialization exists, to be sure, but its functional significance is not captured by the concept of independent modules" (Grossberg 1987*b*: 4). It allows for learned (largely top-down) as well as automatic (bottom-up) processing in object recognition. It offers a new theory of stereopsis. And it makes many testable predictions.

On the other hand—and even more to the point, with respect to black-boxery—the paper rests on a set of mathematically proven theoretical principles. These unify the huge variety of detailed behavioural constraints simulated in the model.

A more recent publication, which explains depth vision and various visual illusions in terms of highly specific parts of the brain, makes the simplicity beneath the complexity even more evident (Grossberg and Howe 2003). To appreciate that simplicity is to understand the model. And the general principles underlying Grossberg's work are clearly intelligible to some people outside his own group at Boston. For—as we've seen—ideas from ART-1 have been used in other connectionists' models, and ART systems are even being used commercially.

One way of putting all this is to point out that it would be misleading to say that the behavioural constraints (about visual illusions, for instance) are "built into" the ART models—still less, that "extra data parameters" are repeatedly "stuffed into" them. Rather, the behavioural details *emerge* from, are *generated* by, the underlying system dynamics. This didn't happen by magic, of course. The design of the system dynamics—the "minimal anatomies", and combinations thereof—was guided by Grossberg's intuitions about what sort of system could generate those (seemingly unrelated) behavioural data. (Intuitions which, as we've seen, even the Los Alamos physicists didn't share.)

The complexity is due to his commitment to biological realism. That is, to his continual addition of further behavioural and neurological constraints (as in the colour/form and stereopsis examples mentioned above) and, when necessary, further theoretical principles. The intention is to *test and expand* the existing theory, not to *complicate and obscure* it by adding innumerable ad hoc hypotheses. Thus far, Grossberg's team, and a fair number of outsiders too, are still able to see the theoretical wood as well as the observable-data trees.

Even so, this approach is not for the faint-hearted. And it remains to be seen whether, in the new century, the CAS group will ever reach a point where even they can't really understand what's going on. The same applies, of course, to 'realistic' brain modelling in general. Anyone who aimed for a *completely* specified model would risk sacrificing understanding to observation. In Marr's terminology, Type-I explanation would threaten to give way to Type-II (see Chapter 7.iii.b).

In short, biological realism could conceivably go too far—especially if the modeller doesn't build the system up from a theoretically parsimonious base. This is one way of expressing the familiar claim that the brain may be too complex for the human mind to understand it. Whether that's true is still an open question, though we shouldn't stop trying yet.

Future "unintelligible" simulations whose performance successfully matched the neuropsychological data would be existence proofs that the brain isn't essentially *mysterious*. But lack of mystery isn't enough for scientific understanding. (The "mystery" of consciousness involves additional issues: see Sections x–xi.)

14.vii. Whole Animals

Kenneth Craik, in the early 1940s, pointed out the importance of "selection pressures" in evolving internal "models" of the environment (see Chapter 4.vi.b). The interests of the animal as a whole were crucial, he said, in shaping such models. But he could give few specific examples.

A fortiori, he couldn't give neuroscientific chapter and verse in describing the *whole* animal. No one at that time could—and it's not even clear that anyone tried. Thinking about the whole animal, as opposed to specific sensory or motor mechanisms, wasn't a practical aim. Moreover, the environmentalist influence of behaviourism kept ethology out of the mainstream (5.ii.c).

Eventually, that changed. The last four decades of the twentieth century saw the gradual rise of what's now called computational neuro-ethology (CNE), a term coined in the late 1980s. CNE's strongest disciplinary links are with neuroscience, ecological psychology, and A-Life. But it has implications for cognitive science in general (Keeley 2000*b*).

One pioneering example, in which the *general* implications were given especial prominence, is discussed in this section. Further examples—focused on crickets, hoverflies, cockroaches, and lampreys—will be described in Chapter 15.vii. All these CNE programmes have generated novel hypotheses about the nervous system, whether in humans or in other animals.

a. CNE—what is it?

CNE is Computational. It's Neural. And it's Ethology. Ethology considers the whole animal's behaviour in its natural habitat, focusing on species-specific adaptations to a particular environmental niche. Neuro-ethology (named in the early 1980s) studies the underlying neural mechanisms. And CNE interprets these in computational terms.

The earliest CNE work was done in the 1960s. The scientist concerned—namely, Arbib—continued his research and expanded his theory over the next forty years, as we'll see (subsections b–c, below). But there was *no* steady growth in interest within the cognitive science community as a whole.

On the contrary, we'll see in Chapter 15.vii that most of the influential CNE research—Arbib excepted—wasn't done until the late 1980s. Randall Beer's "manifesto" (his word) for the field was published in 1990, soon after Christopher Langton's definition of "Artificial Life" (15.xi.b). Partly because Beer allied himself with the newly emerging A-Life community, CNE was now seen in the context of A-Life as much as of neuroscience.

One might wonder why CNE didn't blossom long before then. After all, ethology as such had been growing since the First World War (Chapter 5.ii.c).

One reason was that ethology was overshadowed by behaviourism for many years. Indeed, hardly any of the early work was translated into English before the late 1950s (C. H. Schiller 1957). The behaviourists focused on general mechanisms, studied in laboratory conditions (5.i.a). They saw Konrad Lorenz's fieldwork, for instance, as birdwatching—not science. This wasn't fair: Lorenz had provided systematic observation and even some experiments, not mere anecdotes. But, the power of fashion being what it is, the ethologists were sidelined.

Another reason was that AI hadn't progressed sufficiently. Robotics, in particular, was hugely difficult. Beer's six-legged cockroach robots, for instance, were a triumph of mechanical engineering no less than CNE. By the mid-1990s, however, the *programmable* Khepera robot—designed by Francesco Mondada in 1992–3—could be bought off the shelf. In addition, VLSI techniques could be used to provide (for instance) speedy sensory processing based on neuroscientific data.

A third reason was that neurophysiology itself wasn't far enough advanced until after mid-century (Chapter 2.viii.e). Moreover, it was typically conducted in a reductionist spirit that lost sight of the animal as a whole.

The 'Frog's Eye' work of the late 1950s is a good illustration. It could be regarded as the first exercise in CNE—but if so, this was more by accident than design. Lettvin and his colleagues were driven to consider the frog *as a frog* only by the surprising feature-detectors they found (see Section iii.a). They hadn't set out with the intention of analysing the visual system in terms of predator and prey.

Similarly, in recalling his own "unheard of" results, Hubel has said: "It is hard, now, to think back [to the late 1950s] and realize just how free we were from *any idea of what cortical cells might be doing in an animal's daily life*" (1982: 516; italics added).

If they'd started from an ethological viewpoint, their findings would have been less of a surprise. Indeed, Lettvin's friend Selfridge had already argued, on computational grounds, that ecologically relevant feature-detectors must exist. But he didn't know which, or where, they were: it was Lettvin's team who put the N into the CNE. And it was a research student in their laboratory who would make that "N" *whole*.

b. A wizard from Oz

One of the many people enthused by the 'Frog's Eye' research was Arbib (1940–), an English-born Australian mathematician who arrived at MIT as a graduate student in 1961. He started his Ph.D. with Wiener (later continuing with the probability theorist Henry McKean). Meanwhile, he worked as a research assistant in McCulloch's laboratory until he left in 1963 to go to Stanford (via Europe and Australia).

This seemingly innocuous association with McCulloch had to be kept from Wiener, who became "apoplectic with rage" when, on Arbib's last day, he discovered it (Arbib 2000: 203–4). His vitriolic hatred of McCulloch has been 'explained' in various ways. McCulloch himself told Arbib a story about having involved Wiener's daughter with his Mafia contacts, for her own protection. This was fascinating, says Arbib, but—as with many of McCulloch's stories—probably largely fiction.

The most likely explanation, Arbib now believes, is that Wiener (in 1952) had asked McCulloch to tell him about the brain, and McCulloch's mini-lecture had (characteristically) contained as much conjecture as fact. When, after three years' work, Wiener triumphantly presented a meeting of neurophysiologists with an elegant mathematical theory accounting for everything McCulloch had told him, he was laughed out of court. He hadn't realized that McCulloch was one of those people whose talk is peppered with speculation dressed up as fact—albeit hugely stimulating, insightful, intelligent speculation. (Turing had realized this, but concluded that McCulloch was "a charlatan": Chapter 4.iii.a.)

Nor did Wiener realize it now. Instead, he assumed that McCulloch had maliciously set him up for this fall. With better personal antennae, he would have avoided the humiliation—and the dreadful decline of the young Pitts, whose life was shattered by the feuding (see 4.iii.d).

Lettvin (1999) mentions "a viciously phrased letter" sent by Wiener breaking all connections with McCulloch's group. And he says:

> It had nothing to do with any substantive cause but was the result of a deliberate and cynical manipulation designed to sever Wiener's connection with McCulloch and his group. The details are not edifying. Wiener was victimized as much as the group. (Lettvin 1999)

With no further information on the "details", or on who was doing the "manipulation", it's not clear whether this angry letter was part-prompted by the events described by Arbib. But that there was a rift, and that the effect on Pitts was (as Lettvin puts it) "devastating", isn't open to doubt.

The newly arrived Arbib was already more than familiar with computational ideas. He'd found superior proofs for McCulloch and Pitts' 1943 paper while still an undergraduate (Chapter 4.iii.f).

He very soon co-authored a paper on neural modelling with McCulloch and Cowan, then a 'mature' graduate student alongside Arbib, for the seminal conference on self-organizing systems in Chicago: see Chapter 12.iii.e (McCulloch *et al*. 1962). And shortly after that, at one of Oliver Waddington's maverick meetings on theoretical biology, he would define a self-reproducing automaton based on von Neumann's ideas (see Chapter 15.v.b). So his maths was in excellent shape: he went to McCulloch to learn neurophysiology.

The prime lesson Arbib took from the lab's work on feature-detectors wasn't a conversion to single-cell recording, but the realization that perception serves the interests of the organism concerned. Presumably, then, it's integrated with the creature's motor mechanisms in ecologically appropriate ways. He was also inspired by the Mars robot RETIC (see Section iv.a), because of its concern with the action of *the whole animal*. Kilmer, in fact, was the junior colleague at MIT who had the most influence on him (and later joined Arbib's brain research group at the University of Massachusetts, Amherst).

In short, Arbib's aim was to progress from 'What the Frog's Eye Tells the Frog's Brain' to "What the Frog's Eye Tells the Frog" (Arbib 1981*a*: 23). But whereas the 'Frog's Eye' author Maturana would soon interpret the whole-animal insight in an anti-computational—and highly unorthodox—way, Arbib stayed within the computational camp.

Indeed, he soon became one of its most prominent champions. In 1964 he published an introductory text on the mathematics of automata theory, including McCulloch–Pitts networks (Arbib 1964). To his amazement—he was only 24, and still a Ph.D. student when he wrote it—it got the lead review in *Scientific American*, and a mention in an article on Wiener in the *New York Review of Books*. He now says this was "not so much because of the merit of the book, but the fact that Wiener had just died, and so cybernetics was a hot topic at that time" (J. A. Anderson and Rosenfeld 1998: 223). However that may be, it sold very well.

Eight years later, he added neuroscientific flesh to the computational bones in a widely read book about the brain, tellingly subtitled *An Introduction to Cybernetics as Artificial Intelligence and Brain Theory* (1972). In effect, this was a declaration of intent for his interdisciplinary brain research group at Amherst, where he went after six years at Stanford.

The project was set back by the drying-up of funds for connectionism in the mid-1970s—and Kilmer even deserted the field as a result. After DARPA's crisis meeting in 1987, however, the funding pendulum swung back again (Chapter 12.vii.b). Arbib soon went to the University of Southern California to direct their Brain Project.

The 1980s were hugely busy years for Arbib, but not hugely influential. As remarked above (Section vi.c), most 'pure' neuroscientists didn't take connectionist modelling seriously—especially before PDP became widely visible at the end of the decade. Arbib's pioneering *Brain Theory Newsletter* was discontinued before the wider research community caught up with him.

Eventually, however, his influence grew. His interdisciplinary research was suddenly 'discovered', as other neuroscientists began to express their sensori-motor theories as computer models—and as whole-animal approaches in general gained ground.

In the 1990s, he was Editor of the *Handbook of Brain Theory and Neural Networks* (with a second edition in 2003). He wrote a paper for the AI community recommending biological design principles in robotics (Arbib and Liaw 1995). And he co-authored a book uniting neuroscience and (animal and human) psychology with the computational theory he'd been developing since the early 1970s (Arbib *et al.* 1997). By the turn of the millennium, he was using the recent discovery of 'mirror neurones' to part-explain the evolution of language in the context of his long-established approach (for his latest statement, see Arbib 2005).

In sum, he's been a key player across the whole of cognitive science for over forty years.

c. *Rana computatrix* and its scheming cousins

To find out just what the frog's eye tells the frog, Arbib and his students (starting with Richard Didday) did some behavioural and neurophysiological experiments on the real animals. Their main activity, however, was developing a computer model—more accurately, a still-continuing *series* of models—of sensori-motor integration in the frog (Didday 1976; Arbib 1972, 1982, 1987, 2002*b*; Arbib and Cobas 1991; Cobas and Arbib 1992; Arbib and Lee 1993; Liaw and Arbib 1993; Arbib *et al.* 1997).

Arbib named it *Rana computatrix*. One might naturally assume (many people did, myself included) that this was in memory of Grey Walter's *machina speculatrix*

(Chapter 4.viii.a–b). And indeed, Arbib had already read *The Living Brain* when he first started work on *Rana*. But he wasn't aware of the connection:

> I had read [Grey Walter's book]. But what was interesting was that I had not consciously realized the inspiration for the name *Rana computatrix* until some years later, when Dan Dennett asked if *machina speculatrix* were the inspiration—and I suddenly realized it surely was! (Arbib, personal communication)

So, like Paul McCartney's unrecognized memory of 'Yesterday' (Chapter 1.iii.g), Arbib was recalling someone else's work—in a quite specific way—without knowing that he was doing so. If he hadn't been asked about it, he might still be convinced of his originality today.

Putting the name of his computerized frogs on one side, what about the ideas implemented in them? To some extent, Arbib's early inspiration came from Valentino Braitenberg (see 15.vii.a). He says now (personal communication) that he was "excited" by Braitenberg's ideas on the cerebellum, and "enjoyed" a paper foreshadowing the book on *Vehicles* (Braitenberg and Onesto 1960; Braitenberg 1965). But the main intellectual prompting, believe it or not, came from SHAKEY (see 10.ii.a and iii.c): "My real interest in robots was developed by the work of Nils Nilsson and colleagues at SRI on SHAKEY, from around the time I was at Stanford" (personal communication).

One of the lessons learnt from SHAKEY, and from his own later experience too, was the enormous difficulty involved in not merely ("merely"?) designing robots, but actually building them. After all, SHAKEY itself had got its name not from any of the influential ideas implemented in it, but from the fact that—considered as a mechanical object moving on the floor—it wobbled (see 10.ii.a).

Accordingly, Arbib's frog model was only ever implemented as computer programs. He did consider building hardware robot frogs, and published a paper on robot design (Arbib and Liaw 1995). But his robots were all simulated, not real. (One of his students, Tony Lewis, did eventually build a robot salamander, with a flexible spine and a GA-generated neural controller: M. A. Lewis *et al.* 1994.)

Amphibia weren't Arbib's only interest. From the early 1970s, he also worked on mammals. For instance, his team modelled stereo vision, and motor control by the cerebellum (Arbib *et al.* 1974). Much later, as we'll see, he widened his scope still further, applying the ideas initially developed with respect to frogs to the highest reaches of human thought.

Arbib's artificial frog carried out highly distributed information processing, so developing McCulloch's ideas about "redundancy of command". Initially, Arbib used competing, winner-takes-all, networks (see Chapter 12.ix.a). These modelled the dynamic perception–action cycle, wherein perception leads to action which leads to a new perception . . . and so on. Perceptual recognition depended on a "slide-box" defining a fixed set of categories. And (like RETIC) the system specified a finite set of possible actions, one of which would be activated after competition between the relevant networks.

By 1980, however, fixed networks and slide-boxes had given way to multi-layered perceptual and motor "schemas" (Arbib 1981*a*,*b*). Arbib later said that schema theory "is rooted in the *Critique of Pure Reason* of Immanuel Kant" (Arbib 1995: 11 and sect. 3). But it was mediated by McCulloch's use of Kantian ideas, and the 'Frog's Eye' paper's identification of "genetically built in" neural contexts as "the physiological synthetic *a priori*".

These Kantian ideas, in those behaviourist days, were unorthodox, not to say shocking. However, neuroscientists had Henry Head's example to encourage them (4.vi.a). Accordingly, Arbib—like Bartlett before him (5.ii.b)—borrowed Head's word: what Craik had termed models, he termed schemas. He hadn't used this term initially, but started doing so after friends pointed out the similarity to Bartlett and Jean Piaget—both of whom had spoken of "schemas" (Arbib 1985: 3; S. Gallagher 2004: 53). Indeed, Piaget's constructivism, with its emphasis on continual change in accommodating to the environment, became another important influence.

Schemas were dynamical structures, continually adapted as a result of experience. Each perceptual schema tested for, or (as Grossberg would say) expected, a certain type of object. The simplest ones were feature-detectors under another name. The more complex ones, schema "assemblages", defined general classes. Subtle variations between class members could be identified by "fine-tuning" of the schema's parameters. Similarly, each motor schema specified a general type of action. The simplest of all caused some utterly invariable movement. Usually, however—and unlike the Mars robot—they allowed for fine-tuning to generate movements adapted to circumstances: same action, different movements.

Schemas could be closely associated and/or hierarchically nested—and could be thought of in both neurological and AI terms:

> For [brain theory], the analysis of interacting computing agents called *schema instances* is intermediate between the overall specification of some behavior and the neural networks that subserve it. For [distributed AI], schemas provide a form of knowledge representation which differs from frames and scripts by being of a finer granularity. A schema is more like a molecule than an atom in that schemas may well be linked to others to provide yet more comprehensive schemas. (Arbib and Cobas 1991: 143)

Arbib saw schema theory as a way of coping with the problem posed by Pitts and McCulloch in 1947: how to move between a universal and its instances. It was also a way of answering Marr's early question, how the cerebellum can make the 'right' detailed movements when a general type of action is intended. Indeed, Arbib's student Curtis Boylls had started to model the cerebellum and brainstem motor nuclei in the early 1970s. His main aim was to discover how they could convert a general motor schema (such as grasping something) into specific behaviour (such as grasping *this* thing).

Even as a tadpole, *Rana computatrix* wasn't a toy frog living in a toy world. Arbib's early model of vision was relatively realistic when compared with GOFAI's blocks world, or even Marr (1982), for it computed depth using the optic flow caused by bodily movement. That is, it modelled 'animate' vision.

Moreover, the possible actions were based on ethologists' studies of just what real frogs/toads do in subtly different circumstances. A frog will snap at prey that's perceived as being nearby, for instance, but jump towards prey that's further away; and, in certain circumstances, it will make a detour around a barrier placed between itself and the prey (Arbib 1982; Cobas and Arbib 1992; Arbib and Lee 1993; Collett 1979, 1982).

Neuroscientific realism was attempted too. As early as the late 1960s, Arbib's first student, Didday—like Kilmer, originally an engineer—had started to program a model of the frog's neuro-anatomy (Didday 1976). By the 1990s, *Rana computatrix* included many more neurological details (Arbib *et al.* 1997).

Arbib soon generalized his research beyond frogs. For instance, he provided a theory of the "cognitive maps" first ascribed by Edward Tolman to rats (Chapter 5.iii.b) and later located in the hippocampus by John O'Keefe and Lynn Nadel (1978). This model of approach and avoidance in *Rattus computator* (Lieblich and Arbib 1982) eventually grew to include (visual) Gibsonian affordances—such as *go straight ahead*, *hide*, *eat*, *drink*, and *turn (left/right)*—which often led the rat into currently invisible parts of space, sometimes by a complex route (Guazzelli *et al.* 1998).

After rats, monkeys: *Macaca computatrix* simulated the neural schemas controlling visual saccades in macaque monkeys. It included attentional saccades to new light stimuli, and memory saccades to points of previous interest (Dominey and Arbib 1992).

As for humans, they weren't ignored either. Arbib (1981*b*) published an influential diagram of the functioning of the human hand that would have delighted the heart of Charles Bell (2.viii.f). This integrated motor schemas for moving the arm, rotating the wrist, and pre-shaping the hand to 'fit' the object to be grasped:

> [When] we reach for an object, the brain has to simultaneously figure out the control of the arm and the shaping of the hand. It's not that you get there and then figure out what to do with the hand. The brain is preshaping the hand at the same time that it's coming up with the trajectory . . . [In 1981 I gave] a fairly simple diagram of the interaction between perceptual schemas—figuring out where the object is, what size it is, and what orientation it is in—and the [motor] schemas for control of the arm, control of the hand, and so on, and how they all interacted. (J. A. Anderson and Rosenfeld 1998: 233)

This *Handbook of Physiology* diagram, he now says, is "probably the most successful thing I've done, in terms of the number of reproductions that have occurred in textbooks and papers" (J. A. Anderson and Rosenfeld 1998: 233).

A few years later, he moved from diagram to program. That is, he developed a schema-based program for controlling a (virtual) three-fingered hand (Arbib *et al.* 1985). The hand was designed to perform the central task of the intellectual life: picking up a coffee cup. And, characteristically, the paper discussed the possible neural implementation of the interacting schemas involved.

When Arbib later applied schema theory to high-level cognition and language, however, the neuroscience was largely notional (Arbib *et al.* 1987). The same was true, in spades, when he trod in the footsteps of Hans Driesch (Chapter 2.vii.b), and of John Z. Young and Longuet-Higgins too, and gave the Gifford Lectures on natural theology (Arbib and Hesse 1986: see Chapter 7.i.g).

He co-authored these with Mary Hesse, a distinguished English philosopher of science—and a regular visitor to the Epiphany Philosophers group in the Cambridge apple orchard (Preface, ii). The vagueness was hardly surprising. A schema (assemblage) for a belief system such as Christianity or Islam, or even for component ideas such as salvation or justice, is difficult enough to define in conceptual terms—as philosophers know to their cost. Relating those concepts to detailed neuroscience simply wasn't possible.

Indeed, it may never be possible, *in principle*. Schema theory is expressed at the functional level, between observed behaviour and neural implementation—and functionalists have good reasons for denying any systematic equivalence between conceptual thought and its neural implementation (see Chapter 16.iii–v). One doesn't have to accept the thesis of multiple realizability undiluted—and Arbib certainly wouldn't do so—to grant that many concepts (schemas) can't be mapped onto, or identified with, specific neural mechanisms.

In other words, Arbib used functionally defined 'architectural' theories to interpret *and to guide* his neurology. (In this, he was comparable to Aaron Sloman, who'd been developing a wide-ranging architectural theory, though without the neurology, for many years: see Chapters 5.i.f and 16.ix.c.)

As the century drew to its close Arbib, with Peter Erdi and Eccles's co-author Janos Szentagothai, published a major book on neural organization. (For diverse peer commentaries, see *Behavioral and Brain Sciences* 2000.) Among many, many, other things, this described their computational models of the olfactory system and hippocampus, including schema-based cognition (Arbib *et al.* 1997, ch. 6). They used a dynamical systems approach to model spatio-temporal processes at various different levels, from the subcellular level up (see Section ix.b). And they drew on:

* anatomy (brain structures defined at many levels of analysis);
* physiology (of the cell, the synapse, and EEG);
* psychology (addressing a wide variety of behaviour and cognition, in animals and humans);
* mathematics (abstract analysis of the functions and dynamics involved);
* and various areas of AI.

This was interdisciplinarity in action.

The millennial arrow in Arbib's quiver was a development of Giacomo Rizzolatti's idea that mirror neurones, which he'd discovered in 1995, may have enabled the evolution of language (Rizzolatti and Arbib 1998; Arbib 2002*a*,*b*). A mirror neurone fires not only when a monkey *performs* a certain hand movement, but also when it *observes* that same hand movement performed by another monkey, or by a human.

Arbib listed three possible uses of mirror neurones, including enabling the animal to anticipate, and to imitate, what another animal is doing. Monkeys aren't good at imitation, but people are. In 1994 PET imaging (see Section ix.b) implied that a part of Broca's area 'lights up' when the person makes hand movements; and in 1995, mirror neurones for grasping were indicated there too. Moreover, comparative anatomy suggests that this sub-area may share its evolutionary origin with the 'grasping' area in the monkey's motor cortex. In short, the language area in our brains seems to involve cells capable of aiding gestural communication. Possibly, it may also contain, or be linked to, mirror neurones for facial expressions and speech movements.

(As Arbib pointed out, this hypothesis *does not* address the origins of syntax, negation, or reference to past events. So Chomsky's scepticism about evolutionary explanations isn't allayed: see Chapter 9.iv.e.)

In sum, when Arbib could relate schemas to actual neurology, he did. When he couldn't, he tried to provide computer simulations and/or formal theories that were at least compatible with neuroscience. When he couldn't do *that*, he tolerated vagueness.

But even his Gifford Lectures were delivered with countless glances towards the brain. He was trying to show that a general type of neural processing could underlie a huge range of behaviour—from feeding in frogs to manual dexterity, and even prayer, in *Homo sapiens*.

Arbib's perceptual and motor schemas were analogous to the "T" and "O" of the TOTE units posited in the visionary *Plans and the Structure of Behaviour* (see Chapter 6.iv.c). The creators of both sides of this analogy indulged in optimistic hand-waving. But *Rana computatrix* and its computational cousins incorporated vastly more neuroscientific detail, and much subtler computational insights, than the *Plans* authors could have dreamt of.

Besides being an entire research industry in himself, Arbib has enabled others to engage in a fast-growing neuroscientific/neurocomputational industry. In part, he's done that by his editing of comprehensive interdisciplinary tomes. Very recently, however, he and two colleagues have made available their own object-oriented programming language, NSL (Neural Simulation Language), together with an interesting variety of examples of its use (Weitzenfeld *et al*. 2002).

As we saw in Chapter 10.v.d, an object-oriented language enables the programmer to think at a 'natural' conceptual level. Even more importantly, it can embody a good deal of unseen knowledge within the types of "object" provided. That being so, the objects will—up to a point—behave (and interact) in the naturally expected, appropriate, ways without the programmer having to tell them precisely how to do so. In the case of NSL, the hidden knowledge is drawn from neuroscience. For the language was specially designed to enable people to model *macroscopic* brain structures, as well as lower-level neural networks. Indeed, anatomical structures and schemas can be represented on a number of hierarchical levels. Thanks to NSL, *Rana*'s cousins will surely multiply.

14.viii. Representations Galore

By the end of the 1950s, the notion of mental/cerebral models was a near-universal presupposition in the nascent cognitive science. (Though not in Gibsonian psychology: see Chapter 7.v.e.) In neuroscientific circles, analogue examples were hale and hearty—though still few and far between. In psychology, linguistics, and AI, formal–symbolic representations had the higher profile.

Today, the idea is still prominent in neuroscience. A recent review of research on hand movements, for instance, declared that "*internal models are fundamental* for understanding a range of processes [involved in motor planning, control, and learning]", and cited many others working on that assumption (D. M. Wolpert and Ghahramani 2000: 1217; italics added). In short, neuroscientists differ over what the internal models are like, but *that there are such models* has long been widely agreed. (Widely, but not universally: see subsection d, below.)

I'm taking for granted, here, that "representation"—considered as a theoretical term (what the positivists called an intervening variable)—is interpreted realistically by cognitive scientists, even by those who deny that they exist. That is, it's not merely a helpful shorthand, or *façon de parler*. Philosophers of science who take an instrumentalist view of scientific concepts and theories *in general* would disagree. For them, to say that representations (or electrons, or molecules, or genes . . .) exist is simply to say that it's explanatorily/predictively helpful to talk about them, *not* to say that there are real, independently existing, entities out there which these terms are denoting. But such radical instrumentalism is unusual among working scientists, and I shall ignore it here.
